Key points

- Glycemic control is a fundamental part of the management of type 2 diabetes mellitus. Adequate glycemic control is necessary to address acute symptoms and to prevent, defer, or reduce the severity of chronic microvascular and macrovascular complications.
- Treating type 2 diabetes is complicated by the multivariable and progressive natural history of the disease. Insulin resistance, a progressive decline in β-cell function, defects of other gluco-regulatory hormones, and nutrient metabolism, give rise to a continually changing presentation of the disease that requires therapy to be adjusted accordingly. People with diabetes are often overweight or obese, exhibit substantial comorbidity and elevated cardiovascular risk, and receive many other medications that further complicate treatment.
- Care plans and treatment programs should be tailored to fit the prevailing circumstances of the individual. Lifestyle management (diet and exercise) should be emphasized from the time of diagnosis and reinforced thereafter. Drug treatment should be undertaken promptly if lifestyle intervention does not achieve adequate glycemic control.
- Choice of drug therapy should ideally address underlying pathophysiology, but any safe means of restraining the escalating hyperglycemia may be appropriate. Combinations of differently acting agents are frequently required to provide additive efficacy, and single-tablet, fixed-dose combinations are available to facilitate combination therapy. Contraindications and precautions associated with each component must be respected.
- The biguanide metformin is often selected as initial oral glucose-lowering therapy. It counters insulin resistance and lowers blood glucose through several insulin-dependent and -independent mechanisms, notably reducing hepatic glucose production and also increasing glucose uptake by skeletal muscle. It does not stimulate insulin secretion, carries a low risk of frank hypoglycemia, and does not cause weight gain. Metformin also exerts several potentially beneficial effects on cardiovascular risk factors independently of glycemic control, with evidence of improved long-term cardiovascular outcomes. Metformin may be conveniently combined with other classes of glucose-lowering drugs. Gastrointestinal side effects including diarrhea limit the use of metformin. The rare but serious adverse effect of lactic acidosis precludes the use of the drug in people with significant renal insufficiency, significant liver disease, or any condition predisposing to hypoxia or hypoperfusion including cardiac or respiratory failure.
- Sulfonylureas (e.g. gliclazide, glimepiride, glibenclamide/glyburide, glipizide) act on the pancreatic β cells to stimulate insulin secretion. They bind to the transmembranal complex of sulfonylurea receptors SUR1 with ATP-sensitive Kir6.2 potassium efflux channels. This closes the channels, depolarizes the membrane, opens voltage-dependent calcium channels, and raises intracellular free calcium concentrations. This in turn activates proteins that regulate insulin secretion. The efficacy of sulfonylureas depends on adequate remaining function of the β cells. Hypoglycemia is the most serious adverse effect, particularly with longer acting sulfonylureas and in the elderly. Caution with hepatic and/or renal insufficiency is warranted in accordance with the metabolism and elimination of individual preparations, and interactions with other protein-bound drugs can occur.
- Meglitinides (repaglinide and nateglinide), also known as prandial insulin releasers, are rapid and short-acting insulin secretagogues taken before meals to boost insulin levels during digestion, thereby reducing prandial hyperglycemia and decreasing the risk of interprandial hypoglycemia. They act in a similar manner to sulfonylureas by binding to a "benzamido" site on the SUR1–Kir6.2 complex. They are conveniently used in combination with an agent that reduces insulin resistance.
- Thiazolidinediones (pioglitazone and rosiglitazone) produce a slow-onset glucose-lowering effect, attributed mainly to increased insulin sensitivity. They alter the expression of certain insulin-sensitive genes by stimulating the peroxisome proliferator-activated receptor γ, increasing adipogenesis, and rebalancing the glucose–fatty acid (Randle) cycle. Thiazolidinediones can be used as monotherapy or in combination with other classes of glucose-lowering agents. They have a low risk of hypoglycemia but often cause weight gain. The potential for fluid retention and an attendant risk of congestive heart failure should be borne in mind, especially in

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

combination with insulin. Thiazolidinediones are not recommended for individuals at high risk for cardiac disease or women with reduced bone density, and one or other agent in this class has been discontinued in some countries.

- Dipeptidyl peptidase 4 (DPP-4) inhibitors (sitagliptin, vildagliptin , saxagliptin, linagliptin and alogliptin), also termed gliptins, act predominantly as prandial insulin secretagogues by raising the circulating concentrations of endogenous incretin hormones, notably glucagon-like peptide 1 (GLP-1). This enhances the "incretin" effect of endogenous GLP-1 to potentiate nutrient-stimulated insulin secretion. DPP-4 inhibitors are weight neutral and, as monotherapy, they carry a low risk of interprandial hypoglycemia. They are often used in combination with metformin or a thiazolidinedione.
- Sodium–glucose co-transporter-2 (SGLT-2) inhibitors (canagliflozin, dapagliflozin, empagliflozin) increase the elimination of excess glucose in the urine (glucosuria) by reducing glucose reabsorption from the renal filtrate. They carry a low risk of hypoglycemia and the glucosuria facilitates weight loss. Their action is independent of insulin, enabling use with other glucose-lowering agents irrespective of the extent of insulin resistance or β-cell dysfunction, but their efficacy requires adequate renal function. The glucosuria may increase the risk of genital and urinary tract infection, although an associated osmotic diuresis may assist blood pressure control.
- α-Glucosidase inhibitors (acarbose, miglitol, voglibose) slow the digestion of carbohydrates by competitive inhibition of intestinal α-glucosidase enzymes. This delays glucose absorption and reduces postprandial glucose excursions without stimulating insulin secretion. These agents must be used in conjunction with meals rich in digestible complex carbohydrate. They do not cause weight gain or hypoglycemia as monotherapy and can be used alongside any other glucose-lowering agents.
- The dopamine D2 receptor agonist bromocriptine and the bile sequestrant colesevelam have an indication for the treatment of type 2 diabetes in some countries. Their glucose-lowering mechanisms are unclear but they do not cause weight gain and carry a low risk of hypoglycemia.
- As type 2 diabetes advances, combinations of glucose-lowering agents with different modes of action are often required. Eventually β-cell function can become too severely compromised to support the continued use of oral agents alone and/or other non-insulin treatments. Insulin therapy should then be initiated, continuing one or more other agents where appropriate.

Introduction

Appropriate glycemic control is fundamental to the management of type 2 diabetes mellitus (T2DM). It is required to prevent and relieve acute symptoms and complications of hyperglycemia, prevent, defer, and reduce the severity of microvascular complications, and afford some benefits against macrovascular complications (Table 31.1) [1]. Treatment of the hyperglycemia is an integral part of individualized care that takes account of coexisting diseases and personal circumstances, offers suitable advice on lifestyle and diet, includes other measures to address modifiable cardiovascular risk, selects realistic targets, and facilitates patient education and empowerment, as considered in detail in Part 5. This chapter focuses on the role of oral blood glucose-lowering agents (other glucose-lowering therapies are addressed in Chapters 29 and 32) in the treatment of T2DM [2–5].

Table 31.1 Aims of appropriate glycemic control in T2DM.

Purpose	Complications
Prevent acute symptoms of hyperglycemia	Dehydration, thirst, polyuria, blurred vision, increased infections
Prevent acute complications	Hyperosmolar non-ketotic state
Prevent, defer or reduce severity of chronic vascular complications	Microvascular: retinopathy, nephropathy, neuropathy
	Macrovascular: coronary, cerebrovascular, peripheral vascular

Pathophysiological considerations

The interdependent multiplicity of genetic and environmental factors underlying T2DM gives rise to a highly heterogeneous and progressive natural history [1, 6, 7]. The pathophysiology typically involves defects of insulin secretion *and* insulin action. Obesity, especially visceral adiposity, and abnormalities of glucagon secretion, incretin hormone action, the microbiome, inflammation and neurotransmitters contribute to the disease process, while cellular disturbances of nutrient metabolism participate as both causes and consequences of glucotoxicity and lipotoxicity [8–10]. An ideal approach to therapy might therefore address the basic endocrine defects, but any other safe means of ameliorating the hyperglycemia and attendant biochemical disruptions should provide clinical benefits.

The progressive nature of T2DM was well illustrated by the UK Prospective Diabetes Study (UKPDS), a randomized trial of 5102 individuals with newly diagnosed T2DM followed for a median of 10 years while receiving either "conventional" (diet) therapy or "intensive" therapy with various oral glucose-lowering agents or insulin (Figure 31.1). Note that insulin was introduced earlier than is usual in clinical practice, and insulin was also used as necessary when oral agents were deemed inadequate. Although glycemic control (illustrated by the glycated hemoglobin [HbA_{1c}] level) deteriorated with time irrespective of the treatment, the improvement in glycemic control afforded by intensive therapy (median HbA_{1c} reduced by 0.9% [10 mmol/mol]) was associated with a 12% reduction in overall diabetes-related endpoints and a 25% reduction in microvascular endpoints [11]. An

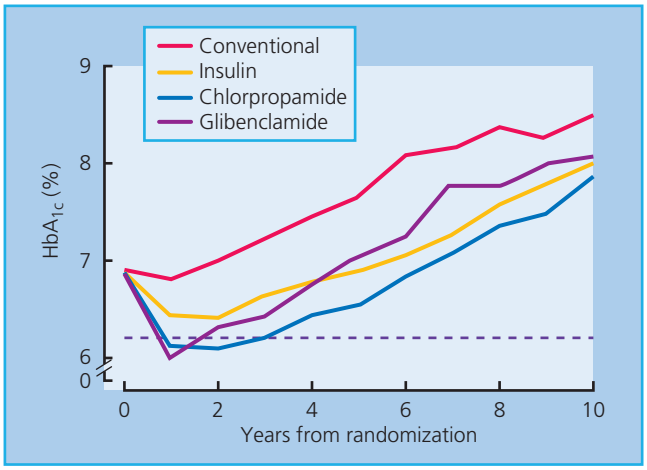

Figure 31.1 The UK Prospective Diabetes Study (UKPDS) shows the progressive rise in HbA_{1c} occurring with time in groups receiving "conventional" (diet) therapy and "intensive" therapy with various glucose-lowering drugs (two sulfonylureas—chlorpropamide and glibenclamide—and insulin). Source: Data from UK Prospective Study (UKPDS) Group [11].

epidemiological analysis showed that benefits of intensive therapy continued to accrue until glucose levels were returned to the normal range [12]. Moreover, the benefits of earlier "intensive" control were continued during an unrandomized post-trial follow-up (median 8.5 years) during which glycemic differences between the former groups were not maintained [13]. This illustrates the glycemic "legacy" effect in which early intensive glycemic control confers an extended reduction in complications, even when control deteriorates at later stages in the disease process.

Other large randomized trials [14–16] have confirmed fewer microvascular complications amongst those receiving more intensive glycemic management (Table 31.2). One such study, the Action to Control Cardiovascular Risk in Diabetes (ACCORD) study, noted increased mortality during highly intensified (5% mortality, 257/5128) versus standard (4% mortality, 205/5123) glycemic management. Although the cause the increased mortality associated with highly intensified management remains uncertain, deaths were more common among those individuals who continued to have poor glycemic control [17]. In this context, it is noteworthy that an acceptable HbA_{1c} value does not exclude excessive daily fluctuations in glycemia with hyperglycemic excursions and hypoglycemic troughs, the latter often unrecognized nocturnally. Survival of a myocardial event appears to be reduced by both hypo- and hyperglycemia [18].

Guidelines and algorithms

Factors to consider when selecting a glycemic target for a particular individual are deliberated in detail in Chapter 33, but it is pertinent to reiterate here that the general principle is to return glycemia safely as close to normal as practicable, while avoiding hypoglycemia, minimizing adverse effects on body weight and potential drug interactions, and observing other necessary cautions and contraindications. An individualized approach is recommended. Current treatment algorithms [3, 4] provide a framework for initiating and intensifying therapy, but clinical judgment should be applied to harmonize this with patient circumstances. Thus, a younger, newly diagnosed individual without comorbidity who is responsive to therapy might be expected to meet a more rigorous target, whereas an elderly, infirm individual with comorbidity or a long history of problems with diabetes control

Table 31.2 Trials comparing intensive with standard (conventional) glycemic control in type 2 diabetes.

Trial	No.	Duration of follow-up (years)	Age (years)	Duration of diabetes (years)	Baseline HbA_{1c} (%)	Intensive HbA_{1c} (%)		Conventional HbA_{1c}%	Relative risk reduction			
									Microvascular		Macrovascular	
									%	*p*	%	*p*
UKPDS	3867[a]	10	53	New	7.1[b]	7.0	vs.	7.9	↓ 25	0.009	↓ 16[c]	0.052[d]
UKPDS (post-trial follow-up)	2998	8.5	63	10	–		–		↓ 24	0.001	↓ 15[c]	0.014

ACCORD[e]	10251	3.5[e]	62	10	8.3	6.4[e]	vs.	7.5	↓ 33	0.005[f]	↓ 10	0.16[b]
VADT	1791	5.6	60	11.5	9.4	6.9	vs.	8.4	↓ 2.5[g]	0.05	↓ 12	0.14[b]

[a] Non-obese participants.
[b] After a 3-month dietary run-in.
[c] Myocardial infarction.
[d] Non-significant.
[e] Intensive therapy discontinued at median 3.5 years because of increased deaths in the intensive (257/5128; 5%) versus conventional (203/5123; 4%) group.
[f] Reduction in new or worsening nephropathy. No effect on incidence of progression of retinopathy.
[g] Any increase in albuminuria.
ACCORD, Action to Control Cardiovascular Risk in Diabetes; ADVANCE, Action in Diabetes and Vascular Disease: Preterax and Diamicron-MR Controlled Evaluation; UKPDS, UK Prospective Diabetes Study; VADT, Veterans Affairs Diabetes Trial.

may require a less rigorous target. Management of hyperglycemia should always be part of a comprehensive management program to address coexisting disease and modifiable cardiovascular risk factors.

It is emphasized that diet, exercise, and other lifestyle measures should be introduced at diagnosis and reinforced at every appropriate opportunity thereafter. These measures can provide valuable blood glucose-lowering efficacy and may initially enable the desired glycemic target to be achieved. However, even when lifestyle advice is successfully implemented, the progressive natural history of the disease dictates that the majority of people with T2DM will later require pharmacological therapy, and this should be introduced promptly if the glycemic target is not met or not maintained.

The main classes of oral glucose-lowering drugs and their principal modes of action are listed in Table 31.3. Not all agents are available in all countries and prescribing information may vary between countries. The main tissues through which agents exert their glucose-lowering effects are illustrated in Figure 31.2, and the main cautions and contraindications are listed in Table 31.4. Although there are several different classes from which to choose, many dilemmas continue to impinge on both strategy and individualization of treatment. For example, an increase in fasting glycemia usually accounts for the majority of the total burden of hyperglycemia in T2DM; ideally, therefore, this should be adequately addressed using appropriate therapy [19]. It is also pertinent to note the link between postprandial hyperglycemic excursions and cardiovascular risk, which mandates the need also to address this component of the hyperglycemic day profile [20]. Additionally, consideration should be given to the improvements in glycemic control that can be achieved through the treatment of obesity [21]. By the time of diagnosis, insulin resistance is usually well established and usually shows only a modest further increase with extended duration of the disease [6, 7]. Nevertheless, the association between insulin resistance and cardiovascular risk warrants the amelioration of insulin resistance as a valued

Table 31.3 Classes of oral glucose-lowering drugs and their main modes of action.

Class with examples	Main mode of glucose-lowering action	Main cellular mechanism of action
Biguanide		
Metformin	Counter insulin resistance (especially decrease hepatic glucose output)	Enhance various insulin-dependent and -independent actions including effects on AMPK, mitochondrial respiratory chain, and insulin receptor signaling
Sulfonylureas		
Glimepiride, gliclazide, glipizide glyburide (= glibenclamide)[a]	Stimulate insulin secretion (typically 6–24 h)	Bind to SUR1 sulfonylurea receptors on pancreatic β cells, which closes ATP-sensitive Kir6.2 potassium channels
Meglitinides		
Repaglinide, nateglinide	Stimulate insulin secretion (faster onset and shorter duration of action than sulfonylureas)	Bind to benzamido site on SUR1 receptors on pancreatic β cells, which closes ATP-sensitive Kir6.2 potassium channels
DPP-4 inhibitors (gliptins)		
Sitagliptin, vildagliptin, saxagliptin, linogliptin, alogliptin	Increase prandial insulin secretion	Inhibit DPP-4 enzyme, which increases plasma half-life of incretin hormones, notably GLP-1
Thiazolidinediones (PPAR-γ agonists)		
Pioglitazone, rosiglitazone[b]	Increase insulin sensitivity (especially increase peripheral glucose utilization)	Activate nuclear receptor PPAR-γ mainly in adipose tissue, which affects insulin action and glucose–fatty acid cycle
Sodium—glucose co-transporter-2 (SGLT-2) inhibitors		
Canagliflozin, dapagliflozin, empagliflozin	Increase elimination of glucose in the urine	Inhibit SGLT-2 transporters in renal proximal tubules
α-Glucosidase inhibitors		
Acarbose, miglitol, voglibose	Slow rate of carbohydrate digestion	Competitive inhibition of intestinal α-glucosidase enzymes
Dopamine agonist		
Bromocriptine[b]	Reduce hepatic glucose production	Central dopaminergic effect
Bile acid sequestrant		
Colesevelam[b]	Not established	Not established

[a] Glyburide is the same active compound as glibenclamide.
[b] Rosiglitazone has been withdrawn in some countries, and bromocriptine and colesevelam are not widely used for the treatment of T2DM.
AMPK, adenosine 5′-monophosphate-activated protein kinase; ATP, adenosine triphosphate; DPP-4, dipeptidyl peptidase 4; GLP-1, glucagon-like peptide-1: PPAR-γ, peroxisome proliferator-activated receptor γ; SGLT-2, sodium–glucose co-transporter-2.

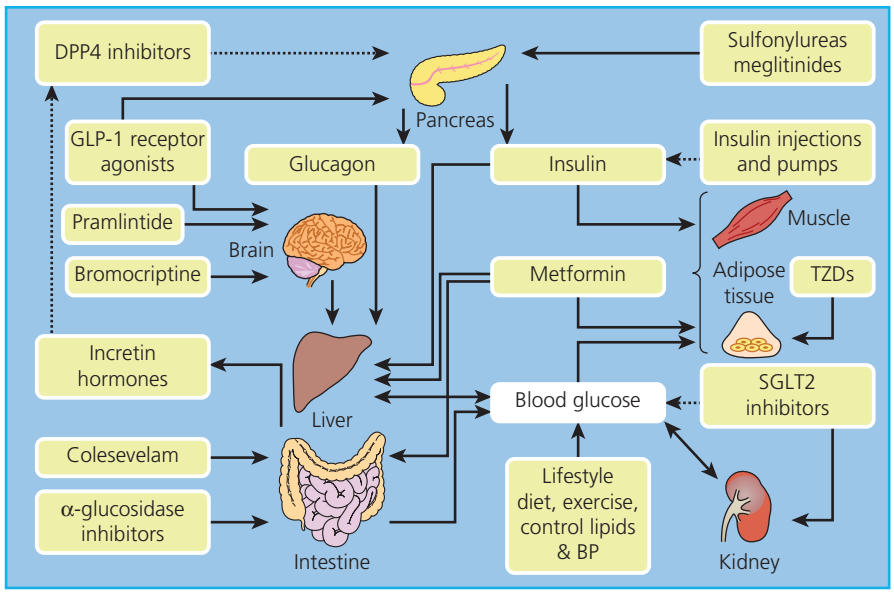

Figure 31.2 Main tissues through which oral glucose-lowering agents exert their glucose-lowering effects TZD: thiazolidinedione.

Table 31.4 General features of the more widely used oral blood glucose-lowering treatments for T2DM including the main cautions and contraindications.

Feature	Metformin	Sulfonylureas	Meglitinides	Thiazolidinediones	SGLT-2 inhibitors	DPP-4 inhibitors	α-Glucosidase inhibitors
HbA_{1c} (%)	↓ 1–2	↓ 1–2	↓ 0.5–1.5[f]	↓ 1–1.5	↓ 0.5–1.5	↓ 0.5–1.5	↓ 0.5–1
Body weight	–/↓	↑	↑/–	↑	↓	–	–
Lipids	–/+	–	–	+/–/×	–/+	–	–/+
Blood pressure	–	–	–	↓/–	↓	–	–

therapeutic strategy. The ongoing deterioration in glycemic control after diagnosis is considered to be largely attributable to a further progressive decline in β-cell function [6, 7]. Thus, preserving β-cell function and mass are important considerations in the quest to maintain long-term glycemic control. If β-cell function deteriorates beyond the capacity of oral agents and non-insulin injectable agents (such as glucagon-like peptide-1 receptor agonists) to provide adequate glycemic control, then the introduction of insulin should not be delayed [22]. Incorporating some or all of the above into the treatment process is inevitably a challenge, and the need to explore suitable combinations of therapies to accommodate the changing status of the disease is common practice [3, 4].

The increasing prevalence of T2DM among younger adults and youth adds an extra long-term dimension to risk–benefit considerations. Although initial adequate intervention remains paramount, there is limited experience with oral glucose-lowering agents in children and adolescents; metformin has been used safely in pediatric practice from 10 years of age, and sulfonylureas have been used in pediatric presentations of certain monogenic forms of diabetes, e.g. maturity-onset diabetes of the young (MODY). Treating T2DM in women who are of childbearing age carries the risk of unplanned pregnancy while receiving oral glucose-lowering agents. Treatment with metformin or a sulfonylurea at the time of conception and during the first trimester has not been shown to have any adverse effects on mother or fetus, and judicious use of metformin has been shown to reduce miscarriage and gestational diabetes. Insulin remains the preferred glucose-lowering medication in pregnancy as there is a substantial evidence base for the safety and flexibility of insulin in gestational diabetes. A paucity of evidence, allied with animal toxicity data or theoretical considerations for some classes, contraindicates thiazolidinediones, gliptins, and sodium–glucose co-transporter-2 (SGLT-2) inhibitors during pregnancy and lactation.

Older people are more vulnerable to most of the cautions and contraindications for glucose-lowering drugs, and a deterioration in pathophysiological status can occur rapidly, necessitating more frequent monitoring. Hypoglycemia is a particular concern in this age group. Although safety must be judged on an individual drug–patient basis, it is noteworthy that several commonly used concomitant medications can impair glycemic control (e.g. glucocorticoids, certain antipsychotics, diuretics and β-blockers), whereas others may have their own minor glucose-lowering effect (e.g. aspirin, some angiotensin-converting enzyme [ACE] inhibitors and mineral supplements) (see Chapter 28). The most frequent interactions with glucose-lowering drugs are summarized in Table 31.5.

Descriptive terminology applied to glucose-lowering drugs may simplify the use of the different agents. Hypoglycemic agents have the capacity to lower blood glucose below normal to the extent of frank hypoglycemia (e.g. sulfonylureas, meglinitides, and insulin). Antihyperglycemic agents can reduce hyperglycemia, but when acting alone they do not usually have the capability to lower blood glucose below normoglycemia to the extent of frank hypoglycemia (e.g. metformin, dipeptidyl peptidase-4 [DPP-4] inhibitors, thiazolidinediones, SGLT-2 inhibitors, glucagon-like

Table 31.5 Drug interactions with oral antidiabetes agents that may affect their glucose-lowering effects.

Agent	Increase glucose-lowering effect	Decrease glucose-lowering effect
Any	Combination with other antidiabetes drugs Minor insulin releasers (e.g. aspirin) Minor insulin sensitivity enhancers (e.g. ACE inhibitors, magnesium or chromium supplements)	Agents that impair insulin action (e.g. glucocorticoids, some antipsychotics, minor effects of diuretics, β-blockers, some β_2-agonists) Impair insulin secretion (e.g. octreotide, some calcium channel blockers)
Metformin	Renal cation secretion competition by cimetidine Minor PK interaction with furosemide and nifedipine	–
Sulfonylureas	Reduce hepatic metabolism (e.g. some antifungals and MAOIs) Displace plasma protein binding (e.g. coumarins, NSAIDs, sulfonamides) Decrease excretion (e.g. probenecid)	K^+–ATP channel openers (e.g. diazoxide) Metabolism secondary to enzyme induction (e.g. rifampicin)
Meglitinides	Reduce hepatic metabolism, gemfibrozil Potentially displace plasma protein binding	Metabolism secondary to enzyme induction (e.g. rifampicin, barbiturates, carbamazepine)
Thiazolidinediones	Reduce hepatic metabolism, gemfibrozil Potentially displace plasma protein binding	Metabolism secondary to enzyme induction (e.g. rifampicin)
SGLT-2 inhibitors	–	Impaired renal function
DPP-4 inhibitors	Potential interactions with liver and renal metabolism and plasma protein binding	–
α-Glucosidase inhibitors	Slow gut motility (e.g. cholestyramine)	Potentially with agents that increase gut motility

peptide-1 (GLP-1) receptor agonists, α-glucosidase inhibitors, bromocriptine, and colesevelam).

Biguanides

Metformin (dimethylbiguanide) is the only biguanide currently used in most countries (Figure 31.3). The history of biguanides stems from a guanidine-rich herb, *Galega officinalis* (goat's rue or French lilac), that was used as a traditional treatment in Europe [23]. Guanidine has a glucose-lowering effect, and several guanidine derivatives were adopted for the treatment of diabetes in the 1920s [24]. These agents all but disappeared as insulin became available, but three biguanides—metformin, phenformin, and buformin—were introduced in the late 1950s. Phenformin and buformin were withdrawn in many countries in the late 1970s because of a high incidence of lactic acidosis. Metformin remained and was introduced into the United States in 1995 [25], and it has since become the most prescribed glucose-lowering agent worldwide [26].

Mode of action

Metformin exerts a range of actions that counter insulin resistance and lower blood glucose; the drug also offers some protection against vascular complications independently of its antihyperglycemic effect (Table 31.6) [27, 28]. At the cellular level, metformin exerts insulin-dependent and -independent effects on glucose metabolism that vary with the concentration of metformin to which the tissue is exposed and the prevailing gluco-regulatory mechanisms in that tissue (Figure 31.4). For example, high concentrations of metformin in the intestinal wall can suppress the mitochondrial respiratory chain at complex 1 independently of insulin and promote anaerobic glycolysis to lactate. The conversion of lactate to glucose in other tissues (increased glucose turnover as part of the Cori cycle) may help to prevent weight gain. Lower concentrations of metformin modestly improve insulin sensitivity in liver and muscle in part by enhancing post-receptor signaling pathways for insulin,

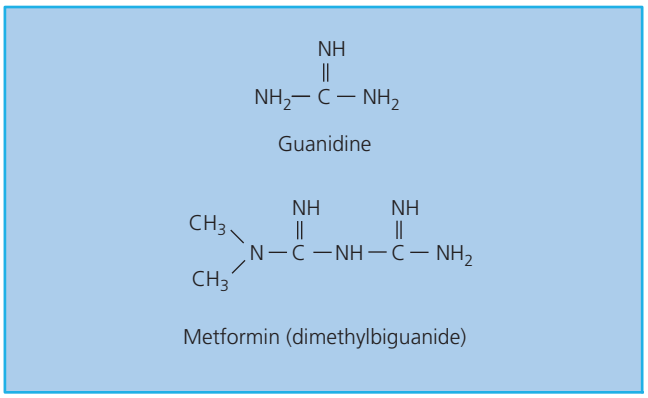

Figure 31.3 Chemical structures of guanidine and metformin.

Table 31.6 Diverse metabolic and vascular effects of metformin.

Features associated with diabetes		Effects of metformin
Hyperglycemia	↓	↓ HGP, ↑ peripheral glucose uptake, ↑ glucose turnover
Insulin resistance	↓	↑ Receptor–postreceptor insulin signals
Hyperinsulinemia	↓	↓ Fasting and often postprandial insulin
Obesity	↓/–	↓ or stabilizes body weight
IGT	↓	↓ Progression to T2DM
Dyslipidemia	↓/–	Modest benefits if abnormal ↓ VLDL-TG, ↓ LDL, ↑ HDL May decrease FA oxidation
Blood pressure	–	No significant effect
Pro-coagulant state	↓	Antithrombotic (↓ fibrinogen, ↓PAI-1, ↓ platelet aggregation)
Endothelial function	↑	↓ Vascular adhesion molecules
Atherosclerosis	↓	↓ MI, ↓ stroke, ↑ vascular reactivity, ↓ cIMT, ↑ life expectancy, antiatherogenic in animals

↑, Increase; ↓, decrease; –, no significant effect.

and also by effects on nutrient metabolism and energy production independently of insulin via activation of adenosine 5′-monophosphate-activated protein kinase (AMPK) [29].

The glucose-lowering efficacy of metformin requires a presence of at least some insulin because metformin does not mimic or activate the genomic effects of insulin. Also, metformin does not stimulate insulin release; its main glucose-lowering effect appears to be a reduction of hepatic glucose production by suppressing gluconeogenesis and glycogenolysis, but not sufficiently to cause frank hypoglycemia when used as monotherapy. Metformin reduces gluconeogenesis by increasing hepatic insulin sensitivity, reducing hepatic glucagon receptor signaling, and decreasing hepatic extraction of some gluconeogenic substrates such as lactate (Figure 31.5). Metformin can enhance insulin-stimulated glucose uptake in skeletal muscle by increasing the translocation of insulin-sensitive glucose transporters (GLUT-4) into the cell membrane and increasing the activity of glycogen synthase, which promotes glycogen synthesis.

Pharmacokinetics

Metformin is rapidly but incompletely absorbed, shows little binding to plasma proteins and is not metabolized, and so it does not interfere with co-administered drugs. Metformin is widely distributed at concentrations similar to plasma (about 10^{-5} mol/L), but much higher concentrations are retained in the walls of the gastrointestinal tract. The plasma half-life ($t_{1/2}$) is about 6 h with elimination of unchanged drug in the urine, mostly within

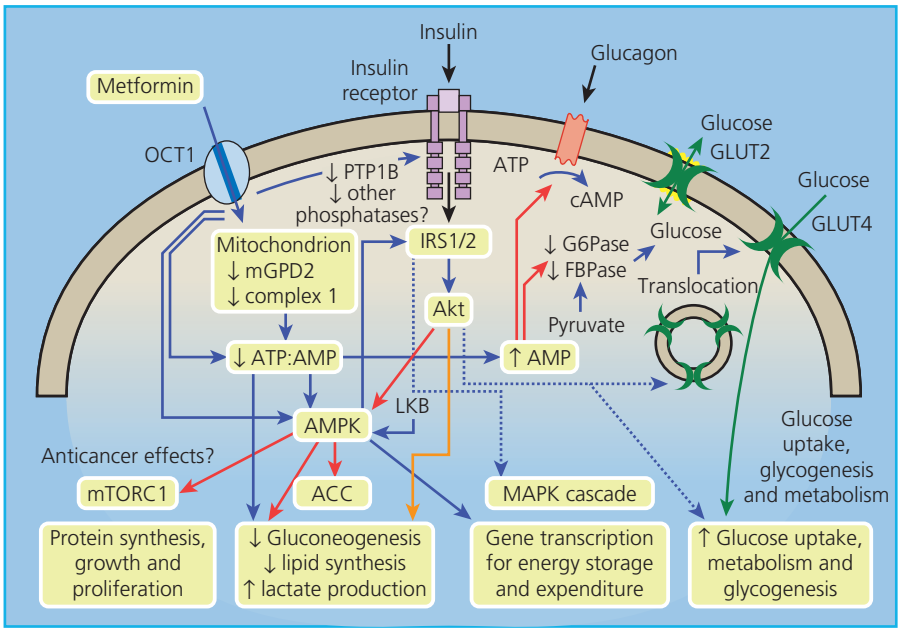

Figure 31.4 Multiple cellular actions of metformin involve insulin-dependent and -independent effects and vary according to the tissue and the level of exposure to metformin. For example, very high exposure to metformin in the intestine can reduce oxidative phosphorylation and promote anaerobic metabolism. Lower concentrations of metformin can improve insulin sensitivity in liver and muscle via effects on insulin receptor signaling and post-receptor signaling pathways of insulin action. Metformin can influence cellular nutrient metabolism and energy production independently of insulin via activation of adenosine 5′-monophosphate (AMP)-activated protein kinase (AMPK). 12 h [30]. Although renal clearance is achieved more by tubular secretion than glomerular filtration, metformin is contraindicated for people with significant impairment of glomerular filtration. Cimetidine is the only drug known to compete for clearance sufficiently to cause a clinically significant increase in plasma metformin concentrations.

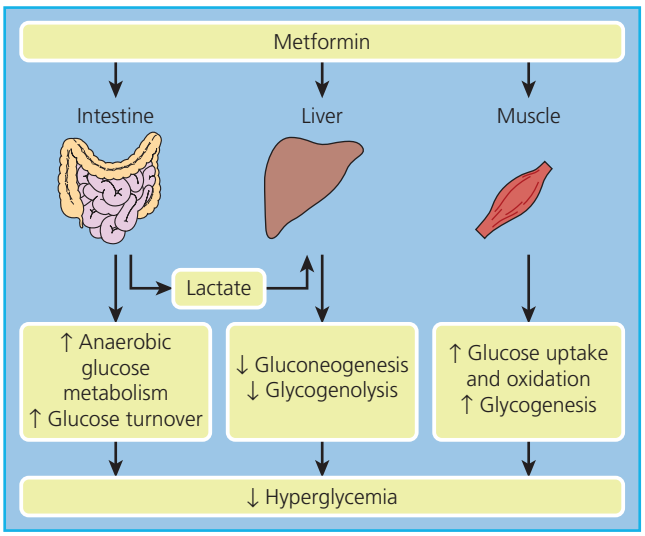

Figure 31.5 Main sites of action of metformin contributing to glucose-lowering effect.

Indications and contraindications

Because metformin does not cause weight gain, it is often preferred for overweight and obese people with T2DM, although it shows similar antihyperglycemic efficacy in normal-weight individuals [31]. To preclude drug accumulation, patient suitability should be considered very carefully if there is any evidence of impaired renal function (e.g. if serum creatinine is >130 μmol/L or creatinine clearance is <60 mL/min), although reduced doses of the drug are permitted in some countries down to an estimated glomerular filtration rate (eGFR) of 30 mL/min/1.73 m^2. Further contraindications include significant cardiac or respiratory insufficiency, or any other condition predisposing to hypoxia or reduced tissue perfusion (e.g. hypotension, septicemia), and also significant liver disease, alcohol abuse, or a history of metabolic acidosis. Because the potential for acute deterioration in renal, cardiopulmonary, and hepatic function should be taken into account, it is difficult to identify precise cutoffs for starting or stopping metformin therapy. With this in mind, metformin can be used in the elderly provided that renal insufficiency and other exclusions are not present. Ovulation can resume in women with anovulatory polycystic ovary syndrome (PCOS), which is an unlicensed

application of the drug in the absence of diabetes [32]. Metformin is also under investigation for a possible inhibitory effect on tumor formation and progression in some tissues.

A standard (so-called immediate release [IR]) tablet, sachet, or liquid formulation of metformin should be taken with meals or immediately before meals to minimize possible gastrointestinal side effects. Treatment should start with 500 or 850 mg once daily, or 500 mg twice daily (divided between the morning and evening meals). The dosage is increased slowly—one tablet at a time—at intervals of about 1–2 weeks until the target level of blood glucose control is attained. If the target is not attained and an additional dose produces no further improvement, the previous dose should be resumed. In the case of monotherapy, combination therapy can be considered by adding a differently acting agent (e.g. an insulin-releasing drug, SGLT-2 inhibitor or thiazolidinedione). The maximal effective dosage of metformin is about 2000 mg/day, taken in divided doses with meals, and the maximum is 2550 or 3000 mg/day in different countries [33].

Slow-release formulations (XR/SR/ER) of metformin are available in most countries; they can be taken once daily in the morning, or if necessary morning and evening. Metformin can also be used in combination with any other class of antidiabetes agent, including insulin, and several fixed-dose combination tablets are available in which metformin is combined with either a sulfonylurea, SGLT-2 inhibitor, DPP-4 inhibitor, or thiazolidinedione (see below). It should be noted that although metformin alone is unlikely to cause serious hypoglycemia, it can occur when metformin is used in combination with an insulin-releasing agent or insulin.

During long-term use of metformin, it is advisable to check at least annually for the emergence of contraindications, particularly renal (as a minimum, serum creatinine). Metformin can reduce gastrointestinal absorption of vitamin B_{12}, and although this is rarely a cause of frank anemia, an annual hemoglobin measurement is recommended, especially for individuals with known or suspected nutritional deficiencies. Metformin should be stopped temporarily when using intravenous radiographic contrast media, or during surgery with general anesthesia or other intercurrent situations in which the exclusion criteria could be invoked. Substitution with insulin may be appropriate at such times [33].

Efficacy

As monotherapy in people whose diabetes is not adequately controlled by lifestyle management, optimally titrated metformin typically reduces fasting plasma glucose by 2–4 mmol/L, corresponding to a decrease in HbA_{1c} by ~1–2% (11–22 mmol/mol) [25, 31, 33, 34]. This is largely independent of body weight, age, and duration of diabetes provided that some β-cell function is still present. To accommodate the progressive nature of T2DM, it is likely that uptitration of dosage and addition of a second agent will be required to maintain glycemic control in the long term.

Metformin carries minimal risk of significant hypoglycemia or weight gain when used as monotherapy. It may lead to a decrease in basal insulin concentrations, notably in people with hyperinsulinemia, which should help to improve insulin sensitivity. Minor improvements in the blood lipid profile have been observed during metformin therapy, mostly in those with hyperlipidemia: plasma concentrations of triglycerides, fatty acids, and low-density lipoprotein (LDL) cholesterol tend to fall, whereas that of high-density lipoprotein (HDL) cholesterol tends to rise [31, 33]. These effects appear to be independent of the antihyperglycemic effect, although a lowering of triglyceride and free fatty acids is likely to help improve insulin sensitivity and benefit the glucose–fatty acid (Randle) cycle.

In the UKPDS, overweight individuals who started oral antidiabetes therapy with metformin showed a 39% reduced risk of myocardial infarction (MI) compared with conventional treatment ($p = 0.01$) [35]. There was no obvious relationship with metformin dosage, suggesting that people who can tolerate only a low dosage of metformin may benefit from continuing the drug, even when other agents are required to achieve adequate glycemic control. The decrease in MI was not related to the extent of the glucose-lowering effect of metformin, or effects on classic cardiovascular risk factors such as blood pressure or plasma lipids. Reported benefits of metformin on various atherothrombotic risk markers and factors have been reported, including reduced carotid intima-media thickness (cIMT), increased fibrinolysis, and reduced concentrations of the antithrombolytic factor plasminogen activator inhibitor-1 (PAI-1) (Table 31.6) [28].

When metformin is added to the regimens of people receiving insulin therapy, a reduction of insulin dosage is often required, consistent with the ability of metformin to improve insulin sensitivity. Similarly, addition of insulin in people already receiving metformin usually requires lesser dosages of insulin and results in less weight gain. Lesser amounts of insulin are also associated with fewer and less severe episodes of hypoglycemia [36, 37]. Although metformin is not indicated for the prevention of diabetes, it is noteworthy that the US Diabetes Prevention Program found metformin to reduce the incidence of new cases of diabetes in overweight and obese participants with impaired glucose tolerance by 33%, compared with a reduced risk of 58% using an intensive regimen of diet and exercise [38]. The preventive effect of metformin was most evident amongst younger, more obese individuals.

Adverse effects

The main tolerability issue with metformin is abdominal discomfort and other gastrointestinal adverse effects, including diarrhea. These are often transient and can be ameliorated by taking the drug with meals and titrating the dose slowly. Symptoms may remit if the dose is reduced, but around 10% of people cannot tolerate the drug at any dose. The most serious adverse event associated with metformin is lactic acidosis; it is rare (probably about 0.03–0.06 cases per 1000 patient-years), but about half of cases are fatal [39]. Because the background incidence of lactic acidosis among people with T2DM has not been established, it is possible that some cases previously attributed to metformin were caused by other factors.

Most reported cases of lactic acidosis in people receiving metformin have been caused by inappropriate prescription, particularly overlooking renal insufficiency. The resulting accumulation of metformin is likely to increase lactate production, and increasing lactate will be aggravated by any hypoxic condition or impaired liver function. Hyperlactatemia occurs in cardiogenic shock and other illnesses that decrease tissue perfusion, so metformin may be only an incidental factor in some cases. Nevertheless, metformin should be stopped immediately in all cases of suspected or proven lactic acidosis, regardless of cause.

Lactic acidosis is typically characterized by a raised blood lactate concentration (e.g. >5 mmol/L), decreased arterial pH and/or bicarbonate concentration with an increased anion gap ($[Na^+] - [Cl^- + HCO_3^-]$ >15 mmol/L). Presenting symptoms are generally non-specific, but often include hyperventilation, malaise, and abdominal discomfort. Treatment should be commenced promptly without waiting to determine whether metformin is a cause; bicarbonate remains the usual therapy, but evidence of its efficacy is limited. Hemodialysis to remove excess metformin can be helpful, and may assist restoration of fluid and electrolyte balance during treatment with high-dose intravenous bicarbonate.

Sulfonylureas

Since their introduction in the 1950s, sulfonylureas have been used extensively as insulin secretagogues for the treatment of T2DM. Sulfonylureas were developed as structural variants of sulfonamides after the latter were reported to cause hypoglycemia [40]. Early sulfonylureas such as carbutamide, tolbutamide, acetohexamide, tolazamide, and chlorpropamide are often referred to as "first generation" compounds. These have been largely superseded by more potent "second-generation" sulfonylureas, notably glibenclamide (= glyburide), gliclazide, glipizide, and glimepiride (Figure 31.6).

Mode of action

Sulfonylureas act directly on the β cells of the islets of Langerhans to stimulate insulin secretion (Figure 31.7). They enter the β cell and bind to the cytosolic surface of the sulfonylurea receptor 1 (SUR1), which forms part of the transmembrane complex of ATP-sensitive Kir6.2 potassium channels (K^+ATP channels) (Figure 31.8) [41, 42]. Binding of a sulfonylurea closes the K^+ATP channel, reducing the efflux of potassium and enabling membrane depolarization. Localized membrane depolarization opens adjacent voltage-dependent L-type calcium channels, increasing calcium influx and raising the cytosolic free calcium concentration. This activates calcium-dependent signaling proteins that control the contractility of microtubules and microfilaments that mediate the exocytotic release of insulin granules. Preformed insulin granules adjacent to the plasma membrane are promptly released ("first-phase" insulin release), followed by a protracted ("second-phase") period of insulin release that begins about 10 min later [43]. The "second phase" of insulin release involves translocation of preformed and newly formed insulin granules to the plasma membrane for secretion. Sulfonylureas continue to stimulate insulin release while they are bound to the SUR1 provided that the β cells are functionally competent. Some desensitization, however, occurs during repeated and protracted stimulation

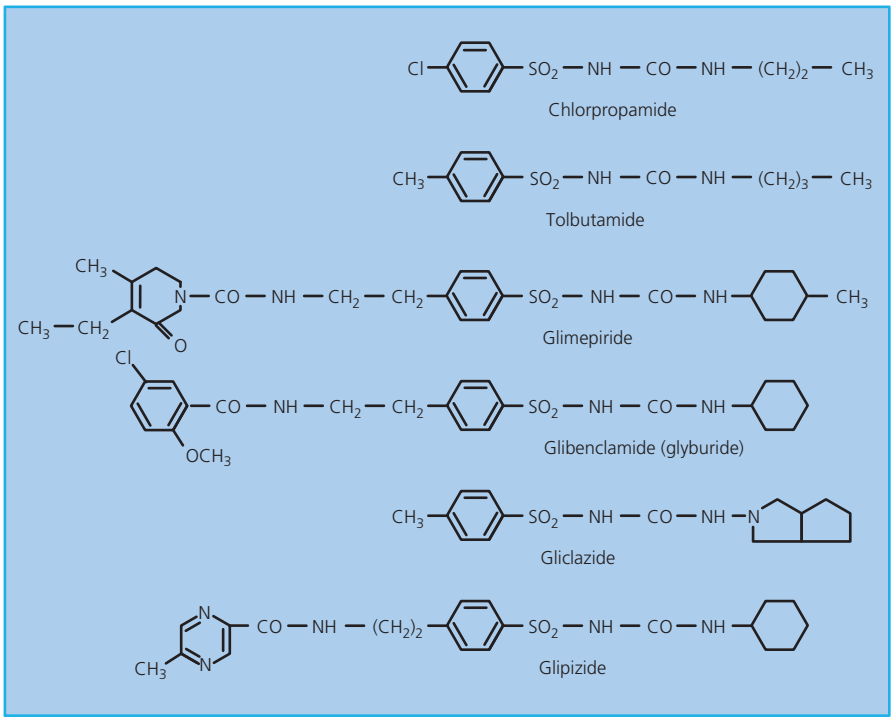

Figure 31.6 Chemical structures of sulfonylureas.

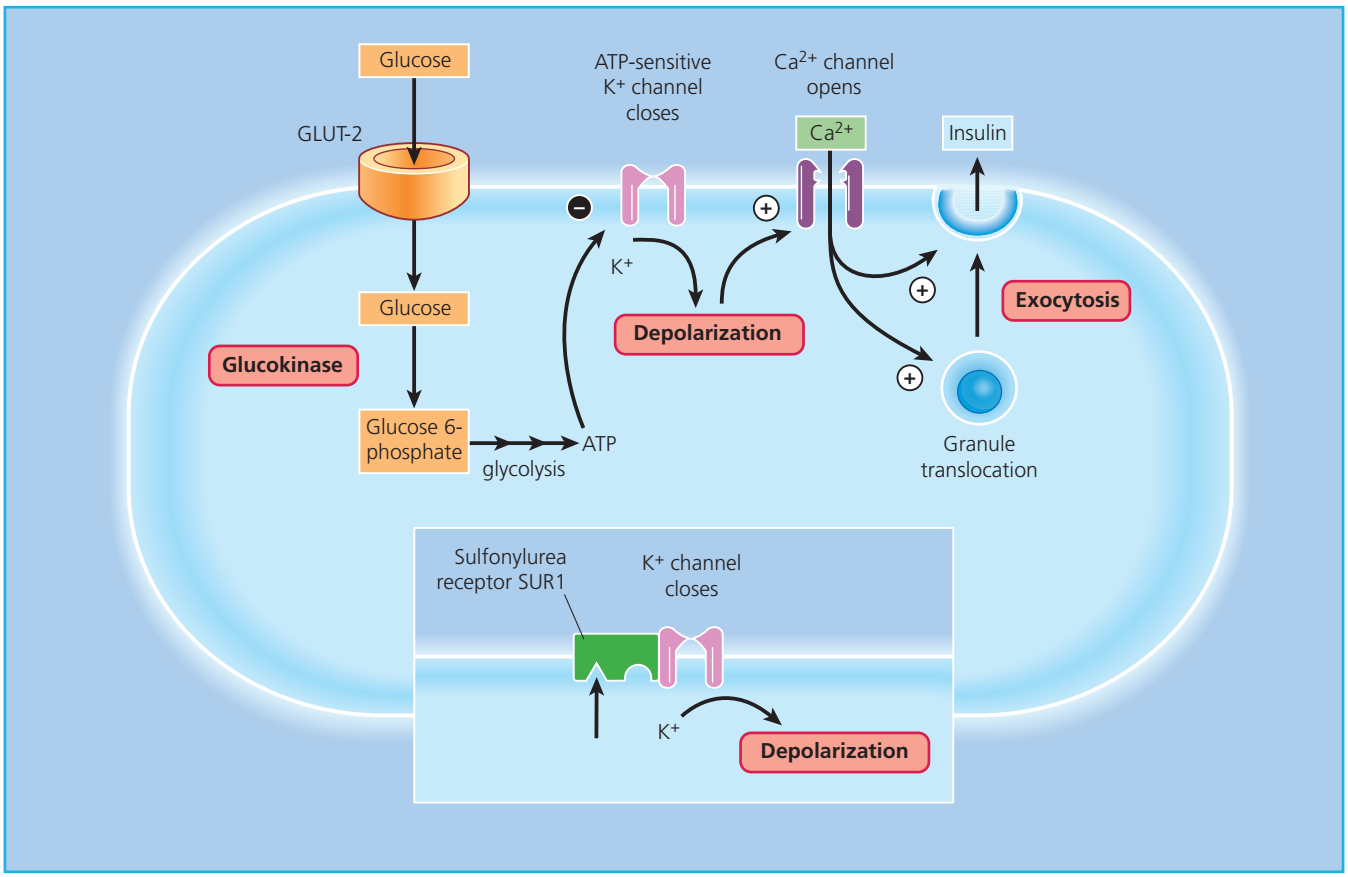

Figure 31.7 Sulfonylureas act on the pancreatic β cell to stimulate insulin secretion. They bind to the cytosolic surface of the sulfonylurea receptor 1 (SUR1), causing closure of ATP-sensitive Kir6.2 potassium channels, depolarizing the plasma membrane, opening calcium channels, and activating calcium-dependent signaling proteins that control insulin exocytosis.

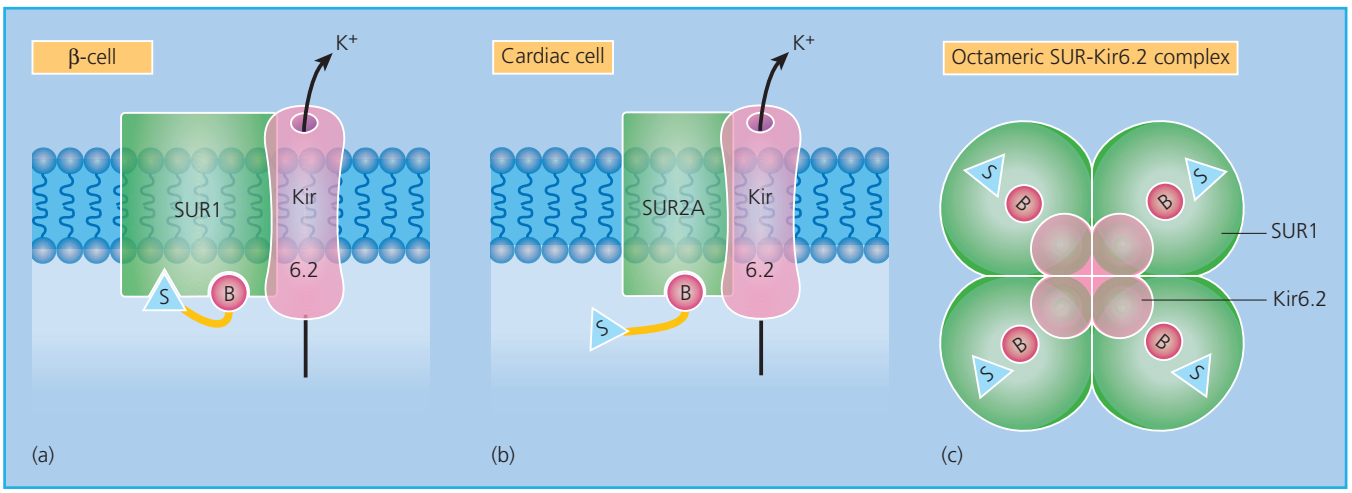

Figure 31.8 This illustrates the transmembrane complex of the SUR1 sulfonylurea receptor and the ATP-sensitive Kir6.2 potassium efflux channel on the pancreatic β cells (a). Each SUR1 has a cytosolic sulfonylurea (S) binding site and a benzamido (B) binding site. SUR2A on cardiac muscle cells (and SUR2B on vascular smooth muscle cells) does not have a sulfonylurea binding site (b). The SUR1–Kir6.2 complex is a non-covalently bonded octamer comprising 4 × SUR1 and 4 × Kir6.2, illustrated from the cytosolic surface to show the sulfonylurea and benzamido binding sites (c). The Kir6.2 molecules are located at the center and form the K^+ efflux pore. The Kir6.2 channel has a cytosolic binding region for ADP/ATP.

Table 31.7 Sulfonylureas.

Agent[a]	Dose range (mg/day)	Duration of action (h)	Metabolites	Elimination
Tolbutamide	500–2000	6–10	Inactive	Urine 100%
Glipizide	2.5–20	6–16	Inactive	Urine ~70%
Gliclazide	40–320	12–20	Inactive	Urine ~65%
Gliclazide MR	30–120	18–24	Inactive	Urine ~65%
Glimepiride	1.0–6.0	12–>24	Active	Urine ~60%
Glibenclamide[b]	1.25–15	12–>24	Active	Bile >50%
Chlorpropamide	100–500	24–50	Active	Urine >90%

[a] New patients are not usually started on first-generation sulfonylureas (tolbutamide, chlorpropamide).
[b] Glibenclamide is also known as glyburide in some countries.
MR, modified release.

[44]. Because sulfonylureas can stimulate insulin release when glucose concentrations are below the normal threshold for glucose-stimulated insulin release (~5 mmol/L), they are capable of causing hypoglycemia, mainly through insulin-induced suppression of hepatic glucose production.

There is some evidence that sulfonylureas exert minor glucose-lowering effects independently of increased insulin secretion [45, 46]. A small reduction in glucagon concentrations, increased peripheral glucose transport and increased hepatic glucose deposition have been reported, but these effects are not considered to be of sufficient magnitude to be clinically relevant.

Pharmacokinetics

Sulfonylureas vary considerably in their pharmacokinetic properties (Table 31.7), which in turn affects their clinical suitability for different individuals [45–47]. They are generally well absorbed, and reach peak plasma concentration in 2–4 h. Sulfonylureas are highly bound to plasma proteins, which can lead to interactions with other protein-bound drugs such as salicylates, sulfonamides, and warfarin. Also, displacement of protein-bound sulfonylurea can increase the risk of hypoglycemia (Table 31.5). Sulfonylureas are metabolized in the liver to varying extents to a range of active and inactive metabolites that are eliminated along with unchanged drug via the bile and urine. Longer acting sulfonylureas can be given once daily but carry a greater risk of hypoglycemia, especially with active metabolites. Sites and rates of metabolism and elimination are also important considerations, especially in older people and individuals with coexisting liver or kidney disease or taking several other medications.

The formulation of some sulfonylureas has been altered to modify the duration of action. For example, a micronized formulation of glibenclamide (termed glyburide) in the USA increases the rate of gastrointestinal absorption for earlier onset of action. A longer acting ("extended-release") formulation of glipizide and a "modified-release" (MR) formulation of gliclazide have been introduced for once-daily dosing. Interestingly, the 30 mg preparation of gliclazide MR gives similar efficacy to 80 mg of unmodified gliclazide and reduces the risk of severe hypoglycemia [48].

Indications and contraindications

Sulfonylureas are widely used as monotherapy and in combination with metformin or a thiazolidinedione. They can also be used with an α-glucosidase inhibitor, and there are individuals who can benefit from a combination of a sulfonylurea with an incretin agent or insulin. Combination of a sulfonylurea with a different type of antidiabetes agent usually affords approximately additive glucose-lowering efficacy, at least initially, but there is increased risk of hypoglycemia. The additive efficacy of a sulfonylurea with another type of insulin secretagogue is dependent on different modes of action on the β cell.

The pharmacological theory of adding a sulfonylurea (or other insulin secretagogue) to insulin therapy for people with T2DM is that subcutaneous insulin injections do not mimic the normal endogenous delivery of more insulin to the liver than to the periphery. Thus, where there is residual endogenous β-cell function, a stimulus to increase delivery of endogenous insulin to the liver should assist in reducing hepatic glucose production, particularly during digestion of a meal. Hence daytime sulfonylurea is sometimes given with bedtime insulin, and this can substantially, if only temporarily, reduce the required insulin dose [46, 47]. Guidelines generally include sulfonylureas as alternative first-line oral therapy where metformin is not appropriate or not tolerated. Because sulfonylurea therapy is associated with weight gain, these agents have customarily been preferred for people who are not overweight.

Sulfonylurea therapy is begun with a low dose, preferably with self-monitoring of blood glucose by the individual at least once daily during the first few weeks. This is especially recommended where there are strong concerns about the potential consequences of hypoglycemia (e.g. in elderly individuals and those living alone, operating machinery, or driving). In general, people who have responded to some extent (but still inadequately) with lifestyle measures and have less marked fasting hyperglycemia are more likely to incur hypoglycemia with a sulfonylurea. The dosage is uptitrated at 2–4-week intervals as required. Hypoglycemia or early hypoglycemic symptoms are the main limitation to dose escalation of sulfonylureas. If evidence of hypoglycemia occurs

before the glycemic target is achieved, or if a dosage increment produces no further glycemic benefit, it is advisable to return to the previous dose. Adjustment of the administration regimen may assist or an alternative class of insulin secretagogue may be more suitable. Where the sulfonylurea is taken as monotherapy and the glycemic target is not achieved, then addition of an agent to reduce insulin resistance or an SGLT-2 inhibitor or an α-glucosidase inhibitor is the usual recourse. Note that the maximal blood glucose-lowering effect of a sulfonylurea is usually achieved at a dose that is well below the recommended maximum, indicating that maximal stimulation of insulin secretion has already been achieved.

Efficacy

As monotherapy in people whose diabetes is inadequately controlled by lifestyle measures, sulfonylureas can be expected to reduce fasting plasma glucose by about 2–4 mmol/L, equating to a decrease in HbA_{1c} of 1–2% (11–22 mmol/mol) [3, 4, 46, 47]. The glucose-lowering effect of sulfonylureas is immediate, and sulfonylureas are particularly effective in the short term. Efficacy is dependent, however, on sufficient reserve of β-cell function, and this is set against the inevitable decline in β-cell function as the natural history of T2DM proceeds. Hence it is expected that the dose will need to be escalated to counter the progressive loss of β-cell function, which can reduce the durability of the glucose-lowering efficacy. A rapid deterioration of glycemic control during sulfonylurea therapy (sometimes termed "secondary sulfonylurea failure") occurs in ~5–10% of people per annum [55]. Although this may possibly vary between compounds, it largely reflects the progression of β-cell failure [3, 4, 46, 47]. Early intervention in people with a greater reserve of β-cell function usually produces a better and longer response to sulfonylureas, although not without risk of hypoglycemia, whereas late intervention in those with severely compromised β-cell function is less effective.

Sulfonylureas generally have little effect on blood lipids. Occasionally, their use will cause a small decrease in plasma triglyceride or increase in HDL cholesterol.

Adverse effects

Weight gain, typically in the range 1–4 kg, is common after initiation of sulfonylurea therapy; it stabilizes by about 6 months [11, 46, 47]. The weight gain probably reflects the anabolic effects of increased plasma insulin concentrations together with reduced loss of glucose in the urine.

Hypoglycemia is a common and potentially the most serious adverse effect of sulfonylurea therapy. Although it is only rarely life threatening in people with T2DM, even mild impairment of neural or motor function can endanger the individual and others, and may predispose to a poor prognosis after a MI [49, 50]. People treated with sulfonylureas should be given instruction on the prevention and recognition of hypoglycemia and the prompt actions required. In the UKPDS, ~20% of sulfonylurea-treated participants reported one or more episodes of hypoglycemic symptoms annually. Other studies have suggested similar rates [11, 46, 47]. Severe hypoglycemia (requiring third-party assistance) during sulfonylurea therapy occurred in ~1% of participants annually in the UKPDS, and lower rates (~0.2–2.5 episodes per 1000 patient-years) have been reported elsewhere. The mortality risk from sulfonylurea-induced hypoglycemia is reported to be 0.014–0.033 per 1000 patient-years [49]. Longer acting sulfonylureas, irregular meals, other antidiabetes drugs, especially insulin, excessive alcohol consumption, already near-normal fasting glycemia, old age, and interacting drugs can predispose to increased risk of hypoglycemia.

Sulfonylurea-induced hypoglycemia requires prompt admission to hospital. Treatment with glucose by continuous intravenous infusion, probably for more than 1 day, is applied to guard against the tendency for a recurrence of hypoglycemia where long-acting sulfonylureas are concerned. If accumulation of chlorpropamide is suspected, renal elimination may be enhanced by forced alkaline diuresis. The vasodilator diazoxide and the somatostatin analog octreotide have been used successfully (but with extreme caution) to inhibit insulin secretion in severe sulfonylurea-induced hypoglycemia. Use of glucagon in people with T2DM should be avoided as this is itself an insulin secretagogue.

Very occasionally, sulfonylureas produce sensitivity reactions, usually transient cutaneous rashes. Erythema multiforme is rare. Fever, jaundice, acute porphyria, photosensitivity, and blood dyscrasias are also rare. Chlorpropamide (no longer in common use) was known for its propensity to cause facial flushing with alcohol and increasing renal sensitivity to antidiuretic hormones, occasionally causing water retention and hyponatremia. Glibenclamide is claimed to have a mild diuretic action.

Although the efficacy of sulfonylureas depends on the stimulation of insulin secretion, this seldom raises plasma insulin concentrations beyond the range of normal individuals without diabetes and those with impaired glucose tolerance (IGT). The suggestion emanating from the University Group Diabetes Program study in the 1960s that tolbutamide-induced hyperinsulinemia might have a detrimental effect on the cardiovascular system remains unsubstantiated.

Further studies on the cardiovascular safety of sulfonylureas were prompted by the finding that two isoforms of the sulfonylurea receptor, SUR2A and SUR2B, are expressed in cardiac muscle and vascular smooth muscle, respectively. These isoforms lack the sulfonylurea binding site but they retain the benzamido binding site (Figure 31.8). Therefore, SUR2A/B can only bind those sulfonylureas that contain a benzamido group (glibenclamide, glipizide, glimepiride) [42]. Sulfonylureas without a benzamido group (e.g. tolbutamide, chlorpropamide, gliclazide) show very little interaction with the cardiac and vascular SUR receptors. The effects of the K^+ATP channel opener nicorandil (an antianginal drug with cardioprotective properties) are blocked by sulfonylureas that have a benzamido group. Compounds with a benzamido group could theoretically interfere with ischemic preconditioning and increase vascular contractility at a time when this might be undesirable (e.g. severe myocardial ischemia).

However, there is no clear evidence that therapeutic concentrations of sulfonylureas exert such an effect. Indeed, hyperglycemic states appear to obviate ischemic preconditioning; but some authorities continue to advocate that the use of sulfonylureas is kept to a minimum in people with overt coronary artery disease [50].

Meglitinides (short-acting prandial insulin releasers)

Meglinide analogs (sometimes termed glinides) were evaluated as potential antidiabetes agents after an observation in the 1980s that meglitinide—the non-sulfonylurea moiety of glibenclamide which contains the benzamido group—could stimulate insulin secretion similarly to a sulfonylurea [51]. The pharmacokinetic properties of these compounds favored a rapid but short-lived insulin secretory effect that suited administration with meals to promote prandial insulin release. By generating a prompt increase of insulin to coincide with meal digestion, these agents help to restore partially the first-phase glucose-induced insulin response that is lost in T2DM. Specifically targeting postprandial hyperglycemia might also address the vascular risk attributed to prandial glucose excursions and reduce the risk of interprandial hypoglycemia [52–54]. Two agents, the meglitinide derivative repaglinide and the structurally related phenylalanine derivative nateglinide, were introduced in 1998 and 2001, respectively, as "prandial insulin releasers" (Figure 31.9). Although acting mainly during the prandial and early postprandial period, their effects extend sufficiently to produce some reduction of fasting hyperglycemia, particularly with repaglinide.

Mode of action

Prandial insulin releasers bind to the benzamido site on the sulfonylurea receptor SUR1 in the plasma membrane of the islet β cells (Figure 31.8). This site is distinct from the sulfonylurea site, but the response to binding is the same as for sulfonylureas, causing closure of the K^+ATP channel. Thus, there is usually no therapeutically additive advantage of using the two types of agents together.

Pharmacokinetics

Repaglinide is almost completely and rapidly absorbed with peak plasma concentrations after about 1 h. It is quickly metabolized in the liver to inactive metabolites, which are mostly excreted in the bile (Table 31.8). Taken about 15 min before a meal, repaglinide produces a prompt insulin response which lasts about 3 h, coinciding with the duration of meal digestion. Nateglinide has a slightly faster onset and shorter duration of action [52–54].

Indications and contraindications

Prandial insulin releasers can be used as monotherapy in people whose diabetes is inadequately controlled by non-pharmacological measures. They are perhaps most suited for individuals who exhibit postprandial glycemic excursions while retaining near-normal fasting glycemia. As rapid-acting insulin releasers, they can be helpful to individuals with irregular lifestyles with unpredictable or missed meals. The lower risk of hypoglycemia also provides a useful option for some older individuals, particularly if other agents are contraindicated, although the need for multiple daily dosages may be a disincentive.

Repaglinide is ideally taken 15–30 min before a meal. Therapy is introduced with a low dose (e.g. 0.5 mg) and glycemic control

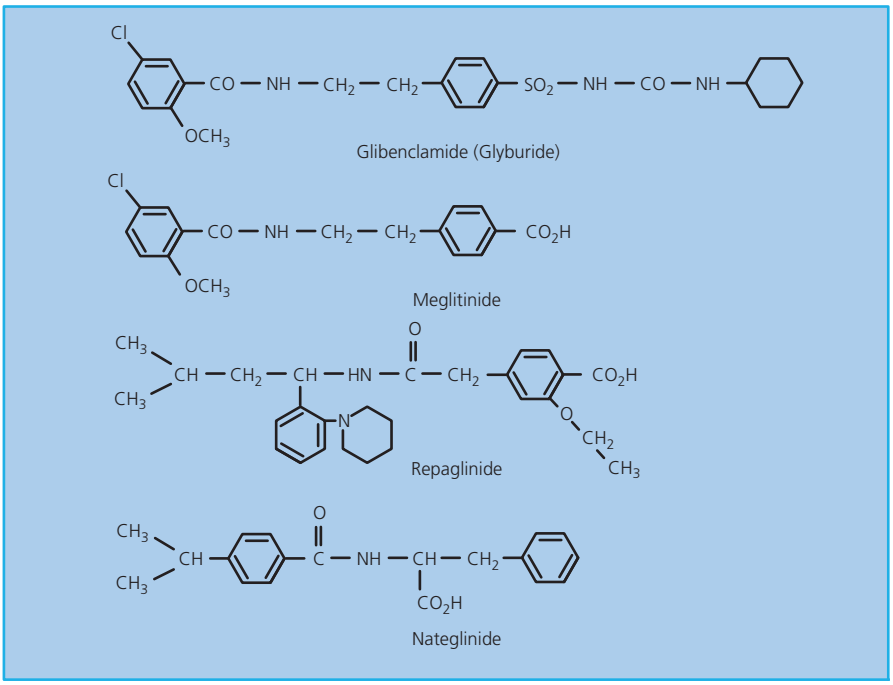

Figure 31.9 Chemical structures of meglitinide and the prandial insulin releasers repaglinide and nateglinide compared with glibenclamide (glyburide).

Table 31.8 The meglitinides: repaglinide and nateglinide.

Agent	Dose range (mg/meal)	Maximum daily dose (mg)	Duration of action (h)	Metabolites	Elimination
Repaglinide	0.5–4.0	16	4–6	Inactive	Bile ~90%
Nateglinide	60–180	540	3–5	One slightly active	Urine ~80%

is monitored during titration every 2 weeks up to a maximum of 4 mg before each main meal. When a meal is not consumed, the corresponding dose of repaglinide should be omitted. With appropriate caution and monitoring, repaglinide can be given to those with moderate renal impairment where some sulfonylureas and metformin are contraindicated.

Nateglinide can be used as monotherapy in much the same way as repaglinide, although nateglinide tends to be faster and shorter acting and requires caution in people with hepatic disease. Note that in some countries, such as the United Kingdom, nateglinide is not licensed for use as monotherapy, only for combination therapy.

If the desired glycemic target is not met with a prandial insulin releaser, early introduction of combination therapy (e.g. with an agent to reduce insulin resistance) can be considered. Prandial insulin releasers can also be useful add-ons to monotherapy with metformin or a thiazolidinedione.

Efficacy

Consistent with their use to boost prandial insulin secretion, repaglinide (0.5–4 mg) and nateglinide (60–180 mg) taken before meals produce dose-dependent increases in insulin concentrations and reduce postprandial hyperglycemia. There is usually a small reduction in fasting hyperglycemia. Reductions in HbA_{1c} are similar to or smaller than with sulfonylureas, as predicted by their shorter duration of action. As add-on to metformin, they can reduce HbA_{1c} by an additional 0.5–1.5% (6–17 mmol/mol).

Adverse effects

Hypoglycemic episodes are fewer and less severe with prandial insulin releasers than with sulfonylureas. Sensitivity reactions, usually transient, are uncommon. Plasma levels of repaglinide may be increased during co-administration with gemfibrozil. Prandial insulin releasers may cause a small increase in body weight when started as initial monotherapy, but body weight is little affected among people switched from a sulfonylurea or when a prandial insulin releaser is combined with metformin.

Thiazolidinediones

The glucose-lowering activity of a thiazolidinedione (ciglitazone) was reported in the early 1980s. In the early 1990s, the peroxisome proliferator-activated receptor (PPAR) family was identified as part of the nuclear receptor superfamily 1, and it became evident that thiazolidinediones were potent agonists of PPAR-γ [55]. The PPAR-γ-mediated transcriptional effects of thiazolidinediones were shown to improve whole-body insulin sensitivity, and troglitazone became the first thiazolidinedione to enter routine clinical use, introduced in the USA in 1997. The drug, however, was associated with fatal cases of idiosyncratic hepatotoxicity and was withdrawn in 2000. Troglitazone was available for only a few weeks in 1997 in the UK. Two other thiazolidinediones, rosiglitazone and pioglitazone (Figure 31.10), which did not show hepatotoxicity, were introduced in the USA in 1999 and in Europe in 2000. Fixed-dose combinations of each agent with metformin are also available.

By 2007, meta-analyses of safety data for rosiglitazone were indicating increased risk of heart failure, MI and cardiovascular deaths, resulting in withdrawal of rosiglitazone in Europe in 2010 and restricted use in the USA (placement on Risk Evaluation and Mitigation Strategy [REMS]) [56]. However, evaluation of a large prospective cardiovascular outcome study with rosiglitazone (Rosiglitazone Evaluated for Cardiac Outcomes and Regulation of Glycemia in Diabetes [RECORD]) did not confirm the increased risk of MI and cardiovascular death, and the REMS restriction in the USA was lifted in 2013. An earlier (2007) study with pioglitazone (Prospective Pioglitazone Clinical Trial in Macrovascular Events [PROactive]) had not shown increased risk of MI or cardiovascular death, and pioglitazone is the only thiazolidinedione available in many countries [57, 58].

Mode of action

Most of the glucose-lowering efficacy of thiazolidinediones appears to be achieved through stimulation of PPAR-γ, leading to increased insulin sensitivity [55, 59]. PPAR-γ is highly expressed in adipose tissue, and to a lesser extent in muscle and liver. When activated it forms a heterodimeric complex with the retinoid X receptor and binds to a nucleotide sequence (AGGTCAXAGGTCA) termed the peroxisome proliferator

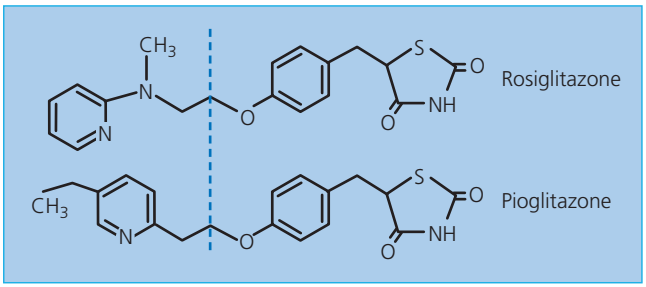

Figure 31.10 Chemical structures of thiazolidinediones rosiglitazone and pioglitazone.

Table 31.9 Examples of key genes activated by thiazolidinediones via stimulation of the peroxisome proliferator-activated receptor γ (PPAR-γ). Not all genes appear to be activated in all tissues. The main effects are in adipose tissue.

↑ Lipoprotein lipase
↑ Fatty acid transporter protein (FATP/CD36)
↑ Adipocyte fatty acid-binding protein (aP2)
↑ Acyl-CoA synthetase
↑ Malic enzyme
↑ Glycerol kinase (in adipocytes?)
↑ PEPCK (adipocytes), ↑ perilipin
↑ GLUT-4 (by derepression), ↑ GLUT-2 (islet β cells)
↓ 11β-Hydroxysteroid dehydrogenase-1
↓ Resistin, ↓ RBP 4
↑ Adiponectin (↑ leptin?)
↓ TNF-α, ↓ IL-6
↓ CRP and some proinflammatory cytokines, ↓ NFκB
↓ PAI-1, ↓ MMP-9
↑ UCP-1 (?)

CRP, C-reactive protein; GLUT, glucose transporter; IL-6, interleukin 6; NFκB, nuclear factor κB; PAI-1, plasminogen activator inhibitor 1; MMP-9, matrix metalloproteinase 9; PEPCK, phosphoenolpyruvate carboxy kinase; RBP, retinol-binding protein; TNF-α, tumor necrosis factor α; UCP-1, uncoupling protein 1.

response element (PPRE) located in the promoter regions of PPAR-responsive genes. In conjunction with co-activators such as PGC-1, this alters the transcriptional activity of a range of insulin-sensitive and other genes (Table 31.9). Many of these genes participate in lipid and carbohydrate metabolism (Figure 31.11). Stimulation of PPAR-γ by a thiazolidinedione promotes differentiation of pre-adipocytes into mature adipocytes; these new small adipocytes are particularly sensitive to insulin, and show increased uptake of fatty acids with increased lipogenesis. This in turn reduces circulating non-esterified (free) fatty acids, which rebalances the glucose–fatty acid (Randle) cycle, facilitating glucose utilization and restricting fatty acid availability as an energy source for hepatic gluconeogenesis. By reducing circulating fatty acids, ectopic lipid deposition in muscle and liver is reduced, which further contributes to improvements of glucose metabolism. Thiazolidinediones also increase mitochondrial biogenesis but may act directly on mitochondria to reduce respiratory function.

Thiazolidinediones increase glucose uptake into adipose tissue and skeletal muscle via increased availability of GLUT-4 glucose transporters. Improvements in insulin sensitivity are likely to be assisted by reduced production of several adipocyte-derived pro-inflammatory cytokines, notably tumor necrosis factor α (TNF-α), which is implicated in muscle insulin resistance. Thiazolidinediones also increase the production of adiponectin, which enhances insulin action and exerts potentially beneficial effects on vascular reactivity. Because PPAR-γ is expressed to a small extent in many tissues, thiazolidinediones can therefore affect responsive genes at these locations, and this has given rise to the tag "pleotropic effects" [59, 60].

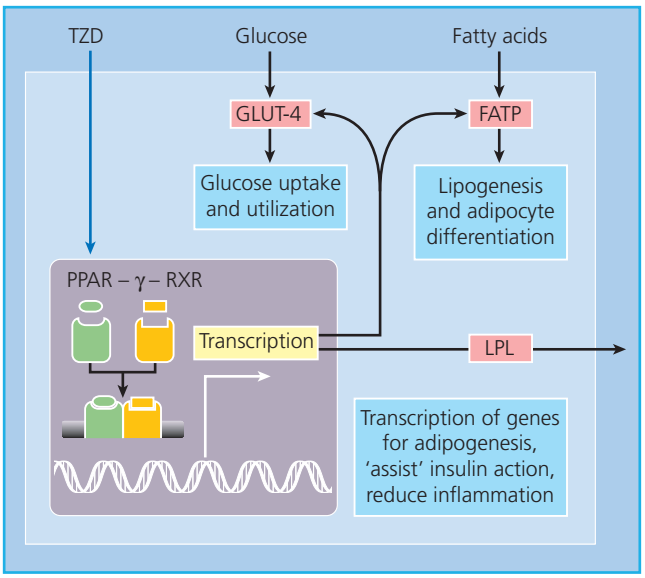

Figure 31.11 Mechanism of action of thiazolidinediones. Most actions of a thiazolidinedione (TZD) are mediated via stimulation of the nuclear peroxisome proliferator-activated receptor γ (PPAR-γ), which is highly expressed in adipose tissue. When stimulated, PPAR-γ forms a heterodimeric complex with the retinoid X receptor (RXR). The complex binds to the peroxisome proliferator response element (PPRE) nucleotide sequence (AGGTCAXAGGTCA) in the promoter regions of certain genes, recruits co-activators, and alters the transcriptional activity of these genes. This modifies nutrient uptake and metabolism, and also the other functions of the cell.

Thiazolidinediones, like metformin, are antihyperglycemic agents and require the presence of sufficient insulin to generate their blood glucose-lowering effect. Plasma insulin concentrations are typically lowered by thiazolidinediones, and there is evidence that long-term viability of islet β cells might be improved [61].

Pharmacokinetics

Absorption of rosiglitazone and pioglitazone is rapid and almost complete, with peak concentrations at 1–2 h, but slightly delayed when taken with food. Both drugs are metabolized extensively by the liver. Rosiglitazone is metabolized mainly by cytochrome P450 isoform CYP2C8 to inactive or only very weakly active metabolites with a plasma $t_{1/2}$ of 100–160 h; these are mostly eliminated in the urine. Pioglitazone is metabolized predominantly by CYP2C8 and CYP3A4 to active metabolites that are eliminated in the bile (Table 31.10). Rosiglitazone can interact with gemfibrozil.

Table 31.10 The thiazolidinediones: pioglitazone and rosiglitazone.

Agent	Dose range (mg/day)	Duration of action (h)	Metabolites	Elimination
Pioglitazone	15–45	~24	Active	Bile >60%
Rosiglitazone	4–8	~24	Inactive	Urine ~64%

Pioglitazone does not appear to cause any clinically significant reductions in plasma concentrations of other drugs metabolized by CYP3A4, such as oral contraceptives. Both thiazolidinediones are almost completely bound to plasma proteins, but their concentrations are not sufficient to interfere with other protein-bound drugs.

Indications and contraindications

Thiazolidinediones can be used as monotherapy in non-obese and obese individuals with T2DM in whom lifestyle does not afford adequate glycemic control. Various treatment algorithms ascribe different positions for thiazolidinediones, but in general they can be used as monotherapy if metformin is inappropriate or not tolerated, and for those in whom an insulin secretagogue is less favored. They are often used to gain additive efficacy in combination with other antidiabetes drugs, particularly metformin [62]. Because of their slow onset of action, it is not straightforward to substitute a thiazolidinedione for either a sulfonylurea or metformin without a temporary deterioration in glycemic control. Combination of a thiazolidinedione with insulin can improve glycemic control while reducing insulin dosages, especially in obese individuals, but requires extra caution as peripheral edema is more common [63].

A particular issue with thiazolidinediones is their propensity for fluid retention with an increased plasma volume of up to 500 mL, a reduced hematocrit, and a decrease in hemoglobin concentration of up to 1 g/dL. Hence the use of thiazolidinediones is contraindicated in people with evidence of heart failure. The exclusion criteria, based on cardiac status, vary between countries; for example, New York Heart Association classes I–IV are exclusions in Europe, whereas classes III and IV are exclusions in the USA [63]. Appropriate clinical monitoring is important, especially for people considered at higher risk for cardiac failure and those showing marked initial weight gain. Despite an increased fluid volume, thiazolidinediones do not increase, and usually slightly decrease, blood pressure.

Although hepatotoxicity has not been a concern with either rosiglitazone or pioglitazone, the troglitazone experience prompted vigilance concerning liver function by measuring serum alanine aminotransferase (ALT) before starting therapy and periodically thereafter. Pre-existing liver disease, development of clinical hepatic dysfunction, or elevated ALT levels >2.5 times the upper limit of normal are contraindications to thiazolidinediones. Interestingly, because of the effects of thiazolidinediones on hepatic fat metabolism, recent studies have suggested that this class of drug might even be useful for the treatment of non-alcoholic steatohepatitis.

If there are no contraindications, a thiazolidinedione can be used in the elderly. A thiazolidinedione can also be considered for individuals with mild renal impairment, but appreciating the potential for edema. Use of a thiazolidinedione in women with anovulatory PCOS can cause ovulation to resume, but thiazolidinediones should not be continued in pregnancy.

Efficacy

Thiazolidinediones produce a slowly generated antihyperglycemic effect, which usually requires 2–3 months to reach maximum effect [55, 61]. This tends to prolong the dose titration process, and because the therapeutic response can vary considerably between individuals, it is appropriate to consider the patient as a non-responder and to switch to another treatment if there is no clinically meaningful effect after 3 months. The two thiazolidinediones have similar blood glucose-lowering effects, reducing HbA_{1c} by around 0.5–1.5% (6–17 mmol/mol). In a long-term monotherapy comparison with metformin or a sulfonylurea (the ADOPT study), rosiglitazone showed a slower onset but a more durable glucose-lowering effect over more than 3 years [61]. Data from clinical trials suggest that the effect of thiazolidinediones may be better in people with greater β-cell reserve and in more overweight individuals, but a clear indicator of the best responders has not been established. Thiazolidinediones do not cause hypoglycemia as monotherapy.

Both thiazolidinediones substantially reduce circulating nonesterified (free) fatty acids, but effects on other components of the plasma lipid profile have been the subject of debate. Rosiglitazone tends to cause a small rise in the total cholesterol concentration, which stabilizes by about 3 months, although this may be mitigated by adequate statin therapy. The effect appears to reflect a rise in both LDL and HDL cholesterol, leaving the LDL : HDL cholesterol ratio and the total : HDL cholesterol ratio little changed or slightly improved. Pioglitazone generally appears to have little effect on total cholesterol, and has frequently reduced triglyceride concentrations in clinical trials. Both thiazolidinediones reduce the proportion of the smaller, more dense (more atherogenic) LDL particles [64].

Weight gain, similar in magnitude to sulfonylurea therapy (typically 1–4 kg) and stabilizing over 6–12 months, is usually observed after initiation of thiazolidinedione therapy. Several studies indicate that the distribution of body fat is altered. The visceral adipose depot is little changed or reduced, while the subcutaneous depot is increased as new small, insulin-sensitive adipocytes are formed [65].

Thiazolidinediones have been reported to exert beneficial effects on a selection of atherothrombotic risk markers, indices of vascular reactivity, and components of the "metabolic syndrome" [63, 65]. For example, thiazolidinediones downregulate PAI-1 expression, decrease urinary albumin excretion to a greater extent than expected for the improvement in glycemic control, reduce cIMT and coronary restenosis, and reduce circulating markers of chronic low-grade inflammation. Thiazolidinediones also reduce the occurrence of new-onset diabetes in individuals with IGT or those with a history of gestational diabetes [66, 67].

Adverse effects

Despite improvements in several atherothrombotic risk factors, the main concerns over thiazolidinediones have focused on the cardiovascular impact of edema, reduced hemoglobin levels, and congestive heart disease. Although long-term cardiovascular

events were reduced during a large prospective study with pioglitazone (PROactive), the cardiovascular safety issues raised over rosiglitazone have reduced confidence in the class [57, 58, 63].

Recent studies have noted an approximate doubling of the risk of a bone fracture—notably at distal sites—amongst postmenopausal women receiving a thiazolidinedione, and possibly a slightly increased risk amongst men [68]. This has been attributed at least in part to a reduction in bone mineral density. Stimulation of PPAR-γ in colonic cells has been reported both to increase and to decrease the risk of tumors in animals and cell models; thus, familial polyposis coli is a contraindication to thiazolidinediones on theoretical grounds. There has been debate concerning a possible increased risk of bladder cancer with pioglitazone, and the drug is not recommended for people with active bladder disease or a history of bladder disease. However, long-term safety analyses have not confirmed a significant increase in risk of bladder cancer with pioglitazone [58, 69].

Hypoglycemia may occur several weeks after adding a thiazolidinedione to a sulfonylurea; self-monitoring of blood glucose can be helpful to identify when the dosage of the sulfonylurea should be reduced. It has been suggested that rosiglitazone is initiated at half maximal dosage with a sulfonylurea.

DPP-4 inhibitors

Dipeptidyl peptidase 4 (DPP-4) inhibitors (often termed gliptins) inhibit the enzyme DPP-4, which is responsible for the rapid degradation of two key incretin hormones, glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide 1 (GLP-1). Thus DPP-4 inhibitors enhance endogenous incretin activity by preventing the rapid degradation of these incretin hormones. The history, structure, and function of incretin hormones, and the therapeutic role of subcutaneously injected GLP-1 receptor agonists such as exenatide, liraglutide, lixisenatide, dulaglutide, and albiglutide, are covered in Chapter 32. Briefly, incretin hormones are secreted from the intestine in response to meal digestion; one of their main actions is to increase glucose-induced insulin secretion by the pancreatic islet β cells, thereby reducing prandial glucose excursions [70–72]. GLP-1 also suppresses glucagon secretion from the islet α cells, exerts a satiety effect, and delays gastric emptying.

It was noted in the 1980s that the incretin effect is reduced in T2DM, and subsequent studies have shown that this is largely due to reduced activity of GLP-1 [73], suggesting that administration of extra GLP-1 might be therapeutically useful. Because GLP-1 is rapidly degraded ($t_{1/2}$ <2 min) by DPP-4, the potential of DPP-4 inhibitors was investigated in the 1990s, giving rise to the introduction of several specific inhibitors [74], notably sitagliptin (2007), vildagliptin (2008), saxagliptin (2008), linagliptin (2011), and alogliptin (2013) (Figure 31.12).

Mode of action

DPP-4 inhibitors act to prevent the aminopeptidase activity of DPP-4; the enzyme is found free in the circulation and tethered to endothelia and other epithelial cells in most tissues, especially in the intestinal mucosa [75]. DPP-4 cleaves the N-terminal dipeptide from peptides that have either an alanine or a proline residue penultimate to the N-terminus. The incretins GLP-1 and GIP are prime targets for DPP-4, and DPP-4 inhibitors more than double their circulating concentrations (but this is not as high as the concentrations of subcutaneously administered GLP-1 receptor agonists) [75, 76]. Raised endogenous incretin concentrations enhance nutrient-induced insulin secretion. Increased insulin biosynthesis and increased β-cell mass have also been noted in some animal studies, but these effects have not been confirmed in clinical studies (Table 31.11). Increased GLP-1 concentrations also suppress excessive glucagon secretion.

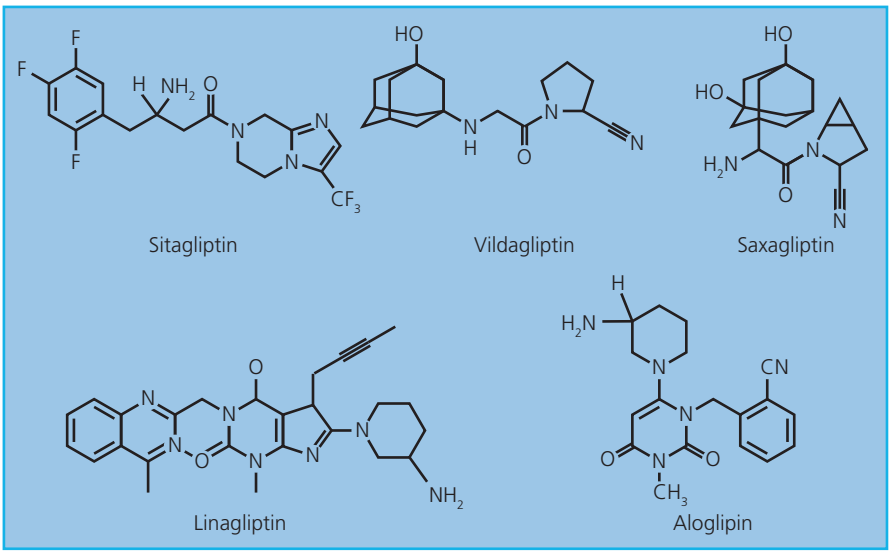

Figure 31.12 Chemical structures of the gliptins (DPP-4 inhibitors) sitagliptin, vildagliptin, saxagliptin, linogliptin, and alogliptin.

Promote lipogenesis	–	✓

[a] Effect observed in animal studies but not confirmed by clinical studies inT2DM.
✓, Yes; –, no effect.

Because these effects are glucose dependent, there is low risk of inducing significant hypoglycemia. The elevation of GLP-1 levels produced by DPP-4 inhibitors is not generally sufficient to create a measurable satiety effect or sufficient slowing of gastric emptying to cause any nausea, and body weight is usually little changed or slightly reduced (Figure 31.13).

Because the incretin-mediated effect of DPP-4 inhibitors potentiates glucose-dependent insulin secretion, the activity period of these agents is mostly prandial. Although they are particularly effective in lowering postprandial hyperglycemia, there is a substantial carryover effect to benefit the control of interprandial glycemia [74, 76]. By contrast, DPP-4 inhibitors do not initiate insulin secretion and so they do not increase basal insulin secretion. Also, they only suppress glucagon secretion in the hyperglycemic state, and so there is a low risk of interprandial "overshoot" into hypoglycemia.

Pharmacokinetics

The pharmacokinetic properties of DPP-4 inhibitors are summarized in Table 31.12. DPP-4 inhibitors are selective, competitive and reversible inhibitors of DPP-4 (IC_{50} in the lower nmol/L range). They mimic the N-terminal dipeptide structure of the incretins, which enables them to block the catalytic site of DPP-4 through either covalent (vildagliptin and saxagliptin) or non-covalent (sitagliptin, linagliptin, and alogliptin) interactions. DPP-4 inhibitors are absorbed rapidly with onset of activity in <10 min of administration and t_{max} achieved mostly within 2 h. They produce >90% inhibition of DPP-4 activity for most of a 24-h period, although the shorter elimination half-life of vildagliptin requires twice-daily administration compared with once daily for other agents in the class. Two DPP-4 inhibitors are substantially metabolized (vildagliptin to inactive metabolites and saxagliptin to active metabolites), whereas the others undergo little metabolism. Linagliptin is eliminated mostly via the bile into the feces and can be used without dose adjustment in people with moderate to severe renal impairment. Other members of the class are eliminated in the urine, necessitating dose reduction in people

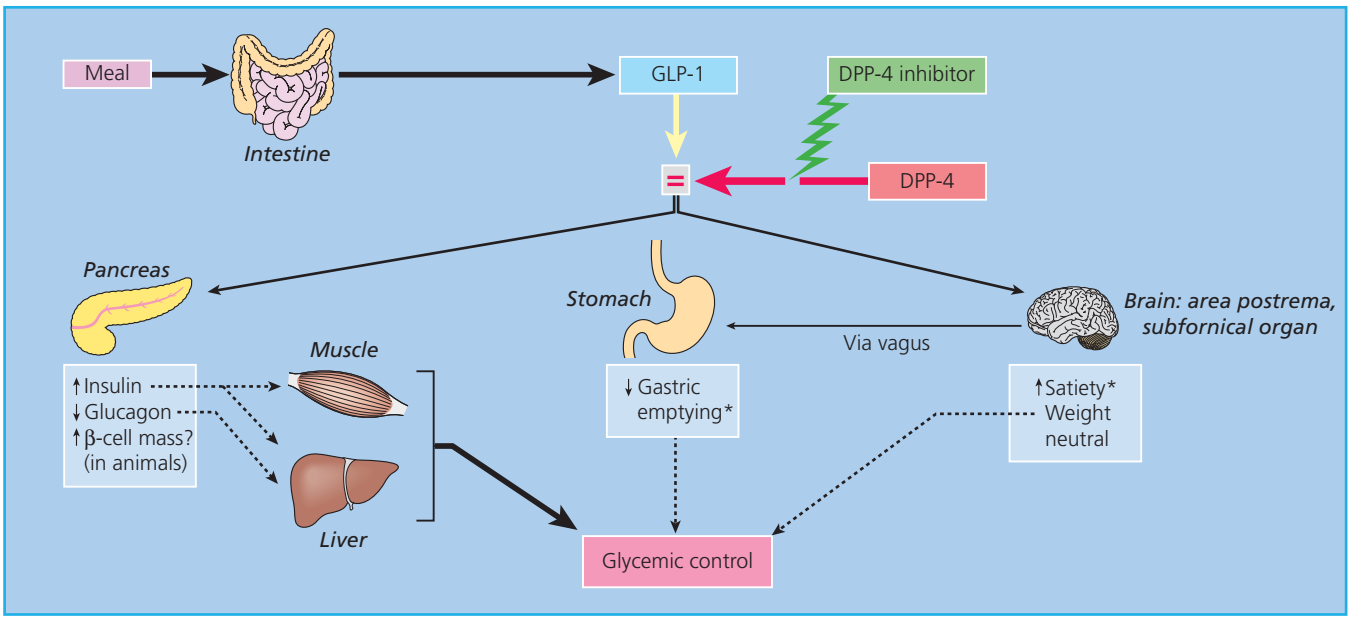

Figure 31.13 Sites of action of DPP-4 inhibitors (gliptins). Incretin hormones such as GLP-1 are released in response to a meal. These hormones are normally degraded rapidly by the enzyme DPP-4. Gliptins act as inhibitors of DPP-4, allowing the normal effects of the incretin hormones to be enhanced. The main site of the enhanced incretin effect is on the pancreas to increase nutrient-induced insulin secretion. GLP-1 also reduces glucagon secretion. *Potential effects to slow gastric emptying and increase satiety probably contribute little to the therapeutic efficacy of DPP-4 inhibitors.

with moderate renal impairment (typically a GFR <50 mL/min) [74, 76].

Indications and contraindications

DPP-4 inhibitors can be used as monotherapy in people with T2DM who have responded inadequately to lifestyle measures, and as "add-on" therapy in people whose diabetes is inadequately controlled by metformin or a thiazolidinedione. Theoretically, they could be used with any other class of oral agent or insulin, as their mode of action on the β cell is different from that of sulfonylureas and meglitinides, and their ability to reduce glucagon levels might be useful as add-on therapy to insulin even without β-cell function. In practice, however, full efficacy in T2DM requires adequate β-cell reserve. Lack of weight gain makes DPP-4 inhibitors suitable for overweight and obese individuals, and the low risk of hypoglycemia when used as monotherapy (and when used with non-insulin-releasing agents) favors their use in people who have only slightly raised basal glycemia, are close to glycemic target, or have unpredictable meal times [74, 76].

Efficacy

The antihyperglycemic effect of DPP-4 inhibitors is quickly generated, with HbA_{1c} values typically reduced by ~0.7–1.0% (8–11 mmol/mol). Postprandial glucose excursions are reduced by ~3 mmol/L and basal glycemia by ~1–1.5 mmol/L. The glucose-dependent mode of action (i.e. DPP-4 inhibitors only potentiate insulin secretion when glucose concentrations are raised) reduces the risk of any significant hypoglycemia, lowering concern over missed meals. Thus, there is no dose titration, but it is recommended that fasting and postprandial glycemia are reviewed after about 2 weeks of therapy, especially when added as a second agent. The incretin-raising effects of DPP-4 inhibitors do not appear to be sufficient to reduce gastric emptying or produce a measurable satiety effect. Accordingly, DPP-4 inhibitors do not cause weight gain and may assist slight weight loss [74, 76–78].

Adverse effects

Substantial clinical experience with DPP-4 inhibitors has indicated a good safety profile to date. In clinical trials (typically 6–12 months), measures of tolerability and adverse events were generally similar to those with placebo or comparator. Owing to their glucose-dependent action on the pancreas, DPP-4 inhibitors carry a low risk of serious hypoglycemia unless administered along with an agent that itself carries significant risk of hypoglycemia. Thus, when a DPP-4 inhibitor is used in combination with a sulfonylurea or with insulin, it may be appropriate initially to lower the dose of the sulfonylurea or insulin, especially for those who are only modestly hyperglycemic and more vulnerable to hypoglycemia. DPP-4 inhibition has been associated with some hyperplasia of the exocrine pancreas, and there is evidence from several prospective and retrospective clinical studies that DPP-4 inhibition can increase the risk of acute pancreatitis in T2DM. Although this has not been consistently observed, or numerical data have not been statistically significant, appropriate caution is recommended and a DPP-4 inhibitor should be stopped if pancreatitis is suspected, and alternative therapy sought for people with a history of pancreatitis. Long-term cardiovascular safety studies have raised the possibility of an increased risk of hospitalization for angina during use of some DPP-4 inhibitors, but the evidence is equivocal [58, 74, 76].

In addition to GLP-1 and GIP, there are many natural substrates for DPP-4, including bradykinin, enkephalins, neuropeptide Y, peptide YY1-36, gastrin-releasing polypeptide, substance P, insulin-like growth factor I, the α chains of thyrotropin, luteinizing hormone, and chorionic gonadotropin, and several chemokines such as monocyte chemotactic protein 1 (MCP-1). Hence DPP-4 inhibitors have the potential to influence the hunger–satiety system, gastrointestinal motility, growth, vascular reactivity, and immune mechanisms, but there is little evidence of any clinically significant changes in these physiological processes [74, 75]. DPP-4 is also the CD26 T-cell activation antigen, but neither CD26 knockout mice nor the DPP-4-specific inhibitors used in animals or humans have shown any significant untoward immune-related effects. The importance of selective DPP-4

inhibition is also noted because inhibition of related enzymes such as DPP-8 and DPP-9 has produced blood dyscrasias and skin lesions in some species, but not in clinical use. No significant drug interactions have been noted with DPP-4 inhibitors, but evidence of reproductive toxicity in animals warrants discontinuation in pregnancy.

SGLT-2 inhibitors

SGLT-2 is highly expressed in the first segment of the proximal tubules of the kidneys, where it is responsible for the reabsorption of ~90% of glucose in the glomerular filtrate. Partial inhibition of SGLT-2 provides a non-insulin-dependent mechanism to reduce glucose reabsorption, eliminate excess glucose in the urine, and so reduce hyperglycemia [79, 80]. Studies in the 1980s showed that phlorizin, a naturally occurring inhibitor of sodium–glucose transporters found in apple tree bark, could reduce hyperglycemia in partially pancreatectomized rodents with diabetes. However, phlorizin was degraded too rapidly in the intestine to be used therapeutically, but chemical modifications to minimize intestinal breakdown and increase selectivity against SGLT-2 have given rise to a class of selective SGLT-2 inhibitors represented by canagliflozin, dapagliflozin, and empagliflozin (Figure 31.14).

Mode of action

SGLT-2 is a high-capacity secondary active co-transporter that transfers one sodium ion with one glucose molecule down an electrochemical gradient for sodium, generated by, for example, the activity of an Na^+–K^+ ATPase pump [81]. SGLT-2 inhibitors interact with SGLT-2 transporters located at the luminal surface of the epithelium lining the initial region of the renal proximal tubules (Figure 31.15). They competitively inhibit the transporter, reducing glucose reabsorption and thereby lowering the renal threshold for glucosuria. In this way, SGLT-2 inhibitors enable ~20–30% of filtered glucose (about 50–100 g glucose/day) to be eliminated in the urine of people with T2DM [82]. As the blood glucose concentration declines, the amount of filtered glucose declines and the glucosuria declines, minimizing the effect of SGLT-2 inhibition in the euglycemic range and avoiding frank hypoglycemia. Because the mechanism is independent of insulin, it will continue to operate under conditions of insulin resistance and β-cell failure, but requires adequate kidney function to filter sufficient glucose for partial SGLT-2 inhibition to create enough glucosuria to impact the hyperglycemia. The glucosuria induced by SGLT-2 inhibition can assist weight loss and generate a mild osmotic diuresis that may contribute to a small reduction in blood pressure [79, 80].

SGLT-2 inhibitors can weakly suppress the activity of SGLT-1 transporters (transfer two sodium ions with one glucose or galactose). SGLT-1 is abundant in the intestine and accounts for the absorption of glucose; it is also expressed in the third (straight descending) segment of the proximal tubules, where it is responsible for ~10% of glucose reabsorption. Canagliflozin may interact with SGLT-1 to defer intestinal glucose absorption slightly more distally along the intestinal tract and possibly reduce SGLT-1 activity in the kidney.

Pharmacokinetics

The pharmacokinetic properties of SGLT-2 inhibitors are summarized in Table 31.13. They reversibly inhibit SGLT-2 at low nmol/L concentrations by blocking the glucose site for several minutes. SGLT-2 inhibitors are taken as once-daily tablets; they are rapidly absorbed with high bioavailability. In plasma they are mostly protein bound and are degraded mainly through glucuronidation by uridine diphosphoglucuronosyltransferases to inactive metabolites. They show little or no inhibition by or induction of P450 isoforms that metabolize other common medications, and no clinically significant drug interactions have been noted [80].

Indications and contraindications

SGLT-2 inhibitors can be used as monotherapy in people with T2DM who have not responded adequately to lifestyle measures, although they are more often used as "add-on" therapy in those whose diabetes is inadequately controlled by metformin or another glucose-lowering agent. In principle, an SGLT-2 inhibitor can be used with any other class of oral agent or insulin, as the mode of action is different from those of all other classes of glucose-lowering agents. Body weight reduction makes an SGLT-2 inhibitor suitable for overweight and obese individuals, and

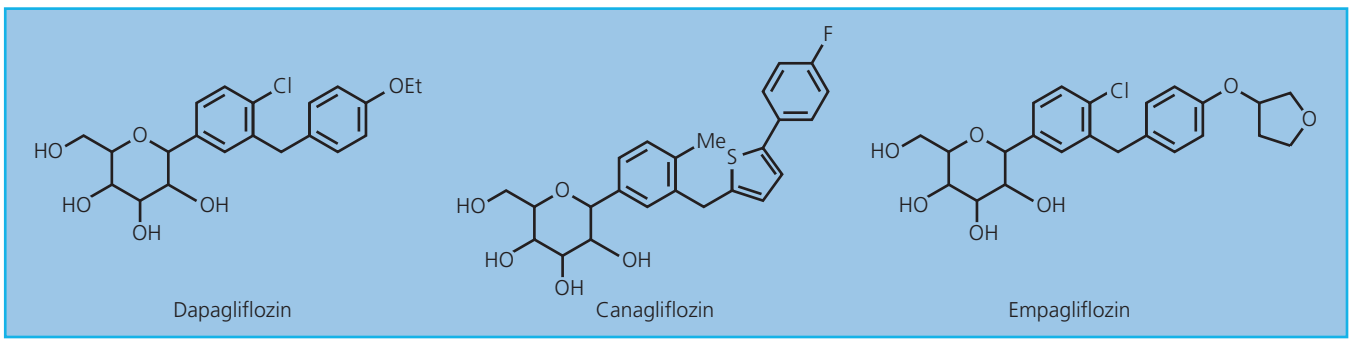

Figure 31.14 Structures of the sodium–glucose co-transporter-2 (SGLT-2) inhibitors dapagliflozin, canagliflozin, and empagliflozin.

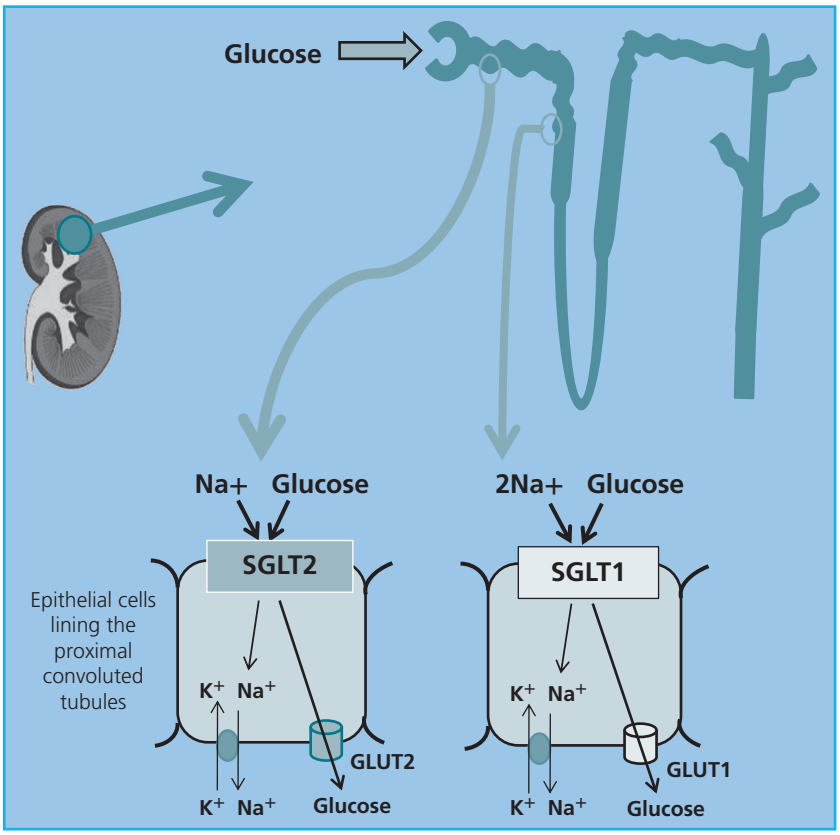

Figure 31.15 Renal sodium–glucose transporters reabsorb glucose from the renal proximal tubules. Glucose is filtered at the glomerulus into the proximal tubule and mostly reabsorbed from the initial region of the proximal tubule via the high-capacity transporter SGLT-2. Remaining glucose is reabsorbed more distally along the proximal tubule via the low-capacity transporter SGLT-1. Source: Bailey, CJ. New drugs for the treatment of diabetes mellitus. In: *International Textbook of Diabetes Mellitus*, 4th edn. John Wiley & Sons, 2015.

the low risk of hypoglycemia renders this class of agent suitable for people with glucose values close to target. Modest reductions of blood pressure in individuals with hypertension may also be expected [80].

Adequate renal function is an important consideration for use of an SGLT-2 inhibitor to enable glucosuric efficacy. Although recommendations may vary slightly between countries, an SGLT-2 inhibitor can be used at full daily dosage for eGFR >60 mL/min. For people with an eGFR value of 45–60 mL/min, a reduced dose (canagliflozin and empagliflozin) or discontinuation (dapagliflozin) is generally suggested. Patients should be informed about the need to remain hydrated and the risk of initial nocturia and genital and urinary tract infections. People with insulin-treated T2DM should ensure that they maintain an adequate insulin dose since insulin is required for many more physiological purposes than glycemic control. At the time of writing, SGLT-2 inhibitors are not approved for use in T1DM and should be discontinued in pregnancy.

Efficacy

The glucose-lowering efficacy of SGLT-2 inhibitors in T2DM has been confirmed in prospective randomized clinical trials during use as monotherapy and in combination with other glucose-lowering therapies including insulin. There is a rapid onset of action to reduce postprandial and basal hyperglycemia. HbA_{1c} is typically reduced by ~0.6–1.2% (7–13 mmol/mol), although larger reductions may be seen in people with severe hyperglycemia and those with good renal function [83, 84]. Efficacy during trials has extended over several years and risk of hypoglycemia has been low unless used in combination with an agent that can itself cause hypoglycemia (such as a sulfonylurea or insulin). Most people achieve a weight loss of ~2–4 kg, which levels out by 6–12 months, possibly reflecting an increase in metabolic efficiency or some increase in food intake as the glucose level declines. The weight loss is predominantly a decrease in fat mass, notably from the visceral adipose depot. In clinical trials involving participants with insulin-treated T2DM, glycemic control is often improved

Table 31.13 Sodium–glucose co-transporter-2 (SGLT-2) inhibitors: dapagliflozin, canagliflozin, and empagliflozin.

Agent	Dose (mg/day)	IC_{50} SGLT2 vs. SGLT1(nM)	t_{max} (h)	C_{max}	$t_{1/2}$ (h)
Dapagliflozin	5–10	1.1 vs. 1390	1–2	~160 ng/mL	~13
Canagliflozin	100–300	2.2 vs. 910	1–2	~1–5 μg/mL	~13
Empagliflozin	10–25	3.1 vs. 8300	~1.5	~250–700 nmol/L	~13

while the insulin dose is slightly lowered, and control is maintained over time without insulin dose escalation. Combination of an SGLT-2 inhibitor with insulin can also reduce the weight gain normally associated with insulin therapy. SGLT-2 inhibitors have also consistently reduced systolic blood pressure by 3–5 mmHg in hypertensive and normotensive individuals with diabetes, with smaller reductions in diastolic blood pressure and without dipping into hypotension.

Adverse effects

The glucosuric effect of SGLT-2 inhibitors increases the risk of genital infections, particularly vulvovaginal mycotic infections in women during the initial months of therapy, and there is also a small increase in the risk of urinary tract infections. The occurrence and severity of these infections can be reduced by appropriate advice when starting therapy and most of these infections respond to standard treatments, often by patient self-management. The osmotic diuresis generated by the glucosuria (usually <500 mL/day) requires patient attention to adequate hydration, especially in hot climates, and should be emphasized when initiating therapy. The GFR may temporarily decline after introduction of an SGLT-2 inhibitor, and extra caution is recommended for people receiving diuretic therapy, although electrolyte imbalances have not been seen in clinical trials [80].

Accounts of atypical ketoacidosis in individuals treated with an SGLT-2 inhibitor have described a hyperosmolar metabolic acidosis with only modest hyperglycemia. Many of these people had T1DM (currently contraindicated) or were insulin-treated patients of unclear diagnosis in whom the insulin dose may have been over-reduced because the hyperglycemia was well controlled with the SGLT-2 inhibitor. Basal insulin should be maintained in insulinopenic individuals, as this reduces lipolysis (thereby reducing the supply of fatty acids for ketogenesis) and is required for other physiological purposes beyond glycemic control. Indeed, people with a history of ketotic episodes are unlikely to be appropriate for SGLT-2 inhibitor therapy; SGLT-2 inhibition may cause a compensatory increase in glucagon release [85], especially at low glucose levels, and this can assist ketogenesis [86].

Because SGLT-2 inhibitors do not interfere with P450 isoenzymes, they do not appear to have any clinically meaningful drug interactions. Minor changes in the circulating lipid profile have been reported with SGLT-2 inhibitors, notably some increases in LDL and HDL cholesterol, but without altering the LDL : HDL ratio. During clinical trials, the numbers of cardiovascular events have generally been similar to or fewer than with comparator therapies. A large prospective long-term (3.1 years) safety study with empagliflozin in participants with T2DM at high cardiovascular risk reported a 14% reduction in a composite endpoint of cardiovascular death and non-fatal MI and stroke, and also a 32% reduction in overall mortality and a 36% reduction in death from cardiovascular causes [87]. The effects became evident during the first few months of treatment and could not be directly attributed to improved glycemic and/or weight control. The results of additional studies are awaited to confirm these findings, assess the extent to which improved blood pressure control may be involved, and determine cardiovascular outcomes with other SGLT-2 inhibitors.

α-Glucosidase inhibitors

Studies conducted in the late 1970s noted that inhibitors of intestinal α-glucosidase enzymes could retard the final steps of carbohydrate digestion with a consequent delay in the absorption of sugars. By the early 1980s, it was demonstrated that this approach could reduce postprandial hyperglycemia in diabetes [88]. Acarbose, the first α-glucosidase inhibitor, was introduced in the early 1990s. Subsequently, two further agents, miglitol and voglibose, were introduced in some countries (Figure 31.16). In people who consume meals containing complex carbohydrate, α-glucosidase inhibitors can effectively reduce postprandial glucose excursions. These agents also have a good safety record but their application has been limited by gastrointestinal side effects and modest efficacy.

Mode of action

α-Glucosidase inhibitors competitively inhibit the activity of α-glucosidase enzymes in the brush border of enterocytes lining the intestinal villi (Figure 31.17). They bind to the enzymes with high affinity, preventing the enzymes from cleaving disaccharides and oligosaccharides into monosaccharides. This delays completion of carbohydrate digestion and can defer the process distally along the intestinal tract, leading to a delay in glucose absorption [88]. Different α-glucosidase inhibitors have different affinities for the various α-glucosidase enzymes. This gives slightly different activity profiles (e.g. acarbose has greatest affinity for glycoamylase > sucrase > maltase > dextrinases, whereas miglitol is a stronger inhibitor of sucrase). It is emphasized that α-glucosidase inhibitors can only be effective if the person is consuming complex digestible carbohydrate. These agents do not significantly affect the absorption of glucose per se. By moving glucose absorption more distally along the intestinal tract, α-glucosidase inhibitors may alter the release of glucose-dependent incretin hormones such as GIP and GLP-1, which enhance nutrient-induced insulin secretion. Hence release of GIP, which occurs mainly from the jejunal mucosa, may be reduced by α-glucosidase inhibitors, whereas secretion of GLP-1 (mostly from the ileal mucosa) is increased. α-Glucosidase inhibitors probably reduce postprandial insulin concentrations through the attenuated rise in postprandial glucose levels [88].

Pharmacokinetics

Acarbose is degraded by amylases in the small intestine and by intestinal bacteria; <2% of the unchanged drug is absorbed along with some of the intestinal degradation products. Absorbed material is mostly eliminated in the urine within 24 h [88]. Miglitol is almost completely absorbed and eliminated unchanged in the urine.

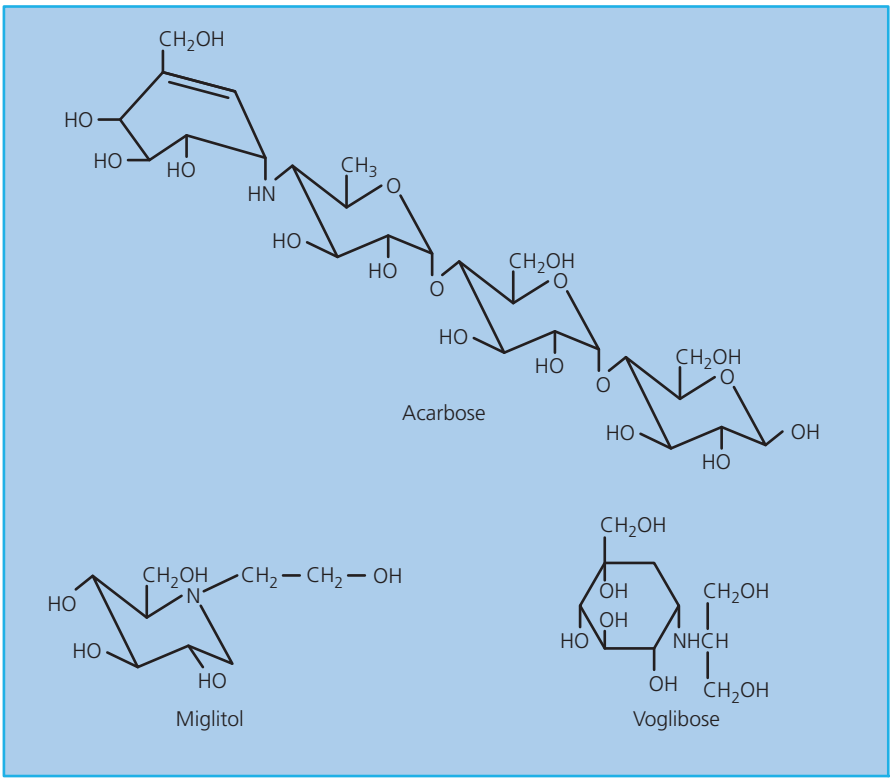

Figure 31.16 Chemical structures of the α-glucosidase inhibitors acarbose, miglitol, and volglibose.

Indications and contraindications

α-Glucosidase inhibitors can be used as monotherapy, usually for people with T2DM with postprandial hyperglycemia but only slightly raised fasting glycemia; however, they are more commonly used as add-on to other therapies, again to target postprandial hyperglycemia [88]. α-Glucosidase inhibitors can also be used to extend the postprandial period to reduce interprandial glycemic troughs or hypoglycemia in individuals receiving a sulfonylurea and/or insulin. Acarbose has also been shown to prevent progression of IGT to T2DM [89], although this is not a licensed use.

When starting an α-glucosidase inhibitor, the person should be advised that a diet containing complex digestible carbohydrate is important. α-Glucosidase inhibitors should be taken with meals, starting with a low dose (e.g. 50 mg/day acarbose) and slowly uptitrated over several weeks. Monitoring of postprandial glycemia is often helpful. Hypoglycemia is unlikely when used as monotherapy, but gastrointestinal symptoms commonly limit

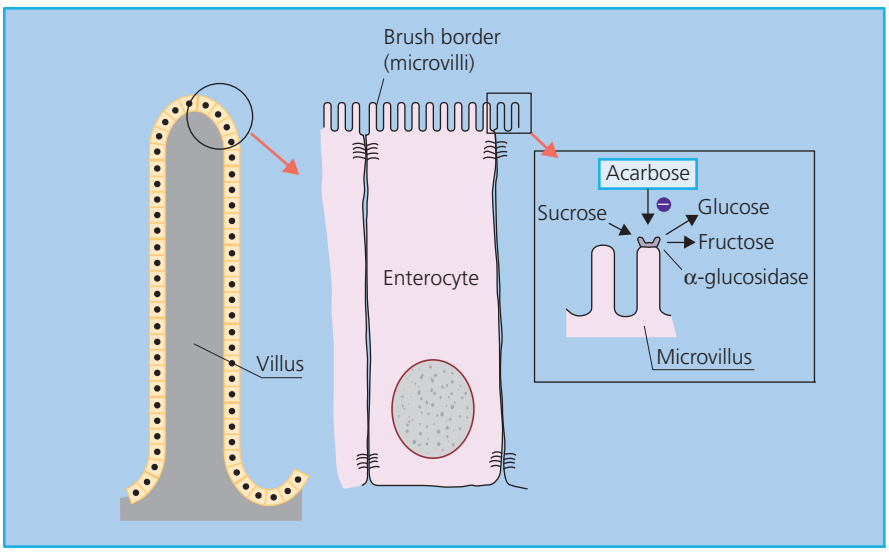

Figure 31.17 Mode of action of α-glucosidase inhibitors. α-Glucosidase inhibitors competitively inhibit the activity of α-glucosidase enzymes in the brush border of enterocytes lining the intestinal villi, preventing these enzymes from cleaving disaccharides and oligosaccharides into monosaccharides. This delays carbohydrate digestion.

initial tolerability and dose titration. Symptoms tend to be reduced by slow titration and usually subside with time, possibly reflecting some adaptation of the intestinal tract, but tolerability is poor.

α-Glucosidase inhibitors are contraindicated for people with a history of chronic intestinal disease, and as high dosages of acarbose can occasionally increase liver enzyme concentrations, it is recommended to measure transaminase concentrations periodically in those receiving a maximum dosage (200 mg acarbose three times daily). Raised liver enzymes should remit as the dosage is reduced, otherwise alternative causes of hepatic dysfunction should be considered.

Efficacy

Because α-glucosidase inhibitors target postprandial glucose excursions during meals that contain complex carbohydrate, their effectiveness is entirely dependent on dietary adherence. As monotherapy, these agents can reduce peak postprandial glucose concentrations by 1–4 mmol/L. The incremental area under the postprandial plasma glucose curve can be more than halved in some individuals, and there is usually some extended duration of effect to modestly lower basal glycemia up to ~1 mmol/L. The decrease in HbA_{1c} can be 0.5–1.0% (6–11 mmol/mol), provided that a high dose of the drug is tolerated and dietary adherence is maintained [90].

Although overall reductions in HbA_{1c} are usually modest, α-glucosidase inhibitors offer several useful features: they do not cause weight gain or frank hypoglycemia and they may reduce interprandial episodes of hypoglycemia. When combined with other antidiabetes agents, α-glucosidase inhibitors can reduce postprandial hyperinsulinemia, and they often lower plasma triglyceride concentrations. Use of an α-glucosidase inhibitor can produce minor alterations to the intestinal absorption of other oral glucose-lowering agents when used in combination therapy, but α-glucosidase inhibitors usually provide additive efficacy gains when used in combination with any other class of antidiabetes agent [88]. There is preliminary evidence that acarbose might reduce major cardiac events, including MI, and prospective studies are ongoing, but it is unclear if this could be caused by the targeting of postprandial hyperglycemia or an independent effect of the drug [91].

Adverse effects

Gastrointestinal side effects represent the main problem with α-glucosidase inhibitors. For example, in the STOP-NIDDM trial, 31% of acarbose-treated participants compared with 19% on placebo discontinued treatment early [89]. If the dosage is too high (relative to the amount of complex carbohydrate in the meal), undigested oligosaccharides pass into the large bowel. These are fermented, causing flatulence, abdominal discomfort, and sometimes diarrhea, but usually ameliorating with slower titration and time. Hypoglycemia is uncommon and there are no clinically significant drug interactions, although use in conjunction with agents affecting gut motility or cholestyramine is not recommended.

Bromocriptine

The dopamine D2 receptor agonist bromocriptine (Figure 31.18), which has long been used to treat pituitary tumors and Parkinson disease (albeit in a different formulation), has an indication for use in the treatment of T2DM in some countries [92, 93].

Mode of action

Studies in animals have noted that the interruption of dopaminergic pathways in the hypothalamus is associated with the development of insulin resistance, and this can be reversed by localized dopamine infusion. Studies in individuals with T2DM suggest that a low dose of a rapid acting formulation of bromocriptine administered early in the morning soon after waking can temporarily boost hypothalamic dopamine. This appears to rebalance several features of the circadian periodicity of glucose homeostasis by reducing sympathetic tone and enhancing the neural suppression of hepatic glucose production. Additionally, there is a reduction of adipose tissue lipolysis and an improvement in peripheral glucose disposal without elevation of plasma insulin, indicating improved peripheral insulin sensitivity [92, 93].

Pharmacokinetics

The low-dose formulation of bromocriptine used for blood glucose lowering is rapidly absorbed (t_{max} by 1 h), highly protein bound, rapidly removed by the liver (mostly metabolized by CYP3A4) and eliminated via the bile; the half-life is ~6 h. Prolactin levels are reduced consistent with increased dopaminergic activity.

Indications and contraindications

Based on considerable experience with the use of bromocriptine for other purposes, use to treat T2DM requires caution if patients are prone to low blood pressure, various psychotic disorders, or somnolence, and exclusion for those who experience migraine or take dopaminergic antagonists. Potential interactions with other medications that influence or may be influenced by changes in

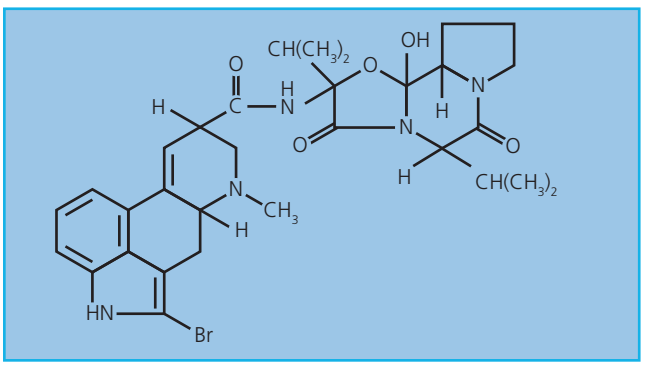

Figure 31.18 Chemical structure of bromocriptine.

CYP3A4 should be appreciated, and evidence regarding use during pregnancy is limited.

Efficacy

In clinical trials, participants with T2DM receiving a low dose (0.8–4.8 mg) of quickly acting bromocriptine early in the morning showed HbA_{1c} reductions of ~0.5–0.7% (5–8 mmol/mol) when taken as monotherapy or in combination with other oral glucose-lowering agents. Fasting and postprandial glucose, fatty acid, and triglyceride concentrations were reduced, insulin was not raised, risk of hypoglycemia was low, and there was no weight gain [92, 93].

Adverse effects

Although high doses of bromocriptine carry some long-term risk for pulmonary and pericardial fibrosis, hypotension, and aggravation of psychotic disorders, these were not seen with low doses during clinical trials for T2DM.

Colesevelam

In addition to its use as a bile acid sequestrant, colesevelam (a polyallylamine derivative) also has an indication for glucose lowering in some countries.

Mode of action

The glucose-lowering mechanism of colesevelam is not clear. By interrupting the enterohepatic circulation of bile acids, colesevelam appears to reduce the availability of bile acids to activate the bile acid receptor-1 (TGR5) and the farnesoid X receptor (FXR), which results in increased hepatic glucose metabolism [94]. A further possibility is that the bile acids are carried more distally along the intestine owing to their entrapment by colesevelam. This could bring more bile acids into contact with TGR5 receptors on L -cells, which could enhance the secretion of GLP-1.

Pharmacokinetics

Up to three 625-mg tablets of colesevelam can be taken with each of two main meals daily; the colesevelam is not absorbed.

Indications and contraindications

Colesevelam requires caution if any intestinal disorders, especially obstruction, are known or suspected. Colesevelam can alter the absorption of other oral medications, including oral glucose-lowering therapies, and dose adjustments may be required.

Efficacy

Clinical trials with colesevelam in T2DM have noted modest reductions of HbA_{1c} of ~0.5% (5 mmol/mol) when used as an add-on to metformin, sulfonylurea, or insulin. There is no effect on body weight, low risk of hypoglycemia, and, consistent with its use in the treatment of hypercholesterolemia, there is usually a reduction in LDL cholesterol [94].

Adverse effects

Colesevelam may increase circulating triglycerides and cause abdominal symptoms, especially constipation.

Antiobesity therapies

Obesity, especially excess visceral adiposity, predisposes to diabetes, complicates glycemic control, and substantially increases the risk of vascular disease [95]. The blood glucose-lowering efficacy of lifestyle measures to reduce adiposity in obese individuals with T2DM is well appreciated, although it is often very difficult to achieve and maintain significant weight loss in these persons. Several studies have noted the reductions in blood glucose that accompany the use of pharmacological antiobesity therapies in T2DM. Whether this is entirely explained by greater weight loss and improved dietary adherence is unclear, because it has been mooted that some antiobesity therapies could have some modest independent glucose-lowering effects [21].

In conjunction with a mildly hypocaloric and reduced-fat diet, the intestinal lipase inhibitor orlistat (120 mg three times daily with meals) can reduce dietary fat absorption by up to 30%. In overweight and obese individuals with T2DM, this typically increases weight reduction by an extra 2–3 kg, and additional reductions in HbA_{1c} of 0.28–1.1% (3–12 mmol/mol) have been reported [21]. Potential improvements in the glucose–fatty acid cycle might be envisaged.

The satiety-inducing serotonin–norepinephrine reuptake inhibitor sibutramine, which is no longer available in most countries owing to cardiovascular side effects, has permitted greater reductions of body weight in overweight and obese people with T2DM, with extra reductions in HbA_{1c} of ~0.6% (7 mmol/mol). The cannabinoid CB1 receptor antagonist rimonabant, now withdrawn owing to psychiatric effects, also improved glycemic control in association with weight loss in individuals with T2DM [21].

Recently emerging antiobesity agents, notably the 5HT2c receptor agonist lorcaserin, a phentermine–topiramate combination (Qsymia), and a bupropion–naltrexone combination (Contrave), have been shown in clinical trials to improve glycemic control in people with T2DM in association with weight loss [21]. It is noted that antiobesity therapies carry their own contraindications, cautions, and side effects and may interfere with the absorption or actions of other therapies, including glucose-lowering agents.

Fixed-dose combinations

As early and intensified interventional approaches to the management of hyperglycemia in individuals with T2DM gain acceptance, the use of combinations of two or more oral agents with different mechanisms of action has become commonplace [96]. To facilitate combination therapy, several fixed-dose, single-tablet combinations have been made available (Table 31.14). These are

Table 31.14 Fixed-dose single-tablet combinations of antidiabetes agents.

Tablet[a]	Components	Strengths (mg)
Glucovance	Metformin + libenclamide	250:1.25, 500:2.5, 500:5
Metaglip	Metformin + glipizide	250:2.5, 500:2.5, 500:5
Avandamet	Metformin + rosiglitazone	500:1, 500:4, 500:2, 1000:2, 1000:4
Competact (Actoplusmet)	Metformin + pioglitazone	500:15, 850:15
Eucreas	Metformin + vildagliptin	850:50, 1000:50
Janumet	Metformin + sitagliptin	500:50, 1000:50
Prandimet	Metformin + repaglinide	500:1, 500:2
Kombiglyze	Metformin + saxagliptin	500:5, 1000:2.5, 1000:5
Jentadueto	Metformin + linagliptin	500:2.5, 850:2.5, 1000:2.5
Kazano (Vipdomet)	Metformin + alogliptin	500:12.5, 1000:12.5
Avaglim (Avandaryl)	Rosiglitazone + glimepiride	4:1, 4:2, 4:4, 8:2, 8:4
Tandemact (Duetact)	Pioglitazone + glimepiride	30:, 45:4
Xigduo	Metformin + dapagliflozin	850:5, 1000:5
Vokanamet	Metformin + canagliflozin	1000:50
Incresync	Pioglitazone + alogliptin	30:12.5
Glyxambi	Empagliflozin + linagliptin	10:5, 25:5
Synjardy	Metformin + empagliflozin	850:5, 850:12.5, 1000:5, 1000:12.5

[a]The availability of tablets and component strengths differ between countries. Names vary between Europe and the USA. Alternative names are given in parentheses.

designed to provide bioequivalence and thereby similar efficacy, although minor adjustments to the formulation may also allow some extra blood glucose-lowering efficacy. Fixed-dose combinations can offer convenience, reduce the "pill burden," and simplify administration regimens, and they may increase adherence compared with equivalent combinations of separate tablets. Lower doses of two different types of agents rather than a high dose of one agent may also provide a way to achieve efficacy while circumventing dose-related side effects. Although single tablets could reduce titration flexibility, most of the commonly used dosage combinations have been accommodated. It is reiterated that any form of combination therapy necessitates the same cautions and contraindications as apply to each active component.

Conclusions

A minimalistic archetypal algorithm to treat hyperglycemia in T2DM is shown in Figure 31.19. This illustrates the typical sequence of pharmacological interventions advocated in most

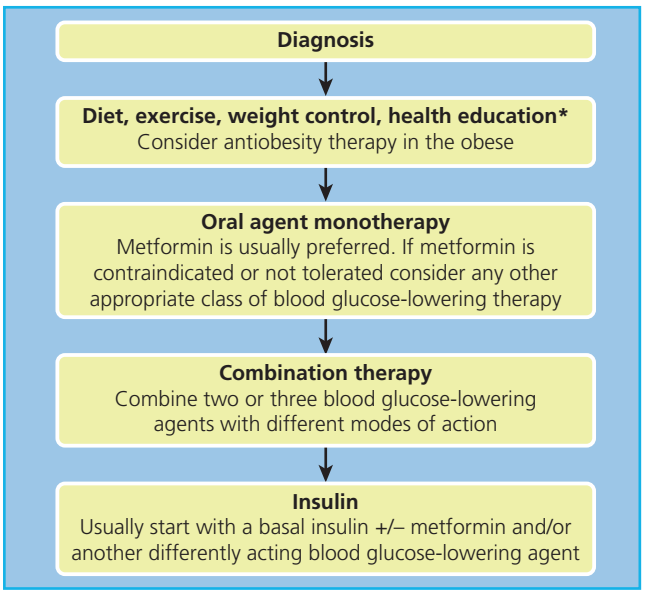

Figure 31.19 Archetypal algorithm used in the treatment of hyperglycemia in type 2 diabetes (except for those presenting with severe hyperglycemia who may require immediate insulin therapy). Start with lifestyle measures (diet and exercise). If the individualized glycemic target is not achieved quickly using lifestyle measures, then add pharmacological therapy without delay. The selected monotherapy is uptitrated to achieve the desired glycemic effect. If an uptitration step does not add benefit or is not tolerated, revert back a step. When the desired glycemic effect is not achieved or adequate titration is not tolerated, move promptly to the addition of a second agent with a different mode of action and uptitrate. If the desired glycemic control is not achieved or maintained, consider triple therapy or introduce insulin while maintaining one or two of the existing therapies where appropriate. Respect drug cautions and contraindications at all times, monitor as required, and try to select glycemic targets that are realistic, safely achievable, and avoid hypoglycemia. Various guidelines (e.g. see [3, 4]) offer more detail with suggested glycemic targets and suggested sequence orders for the introduction of the pharmacotherapies. *Lifestyle advice reinforced throughout.

current guidelines. Guidelines should be interpreted with flexibility, however, to ensure that the care plan, treatment targets, and selection of therapies are individualized to suit the circumstances of the patient. The value of lifestyle intervention as initial and ongoing therapy in conjunction with pharmacological agents should not be underestimated. In view of the progressive natural history of T2DM, the introduction of drug therapy, the need for periodic uptitration of dosage, and the use of combination therapy can be expected for most people with T2DM.

A range of differently acting oral agents is available: metformin and thiazolidinediones counter insulin resistance; sulfonylureas, meglitinides, and DPP-4 inhibitors increase insulin secretion; SGLT-2 inhibitors increase renal glucose elimination; and α-glucosidase inhibitors slow carbohydrate digestion. Additionally, injected GLP-1 receptor agonists increase insulin secretion and reduce glucagon. When adequate control is not achieved or not maintained, it is important to proceed to the next therapeutic stage without delay to avoid periods of excessive hyperglycemia.

Insulin should be considered when other therapies do not provide adequate glycemic control or are unsuitable. Integrated management to address cardiovascular risk and comorbid conditions is essential. Glucose monitoring, making therapeutic adjustments for efficacy, safety, avoidance of hypoglycemia, and contraindications, requires constant vigilance and forms an integral part of the treatment process. Early, effective, and sustained glycemic control is essential to minimize the risk for vascular complications later in life.

32 Non-Insulin Parenteral Therapies

Tina Vilsbøll, Mikkel Christensen, Tina Jorsal, and Filip K. Knop
Center for Diabetes Research, Gentofte Hospital, University of Copenhagen, Hellerup, Denmark

Key points

- Glucagon-like peptide-1 (GLP-1) is a blood glucose-lowering (via insulinotropic and glucagonostatic effects) and satiety-promoting hormone secreted from enteroendocrine L-cells found in the intestinal epithelium.
- The most robust physiological stimulus for GLP-1 secretion is meal ingestion and within 5–15 min after food ingestion, plasma concentrations of GLP-1 start to rise.
- Glucose-lowering drugs based on the physiological effects of GLP-1 are part of the treatment algorithms and guidelines for type 2 diabetes.
- GLP-1 receptor agonists target a broad spectrum of the pathophysiology of type 2 diabetes and improve glucose homeostasis with low risk of hypoglycemia combined with body weight loss.
- Differences in structure, pharmacokinetics, and size of the different GLP-1 receptor agonists are important, as the dosing schedule (convenience), efficacy, and tolerability depend on these differences.
- Adverse events to GLP-1 receptor agonists are typically of gastrointestinal character (mainly nausea, vomiting, and diarrhea) and seem to diminish over time.
- Two outcome studies involving the GLP-1 receptor agonists have been finalized; 1) the LEADER trial demonstrating that fewer participants died from cardiovascular causes during treatment with liraglutide (long-acting GLP-1 receptor agonist) treatment than with placebo, and 2) ELIXA evaluating lixisenatide (short-acting GLP-1 receptor agonist) showing non-inferiority compared to placebo in terms of cardiovascular outcomes. Several other cardiovascular outcome trials are underway.
- Amylin is co-secreted with insulin from the pancreatic beta cells and has been shown to reduce gastric emptying appetite and glucagon secretion.
- Amylin analogs are used to obtain clinically beneficial glycemic control and body weight loss in individuals with diabetes.
- Preclinical data suggest that a single-molecule dual or triple agonist approach, e.g. involving amylin and GLP-1 dual receptor agonism, may be as efficient as co-administration of the individual peptides.

Introduction

During recent decades, the globally increasing prevalence of obesity and associated type 2 diabetes has promoted extensive research with the aim of clarifying the physiological and pharmacological role of pancreas- and gut-derived peptide hormones in the regulation of glucose homeostasis and feeding behavior.

Glucagon-like peptide-1 (GLP-1) and GLP-1 receptor agonists (GLP-1RAs)

Introduction

Over the last decade, glucose-lowering drugs based on the physiological effects of the gut incretin hormone glucagon-like peptide-1 (GLP-1) have been introduced into the international type 2 diabetes treatment algorithms and guidelines [1, 2]. The inclusion of GLP-1-based treatment modalities (i.e. the orally available dipeptidyl peptidase 4 [DPP-4] inhibitors (Chapter 31) and the parenteral GLP-1 receptor agonists [GLP-1RAs]) in the armamentarium of glucose-lowering drugs has increased treatment options and helped clinicians tailor individualized treatments for their patients with type 2 diabetes (as recommended in modern treatment guidelines). In particular, the introduction of the injectable GLP-1RAs with their glucose-dependent glucose-lowering action (active only when plasma glucose levels are high) and the consequent low risk of hypoglycemia, combined with their body weight-reducing effect, has been welcomed by healthcare providers and people with diabetes. Owing to the increased requirements of regulatory agencies (particularly the US Food and Drug Administration [FDA] and European Medicines Agency [EMA]) for extensive safety data on new glucose-lowering drugs coinciding with the course of development of most incretin-based drugs, this drug class represents one of the most thoroughly investigated and monitored. Thus, despite the relatively young age of incretin-based drugs a considerable amount of data on safety and efficacy on this drug class exists. Owing to the body weight-reducing effect of GLP-1 receptor (GLP-1R) activation, one GLP-1RA has also been approved for the treatment of

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

overweight/obesity and currently several studies are evaluating the applicability of GLP-1RA treatment in other disease states and high-risk conditions. In the first part of the chapter, a historical overview of the investigations leading to the discovery of the gut incretin hormone GLP-1 and its potential as a glucose-lowering drug is presented, the physiology of native GLP-1 is outlined, and the pharmacology, safety, and efficacy of the individual GLP-1RAs currently available for the treatment of type 2 diabetes are considered. Finally, perspectives for GLP-1RA treatment within other disease areas and their potential position in future treatment algorithms are highlighted.

Historical overview

The introduction of GLP-1-based treatment modalities in the beginning of the third millennium was the result of a century of investigations. In 1906, extracts of mucosa from porcine small intestine were tested by Moore et al. as a treatment for diabetes in the hope that "the pancreas secretion might be stimulated by the substance of the nature of a hormone yielded by the duodenal mucosa membrane" [3]. In 1928, Zunz and LaBarre described a hypoglycemic effect following injection of extracts from small intestinal mucosa and, using cross-circulation experiments, they were able to show that the effect was mediated through the pancreas [4]. Four years later, LaBarre named the unidentified substance thought to exert this effect "incretin" in order to dissociate it from secretin (which stimulates exocrine pancreatic secretion) discovered by Bayliss and Starling at the beginning of the century [5]. Then, in 1964, McIntyre et al. and Elrick et al. demonstrated that orally administered glucose evokes a greater insulin response than does intravenously administered glucose, and both groups hypothesized that gut-derived factors could have potentiating effects on insulin secretion after oral ingestion of glucose [6, 7]. A few years later, in 1967, this finding was confirmed by Perley and Kipnis, who administered oral glucose and, on a separate day, copied the oral glucose curve with an isoglycemic intravenous (i.v.) glucose infusion in obese and normal-weight people with diabetes and in healthy people without diabetes [8]. They concluded that the insulin response to isoglycemic i.v. glucose administration only amounted to 30–40% of that seen after oral administration of glucose; they had come across the "the incretin effect" (i.e. the phenomenon of oral glucose eliciting a higher insulin response than i.v. glucose at identical plasma glucose profiles). However, at that time, the insulinotropic substance eliciting this effect was unknown.

In 1970, gastric inhibitory polypeptide, secreted from small intestinal endocrine K cells in response to ingestion of nutrients, was discovered [9] and, eventually, the 42 amino acid polypeptide was shown to be insulinotropic at elevated glucose concentrations and was renamed glucose-dependent insulinotropic polypeptide (GIP) [10]. Later, experimental and clinical studies suggested that the gut produces more than a single insulinotropic hormone of importance for glucose homeostasis [11]. In 1983, the gene encoding the human pancreatic hormone, glucagon, was cloned, and the structure of its precursor, proglucagon, was surprisingly shown to include the sequence of two glucagon-like peptides (including GLP-1 [Figure 32.1]) in addition to glucagon itself [12]. The gene was found to be expressed in both pancreatic α cells and enteroendocrine L cells in the small intestine [13]. The primary transcripts and translational products of the gene in the two types of cells are identical but, as illustrated in Figure 32.2, the post-translational processing was shown to differ in the two tissues [13–15]. In the pancreas, proglucagon is cleaved by prohormone convertase 2 to glucagon, glicentin-related pancreatic peptide (GRPP) and a major proglucagon fragment. Apart from glucagon, these fragments seem to be biologically inactive. In contrast, in the intestinal L cells, proglucagon is processed by prohormone convertase 1/3 to GLP-1, glucagon-like peptide-2 (GLP-2), and glicentin. The 30 amino acid peptide GLP-1 was found to be secreted in response to ingestion of nutrients and to be strongly insulinotropic, an incretin hormone [16, 17]. GLP-2 is also secreted in response to ingestion of nutrients and is a key regulator of small intestinal growth. The bioactive forms of GLP-1,

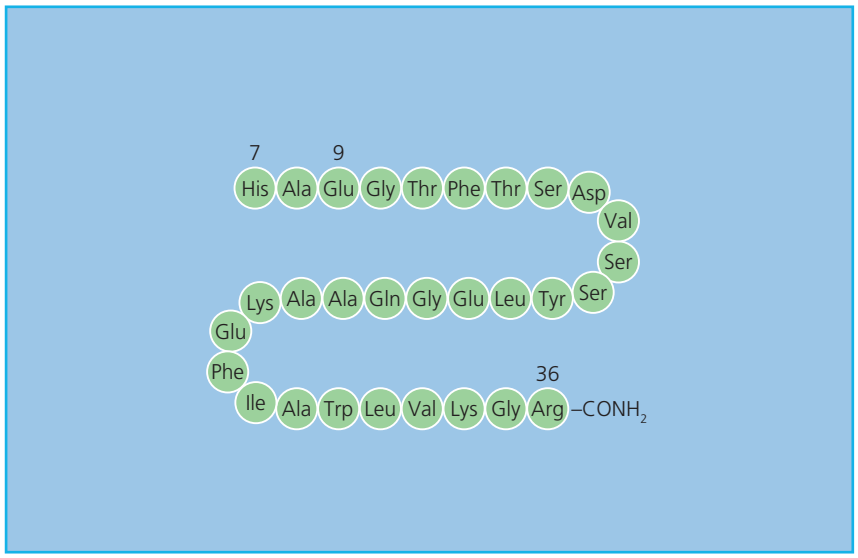

Figure 32.1 Native human GLP-1 circulates as GLP-1(7–36) amide (illustrated here) or glycine extended GLP-1(7–37). The enzyme dipeptidyl peptidase 4 (DPP-4) inactivates the hormone by cleaving off the two N-terminal amino acids (His and Ala).

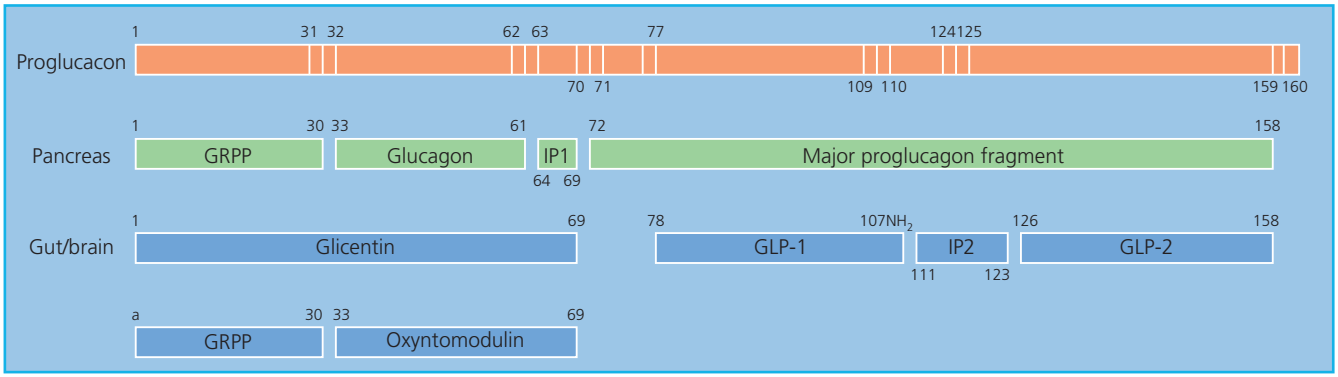

Figure 32.2 Proglucagon processing in human pancreatic α cells (by prohormone convertase 2) and in enteroendocrine L cells in the small intestine (by prohormone convertase 1/3). In proglucagon producing neurons in the nucleus tractus solitarii (brain), proglucagon is most likely processed by prohormone convertase 1/3 as in the gut.

amidated and glycine extended GLP-1, respectively, are designated GLP-$1_{7–36\ amide}$ and GLP-$1_{7–37}$ (Figure 32.1).

Many hormones have been suspected to contribute to the incretin effect, but today there is ample evidence to suggest that the incretin effect is mainly conveyed by the two incretin hormones GIP and GLP-1. In 1983, Nauck et al. showed that the incretin effect is reduced in persons with type 2 diabetes [18]. The precise mechanisms behind this pathophysiological characteristic remain somewhat controversial. In the 2000s, publications reported reduced secretion of GLP-1 in individuals with type 2 diabetes [19, 20], but recent meta-analyses suggest that the secretion of GLP-1 among persons with type 2 diabetes, in general, is normal [21, 22]. In contrast to the severely reduced insulinotropic effect of GIP in type 2 diabetes [23], the insulinotropic effect of GLP-1 has consistently been shown to be sustained in these individuals, albeit with reduced potency.

The reduced incretin effect in type 2 diabetes, the early reports on reduced postprandial GLP-1 responses, and the preserved glucose-dependent insulinotropic and glucagonostatic (see below) effects of GLP-1 constituted important incentives to pursue GLP-1 as a target for the treatment of type 2 diabetes. In contrast, the other incretin hormone, GIP, was not pursued as an antidiabetes target owing to its severely diminished insulinotropic effect in type 2 diabetes combined with reports suggesting glucagonotropic effects of GIP. Also, studies have suggested that GIP may act as a fat storage hormone promoting lipogenesis, adipokine secretion, and weight gain. Nevertheless, as GIP, like GLP-1, is a substrate of DPP-4, it may contribute to the glucose-lowering effect of DPP-4 inhibitors (see Chapter 31) and dual or even triple hormonal receptor agonists involving GIP receptor stimulation are currently being given new scientific and pharmaceutical attention.

GLP-1 physiology and antidiabetes actions

Proglucagon distribution, GLP-1 release, and metabolism

The glucagon gene is expressed in pancreatic α cells as well as in the enteroendocrine L cells and a subset of central nervous system [CNS] neurons in the nucleus tractus solitarii. The processing of proglucagon into "pancreatic" glucagon or "intestinal" GLP-1 (and GLP-2) depends on tissue-specific prohormone convertases (Figure 32.2). In the pancreas, prohormone convertase 2 represents the predominant prohormone convertase and, therefore, glucagon production is favored. Conversely, in the gut, prohormone convertase 1/3 is abundant and processing of proglucagon predominantly yields the hormones GLP-1 and GLP-2 (and oxyntomodulin) (Figure 32.2). Nevertheless, the distribution of the two prohormone convertases may not be as stringent as previously considered and small amounts of GLP-1/GLP-2 may be formed in the pancreas, and similarly, gut-derived glucagon secretion can also occur.

The most robust physiological stimulus for GLP-1 secretion is meal ingestion. Within 5–15 min after ingestion of a meal, plasma concentrations of GLP-1 start to rise and peak levels are typically reached after 45–60 min (Figure 32.3). Fat, carbohydrates, and protein all stimulate GLP-1 secretion. The interaction of nutrients with luminal microvilli of the L cell apical parts results in secretion of GLP-1 from the baso-lateral parts into the intestinal bloodstream. In this process, associations between glucose absorption and metabolism within the L cell and GLP-1 secretion has been observed. Furthermore, L cells express several G protein-coupled

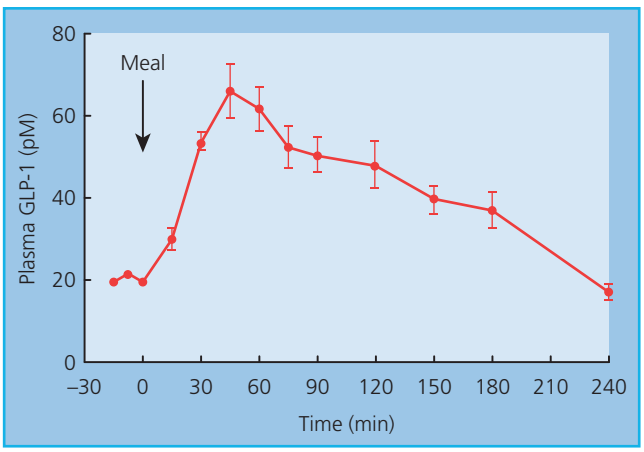

Figure 32.3 Mean postprandial plasma concentrations (± standard error of the mean) of glucagon-like peptide-1 (GLP-1) in healthy individuals. Source: Unpublished data, Filip K. Knop.

receptors, which can be activated by short- and long-chain fatty acids, bile acids, and possibly other factors that thereby stimulate GLP-1 secretion. In addition, paracrine (e.g. via somatostatin and GIP) and neurohormonal mechanisms (via vagus and sympathetic neural activation) have been suggested to contribute to postprandial GLP-1 secretion.

After secretion, GLP-1 is degraded by the enzyme DPP-4. This enzyme is widely expressed and is highly active in the liver, the intestinal and renal brush border membranes, and the lungs. It is also found on capillary surfaces and in a soluble form in plasma. DPP-4 cleaves off the two N-terminal amino acids of peptides with a penultimate proline or alanine residue, and for GLP-1 this abolishes its insulinotropic activity completely. Thus, after secretion of GLP-1, the active hormone is rapidly degraded to an inactive metabolite in the circulation, resulting in a clearance, which exceeds cardiac output, and an apparent half-life of 1–1.5 min. The truncated metabolite is eliminated more slowly through the kidneys and endogenous protease activity, with a half-life of 4–5 min.

GLP-1 receptor distribution and physiological effects of GLP-1

The GLP-1R is found within the pancreas, lung, adipose tissue, kidney, heart, vascular smooth muscle, the peripheral nervous system, and a number of specific nuclei in the CNS [24]. The exact effect of receptor activation in a number of these tissues remains to be established, and here emphasis will be put on receptor activation that relates to the clinical effects observed with GLP-1RA treatment. These include glucose-dependent insulin secretion, inhibition of glucagon secretion, delayed gastric emptying, and decreased appetite/increased satiety. Other potential beneficial effects on the cardiovascular system and CNS, for example, have been suggested from mainly *in vitro* or animal studies, and the translation to human (patho)physiology and their potential as pharmacological targets are currently being investigated.

Effects on pancreatic insulin and glucagon secretion

Specific receptors for GLP-1 are found in the pancreatic β-cell plasma membrane. The receptor belongs to the glucagon subfamily of G protein-coupled receptors. Following binding and subsequent activation of the receptor, several intracellular pathways are initiated [24], which ultimately results in intracellular accumulation of cyclic adenosine monophosphate, closure of ATP-sensitive K^+ channels, elevation of cytosolic Ca^{2+} concentrations, and mobilization and exocytosis of insulin-containing granules. Importantly, GLP-1R activation in β cells leads only to insulin secretion when glucose concentrations are elevated above 4–5 mmol/L [25]. Thus, GLP-1 can be perceived to act as a β-cell sensitizer potentiating glucose-induced insulin secretion. In addition to its glucose-dependent insulinotropic effect, GLP-1 enhances all steps of insulin biosynthesis and also insulin gene transcription. Furthermore, GLP-1 has been shown to be involved in β-cell growth and differentiation and may protect β cells from apoptosis [24]. However, the role of these cell cycle regulatory mechanisms in relation to human physiology and pathophysiology, and also GLP-1RA treatment, remains to be established.

In pancreatic α cells, GLP-1 exerts glucagon suppressive effects. As for its insulinotropic effect in β cells, this glucagonostatic effect is glucose dependent and is likewise only active when plasma glucose levels are elevated above 4–5 mmol/L. The mechanisms by which GLP-1 reduces α-cell secretion of glucagon remain incompletely understood. Thus, it is controversial whether GLP-1-induced glucagon suppression is mediated via GLP-1Rs on pancreatic α cells (which have been shown to exist in small amounts in some studies whereas other studies have failed to detect them) or whether indirect mechanisms (e.g. via glucagon-suppressive effects of β-cell secretory products and/or somatostatin from pancreatic δ cells) are at play.

Effects on the gastrointestinal tract

GLP-1 reduces gastrointestinal motility and intermittent GLP-1R activation has a pronounced effect on gastric emptying of both liquid and solid meals [26]. This phenomenon has been referred to as the "ileal brake" (i.e. GLP-1 secreted from enteroendocrine cells in the distal small intestine slows further delivery of nutrients to the small intestines from the stomach) [27]. GLP-1-induced deceleration of gastric emptying translates into dramatically reduced postprandial plasma glucose excursions [28]. Of note, prolonged GLP-1R activation leads to tachyphylaxis of this effect [29], which most likely explains the sustained effect of short-acting GLP-1RA on postprandial blood glucose excursions and the lesser effects seen with long-acting GLP-1RA (see below) [30].

Effects on appetite and food intake

GLP-1Rs are found in both the peripheral nervous system and in the CNS with GLP-1R positive neurons in hypothalamus and the brain stem. Activation of GLP-1Rs in the brain is believed to be responsible for the reduced appetite and food intake observed after administration of GLP-1. The pathways controlling modulation of food intake by GLP-1 may, nevertheless, involve GLP-1R activation in neurons of both the peripheral nervous system and the CNS [24]. Importantly, infusion of GLP-1 in lean and obese individuals with and without diabetes causes dose-dependent reductions in satiety measures and *ad libitum* food intake. Furthermore, studies using the specific GLP-1R antagonist exendin 9-39 suggest that GLP-1R activation is important for these effects. On the other hand, GLP-1R knockout mice are not obese [31], indicating that GLP-1R activation is not a prerequisite for body weight regulation. Nevertheless, there seems little doubt that GLP-1R activation and its related effects on appetite and food intake constitute an important part of the body weight-lowering effect of pharmaceutical GLP-1RAs.

Other effects

In line with the widespread distribution of the GLP-1R, it has been suggested that GLP-1 exerts multiple effects in addition to those mentioned above. A few of these, with potential clinical relevance, are highlighted below.

The effects of GLP-1 on the heart in animal models have attracted much attention. Mice lacking the GLP-1R exhibit impaired left ventricular contractility and diastolic function, and also impaired responses to exogenous epinephrine [32]. Furthermore, some studies have indicated that GLP-1 protects the ischemic and reperfused myocardium in rats [33], improves the ejection fraction in people treated with angioplasty after acute myocardial infarction [34], and improves left ventricular function and systemic hemodynamics in dogs with induced dilated cardiomyopathy [35]. In addition, GLP-1 has been found to reduce the postprandial rise in triglycerides and lower the concentration of free fatty acids in healthy people [36], and improve endothelial dysfunction in individuals with type 2 diabetes and coronary heart disease [37]. These promising findings from preclinical and small-scale clinical studies and the effect of GLP-1RAs on cardiovascular endpoints in larger clinical studies, including a recent cardiovascular outcome study [38] have convincingly demonstrated cardiovascular benefits. Furthermore, the small, but significant, increase in heart rate during treatment with GLP-1RAs, most likely mediated by GLP-1Rs in the sinoatrial node ([39]; see below), did not appear to confer any cardiovascular safety risk.

GLP-1 increases natriuresis through inhibition of the Na^+/H^+ exchanger in the proximal tubules. This may in part explain why GLP-1RAs have subtle antihypertensive effects [39, 40]. Although preclinical studies suggest that atrial natriuretic peptide or the renin–angiotensin system may be involved in GLP-1's natriuretic and proposed diuretic effects [41], in human studies this does not seem to be the case. Likewise, results from rodent studies suggesting renoprotection of GLP-1 (beyond what can be expected from GLP-1-induced metabolic improvements) in models of diabetic nephropathy and acute kidney injury have not yet been confirmed in human studies.

Finally, GLP-1 has been associated with improved learning in rats and has also displayed neuroprotective effects but, again, human studies have so far not been able to establish GLP-1 as a neuroprotective hormone or provided convincing evidence for significant effects of GLP-1R agonism on neurodegenerative diseases [42].

As alluded to above, most of what is known about GLP-1's pleiotropic physiological effects stems from studies in pancreatic islet function particularly β-cell function. It is well acknowledged that GLP-1-induced insulinotropic and glucagonostatic effects represent the main mediators of the normalization of fasting plasma glucose and diurnal plasma glucose excursions and also improved glycemic control observed in studies utilizing native GLP-1 in people with type 2 diabetes [43–46]. Such studies have been of great importance to the development of GLP-1RAs.

GLP-1 receptor agonists for the treatment of diabetes

In 2005, the GLP-1RAs were introduced into clinical practice, and since 2009 they have been part of the joint position statements on treatment of type 2 diabetes by the European Association for the Study of Diabetes (EASD) and the American Diabetes Association (ADA) [1, 2]. The GLP-1RAs are based on the pleiotropic effects

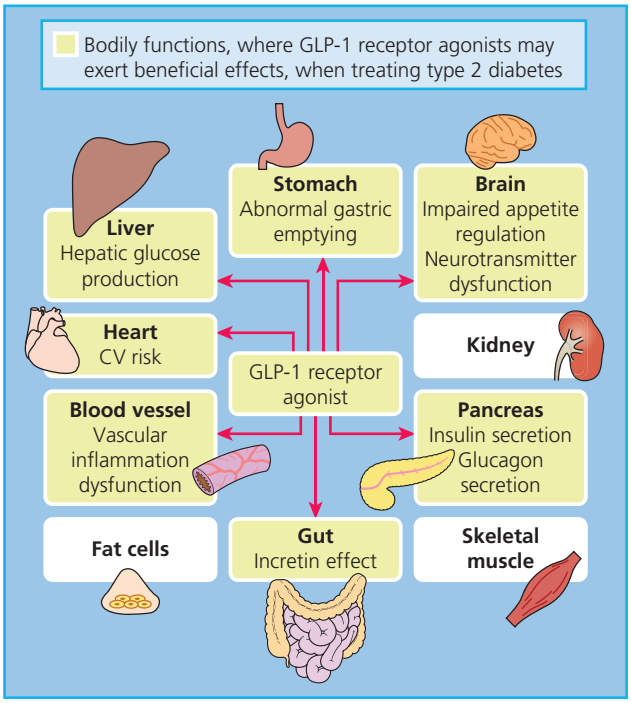

Figure 32.4 GLP-1 receptor agonists act at multiple sites to affect glycemia, weight, and comorbidities of type 2 diabetes.

of the native gut hormone GLP-1, target a broad spectrum of the multifaceted pathophysiology of type 2 diabetes, and improve glucose homeostasis (Figure 32.4) with low risk of hypoglycemia combined with a body weight loss [47]. Furthermore, they exert beneficial effects by reducing cardiovascular events. The introduction of the GLP-1RAs has generated substantial clinical interest and an increasing number of prescriptions have been handed out by clinicians worldwide (Figure 32.5).

As several GLP-1RAs are emerging, it has become apparent that there are clinically relevant differences between them, making the therapeutic field challenging to navigate. Currently, a total of six GLP-1RAs are approved for treating people with type 2 diabetes (Figure 32.6). The major challenge in developing a GLP-1RA is that native GLP-1 is very rapidly degraded by the enzyme DPP-4, resulting in a short half-life (1–1.5 minutes) [48]. To overcome this, GLP-1RAs resistant to degradation by DPP-4 have been developed using two different strategies.

The first strategy is based on the naturally occurring polypeptide exendin-4, which was originally isolated from the saliva of the lizard *Heloderma suspectum*. Exendin-4 is DPP-4 resistant and activates the GLP-1R with equal efficacy as native GLP-1. The other strategy is based on the structure of native GLP-1, with a few amino acid alterations that protect the molecule from being degraded by DPP-4. The main difference between the GLP-1RAs resides in the pharmacokinetic profiles that largely divide them into short-acting and long-acting GLP-1RAs (Figure 32.7). The short-acting GLP-1RAs are readily absorbed after subcutaneous injection and are resistant to degradation by DPP-4, but are still subject to renal elimination, which confers a plasma half-life of

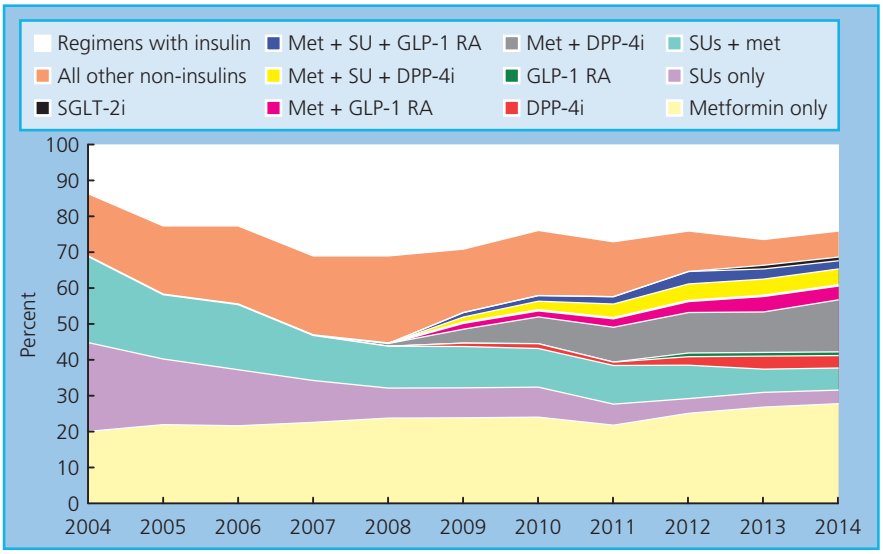

Figure 32.5 Trends of glucose-lowering drugs prescribed by specialists in Europe from 2004 until 2014. SU, sulfonylurea; MET, metformin; DPP-4i, dipeptidyl peptidase 4 inhibitors; GLP-1RA, glucagon-like peptide-1 receptor agonists; SGLT2-i, sodium glucose cotransporter 2 inhibitors.

~2–4 h for these agents [49, 50]. They are administered twice daily (exenatide) or once daily (lixisenatide), which results in relatively large fluctuations in plasma concentrations during the day, and intermittent activation of GLP-1Rs. With regard to the continuous-acting peptides, different modifications have been applied in order to obtain an even longer duration without changing the receptor activation capability. These modifications include (1) incorporation of the GLP-RA in injectable

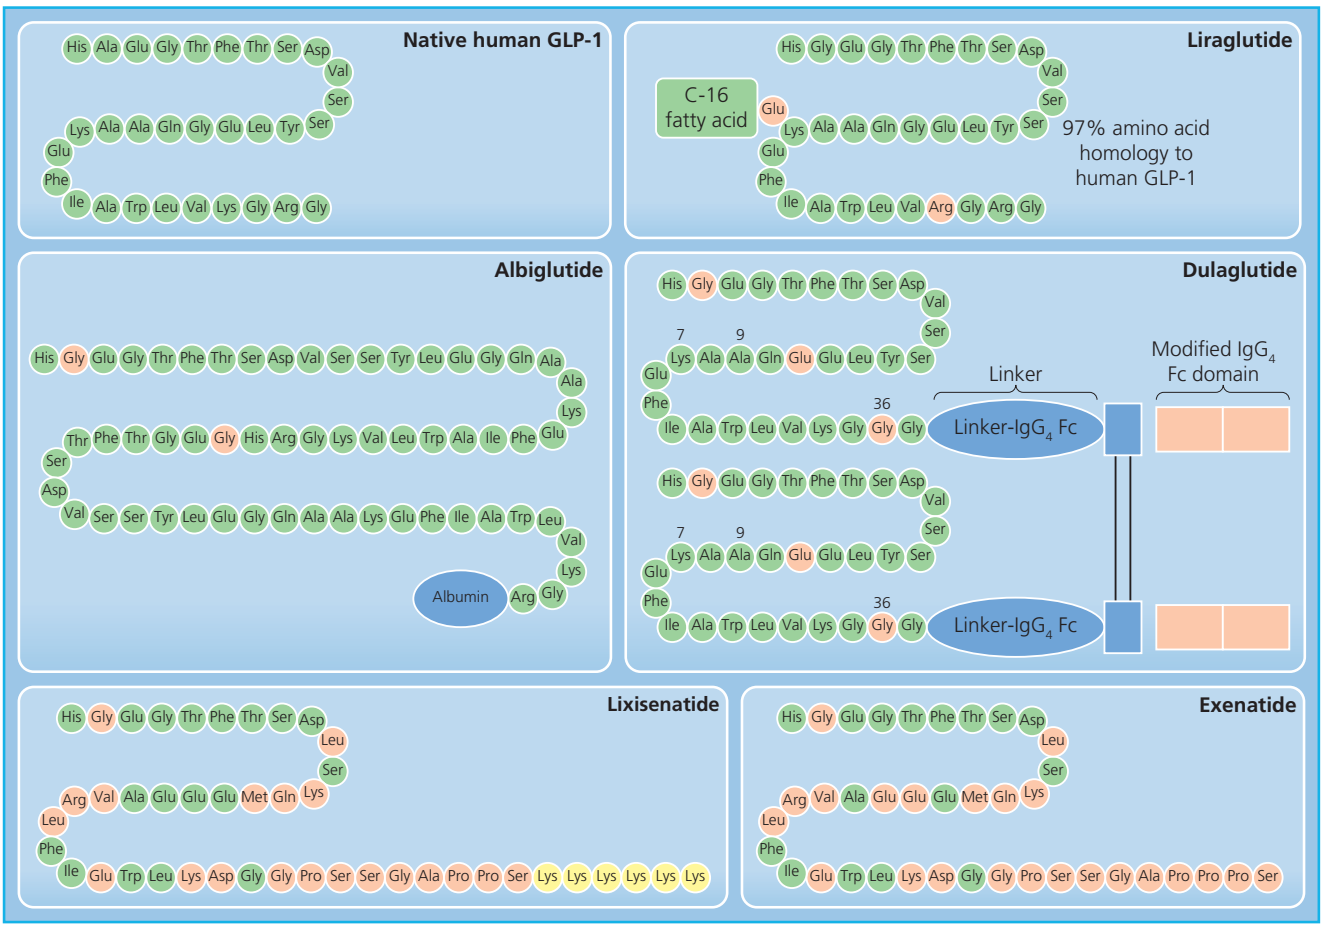

Figure 32.6 Structure comparisons of approved GLP-1 receptor agonists.

Increasing half-life

Category	Agent	Half-life
Short-acting < 24 hours	Exenatide, twice-daily Byetta®	2.4 hours
	Lixisenatide, once-daily Lyxymia®	3 hours
Long-acting ≥ 24 hours	Liraglutide, once-daily Victoza®	13 hours
	Dulaglutide, once-weekly Trulicity®	~4 days
	Albiglutide, once-weekly Tanzeum/Eperzan®	5–8 days
	Exenatide, once-weekly Bydureon®	14 days

Figure 32.7 Glucagon-like peptide-1 receptor agonists pharmacokinetic properties: short- versus long-acting.

microspheres (exenatide once weekly), (2) attachment of a fatty acid side-chain, which allows reversible binding to albumin (liraglutide), and (3) fusion with the Fc fragment of immunoglobulin G (dulaglutide) or larger carrier molecules such as albumin (albiglutide) (Figure 32.6). The longer half-lives of these compounds allows administration with longer intervals while at the same time reducing fluctuations of plasma peptide levels, resulting in continuous activation of the GLP-1Rs. Lastly, the compounds can be subdivided based on their size, as some of the chemical modifications alter the size of the active molecules dramatically. The differences in structure, pharmacokinetics, and size of the GLP-1R agonists are important, as the efficacy and tolerability seem dependent on these differences.

Clinical efficacy and side effects of available GLP-1RA

Short-acting GLP-1RA

Exenatide twice daily

Exenatide, the first available GLP-1RA, was introduced to the market in the United States in 2005 and in Europe in 2007 (Byetta). Exenatide is a synthetic version of exendin-4, which shares only 53% amino acid sequence homology with human GLP-1 (Figure 32.6) [51]. Exenatide is primarily cleared in the kidneys by glomerular filtration [49], and the half-life after subcutaneous (s.c.) injection is ~2.4 h with detectable plasma concentrations up to 10 h after injection [52]. Because of its pharmacokinetics in renal impairment, exenatide should not be used for people with a creatinine clearance of 30 mL/min or less. Exenatide is recommended for twice-daily administration starting at 5 μg twice daily, which may be increased to 10 μg twice daily after one month if well tolerated by the patient. In order to obtain the maximum effect, exenatide should be injected within 60 min before the two main meals. The clinical effects of exenatide twice daily were investigated in the AC2993 Diabetes Management for Improving Glucose Outcome (AMIGO) trials [51, 53, 54]. These trials showed significant reductions in glycated hemoglobin (HbA_{1c}) of ~1.0–1.2% compared with placebo, and a modest reduction in fasting plasma glucose of ~1.0–1.4 mmol/L compared with placebo. Interestingly, the postprandial plasma glucose excursions were blunted in the exenatide-treated participants compared with the placebo group, presumably driven primarily by a substantial deceleration in gastric emptying. Importantly, the effect on postprandial plasma glucose was only evident during meals with concomitant drug administration, i.e. not during lunch where no drug was administered [55]. The effect on gastric emptying and postprandial plasma glucose excursions of exenatide twice daily has been shown to be sustained over a 30-week treatment period [54]. The average weight loss amounted to 1.6 kg in the exenatide-treated groups. In obese people with type 2 diabetes treated with insulin plus oral antidiabetes drugs, addition of exenatide generally caused body weight loss of more than 5 kg, improved glycemic control over 26 weeks, and decreased total daily doses of insulin [56]. Significant reductions in systolic blood pressure compared with placebo (a difference of 2.8 mmHg) have been reported after 6 months of treatment with exenatide [57]. There were no counter-regulatory increases in heart rate likely because of the short half-life of exenatide [58]. The main side effects of exenatide are mild to moderate nausea, diarrhea, and vomiting [59]. The risk of hypoglycemia is low with exenatide in monotherapy and as add-on to metformin because of the glucose-dependent insulinotropic and glucagonostatic effects. In most exenatide trials, when combined with a sulfonylurea the incidence of minor hypoglycemic events increased compared with placebo (14–36%). No cardiovascular outcome trial with twice-weekly exenatide has been reported or is ongoing, perhaps owing to its introduction to the market before this was mandatory.

Lixisenatide once daily

Lixisenatide was approved for the treatment of type 2 diabetes in Europe in 2013 (Lyxumia) and in the USA in July 2016 (Adlyxin) [60]. As with exenatide, lixisenatide is based on exendin-4, but with a deletion of a proline and an addition of six lysine amino acids at the C-terminus [61] (Figure 32.6). These alterations result in a half-life of 2–3 h after s.c. injection, which would normally favor a twice-daily dosing treatment-regimen (Figure 32.7). However, clinical trials have demonstrated efficacy and tolerability with a once-daily dose of 20 μg [50, 62] as evaluated in the clinical trial program GetGoal [62–65]. These trials showed that lixisenatide significantly lowered mean HbA_{1c} levels by 0.5–0.9% (mean baseline of 8.0%) and resulted in moderate reductions of fasting plasma glucose (0.8–1.2 mmol/L) compared with placebo. Lixisenatide showed pronounced effects on postprandial plasma glucose with a 75% (~5 mmol/L) reduction in postprandial plasma glucose excursions during a standardized meal test compared with placebo, but only when the drug was administered immediately before food ingestion [59]. As with exenatide, this marked effect on one meal is presumably driven by the prominent effect of lixisenatide to decelerate gastric emptying, an effect shown to be substantial and sustained also after 4 weeks of treatment [66]. A dose-dependent decrease in body weight ranging from 0 to 3 kg with the 20 μg once-daily dosing, in some

studies not superior to placebo [67], was observed with lixisenatide [68]. The most common side effects of lixisenatide treatment are of gastrointestinal origin (nausea and diarrhea), consistent with other GLP-1RA [60]. A head-to-head trial of lixisenatide versus exenatide twice daily reported non-inferiority of lixisenatide with regard to HbA_{1c} reduction and slightly better tolerability with nausea (25 vs. 35%), diarrhea (10 vs. 13%), and vomiting (10 vs. 13%), and fewer episodes of symptomatic hypoglycemia (3 vs. 8%) with lixisenatide treatment. However, lixisenatide treatment was inferior with regard to weight loss (3 vs. 4 kg, respectively) [64].

The ELIXA (Evaluation of Cardiovascular Outcomes in Patients With Type 2 Diabetes After Acute Coronary Syndrome During Treatment With Lixisenatide) was the first event-driven cardiovascular outcomes study to provide data for a GLP-1RA [69]. The trial was designed to evaluate cardiovascular risk, comparing lixisenatide with placebo in a high-risk population of adults with type 2 diabetes. A total of 6068 individuals with type 2 diabetes and recent spontaneous acute coronary syndrome event participated in the trial. The composite primary endpoint, which was evaluated for non-inferiority and superiority, comprised cardiovascular death, non-fatal myocardial infarction, non-fatal stroke, and hospitalization for unstable angina [69]. The trial demonstrated that lixisenatide did not affect the incidence of cardiovascular events compared with placebo.

Continuous-acting GLP-1RA

Exenatide once weekly

Exenatide was developed as an extended-release formulation approved in Europe in 2011 and in the USA in the beginning of 2012 (Bydureon). Exenatide once weekly contains exendin-4 (i.e. the same active substance as exenatide twice daily) encased in microspheres made of biodegradable polymer poly(D,L-lactide-*co*-glycolide) (Figure 32.6) [70]. The peptide has a sustained release from the microspheres in three phases: initial release (first 48 h), diffusion (~2 weeks), and erosion release (~7 weeks) [71]. The pharmacokinetic profile depends almost solely on the absorption, and over time the biologically active exenatide given as a weekly injection is derived from multiple previous injections undergoing different phases of microsphere dissolution (Figure 32.7). When administered once weekly (2 mg per dose), the mean plasma concentrations of exenatide reach therapeutic levels after ~2–4 weeks, and steady-state levels are obtained once microsphere dissolution begins after ~6–7 weeks [70, 72]. Plasma levels of exenatide gradually decrease over 3 months once treatment is discontinued [72]. The exenatide-filled microspheres require suspension in an aqueous diluent immediately before injection. Recently, a new dual-chamber pen was developed for administration of exenatide once weekly, aiming to simplify microsphere reconstitution, increase usability, and reduce user errors [73, 74]. The extended-release formulation of exenatide once weekly was examined in the clinical trial program DURATION (Diabetes therapy Utilization: Researching changes in HbA_{1c} weight And other factors Through Intervention with exenatide ONce weekly) [75–80]. In these trials, once-weekly exenatide was compared with the twice-daily formulation of exenatide in two head-to-head studies [77, 79] and it was demonstrated that once-weekly exenatide was superior to twice-daily exenatide (HbA_{1c} reductions, 1.6 vs. 0.9% and 1.9 vs. 1.5%; fasting plasma glucose reductions, 1.9 vs. 0.7 mmol/L and 2.3 vs. 1.4 mmol/L). Although both therapies reduced postprandial plasma glucose excursions, the absolute reduction in postprandial plasma glucose excursions was greatest with the twice-daily compound, driven by a greater effect during the morning and evening meals (related to the twice-daily administrations of exenatide) [79]. The lesser effect on gastric emptying and postprandial plasma glucose excursions of the continuous-acting compound is not explained by differences in plasma exenatide concentrations [79, 80]. Similar reductions in body weight were apparent with both formulations of exenatide, which were generally well tolerated. The most frequent adverse event, nausea, was less common with the once-weekly than the twice-daily compound (14 vs. 35%) [78]. Exenatide once weekly was also compared in a head-to-head trial with the continuous-acting compound liraglutide [78], with greater reductions in HbA_{1c} (1.5 vs. 1.3%) and a greater weight loss (3.9 vs. 2.7 kg) in the liraglutide-treated group compared with the once-weekly exenatide-treated group, but once-weekly exenatide was better tolerated than liraglutide (nausea 9 vs. 21%; diarrhea 6 vs. 13%; vomiting 4 vs. 11%, respectively) [78].

In June 2010, the first participant out of around 14,000 was recruited in to the EXSCEL study (EXenatide Study of Cardiovascular Event Lowering). The trial is ongoing and data are expected to be presented in 2018 [81]. The study will compare the impact of adding exenatide once weekly to usual care versus usual care without exenatide with respect to major cardiovascular outcomes (as measured by a primary composite endpoint of cardiovascular-related death, non-fatal myocardial infarction, or non-fatal stroke).

Liraglutide once daily

Liraglutide was approved for clinical use in Europe in 2009 and in the USA in 2010 (Victoza). The structure of liraglutide is based on native GLP-1 with an Arg34Lys substitution and an addition of a 16-carbon fatty acid side-chain at Lys26, leaving liraglutide with a 97% homology with native GLP-1 [82] (Figure 32.6). The fatty acid side-chain enables the compound to be bound non-covalently to albumin and ensures that only 1–2% of liraglutide is circulating as free peptide in plasma after s.c. injection [83]. As a result, the half-life of liraglutide is ~11–15 h and a once-daily dosing ensures continuous activation of GLP-1Rs (Figure 32.7). Liraglutide is administered as an injection of 0.6 mg/day as the starting dose for 1 week and thereafter titrated to 1.2 mg/day. If it is well tolerated and further effect is needed, the dose can be further uptitrated to 1.8 mg/ day. The effects of liraglutide have been investigated in the clinical trial program LEAD (Liraglutide Effect and Action in Diabetes) [84–90]. Liraglutide significantly lowered HbA_{1c} by 0.8–1.5%, fasting plasma glucose by up to 2.6 mmol/L, and induced a weight loss in the range 2–3 kg compared with

the placebo-treated group. Liraglutide also reduced postprandial plasma glucose excursions by ~1.7–2.5 mmol/L compared with placebo; this effect was, however, primarily mediated by a decrease in preprandial (e.g. fasting) glucose values, which is consistent with the observation that liraglutide has small to moderate effects on gastric emptying [90]. The LEAD studies reported significant reductions in systolic blood pressure of up to 6 mmHg, but also a small increase in heart rate of 2–4 beats per minute (bpm) in the liraglutide-treated group [58, 88, 90]. The most frequently reported adverse events were gastrointestinal (nausea; mild and less persistent compared with treatment with exenatide twice daily) [91]. Rates of minor hypoglycemia (plasma glucose <3.1 mmol/L) ranged from 8% with liraglutide monotherapy to 24% in combination with a sulfonylurea [92]. Liraglutide has been compared in head-to-head trials with the two short-acting GLP-1RAs exenatide twice daily and lixisenatide [91, 93]. Compared with exenatide twice daily, significantly greater reductions of HbA_{1c} levels with liraglutide were observed (0.8 vs. 1.1%), and also greater reductions in fasting plasma glucose (0.6 vs. 1.6 mmol/L). Postprandial plasma glucose control was better with exenatide twice daily than with liraglutide after breakfast and dinner (estimated treatment difference of 1.3 and 1.9 mmol/L, respectively), with insignificant differences after lunch [91]. Body weight reductions were equal between the two groups (3.2 kg with liraglutide vs. 2.9 kg with exenatide) [91]. In a head-to-head trial, in which liraglutide was compared with lixisenatide, lixisenatide reduced postprandial plasma glucose excursions to a greater extent after breakfast than liraglutide, but HbA_{1c} reductions (0.5 vs. 0.3%) and fasting plasma glucose reductions (1.3 vs. 0.3 mmol/L) were significantly greater with liraglutide [93]. A significant reduction in systolic blood pressure was apparent in both groups, whereas heart rate decreased with lixisenatide, but increased with liraglutide (–3.6 vs. 5.3 bpm). Body weight reductions were apparent in both groups, but significantly greater in the participants treated with liraglutide (2.4 vs. 1.6 kg). Liraglutide has also been compared in head-to-head trials with two continuous-acting GLP-1RAs. Both trials demonstrated superiority for liraglutide compared with once-weekly dulaglutide (body weight [94]) and once-weekly albiglutide (glycemic control and body weight [95]).

The LEADER (Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results–A Long Term Evaluation) trial was initiated in 2010 [96, 97] and the results were presented in June 2016 [38]. The trial was designed to examine the cardiovascular effect of treatment with liraglutide compared to placebo in a population of adults with type 2 diabetes and high cardiovascular risk. In this double-blind trial, the participants were randomized to receive liraglutide (titrated to 1.8 mg once daily) or placebo. The primary composite outcome was the first occurrence of death from cardiovascular cause, non-fatal myocardial infarction, or non-fatal stroke. 9,340 people underwent randomization and the median follow-up was 3.8 years. The primary outcome occurred in significantly fewer participants in the liraglutide group (608 of 4,668 [13.0%]) than in the placebo group (694 of 4,672 [14.9%]) (hazard ratio, 0.87; 95% CI, 0.78 to 0.97; P<0.001). Furthermore, fewer people died from cardiovascular causes in the liraglutide group than in the placebo group, and all-cause mortality was lower in the liraglutide group. The rates of nonfatal myocardial infarction, nonfatal stroke, and hospitalization for heart failure were non-significantly lower in the liraglutide group than in the placebo group. 66 participants would need to be treated with liraglutide for 3 years to prevent one event included in the primary outcome and 98 would need to be treated to prevent a death from any cause.

Dulaglutide once weekly

Dulaglutide (Trulicity) was approved in 2014 by the FDA and 2015 by EMA. It consists of two GLP-1 moieties covalently linked to a human immunoglobulin G (IgG) 4-Fc heavy chain, which acts as an inert plasma carrier (Figure 32.6). The combination of dulaglutide's large size, which limits renal clearance, and three amino acid substitutions (compared with native human GLP-1), which promote DPP-4 resistance, substantially prolongs biological activity [98]. As a result, the half-life of dulaglutide is ~90 h, and a once-weekly dosing ensures continued exposure of the GLP-1Rs (Figure 32.7). The recommended starting dose of Dulaglutide is 0.75 mg, which can be increased to 1.5 mg dose for additional glycemic control. A phase II study examining the efficacy and safety of dulaglutide in doses ranging from 0.5 to 2.0 mg reported significant reductions in HbA_{1c} ranging from 1.3 to 1.5% compared with a reduction of 0.3% in the placebo group [99]. Dulaglutide, used as a 1.5-mg once-weekly dose, has been examined in the clinical trial program AWARD (Assessment of Weekly AdministRation of LY2189265 in Diabetes), and has also been compared head-to-head with exenatide twice daily and liraglutide. Clinical trials showed dose-dependent reductions of HbA_{1c} of up to 1.6%, reductions in fasting plasma glucose of up to 2.7 mmol/L, and weight reductions of up to 3.2 kg. Safety data indicate a low incidence of hypoglycemia and the most frequently reported adverse events were gastrointestinal, primarily nausea, which seemed to reduce over time. AWARD-4 was a randomized, open-label, 52-week comparison of the effects of dulaglutide and insulin glargine, both in combination with insulin lispro, in 884 people with type 2 diabetes. The dulaglutide 1.5-mg dose in combination with insulin lispro showed a statistically superior reduction in HbA_{1c} from baseline compared with insulin glargine in combination with insulin lispro at 26 weeks [100]. AWARD-6 was a randomized, open-label, 52-week, parallel-arm study comparing the effects of dulaglutide with those of once-daily liraglutide in 599 people with type 2 diabetes on concomitant metformin. Dulaglutide 1.5 mg showed non-inferiority to liraglutide 1.8 mg for HbA_{1c} reduction after 26 weeks, but a greater weight loss was seen in the liraglutide-treated group (3.9 kg) compared with the once-weekly dulaglutide-treated group (2.7 kg) [94]. The most common adverse events were nausea (10–15%) and diarrhea (9%). As for the other continuous-acting GLP-1RA, a sustained increase in heart rate by up to 5 bpm was seen in the dulaglutide-treated participants included in the AWARD program. The REWIND (Researching Cardiovascular Events With a Weekly Incretin in

Diabetes) trial (to be completed in 2019) is set to assess the effect of 1.5 mg dulaglutide on cardiovascular outcomes when added to existing glucose-lowering regimens [101]. The primary objective is to test whether dulaglutide (compared with placebo) can reduce the occurrence of death from cardiovascular causes, non-fatal myocardial infarction, or non-fatal stroke in people with type 2 diabetes.

Albiglutide once weekly

Albiglutide is a once-weekly GLP-1RA for s.c. administration approved in 2014 in both the USA (Tanzeum) and Europe (Eperzan). Albiglutide (previously named albugon) is generated in the yeast species *Saccaromyces cerevisiae* by recombinant DNA technology and the resulting therapeutic fusion protein consists of two sequential copies of modified human GLP-1 linked to human albumin, which owing to molecular size limits the renal elimination (Figure 32.6) [102]. Peak plasma levels of albiglutide are achieved 2–5 days after s.c. injection, and the half-life is ~5–8 days, making it suitable for once-weekly dosing [103] (Figure 32.7). The recommended weekly dose is 30 mg, with the possibility of up-titration to 50 mg based on individual glycemic response. A clinical phase II study showed that treatment with albiglutide (30 mg once weekly) reduced HbA_{1c} and fasting plasma glucose levels significantly greater than treatment with twice-daily exenatide (HbA_{1c} reductions of 0.9 vs. 0.5% and fasting plasma glucose reductions of 1.4 vs. 0.8 mmol/L, respectively) [104]. However, the weight loss (1.4 kg) was significantly less with albiglutide than with twice-daily exenatide (2.4 kg). Albiglutide has been examined in the clinical-trial program HARMONY, including a head-to-head comparison with liraglutide [95]. This study reported superiority of liraglutide compared with albiglutide with respect to HbA_{1c} reductions (1.0 vs. 0.8 mmol/L), fasting plasma glucose reductions (1.7 vs. 1.2 mmol/L), and body weight loss (2.2 vs. 0.6 kg). Albiglutide was, however, better tolerated than liraglutide with fewer gastrointestinal side effects (nausea, 10 vs. 29%; vomiting, 5 vs. 9%) and a lower incidence of mild hypoglycemia (16 vs. 21%). Local skin reactions at the injection site were more common in the group treated with albiglutide (13 vs. 5%). A study to determine the effect of albiglutide, when added to standard blood glucose-lowering therapies, on major cardiovascular events in individuals with type 2 diabetes (HARMONY Outcomes) was initiated in July 2014; 9400 participants will be enrolled, and data are expected in 2019 [105].

Safety issues

The safety of GLP-1RAs has been extensively studied in preclinical studies and large clinical trial programs. The most common adverse events observed in clinical trials with GLP-1RAs involve the gastrointestinal system, mainly nausea, vomiting, and diarrhea, and these events diminish over time. Differences exist in the reported occurrence of these gastrointestinal effects between each GLP-1RA (as described above). Other identified potential safety issues include hypoglycemia, pancreatic adverse events, thyroid neoplasms, immunogenicity issues, and interactions with other medicinal products [52, 71, 83, 106–108].

Hypoglycemia

In monotherapy or combination with other antidiabetes agents that have a low risk of hypoglycemia, e.g. metformin and pioglitazone, the GLP-1RAs causes minor hypoglycemia in 1–7% of treated individuals (with almost no severe hypoglycemia events) depending on the study population and GLP-1RA [52, 71, 83, 107, 108]. In trials in which the GLP-1RAs were combined with a hypoglycemia-prone antidiabetes agent, e.g. a sulfonylurea or insulin, the incidence of minor hypoglycemia was, as expected, significantly higher (up to one-third of participants), again depending on trial duration, glycemic control, and study population and also the dose of insulin and/or sulfonylurea.

Pancreatic adverse events

Acute pancreatitis is listed as an adverse event for all GLP-1RAs [52, 71, 83, 107, 108]. Since the introduction of GLP-1-based therapy, pancreatic adverse effects, in particular pancreatitis and pancreatic cancer, have been a major concern. So far there are no data to suggest differences in adverse pancreatic effects between the GLP-1RAs (e.g. between short- and continuous-acting agents [109]). Reports of acute pancreatitis and pancreatic cancer were reported extremely rarely in the clinical trials with the GLP-1RAs [110]. However, there have been numerous postmarketing reports of pancreatitis and pancreatic cancer associated with the GLP-1-based therapy. The causality in these mainly spontaneous reports is difficult to interpret, as persons with type 2 diabetes generally have an up to three times higher risk of pancreatitis than those without diabetes [111]. According to an analysis of the FDA adverse event reporting database conducted by Elashoff et al. [112], pancreatitis was reported as an adverse event more than six times as frequently for people administered exenatide compared with other (non-GLP-1-based) therapies for diabetes. Based on these uncertainties, the regulatory agencies in Europe (EMA) and the USA (FDA) in 2013–2014 undertook an extensive appraisal of the existing preclinical and clinical safety data together with the observational evidence. The conclusion was that data were inconsistent with a causal association between GLP-1R activation and pancreatic adverse effects, but owing to the uncertainty of the estimates, a causal role could not be completely excluded [106]. At present, it remains uncertain whether the frequent reporting is the product of reporting bias or represents a slightly increased risk of pancreatitis with the treatment. Data from ELIXA trial and the LEADER trial after 25 months and 3.8 years of exposure to lixisenatide and liraglutide, respectively, showed that the incidence of pancreatitis was numerically but not statistically significantly lower in the GLP-1RA groups than in the placebo groups [38, 39]. Individuals started on treatment with any of the GLP-1RAs should be informed of the potential risk and characteristic symptoms of acute pancreatitis; and caution is advised when prescribing GLP-1RAs to those with a risk of or a history of pancreatitis [52, 71, 83, 107, 108].

Thyroid adverse events

The preclinical development program of several GLP-1RAs exposed significant increases in thyroid C-cell tumors in rodents

[52, 71, 83, 107, 108]. The fact that these C-cell neoplasms were not detected in monkeys [113] suggests important species differences. Accordingly, in comparison with the situation in rodent thyroid glands, human C cells are much less abundant in human thyroid tissue and, importantly, GLP-1Rs are present in much lower amounts per C cell [113]. Thyroid events were closely monitored (by repeated measurements of calcitonin) in the clinical trial programs and in postmarketing surveillance and cardiovascular outcome trials. Today, no safety signals are pointing towards the risk of thyroid cancers in humans [38, 114].

Immunogenicity issues

The GLP-1RAs are fairly large molecules that raise an immune response in some individuals, evidenced by increasing titers of antibodies directed against epitopes on the GLP-1RA. Generally, the GLP-1RAs that are based on exendin-4 (exenatide and lixisenatide) raise more antibodies, which can be detected in 25–74% of those treated, than the GLP-1RAs based on native human GLP-1 (liraglutide, albiglutide, and dulaglutide) (antibodies detected in 1–9%). There is conflicting evidence on the clinical relevance of these antibodies [67, 94, 115, 116], but particularly high levels (titers) of antibodies, which when measured are present in 1–6% of patients, may limit the clinical effects of at least some of the GLP-1RAs (as is evident with exenatide) [116, 117]. Interestingly, injection-site reactions are more frequent in people who develop antibodies compared with those who did not [71]. However, other excipients in the drug formulation (e.g. the prolonged-release delivery systems in the GLP-1RA for once-weekly administration) are also important factors in the development of injection-site reactions. Thus, exenatide once weekly caused much more injection site pruritus than exenatide twice daily (18 vs. 1%) [79], and injection-site reactions occurred in more people given albiglutide than in those given liraglutide (13 vs. 5%) [95].

Interactions with other medical products

None of the GLP-1RAs interact with the hepatic metabolism of other medicinal products; specific interactions with acetaminophen, digoxin, oral contraceptives, lisinopril, metformin, hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors, and warfarin have been studied in clinical trials [52, 71, 83, 107, 108]. However, all of the GLP-1RAs delay gastric emptying with acute dosing, and therefore have the potential to prolong and increase or decrease the absorption of concomitantly administered oral medicinal products [52, 71, 83, 107, 108]. Importantly, the effect on gastric emptying diminishes with time for the continuous-acting GLP-1RAs owing to fairly rapid tachyphylaxis already evident from the first day of treatment [29, 109]. Therefore, the interaction through delayed gastric emptying is clinically relevant only with the short-acting GLP-1RAs and concomitant administration of medicinal products with a narrow therapeutic–toxic ratio that require careful clinical or biochemical monitoring. The interaction can be alleviated by the administration of the other medicinal product 1 h before or 4 h after the administration of the short-acting GLP-1RAs [52, 60].

Perspectives for the GLP-1RAs

Dulaglutide was the fifth GLP-1RA to reach the market since exenatide twice daily was introduced in 2005. A few other GLP-1RAs are in clinical development. A promising one is semaglutide, which essentially is a further development of liraglutide. Semaglutide is based on native GLP-1 with further modifications in the N-terminus and prolongation of the fatty acid side-chain compared to liraglutide, which increase affinity to albumin and prolong the half-life to ~6–7 days, making it suitable for once-weekly dosing. Interestingly, in late 2016, results were published showing that semaglutide significantly reduces the risk of major adverse cardiovascular events in the SUSTAIN 6 trial, which included approximately 3300 people with type 2 diabetes (ClinicalTrials.gov number, NCT01720446). Semaglutide is also in clinical development as an oral version combined with a small-molecule transporter protein to increase bioavailability [118]. Additionally, several multifunctional peptides that combine GLP-1R agonism with affinity towards other peptide hormone receptors involved in human metabolism (e.g. GIP, cholecystokinin [CCK] and/or glucagon (for a review, see [119]) are also in very early clinical development, which may broaden the scope of the GLP-1RAs.

What will be the future for these drugs? There is already widespread clinical use of GLP-1RAs, in particular liraglutide. The LEADER cardiovascular outcome trial with liraglutide [38] demonstrated the long sought macrovascular benefit that is actually the main incentive for treatment with a second-line antidiabetes agent. The only completed cardiovascular outcome trial in a short-acting GLP-1RA, the ELIXA study investigating lixisenatide [69, 120], showed no beneficial effects on cardiovascular events or mortality, while microvascular endpoints have not been reported. In retrospect, the ELIXA trial, by including only individuals with severe cardiovascular disease and a recent acute coronary event, could be construed as being designed to accrue cardiovascular events rapidly in both groups, but at the cost of limiting the possibility of finding a beneficial effect. Nevertheless, the uniformity of the GLP-1RAs as a drug class is now questioned. Whether other short or long acting GLP-1RAs are able to demonstrate benefits of similar size will be crucial in determining their position in clinical use and the future revisions of treatment guidelines [121]. Solid clinical data exist only for some of the long-acting GLP-1RAs, and these data show clear benefit in terms of reducing mortality and support their clinical use and even prioritization in the clinical guidelines.

Conclusion

The GLP-1RAs target the multifaceted pathophysiology of type 2 diabetes with positive effects on both α- and β-cell dysfunction and provide improvements in fasting plasma glucose, postprandial plasma glucose, and HbA_{1c} with a relatively low risk of hypoglycemia and notably accompanied by a weight loss. There are some clinically relevant differences between the GLP-1RAs. The continuous-acting GLP-1RAs seem to be preferable if a large reduction in HbA_{1c} is the primary therapeutic aim, and when frequent administration and daily timing of injections are

undesirable for the person with diabetes. On the other hand, the short-acting compounds may be preferable if postprandial plasma glucose excursions are the major problem. Additionally, the need for weight reduction and the individual tolerability of the compounds should be considered when choosing between the GLP-1RAs. The differences between the GLP-1RAs enable physicians to choose the compound with the clinical profile that is most likely to benefit the patient. At the moment there is no distinction between the various GLP-1RAs in the position statement from the ADA and the EASD [1, 2]. So far one cardiovascular outcome study (ELIXA) showed non-inferiority to placebo using a short acting GLP-1RA (lixisenatide) compared to placebo. However, two trials (LEADER and SUSTAIN6) using continuous acting GLP-1RA in people with type 2 diabetes at high cardiovascular risk have demonstrated a reduction in cardiovascular events in those treated with the GLP-1RA compared with placebo on a background of standard care. Several other studies are currently underway for the available and emerging GLP-1RAs including head-to-head trials, trials evaluating safety and long-term effects, combinations with insulin preparations, and anti-obesity studies.

Amylin and amylin analogs

Introduction and historical overview

Amylin's precursor, a 67 amino acid polypeptide, is produced in pancreatic β cells and processed by prohormone convertase 2 and prohormone convertase 1/3 to the mature 37 amino acid hormone [122]. Amylin is the major constituent of amyloid deposits in the pancreatic islets of Langerhans in type 2 diabetes. Amyloid deposits were discovered a century ago and described as a pathological feature of people with diabetes and those with insulinomas. In 1987, two research groups, independently of each other, isolated amylin from amyloid deposits and speculated on whether it had important endocrine effects, hence the initial name of amylin: islet amyloid polypeptide (IAPP) [123, 124]. The hormone is stored and secreted together with insulin from the pancreatic β cells [125]. Thus, type 1 diabetes is considered an amylin-deficient state owing to the destruction of β cells. Amylin and insulin exhibit complementary roles in the regulation of plasma glucose [126]. The physiological actions of amylin involve inhibition of appetite and gastric emptying along with suppression of glucagon secretion in relation to meal intake. With the development of amylin analogs, the physiological actions are used to obtain clinically beneficial effects on glycemic control and body weight in the treatment of type 1 and type 2 diabetes.

Amylin physiology

Amylin release, metabolism, and regulation of secretion

Amylin and insulin share the same processing enzymes, are stored together in secretory granules, and are co-released from the pancreatic β cells [127]. The release of amylin is stimulated by ingestion of nutrients and gut-derived incretin hormones (GLP-1 and GIP) and through neural signaling. Thus, under physiological conditions, amylin is acutely released during a meal. Amylin is released together with insulin in a corresponding high-frequency pulsatile pattern, but at a 1:100 ratio. Deviation from this secretion pattern has been observed in morbid conditions such as pancreas cancer, diabetes, and obesity in humans and with pharmacological intervention (e.g. dexamethasone). The underlying mechanisms of the altered amylin secretion pattern and its potential implications are unknown at present [128]. Amylin circulates in equimolar amounts in a biologically active non-glycosylated form and an inactive glycosylated form. In contrast to insulin, which is eliminated primarily in the liver, amylin is eliminated mainly through renal metabolism [125].

The amylin receptor

Amylin is similar in amino acid sequence and structure to other important peptide hormones such as calcitonin, which regulates calcium and phosphorus metabolism, calcitonin gene-related peptide, and adrenomedullin, both of which impart vasodilation. Together they are grouped as the CT peptide family. Amylin acts on a composite receptor comprised of two parts. The "core" part consists of a calcitonin receptor (CR), which is a transmembrane class B G protein-coupled receptor (GPR) [129, 130]. Two splice variants of the CR (a and b) exist, and they are complexed with one of three receptor activity modifying proteins (RAMP1, RAMP2, or RAMP3), creating diverse amylin receptors (AMY1, AMY2, and AMY3) [131]. Amylin appears to bind with high affinity to all of the six different receptors emerging (Table 32.1) [130].

Central effects of amylin on appetite and food intake

Amylin and the gut-derived incretin hormone GLP-1 share many characteristics and have overlapping physiological properties. Both peptide hormones slow nutrient delivery to the small intestine by decelerating gastric emptying, they suppress postprandial glucagon secretion and they reduce appetite, albeit through seemingly different pathways [132]. Dose–response studies performed in rats investigating the influence on gastric emptying exerted

Table 32.1 Amylin stimulates receptors comprised of a class B G protein-coupled receptor (GPR) and a receptor activity-modifying protein (RAMP). The GPR component is a splice variant of the calcitonin receptor, $CT_{(a)}/CT_{(b)}$, complexed with either RAMP1, RAMP2, or RAMP3. The dimerized receptor is referred to as AMY1, AMY2, and AMY3 corresponding to each respective RAMP with either an (a) or (b) in the subscript to define which splice variant of the calcitonin receptor is in the complex.

	CT receptor	
RAMP	$CT_{(a)}$	$CT_{(b)}$
RAMP1	$AMY1_{(a)}$	$AMY1_{(b)}$
RAMP2	$AMY2_{(a)}$	$AMY2_{(b)}$
RAMP3	$AMY3_{(a)}$	$AMY3_{(b)}$

by several different subcutaneously injected gastrointestinal hormones (GLP-1, GIP, cholecystokinin octapeptide [CCK-8], glucagon, and pancreatic peptide) showed that amylin was the most potent inhibitor of these [133]. In contrast, s.c. injection of a selective amylin antagonist in rats revealed an acceleration of gastric emptying [134]. Importantly, it has been demonstrated that the ability of amylin to inhibit gastric emptying is overridden by the occurrence of hypoglycemia [135]. The best characterized anorectic function of amylin is to reduce meal size. A solid argument indicating that amylin is a physiological regulator of meal size is provided by studies showing that peripherally or centrally infused amylin antagonists produce an opposite effect to that of amylin, i.e. an increase in food intake, mainly via a meal size effect. It remains to be clarified whether amylin also has an effect on postprandial satiety [136, 137]. Whereas the feeding inhibitory actions of endogenous GLP-1 seem to be both centrally and peripherally mediated (given that intact vagal afferent signaling from the intestines is required), amylin appears to exert its actions via direct effects on the CNS only [132]. c-Fos expression (a marker of neuronal activity) is induced by amylin in target neurons in different brain regions involved with metabolic control. The area postrema located in the hindbrain is considered to be the primary and most important site of amylin action. This assumption is based on studies of rodents undergoing area postrema ablation, which demonstrated a complete abrogation of amylin's anorexigenic effects [138, 139]. Subsequent to area postrema activation, the amylin signal is conveyed to the forebrain via distinct relay stations and to regions of hypothalamus known to be involved in feeding behavior. Within the lateral hypothalamic area, amylin diminishes the expression of orexigenic neuropeptides such as orexin and MCH (melanin-concentrating hormone) [128, 139, 140]. The area postrema is favorably located as a target of central hormone action owing to the permeable blood–brain barrier in this region [141]. Other brain sites suggested to be important contributors to amylin's anorexic effects include the subfornical organ, nucleus accumbens, and the dorsal raphe of the brainstem [138, 139]. Whether amylin also exerts peripheral actions has been investigated in muscle, liver, and adipose tissue of mice and adipose tissue of humans by Moon et al. [142, 143], and physiological effects were clearly evident with stimulation of distinct signaling pathways after application of amylin. However, no studies have confirmed the presence of amylin receptors in these peripheral tissues [139].

Amylin analogs

In the treatment of diabetes

The discovery of amylin's glucose- and body weight-lowering effects makes it attractive for medical purposes. However, the instability and propensity to self-aggregate made the clinical use of human amylin difficult [125]. The problem was solved by substituting a few amino acids in the human sequence of amylin with proline residues (at positions 25, 28, and 29) [132]. This enhanced the solubility and markedly reduced amyloid fibril formation of the bioactive peptide [144]. The actions and pharmacokinetic and pharmacodynamic properties of a synthetic amylin analog, pramlintide, were found to be very similar to those of native amylin [125]. Numerous clinical trials tested the efficacy and safety of pramlintide ahead of its approval by the FDA in March 2005. Currently, pramlintide, the only available amylin analog, is marketed in the USA as Symlin. The drug is approved for adjunct treatment of type 1 and type 2 diabetes, when optimal glucose control is not achieved with insulin administration alone or combined with other glucose-lowering drugs [145]. Pramlintide is administered parallel to meal-time insulin therapy [144]. The plasma half-life is ~48 min when injected s.c. in the thigh or the abdomen. The drug is primarily eliminated by the kidneys, like native amylin [146]. The most common adverse events related to pramlintide treatment are of gastrointestinal origin, e.g. decreased appetite, vomiting, and stomach pain with mild-to-moderate nausea being most frequent. However, these effects are generally transient and can be minimized by starting with a low dose and slow titration. No direct correlation between gastrointestinal symptoms and the therapy-induced weight loss has been found [147]. Although pramlintide is considered to be well tolerated overall, it is associated with an increased risk of insulin-induced severe hypoglycemia, particularly in people with type 1 diabetes [148]. Another second-generation amylin analog, davalintide, was subsequently developed. Since phase II studies did not demonstrate superiority of davalintide in terms of efficacy, and showed a tolerability profile and body weight-lowering effect similar to pramlintide, the drug was discontinued in development but has been used in clinical studies investigating the effects of amylin [149].

Studies evaluating pramlintide therapy in humans

In the mid-1990s, several clinical studies investigating the acute and short-term effects of pramlintide were performed, e.g. Kolterman investigated pramlintide given prior to a liquid meal (consisting of 350 kcal with 24% protein, 21% fat, and 55% carbohydrate) to individuals with type 1 or type 2 diabetes [150]. Considerable reductions in postprandial glucose excursions and 24-h glucose profile were demonstrated following pramlintide administration in both diabetes groups. These glycemic improvements were observed in acute studies and also with continued dosing for 2–4 weeks and are likely due to decreased gastric emptying and reduced glucagon release. The suppression of gastric emptying in diabetes exerted by amylin is well documented, although the specific mechanisms behind are still unknown [151]. Chapman et al. demonstrated that the acute hypophagic effects of pramlintide do not only apply to people who are obese or diagnosed with diabetes: a single low-dose (30 μg) pramlintide injection in healthy, normal-weight volunteers induced reduction in food intake and meal duration compared with placebo [152].

Several larger long-term trials with pramlintide have also been conducted. Hollander et al. [153] investigated HbA_{1c} and weight control with adjuvant pramlintide therapy in individuals with type 2 diabetes ($n = 656$) with $HbA_{1c} \geq 8\%$ and who were requiring insulin treatment either alone or combined with oral antidiabetes

medications at baseline. Participants were randomized to receive pramlintide at different doses or placebo for 52 weeks. Treatment with pramlintide 120 µg twice daily led to a reduction from baseline in HbA_{1c} of −0.68%, which was sustained at week 52 (HbA_{1c} −0.62%). This was significantly greater than what was observed with placebo (HbA_{1c} ~0.25%). At week 26, the body weight in participants receiving pramlintide was significantly and dose-dependently decreased from baseline by −0.7 kg with 90 µg twice daily and −1.1 kg with 120 µg twice daily, whereas placebo-treated participants experienced a +0.3 kg change in body weight. At week 52, the body weight change from baseline was sustained in those receiving 120 µg twice daily (−1.4 kg), whereas this was not achieved in people treated with 90 µg twice daily (−0.5 kg) or placebo (+0.7 kg) [153]. The overweight participants (BMI >25 kg/m^2) with type 2 diabetes, who received pramlintide 120 µg twice daily in the study, were included in a pooled post hoc analysis with corresponding participants from another large-scale trial (total $n = 1155$) [154]. Significant reductions in both HbA_{1c} (−0.43%) and body weight (−2.0 kg) from baseline to week 26 (compared with placebo) were found with adjunctive pramlintide therapy. These data indicate that pramlintide added to insulin therapy yields further reductions in HbA_{1c} and a concomitant weight loss in individuals with type 2 diabetes. Furthermore, the risk of severe hypoglycemia was not increased [155].

Future perspectives: amylin incorporated in dual agonist?

Since pramlintide is indicated solely as a supplement to insulin and both peptides must be administered several times per day with s.c. injections, a combination of the two therapies is desirable for people with diabetes in order to reduce the number of injections. At present it is not possible to mix insulin and pramlintide and administer the two drugs in one pen owing to biochemical incompatibility. Perhaps in the future, advanced biotechnology might produce a dual-chamber, double-gauged pen delivering both peptides simultaneously. A novel approach in the pharmaceutical industry is to chemically design multifunctional peptides, e.g. by making a hybrid of two peptides bound together directly or via a linker. These so called "phybrids" are able to act on two (or more) distinct receptors and thereby induce additive or even synergistic beneficial effects and potentially limiting adverse effects [119]. Interestingly, Trevaskis et al. designed two kinds of phybrids combining GLP-1 (exenatide) and amylin (davalintide) modules with different covalent links [141]. The individual phybrids were administered via subcutaneously implanted minipumps in an obese diabetic mouse model (Lep^{ob}/Lep^{ob}). Sustained infusions reduced blood glucose and HbA_{1c} equivalently to exenatide, but both phybrids induced greater weight loss compared with exenatide administration alone. The phybrids reduced food intake and body weight in a dose-dependent manner in diet-induced obese rats. The body weight loss was equal to that with co-infusion of davalintide and exenatide, but greater than that achieved using davalintide and exenatide administration alone. These preclinical data suggest that a single-molecule phybrid approach involving amylin and GLP-1 dual agonism may be just as efficient as co-administration of the individual peptides [141, 156]. In the search into renewing and optimizing the treatment of diabetes and obesity, such co-agonists are likely to go into clinical development.

33 How to Use Type 2 Diabetes Treatments in Clinical Practice: Combination Therapies

Silvio E. Inzucchi[1] and David R. Matthews[2]

[1] Yale School of Medicine and Yale Diabetes Center, Yale – New Haven Hospital, New Haven, CT, USA
[2] Harris Manchester College, Oxford, and Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Oxford, UK

Key points

- Twelve drug classes (including insulin) are now available to lower glucose in individuals with type 2 diabetes.
- Each antihyperglycemic drug class has a unique mechanism of action, a specific glucose-lowering efficacy, and certain side effects and risks, and some categories also carry specific non-glycemic benefits.
- Metformin is the standard initial drug therapy; in people not achieving control with metformin alone, other drugs are added in sequence—most people will eventually require 2–3 agents for optimal control.
- To achieve glycemic control, many people, particularly those with longer standing disease, will ultimately require insulin, usually beginning with a single injection of a basal formulation once daily.
- In order to arrive at the best regimen for each patient, the clinician should weigh the glucose-lowering efficacy of each drug, with its potential risks and benefits, in addition to its cost.
- The ADA–EASD position statement (2012, updated in 2015) provides rational recommendations for initial and combination glucose-lowering therapy in type 2 diabetes.

Introduction

Optimal care of the person with diabetes involves a comprehensive, multisystem approach to address not only hyperglycemia, but also the frequent companion comorbidities of obesity, hypertension, and dyslipidemia. The main goals of therapy are to avoid symptoms of hyperosmolality and to prevent or delay the long-term sequelae of the disease, including both microvascular and macrovascular complications. At the same time, the potential negative impact of treatments on quality of life should be minimized (See Chapter 23). This composite outcome is not necessarily easy to achieve owing to the limitations of our current therapies, each of which carries some risk of adverse effects, requires adherence on the patient's part, and involves some measurable cost, to either the person with diabetes, insurers, or governments. In this chapter, we review combination pharmacological therapies for people with type 2 diabetes mellitus (T2DM), with a focus on non-insulin glucose-lowering medications. Of course, such treatments cannot be considered as stand-alone therapies. They are always a component of a comprehensive risk-reduction strategy that includes treatments to lower blood pressure, improve circulating lipid concentrations, and reduce platelet hyperactivity. When one considers the significant polypharmacy that this may involve, it is contingent on the practitioner to recommend the proper *balance* of medications, trying to minimize side effects, complexity, and cost, while encouraging adherence to prescription medicines and to the lifestyle choices that are so important in optimizing clinical outcomes.

Reducing glucose concentrations towards the normal range has been unequivocally proven to reduce the incidence and progression of microvascular complications in both type 1 diabetes (T1DM) [1] and T2DM [2]. The most consistent data pertain to the prevention or stabilization of retinopathy and nephropathy. The evidence of an impact of diabetes management on neuropathy is less robust. Moreover, preventing cardiovascular events from improving glycemic control (with the surrogate endpoint of glycated hemoglobin [HbA_{1c}]) has not been unequivocally demonstrated, although there may be certain benefits in this regard from specific drug strategies used to lower glucose [3], but, crucially, interventions to improve cardiovascular outcomes include the management of hypertension and hyperlipidemia. Glucose lowering plays a role in the prevention of cardiovascular disease, and especially so early in the disease process [4]. The effects are probably mediated by slowing the atherosclerotic process and therefore are slow, i.e. measured over years rather than months. The early effect of reducing glucose to or towards the normal range is undoubtedly the prevention of microvascular disease.

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

Efforts to lower glucose are often thwarted by drug side effects, particularly unwanted hypoglycemia when sulfonylurea drugs or insulin are used. Progressive β-cell failure [5] means that therapies often need to be uptitrated even to maintain the status quo. A pragmatic approach is to recommend that glucose levels be lowered as much as is feasible, taking into account overall goals of care, patient capacities and support structure, and the adverse effects and costs of treatments. Even in the hands of the specialist, the optimal titration of an effective, well-tolerated antihyperglycemic regimen is frequently a great challenge, especially in those with long-standing disease.

Pathophysiological rationale for using multiple therapies

Combination glucose-lowering therapy is frequently required in individuals with T2DM because of the multiplicity of pathophysiological defects that lead to increased blood glucose concentrations [6] (Figure 33.1). A proper understanding of optimal pharmacological approaches requires an appreciation of the metabolic abnormalities that characterize the disease.

One of the earliest of such features detected in persons at risk for T2DM was resistance to the action of insulin in peripheral tissues, mainly skeletal muscle and adipocytes. This appears to be driven by obesity and also genetic factors and involves molecular abnormalities in post-receptor insulin signaling, probably related to the build-up of fatty acid metabolites within the cell leading to deranged mitochondrial function [7]. Initially, the pancreatic response to insulin resistance is to augment insulin secretion in a homeostatic drive to maintain blood glucose concentrations within the normal range. However, in some individuals, such a response cannot be sustained over time. As a result, there is a gradual diminution in pancreatic insulin secretion, leading to a slow but predictable increase in circulating blood glucose levels [6].

This is readily detected in the postprandial setting or with glucose tolerance testing, when the demand for increased insulin significantly outstrips the β-cell's secretory capacity. However, basal glucose concentrations also reflect this defect [8], and fasting hyperglycemia is now most frequently used as an appropriate index, rather than the more complex oral glucose challenge.

The molecular mechanisms underlying β-cell dysfunction remain controversial, with evidence for a variety of potential factors, including glucotoxicity, lipotoxicity, oxidative stress, and the extracellular accumulation of amorphous islet amylin polypeptide (IAPP) [9]. It is important to emphasize that although insulin resistance provides a fertile condition for diabetes to develop, it is islet dysfunction that determines the progression to diabetes. This includes both relative insulin secretory deficiency of the β cell and failure to suppress glucagon secretion by the α cell. Abnormalities in the incretin system have also been recognized as a contributing factor to abnormal islet cell behavior [10].

The liver plays a major role in the increased blood glucose concentrations in T2DM. Augmented endogenous glucose production, a manifestation of *hepatic* insulin resistance, contributes to hyperglycemia in both fasting and postprandial settings [11]. This may also partly relate to hyperglucagonemia, given that this islet hormone is a significant driver of hepatic glycogenolysis and gluconeogenesis.

Finally, urinary excretion can be a compensatory mechanism to rid the body of excess glucose when pathological hyperglycemia occurs above the normal renal threshold. This threshold is paradoxically raised in people with T2DM, who are consequently *less* glucosuric than would be expected based on their prevailing circulating blood glucose concentrations [12]. This may relate

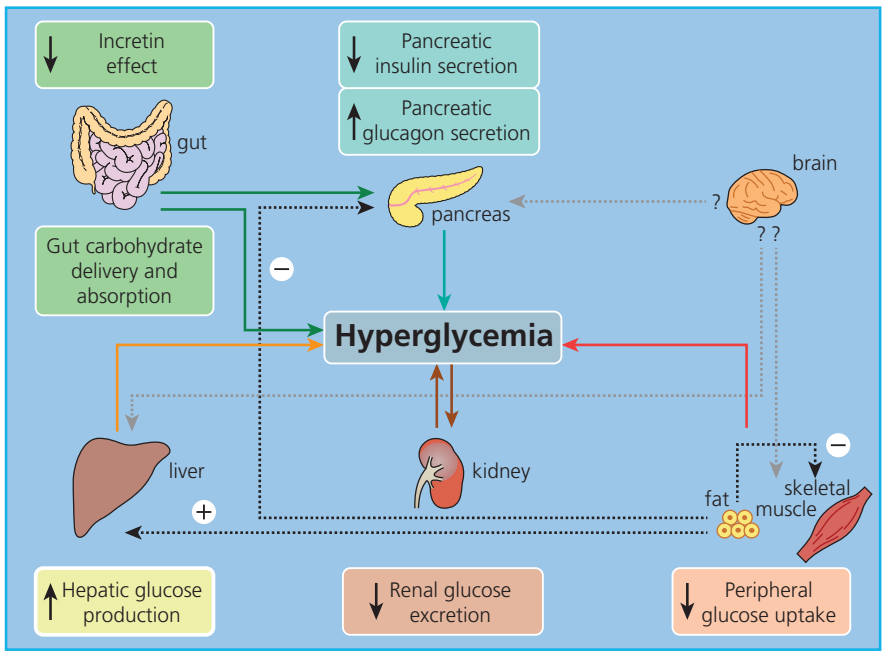

Figure 33.1 The multiple pathophysiological defects that lead to T2DM. The abnormalities described are expressed variably in patients. Most individuals with T2DM have derangements in both insulin supply and insulin action. More recently, abnormal incretin system has been described in addition to inadequate renal clearance of glucose. Many of these metabolic axes are in part driven by the brain but the link to diabetes remains unclear.

to overexpression of the main glucose transporter on the luminal side of the nephron, the sodium–glucose co-transporter-2 (SGLT-2) [13].

Because T2DM is a heterogeneous disease, these abnormalities are present to a variable extent from one individual to another. In practice, clinicians do not necessarily test for their presence or severity, although there are certain clinical features that might suggest greater or lesser perturbation in a specific a domain. For example, those with "metabolic syndrome," a classical constellation of physical and biochemical characteristics that include abdominal obesity, hypertension, hypertriglyceridemia, hyperglycemia, inflammation, and increased risk of atherosclerosis, usually demonstrate significant insulin resistance [14]. The contributions of insulin resistance and β-cell dysfunction vary to some extent by ethnic group [15–17]. Individuals with relatively higher fasting blood glucose levels achieve that through the augmentation of hepatic glucose production. In contradistinction, those with predominant postprandial hyperglycemia exhibit more peripheral insulin resistance and/or more significant β-cell dysfunction. Irrespective of the dominant feature, which is difficult to measure outside a clinical research center, *most* people with T2DM exhibit *both* insulin resistance *and* insulin deficiency [6]. Accordingly, most drugs will reduce glucose to some extent in the majority of individuals, although certain agents (and therefore certain combinations) may be more efficacious in certain people. Understanding the pathogenesis of diabetes will provide the clinician with a framework to understand how each of the drug categories (and their combinations) reduces glycemia based on their unique mechanism of action. This will not only lead to a deeper understanding of the disease and its treatment, but may also allow for more refined, individualized approaches to patient care. Admittedly, however, there are few data to support the notion that attempting to match a drug's mechanism to a patient's predominant pathophysiological defect results in any better control than a more traditional, iterative approach during the longitudinal care of the person with diabetes.

Individual glucose-lowering drug classes

A further description of each of the individual antidiabetes drug classes is given in chapters 29, 31 and 30 (Table 33.1).

Major classes

Sulfonylureas

Sulfonylureas have been available since the early 1950s and remain one of the standard therapies for T2DM [18]. Their mechanism of action involves binding to the sulfonylurea receptor on the cell surface of pancreatic β cells, leading to closure of ATP-sensitive K^+ (K-ATP) channels. This, in turn, depolarizes the plasma membrane, allowing an influx of calcium ions and consequent insulin secretion. Notably, the effects of sulfonylureas are not glucose dependent, and therefore this drug class carries the risk of hypoglycemia, which in some circumstances can be severe and prolonged.

First-generation agents (chlorpropamide, tolbutamide, tolazamide, and acetohexamide) are no longer in widespread use. Currently available second-generation sulfonylureas include glyburide/glibenclamide, glipizide, and glimepiride, with subtle differences in their durations of action and metabolic fates. Glyburide has the longest receptor binding half-life (although its plasma half-life is short). It has a significantly active glucose-lowering hepatic metabolite that is renally cleared. Accordingly, this agent is associated with a high risk of hypoglycemia and should generally be avoided in older persons and those with compromised renal disease [19]. An additional side effect of sulfonylureas is modest weight gain (2–3 kg.) This category is also associated with a higher secondary failure rate than for other drugs, such as metformin and thiazolidinediones, an effect ascribed by some to "pancreatic exhaustion" [20]. Hence they are considered less durable than these other agents in most people with diabetes. In the UK Prospective Diabetes Study (UKPDS) [2], involving 5102 individuals newly diagnosed with T2DM, those treated with sulfonylureas (analyzed in conjunction with those assigned to initial insulin therapy) experienced significantly better microvascular outcomes (–25%; $p = 0.001$; mainly retinopathy, albuminuria) than those treated with diet alone. There was an insignificant trend towards fewer myocardial infarctions (MI) (–15%; $p = 0.052$) and no effect on either all-cause or diabetes-related mortality.

In some observational studies, sulfonylureas have been associated with increased cardiovascular events compared with metformin and, at times, other oral antihyperglycemic drugs [21, 22]. Interestingly, in an older study, the UGDP, tolbutamide was associated with greater cardiovascular mortality than insulin therapy [23]. Dating from this observation, although the study had many methodological limitations (including large imbalances in the randomization relating to ECG abnormalities and angina [24]), the sulfonylurea drug class carries a "black-box" US Food and Drug Administration (FDA) warning [25]. Importantly, although sulfonylureas were not associated with a significant reduction in MI in the main UKPDS, in its follow-up study, during which the originally assigned participants were not necessarily still on their study treatment, the benefit regarding MI became significant, owing to the accumulation of more events [26]. The point estimate for the effect showed a 15% reduced risk (hazard ratio 0.85; $p = 0.01$).

Sulfonylureas may be used in combination with metformin and most other antihyperglycemic categories with the exception of the less commonly used drug class known as meglitinides, which are similar in their mechanism of action. Since the first combination therapy trial published by Defronzo and Goodman [27] (see Dual combination therapy), many additional studies involving combinations with thiazolidinediones, dipeptidyl peptidase (DPP)-4 inhibitors, glucagon-like peptide (GLP)-1 receptor agonists, and SGLT-2 inhibitors have consistently shown improved glycemic control compared with baseline therapies, either with or without metformin [28–31]. Combinations with insulin have also been studied extensively [32], although this specific pairing has become less popular over time (see Combinations with insulin).

Table 33.1 Specific properties of available glucose-lowering agents that guide combination therapy choices in patients with T2DM.

Class	Compound(s)	Cellular mechanism	Primary physiological action(s)	Advantages	Disadvantages	Cost
Biguanides	• Metformin	Activates AMP-kinase; inhibition of mitochondrial GDP; increase in intestinal GLP-1 release	↓ Hepatic glucose production	• Extensive experience • No hypoglycemia • Likely ↓ CVD events (UKPDS)	• Gastrointestinal side effects (diarrhea, abdominal cramping) • Lactic acidosis risk (rare) • Vitamin B_{12} deficiency • Multiple contraindications: CKD, acidosis, hypoxia, dehydration, etc.	Low
Sulfonylureas	• Glyburide/ glibenclamide • Glipizide • Gliclazide[a] • Glimepiride	Closes K_{ATP} channels on β-Cell plasma membranes	↑ Insulin secretion	• Extensive experience • ↓ Microvascular risk (UKPDS)	• Hypoglycemia • ↑ Weight • ? Blunts myocardial ischemic preconditioning • Low durability	Low
Meglitinides (glinides)	• Repaglinide • Nateglinide	Closes K_{ATP} channels on β-cell plasma membranes	↑ Insulin secretion	• ↓ Postprandial glucose excursions • Dosing flexibility	• Hypoglycemia • ↑ Weight • ? Blunts myocardial ischemic preconditioning • Frequent dosing schedule	High
Thiazolidinediones	• Pioglitazone • Rosiglitazone[b]	Activates the nuclear transcription factor PPAR-γ	↑ Insulin sensitivity	• No hypoglycemia • Durability • ↑ HDL-C • ↓ Triglycerides (pioglitazone) • ? ↓ CVD events (ProACTIVE, pioglitazone)	• ↑ Weight • Edema/HF • Bone fractures • ↑ LDL-C (rosiglitazone) • ? ↑ MI (meta-analyses, rosiglitazone)	Low
α-Glucosidase inhibitors[a]	• Acarbose • Miglitol	Inhibits intestinal α-glucosidase	Slows intestinal carbohydrate digestion/absorption	• No hypoglycemia • ↓ Postprandial glucose excursions • ? ↓ CVD events (STOP-NIDDM) • Non-systemic	• Generally modest HbA_{1c} efficacy • Gastrointestinal side effects (flatulence, diarrhea) • Frequent dosing schedule	Moderate
DPP-4 inhibitors	• Sitagliptin • Vildagliptin[a] • Saxagliptin • Linagliptin • Alogliptin	Inhibits DPP-4 activity, increasing postprandial active incretin (GLP-1, GIP) concentrations	↑ Insulin secretion (glucose-dependent) ↓ Glucagon secretion (glucose-dependent)	• No hypoglycemia • Well tolerated	• Generally modest HbA_{1c} efficacy • Urticaria/angioedema • ? Acute pancreatitis • ? ↑ HF hospitalization (saxagliptin)	High

[a]Not licensed in the USA.
[b]Limited use in the USA/Europe.
AMP, adenosine monophosphate; CKD, chronic kidney disease; CVD, cardiovascular disease; DPP-4, dipeptidyl peptidase 4; GLP-1, glucagon-like peptide 1; HDL-C, high-density lipoprotein cholesterol; HF, heart failure; LDL-C, low-density lipoprotein cholesterol; PPAR, peroxisome proliferator-activated receptor; ProACTIVE, Prospective Pioglitazone Clinical Trial in Macrovascular Events; UKPDS, United Kingdom Prospective Diabetes Study.

(continued)

Bile acid sequestrants	• Colesevelam	Binds bile acids in intestinal tract, increasing hepatic bile acid production; ? activation of farnesoid X receptor (FXR) in liver; ? activation of TGR5 receptor in GI tract	? ↓ Hepatic glucose production ? ↑ Incretin levels	• No hypoglycemia • ↓ LDL-C	• Generally modest A1c efficacy • Constipation • ↑ Triglycerides • May ↓ absorption of other medications	High
Dopamine-2 agonists	• Bromocriptine (quick-release)[c]	Activates dopaminergic receptors	Modulates hypothalamic regulation of metabolism ↑ Insulin sensitivity	• No hypoglycemia • ? ↓ CVD events (Cycloset Safety Trial)	• Generally modest HbA_{1c} efficacy • Dizziness/syncope • Nausea • Fatigue • Rhinitis	High
SGLT-2 inhibitors	• Canagliflozin • Dapagliflozin • Empagliflozin	Inhibits the sodium–glucose co-transporter 2 in the proximal nephron	Blocks glucose reabsorption by the kidney, increasing glucosuria	• No hypoglycemia • ↓ Weight • ↓ Blood pressure • Effective at all stages of T2DM • ↓ CV mortality and HF hospitalization (EMPA-REG Outcome, empagliflozin)	• Genitourinary infections • Polyuria • Volume depletion/hypotension/dizziness • ↑ Risk of DKA • ↑ LDL-C • ↑ Creatinine (transient) • ? ↑ Fractures (canagliflozin)	High
GLP-1 receptor agonists	• Exenatide • Exenatide extended release • Liraglutide • Albiglutide • Lixisenatide[a] • Dulaglutide	Activates GLP-1 receptors	↑ Insulin secretion (glucose-dependent) ↓ Glucagon secretion (glucose-dependent) Slows gastric emptying ↑ Satiety	• No hypoglycemia • ↓ Weight • ↓ Postprandial glucose excursions • ? Potential for improved β-cell mass/function (preliminary data) • ? Cardiovascular protective actions	• Gastrointestinal side effects (nausea/ vomiting) • ? Acute pancreatitis • C-cell hyperplasia/medullary thyroid tumors in animals • Injectable • Training requirements	High

LEADER, Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results; UKPDS, United Kingdom Prospective Diabetes Study.

In the 2012 American Diabetes Association (ADA) and European Association for the Study of Diabetes (EASD) position statement on the management of hyperglycemia in type 2 diabetes [33] and its 2015 update [34], the sulfonylureas were included as an option for dual therapy after metformin (Figure 33.2). This was based on this class's low cost, wide accessibility, and documented efficacy, and the evidence of benefit on microvascular complications. However, the writing group included cautionary statements about hypoglycemia risk. With the advent and growing popularity of several drug classes that do not (by themselves) increase the risk of hypoglycemia and which have been proven to at least be safe from a cardiovascular standpoint, this class of medication is likely to be used less frequently in the future. In most studies involving people on baseline sulfonylurea treatment, the addition of a drug that may not itself be associated with hypoglycemia still increases the risk of hypoglycemia. Accordingly, in people whose glycemic control is close to target, the addition of a second agent may require some adjustment in the secretagogue dose.

Some sulfonylureas are available in fixed-dose combinations with metformin (short-acting) and thiazolidinediones (see Table 33.2).

Metformin

Metformin, a member of the biguanide class, has been used clinically since the 1950s, and has been available in the United States since 1995. Its mechanism of action still remains incompletely understood. The drug reduces hepatic glucose production [35]. This may be through activation of AMP-kinase [36], although more recent data suggest an effect through the inhibition of mitochondrial glycerolphosphate dehydrogenase (mGDP), blocking ingress of hydrogen ions into the mitochondria [37]. This increases the cytosolic redox state, suppressing gluconeogenesis. Other investigators have found that metformin increases the release of intestinal GLP-1 [38]. The glucose-lowering effect of metformin may therefore be multidimensional and may vary to some extent with dose. With HbA_{1c} reducing potency on a par with sulfonylureas, the major advantage of metformin is its ability to lower glucose without inducing hypoglycemia. Although often considered as a drug that results in weight loss, over time metformin is actually weight neutral in most people. The drug has been associated with several benefits on certain cardiovascular risk factors, such as proatherogenic lipoproteins and the inflammatory mediator C-reactive protein [39]. In fact, to date, it is the only glucose-lowering agent to be linked to a reduction in MI in people with newly diagnosed T2DM, an effect demonstrated in a sub-study within the UKPDS in which 753 drug-naive, overweight people with T2DM were randomized to metformin monotherapy versus diet therapy or sulfonylurea/insulin [40]. The metformin group experienced a 49% reduction ($p = 0.01$) in MI compared with the diet-controlled control group, a trend towards fewer such events compared with the sulfonylurea/insulin group (whose glucose levels were lowered to an equivalent degree), and statistically significantly fewer stroke events compared with the sulfonylurea/insulin group. This apparent macrovascular effect of metformin on MI persisted in the UKPDS study, with follow-up extending out an additional decade (relative risk reduction 43%; $p = 0.005$) [26].

Another sub-study within the UKPDS, however, focused on individuals who were not controlled on sulfonylurea monotherapy. They were then randomized to the addition of metformin in combination with the sulfonylurea or continued sulfonylurea monotherapy. For reasons that are still unclear, those assigned to combination therapy experienced a nearly twofold increase in diabetes-related mortality to those left on secretagogue monotherapy (relative risk [RR] 1.96; $p = 0.039$) [41]. In a post hoc epidemiological analysis of the UKPDS, such a risk could not be documented in all people treated with this combination in the entire study. Moreover, in the UKPDS follow-up, the risk in those originally randomized to combination metformin–sulfonylurea disappeared over time [42]. Most have therefore concluded that the initial finding that raised concerns about a deleterious effect of the combination was likely to be a chance finding.

Another smaller, randomized trial (HOME) showed less cardiovascular disease (CVD) (RR 0.61; $p = 0.02$) events in people with insulin-treated T2DM who had metformin added to their regimen versus further titration of the insulin dose [43]. These findings have been buttressed by several large, retrospective trials that showed fewer CVD events in those treated with metformin monotherapy versus sulfonylurea monotherapy [44–47].

Data such as these have resulted in metformin being considered, by most professional organizations, as the optimal initial therapy for individuals with T2DM who are not able to control their glucose levels through lifestyle change alone. In the ADA–EASD position statement on the management of hyperglycemia in T2DM [33, 34], metformin has a prominent role as foundation therapy, to which other drugs are added if additional glucose-lowering is necessary (Figure 33.2). Since the original combination therapy trial that demonstrated an additional glucose-lowering effect from adding metformin to failing glyburide therapy [27], dozens of trials have resulted in similar conclusions, whether from adding metformin to other glucose-lowering drugs (e.g. insulin) or, more commonly, adding another agent (e.g. thiazolidinediones, DPP-4 inhibitors, GLP-1 receptor agonists, SGLT-2 inhibitors, or insulin) to baseline metformin therapy [48–51]. In fact, all new T2DM therapies are now tested early on in their course of development as add-on to metformin, given the latter's established role as the optimal initial therapy.

There are several contraindications to metformin that deserve mention, some of which pertain to other drugs with which it may be prescribed. Because of their effects on mitochondrial respiration, members of the biguanide group have been linked to increased risk of lactic acidosis [52] (the original biguanide, phenformin, was actually removed from the market owing to excessive rates of this often lethal metabolic complication). Lactic acidosis is typically observed in the setting of other medical illness, especially those that result in hemodynamic collapse and renal failure. Because metformin is excreted unchanged in the urine, its circulating levels increase potentially into a toxic range when renal

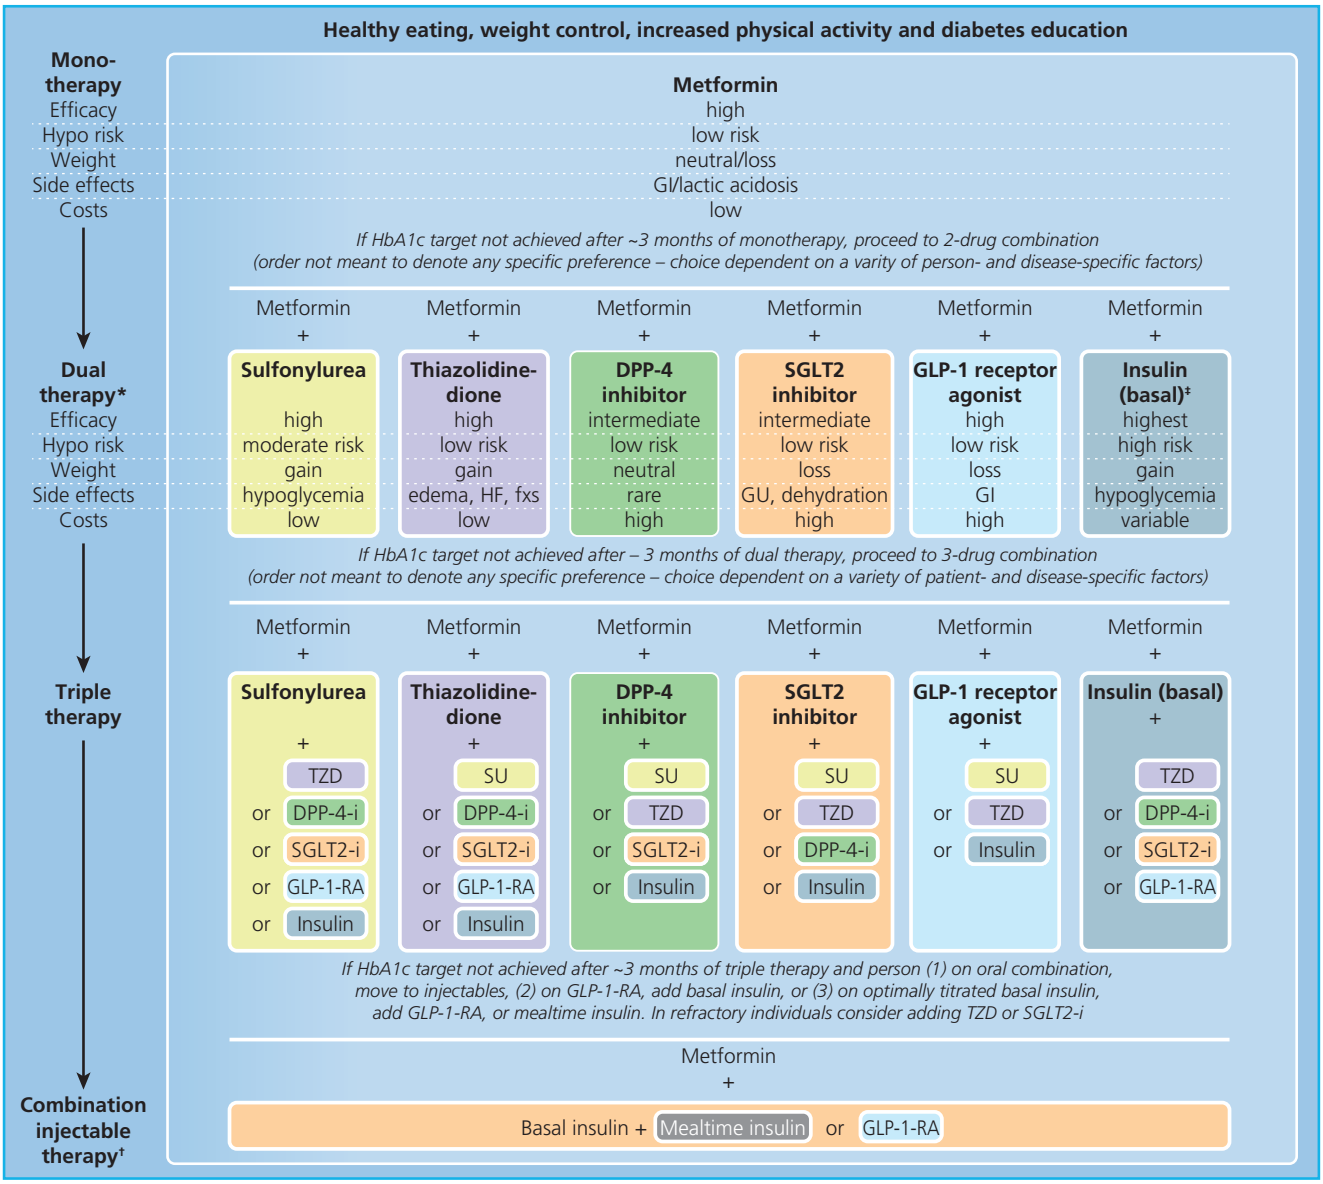

Figure 33.2 General recommendations from the 2015 update to the ADA–EASD position statement on management of hyperglycemia in T2DM [34]. Potential sequences of antihyperglycemic therapy for people with T2DM are displayed, the usual transition being vertical, from top to bottom (although horizontal movement with therapy stages is also possible, depending on the circumstances.) In most people, begin with lifestyle changes; metformin monotherapy is added at, or soon after, diagnosis, unless there are contraindications. If the HbA_{1c} target is not achieved after ~3 months, consider one of the six treatment options combined with metformin: SU, TZD, DPP-4-i, SGLT-2-i, GLP-1-RA, or basal insulin—the order in the chart not meant to denote any specific preference. Drug choice is based on patient preferences in addition to various patient, disease, and drug characteristics, the goal being to reduce glucose concentrations while minimizing side effects, especially hypoglycemia. The figure emphasizes drugs in common use in the USA and/or Europe. In patients intolerant of or with contraindications for metformin, consider initial drug from other classes depicted under *Dual therapy* and proceed accordingly. Consider initiating therapy with a dual combination when the HbA_{1c} ≥9% to achieve glycemic targets more rapidly. Insulin has the advantage of being effective where other agents may not be and should be considered a part of any combination regimen when hyperglycemia is severe, especially if the individual is symptomatic or if any catabolic features (weight loss, any ketosis) are evident. Consider initiating combination insulin injectable therapy when BG ≥300–350 mg/dL (16.7–19.4 mmol/l) and/or HbA_{1c} ≥10–12%. As the patient's glucose toxicity resolves, the regimen can potentially be subsequently simplified. *Consider initial therapy at this stage when HbA_{1c} ≥9%. †Consider initial therapy at this stage when BG ≥300–350 mg/dL (16.7–19.4 mmol/l) and/or HbA_{1c} ≥10–12%, especially if the person is symptomatic or if catabolic features are present, in which case basal insulin + mealtime insulin is the preferred initial regimen. ‡Usually a basal insulin (NPH, glargine, detemir, degludec). Abbreviations: DPP-4-i, DPP-4 inhibitor; Fxs, bone fractures; GI, gastrointestinal; SGLT-2, sodium–glucose co-transporter 2; GLP-1-RA, GLP-1 receptor agonist; HF, heart failure; SU, sulfonylurea; BG, blood glucose. Table 33.2 Available fixed-dose combinations of glucose-lowering agents of different classes.

Combination	Components
Secretagogue-Biguanide	**Secretagogue-Thiazolidinedione**
Glyburide-Metformin	Glimepiride-Rosiglitazone
Glipizide-Metformin	Glimepiride-Pioglitazone
Repaglinide-Metformin	
Thiazolidinedione-Biguanide	**DPP-4 inhibitor-Thiazolidinedione**
Rosiglitazone-Metformin	Alogliptin-Pioglitazone
Pioglitazone-Metformin	
DPP-4 inhibitor-Biguanide	**DPP-4 inhibitor-SGLT2 inhibitor**
Sitagliptin-Metformin	Linagliptin-Empagliflozin
Saxagliptin-Metformin	
Alogliptin-Metformin	
Linagliptin-Metformin	
SGLT2 inhibitor-Biguanide	**GLP-1 Receptor Agonist-Insulin**
Canagliflozin-Metformin	Lixisenatide-Glargine
Dapagliflozin-Metformin	Liraglutide-Degludec
Empagliflozin-Metformin	

function is severely impaired. In the USA, the prescribing guidelines contraindicate use of metformin when the serum creatinine reaches 1.5 mg/dL or higher in men and 1.4 mg/dL or higher in women [53]. In the United Kingdom, prescribing guidelines are based on estimated glomerular filtration rate (eGFR), with the drug allowed down to 45 mL/min, dose adjustments between 30 and 45 mL/min, and discontinuation after the eGFR falls below 30 mL/min (or when the serum creatinine exceeds 1.7 mg/dL) [54]. There have recently been calls in the USA to harmonize the prescribing label with that used in the UK, given the paucity of evidence that metformin poses risk when used in those with mild to moderate chronic kidney disease (CKD) [55]. Indeed, some observational data suggest an actual mortality *benefit* in these individuals [56]. Since many other drugs with which metformin is used in combination (such as sulfonylureas, certain DPP-4 inhibitors, certain GLP-1 receptor agonists, and SGLT-2 inhibitors) have prescribing stipulations for individuals with decreased kidney function, great care is needed when using most combination glucose-lowering therapy in T2DM. In addition to advanced renal disease, metformin should also not be used in those with acidosis, dehydration, severe heart failure, or liver disease, or in chronic alcoholics, all due to an increased risk of developing lactic acidosis.

Thiazolidinediones

The thiazolidinediones, or glitazones, became available in the mid-1990s amidst substantial interest in their potential not only to reduce insulin resistance but also to improve cardiovascular outcomes [57]. The original thiazolidinedione, troglitazone, was removed from the market owing to hepatotoxicity, after rosiglitazone and pioglitazone had become available. These insulin-sensitizing drugs activate the nuclear hormone receptor peroxisome proliferator-activated receptor (PPAR-γ), with predominant metabolic effects in adipocytes (promotion of differentiation and modulation of adipokine secretion) and skeletal muscle (augmentation of insulin-mediated peripheral glucose uptake) [58]. There may also be a beneficial effect on the efficiency of β-cell function [59]. The thiazolidinediones thus reduce both blood glucose and insulin levels and are not associated with hypoglycemia when used as monotherapy. Preclinical data and studies in humans involving surrogate markers of atherosclerosis had suggested a potentially important effect on reducing cardiovascular complications [60]. However, the results from studies that examined actual clinical macrovascular events have been mixed. Pioglitazone, when added to background T2DM therapy, was associated with a 16% reduction in major adverse cardiovascular events (MACE) in the PROactive study, although the study's primary outcome, which was a broad composite that included peripheral vascular complications, proved neutral [61]. Rosiglitazone has had a highly controversial history. In 2007, a meta-analysis of phase III and IV studies suggested an actual *increase* (43%) in MI risk [62]. These data led to a rapid curtailment of the prescriptions of this once popular drug across the world and many countries proceeded to withdraw this thiazolidinedione from their markets. By contrast, and consistent with the PROactive study results, a similarly designed meta-analysis of pioglitazone trials found a benefit (–18%) on cardiovascular events [63]. Subsequently, however, a randomized clinical trial (RECORD) demonstrated a neutral effect of rosiglitazone on cardiovascular events, although this information came too late to reinvigorate interest in the compound [64].

There have been additional concerns that have rendered the entire thiazolidinedione drug class less popular over time. The most important concerns the weight gain that characterizes thiazolidinedione therapy, usually of the order of 4 kg over the first year [65]. The more recent availability of glucose-lowering drugs that lead to weight loss (GLP-1 receptor agonists, SGLT-2 inhibitors) or are at least weight neutral (DPP-4 inhibitors) has contributed to decreased use of this class. The thiazolidinediones are also associated with increased rates of peripheral edema, the result of activation of sodium retention at the distal renal tubule [66]. For this reason, the risk of heart failure and heart failure hospitalization is also increased [67]. There is no known deleterious effect on ventricular function, however. Bone loss and an increase in fracture rates in women have been found in multiple studies [68]. Finally, the question of an increased risk of carcinoma of the bladder has been raised with pioglitazone, although a recent 10-year follow-up review involving nearly 200,000 people with T2DM within the Kaiser Permanente of Northern California system found no such risk [69].

In spite of these considerable concerns, the thiazolidinediones are unique amongst diabetes therapies in that they have been demonstrated to have greater durability in glycemic effectiveness compared with metformin and sulfonylureas [70], perhaps

reflecting an overall beneficial effect on β-cell function due to decreasing insulin secretory demands.

Thiazolidinediones lower glucose and HbA_{1c} to similar extents to metformin and sulfonylureas (1–1.5%). Since their inception, the thiazolidinediones have been used almost exclusively in combination regimens. One early study demonstrated efficacy in combination with metformin [71] and, since then, they have been tested and used in combinations with most other major antihyperglycemic drug classes, including sulfonylureas, DPP-4 inhibitors, GLP-1 receptor agonists (RAs), SGLT-2 inhibitors, and insulin [72–76]. The thiazolidinediones are also available in fixed-dose combinations with metformin (short-acting), sulfonylureas, and a DPP-4 inhibitor (pioglitazone–alogliptin.)

As with metformin and all sulfonylureas, pioglitazone is now available in cost-effective generic formulations. Despite the concerns raised over the years about safety, these remain endorsed as reasonable second-line agents by in the latest ADA–EASD position statement on the management of hyperglycemia in type 2 diabetes (see Guidelines and Figure 33.2) [33, 34].

Incretin-based therapy

The incretin system is represented by the intestinal hormones GLP-1 and glucose-dependent insulinotropic peptide (GIP), which stimulate glucose-dependent pancreatic insulin secretion and suppress glucagon secretion. GLP-1 also delays gastric emptying and enhances satiety [77]. The incretins are secreted in response to meal ingestion. They are rapidly degraded by the widely expressed protease DPP-4, rendering biological half-lives of just a few minutes. Developers of glucose-lowering medicines have taken two approaches to capitalize on this physiology. One is to synthesize injectable GLP-1 receptor (R) agonists (A) that are resistant to DPP-4, and the other is to produce oral inhibitors of DPP-4. Both classes are referred to as *incretin enhancers*.

GLP-1 receptor agonists

GLP-1 receptor agonists (exenatide, liraglutide, lixisenatide, albiglutide, dulaglutide) are injectable agents that mimic the effects of endogenous GLP-1 [78]. They thereby increase insulin secretion in a glucose-dependent fashion, decrease glucagon secretion, and delay gastric emptying, the last being an effect that appears to wane over time. Their use is characterized by decreased appetite, lower calorie consumption, and weight loss. The class is associated with small reductions in blood pressure, and some beneficial lipid and anti-inflammatory effects (decreased triglycerides and C-reactive protein). Although a specific formulation of liraglutide (high-dose) is now available as an antiobesity drug, the GLP-1RAs are almost exclusively used in combination therapy for those with T2DM, classically with metformin with or without additional oral agents. A common scenario is their use as a third-line agent after failure to control blood glucose with two agents, such as metformin–sulfonylurea or metformin–thiazolidinedione. At the time of this writing, there are no published studies on the combination of GLP-1RA plus an SGLT-2 inhibitor, an obviously attractive regimen with potentially enhanced weight loss effects. The class should not be used in conjunction with DPP-4 inhibitors given their overlapping mechanisms of action and the inherent resistance of the GLP-1RAs to enzymatic breakdown by DPP-4.

The GLP-1RAs have also been studied extensively with insulin and two products in fixed-ratio combination products with basal insulin analogs (liraglutide–insulin degludec, lixisentatide–insulin glargine) have been approved or submitted to the regulatory approval process.

Most of the members of this class reduce HbA_{1c} by ~1–2% over placebo, with larger changes noted with the longer-acting formulations [79], perhaps a reflection of better adherence. Their efficacy is therefore generally on a par with those of the other three older medications used in T2DM, metformin, sulfonylureas, and thiazolidinediones. The GLP-1RAs appear to be more efficacious than the class of glucose-lowering drugs with which they are often compared, the DPP-4 inhibitors. The GLP-1RAs result in a body weight loss of 2–4 kg over the first 6–12 months of therapy, which appears to be sustained over long-term use [80]. This category of diabetes medication is becoming an increasingly favored option in obese individuals.

The GLP-1RAs are gaining in popularity in combination with basal insulin, with studies demonstrating equal efficacy on HbA_{1c}, with weight loss instead of weight gain, and less hypoglycemia risk, as compared with the addition of mealtime insulin—the usual strategy in people not controlled with basal insulin alone [81]. (see Combinations with insulin). The longer-acting formulations are more convenient, although the ease of use of the various injection pen devices differs to some extent from product to product. Accordingly, good patient instruction on proper pen use is important.

Side effects mainly relate to the gastrointestinal system. Particularly during the initiation of therapy, many people will develop nausea and in some cases vomiting. These symptoms generally abate over time. Slow dose uptitration is important for minimizing these effects, which probably relate to a slowing of gastric emptying. The agents should not be used in individuals with gastroparesis. There have been some lingering concerns about the risk of pancreatitis or even pancreatic malignancy with the GLP-1RAs, with animal studies showing subtle changes of unknown significance in the exocrine pancreas at very high doses. Observational studies have demonstrated no measurable increase in rates of pancreatitis in cohorts treated with these agents, although in randomized trials, small imbalances have been reported. Nevertheless, the overall incidence remains low [82]. Notably, people with T2DM, particularly those who are obese (in whom the drug may be used to a greater extent), are predisposed to both biliary disease and hypertriglyceridemia, both themselves risk factors for pancreatitis. The GLP-1RAs remain contraindicated in anyone with a prior history of pancreatitis.

This class of drug is extremely expensive, ~100 times the cost of generically available diabetes drugs. In addition, they are available only in injectable forms. They are therefore typically reserved for those individuals who have adequate insurance coverage and when other agents have failed.

There is substantial evidence from preclinical studies in animal models, investigations involving cardiovascular risk surrogates and/or markers in humans, and also some small mechanistic human studies to suggest that GLP-1RA therapy may advantageous for the cardiovascular system [83]. Whether this may relate to direct cardiac and/or vascular effects of the drugs, or the ability to lower glucose with weight gain and without hypoglycemia, or some other off-target effect is not clear. After the 2008 *Guidance to Industry* from the US Food and Drug Administration (FDA) concerning cardiovascular safety of diabetes therapies [84], the GLP-1RAs are currently under investigation in large outcomes trials of 2–4 years' duration for their effects on cardiovascular outcomes in high-risk individuals. Most of the trials have been additionally powered to demonstrate cardiovascular effectiveness. The initial cardiovascular outcome trial to report involved lixisenatide in people with recent acute coronary syndrome—the ELIXA trial, involving 6075 participants studied over 2 years [85]. The MACE rates were equivalent between the group assigned to lixisenatide versus placebo, added to background diabetes therapy. (Notably, in light of the concerns described below regarding DPP-4 inhibitors and possible heart failure risk, there was no signal of such an effect in this trial.) At the time of publication, the LEADER trial results were released. In 9340 participants at high CV risk, treatment with the GLP-1RA liraglutide resulted in a 13% relative risk reduction (HR = 0.87; 95% CI 0.78–0.97; $p = 0.011$) in MACE and a 22% reduction CV death (HR = 0.78; 95% CI 0.66–0.93; $p = 0.007$). In contrast to EMPA-REG, each component of 3-point MACE appeared to contribute to the composite outcome [85a]. Time will tell whether any of the other GLP-1RAs will prove to be both safe and potentially beneficial on hard cardiac outcomes. The trials currently under way include, EXSCEL (weekly exenatide), SUSTAIN (weekly semaglutide), and REWIND (weekly dulaglutide). GLP-1RA of even longer duration of action are also under investigation.

GLP-1RAs were endorsed as options in combination regimens after metformin by the 2012 ADA–EASD position statement on the management of hyperglycemia in type 2 diabetes [33]. The position statement's update in 2015 underscored the growing importance of the class in combination regimens with basal insulin (Figure 33.2) [34] (see Combinations with insulin).

DPP-4 inhibitors

These oral agents are potent and durable inhibitors of the protease enzyme that rapidly degrades the endogenous incretin hormones GLP-1 and GIP [86]. They thereby allow endogenous incretin hormone levels to rise to a higher concentration and in a more sustained fashion in the postprandial setting. The levels of incretin hormones achieved after DPP-4 inhibition, however, are substantially lower than the more pharmacological concentrations reached through the administration of GLP-1RAs. Currently available compounds include sitagliptin, vildagliptin, saxagliptin, alogliptin, and linagliptin. In monotherapy, they appear to be somewhat less potent than other agents, with HbA_{1c} reductions in the 0.6–0.8% range [87, 88]. As with other glucose-lowering drugs, efficacy is greater in those individuals with higher baseline HbA_{1c} levels. When compared directly, in head-to-head trials, with sulfonylureas and thiazolidinediones, the DPP-4 inhibitors reduce HbA_{1c} equivalently, but to a lesser extent than metformin, GLP-1RAs, and SGLT-2 inhibitors [87–91]. One advantage of this class of glucose-lowering drug is fewer side effects than with most other categories, with no significant hypoglycemia, weight gain, gastrointestinal intolerance, or edema. In fact, they are now widely viewed as the best tolerated of the most commonly used antihyperglycemic agents.

The DPP-4 inhibitors are not commonly used as monotherapy and are often prescribed in conjunction with metformin or other drugs, such as sulfonylureas, thiazolidinediones, SGLT-2 inhibitors, and sometimes basal insulin [92–95]. They should not be used in conjunction with GLP-1RAs, which share a similar mechanism of action. Most of the currently available DPP-4 inhibitors are available in fixed-dose combinations with metformin, both short-acting and in some circumstances long-acting formulations. A single fixed-dose combination with a thiazolidinedione exists (aloglipin–pioglitazone). Recently, fixed-dose combinations with SGLT-2 inhibitors have also become available.

The adverse effect profile of the DPP-4 inhibitors is similar to that of placebo. Urticaria and other allergic skin eruptions are the most commonly reported effects. As with the GLP-1RAs, there remains some concern about possible pancreatitis risk, but large retrospective studies have not found any distinct increase in the incidence of pancreatitis in people using this drug class [96]. In some clinical trials, a slightly greater number of pancreatitis cases have been reported in the DPP-4 inhibitor arm but, as with the GLP-1RAs, the frequency remains very low. These drugs should not be used in anyone with a prior history of pancreatitis.

Preclinical studies had suggested a possible beneficial effect on atherosclerosis, either via direct effects on the vasculature and/or heart from DPP-4 inhibition or from higher levels of GLP-1 [97]. Three large cardiovascular outcome studies (SAVOR, EXAMINE, and TECOS) have unequivocally demonstrated these drugs to be essentially neutral on MACE, at least over the relatively brief time course (1–2-year median follow-up) of these types of trials [98–100]. In one of these investigations, SAVOR, participants assigned to saxagliptin experienced a 27% greater risk ($p = 0.007$) of hospitalization for heart failure [98]. The precise etiology of such an effect, if it is more than a chance finding, remains elusive. DPP-4 inhibition is not known to increase the circulating concentrations of any molecule that serves as a natriuretic factor or any that might have effects on cardiac contractility. Notably, in both EXAMINE (which used alogliptin) and TECOS (sitagliptin), no increase in heart failure was detected in the active therapy group. One cardiovascular outcome study with a DPP-4 inhibitor, CAROLINA (using linagliptin), is still ongoing [101].

The DPP-4 inhibitors are as all available members of the class are branded products. These drugs were also been endorsed as options in combination regimens after metformin in the 2012 ADA–EASD position statement on the management of hyperglycemia in type 2 diabetes [33] and its update in 2015 (Figure 33.2) [34].

SGLT-2 inhibitors

The newest glucose-lowering category is the sodium–glucose co-transporter (SGLT)-2 inhibitors (canagliflozin, dapagliflozin, and empagliflozin.) These drugs inhibit SGLT-2 in the proximal nephron, thereby blocking glucose reclamation and increasing glucosuria [102]. This transporter is responsible for ~90% of glucose reabsorption from the glomerular filtrate (SGLT-1, which is more highly expressed in the gut, modulating glucose absorption, comprises the remaining 10%). In people treated with drugs of this type, urinary glucose losses are in the 60–80 g/day range, resulting in a daily calorie reduction of about 400 kcal and an average weight reduction of 2–3 kg over the course of 6–12 months. This is a sustained effect but, interestingly, not progressive with longer-term use. Because of a mild osmotic diuretic effect, these agents can also decrease blood pressure (by 3–4 mmHg systolic and 1–2 mmHg diastolic). HbA_{1c} reductions range between 0.6 and 1.0%; as with all antihyperglycemic drugs, greater reductions are seen in those with higher baseline values [103, 104].

Adverse effects relate mainly to the genitourinary system. Owing to increased glucose concentration in the urine, an increase in genital mycotic (yeast) infections is seen, most frequently in women (vulvo-vaginitis), but also in men (balanitis). In some but not all studies, an increase in urinary tract infections has also been detected. Owing to the drugs' mechanism of action, individuals tend to perceive an increase in urine frequency and flow, and this may become a challenge in those with urinary incontinence or in men with bladder outlet obstruction from prostatic hypertrophy. Symptoms of volume contraction may also occur (dehydration, orthostasis). A mild increase in serum creatinine can also be measured soon after medication initiation, but this effect is not a toxic effect per se, but one that reflects decreased vascular volume and renal perfusion. Importantly, it reverses upon drug discontinuation. In fact, these agents appear to decrease urinary albumin : creatinine ratios [105], although their long-term effects on renal preservation are unknown. Fracture rates have also been reported to be increased with at least one member of this class, possibly the result of increase urinary calcium losses and secondary hyperparathyroidism [106].

One unique aspect of the SGLT-2 inhibitors is that their mode of action is independent of insulin. Hence they can be effective across the various stages of diabetes, from recent-onset to late-stage disease. One the other hand, because their mechanism requires both adequate filtration of glucose and sufficient urinary delivery of drug compound to the luminal surface of renal proximal tubular cells, they are less effective in lowering glucose in people with reduced kidney function (eGFR <45–60 mL/min).

As with all newer agents for T2DM, their impact on cardiovascular complications of diabetes is also under study. Because they improve several cardiovascular risk factors (glucose, blood pressure, weight, and albuminuria) without inducing hypoglycemia, there was some anticipation of a benefit by some [107]. The first cardiovascular outcomes trial to report with this class was with epagiflozin (EMPA-REG OUTCOME) [108], in which 7020 participants with T2DM and overt CVD (mean age 63 years, HbA_{1c} 8.1%) were randomized to empagliflozin or placebo, on a background antihyperglycemia therapy. Glycemic control improved and there was a 1–2 kg weight loss and a reduction in systolic blood pressure of 2–3 mmHg in the active therapy groups. The primary cardiovascular outcome (3-point major adverse cardiovascular events) was reduced by 14% in the empagliflozin group (hazard ratio [HR] 0.86; 95% confidence interval [CI]: 0.74–0.99; $p = 0.038$). This appeared to be driven mainly by a reduction in CVD death of 38% (HR 0.62; 95% CI: 0.49–0.77; $p < 0.0001$). Heart failure hospitalization was reduced with empagliflozin (HR 0.65; 95% CI: 0.50–0.85; $p = 0.0017$), as was all-cause mortality (HR 0.68; 95% CI: 0.57–0.82; $p < 0.0001$). The cumulative incidence curves for each of the positive outcomes began to diverge at about 2–3 months, suggesting a rapid effect, unlikely to have been driven by glucose or attenuation of atherosclerosis. The mechanisms of the benefit remains unclear, but may partially relate to the drug's osmotic diuretic effect.

Several other large cardiovascular outcome trials with SGLT-2 inhibitors are currently under way, including CANVAS (using canagliflozin) and DECLARE (dapagliflozin).

The SGLT-2 inhibitors are mainly used in combination regimens with metformin [109] or other antihyperglycemic drugs, including insulin [31, 75, 95, 110], and rarely as monotherapy. Most are available in fixed-dose combinations with metformin or with DPP-4 inhibitors. According to the updated ADA–EASD position statement on the management of hyperglycemia in type 2 diabetes [34], they may be used in combination with virtually any other drug, although combined therapy with GLP-1RAs could not be endorsed due to lack of clinical trial reports at the time of publication (Figure 33.2).

Insulins

Insulin therapy is unique among all T2DM treatments because of its theoretically limitless ability to lower blood glucose concentrations and HbA_{1c}, restrained only by the development of hypoglycemia. Of all glucose-lowering therapies, insulin is associated with the highest rates of this complication, which in certain circumstances can be severe and life threatening. Other notable side effects include weight gain, which appears to correlate with the amount of HbA_{1c} lowering. Since most insulin products are injectables and have a relatively narrow therapeutic window, and a very wide range of possible dosages, significant patient education is required for effective and safe use. Modern disposable, prefilled pen devices have made the administration of insulin easier than with traditional vials and syringes. Recently, an inhaled insulin product for mealtime use has become available. Irrespective of the modality of administration, insulin therapy in general requires more frequent self-monitoring of blood glucose (SMBG) with home capillary blood glucose meters and comprehensive instruction regarding the detection, documentation, and treatment of hypoglycemic episodes.

An extensive discussion of the various insulin formulations and strategies is beyond the scope of this chapter (see Chapter 29). for more information.) Dose timing and frequency are generally

based on pharmacokinetic properties. For example, the longer acting basal insulin analogues (glargine, detemir, degludec) are administered once daily (detemir can sometimes require twice daily injections.) Rapid-acting insulin analogues (lispro, aspart, glulisine), with their fast onset and brief time course of action are optimally timed just before meals to prevent or minimize postprandial glucose excursions.

In T1DM, combination insulin therapy using the so-called "basal-bolus" approach comprises a basal insulin dose once or twice daily along with mealtime rapid-acting insulin three times daily. An increasingly popular alternative is an insulin pump (continuous subcutaneous insulin infusion [CSII]) to deliver both basal rates and mealtime boluses with a single insulin type, in almost all circumstances a rapid-acting analog. In T2DM, in contrast, the insulin deficiency is, by definition, relative and usually not profound, that is, some endogenous insulin secretion persists well into late stages of disease. As a result, many people who no longer respond to non-insulin therapies (e.g. oral glucose-lowering agents and/or a GLP-1RA injectable) will experience satisfactory control with a single injection of a basal insulin alone [111]. This strategy can be used alone, or more commonly with metformin, to blunt weight gain and minimize the insulin dose required [112, 113]. Other agents in addition to metformin can also be paired with insulin, but their continued use should take into account both complexity and cost, and in some circumstances side effects. The use of secretagogues with insulin has decreasing popularity, but thiazolidinediones, DPP-4 inhibitors, SGLT-2 inhibitors and GLP-1RAs are used appropriately [33, 34].

In T2DM, when basal insulin is no longer sufficient to achieve HbA_{1c} targets, the next step is *combination injectable therapy*. There are several choices here, as described in the updated 2012 ADA–EASD position statement on the management of hyperglycemia in type 2 diabetes (Figure 33.3). The simplest is to switch the basal insulin to a *premixed insulin*, typically dosed twice daily before breakfast and the evening meal [33]. These fixed combinations of intermediate and either short- or rapid-acting insulin provide some basal insulin with mealtime coverage at two meal sittings, with lunchtime coverage being omitted. The formulations available include 70:30, 75:25, and 50:50 ratios of intermediate to short- or rapid-acting insulin, depending on the specific product. Since the ratios are fixed, they are less flexible than in other insulin strategies.

A second approach is more complex but ostensibly more flexible and appropriate for those individuals who have the capacity to handle two separate insulins. This is the classical basal bolus approach as used in T1DM, with the option of less frequent (two per day) injections—sometimes referred to as "basal plus": a combination of a basal insulin once daily with coverage of the *main* meal (i.e. that of the highest caloric content) with a rapid-acting insulin [33]. The dose of the basal insulin is more or less fixed, but that of the mealtime insulin can be (and ideally should be) adjusted according to the planned carbohydrate content of the meal (more insulin for more grams), typically in ratios of 1 unit to 10–20 g of carbohydrate. The dose can also be adjusted to the premeal blood glucose reading, such as adding a "correction" amount of insulin to the calculated mealtime dose. For example, an additional 1–2 units can be administered for every 3 mmol/L (~50 mg/dL) starting at a threshold of 9 mmol/L (~150 mg/dL). A third adjustment is to the anticipated activity level after the meal (e.g. reducing by 25% if physical exertion is planned). Of course, not everyone is able to make these more complex treatment decisions safely. Therefore, many people administer bolus insulin therapy more simply with *fixed* doses, which is successful provided that the carbohydrate content is roughly equivalent from meal to meal and from day to day. As the individual on basal plus becomes familiar with mealtime insulin administration, if the HbA_{1c} remains above target, additional preprandial injections can be encouraged before other meals. Of course, the greater the number of injections the more likely it is there will be weight gain and hypoglycemic episodes (and also errors in dosing), and so a comprehensive educational program is mandatory for anyone proceeding to these more complex regimens.

A third and emerging approach to combination injectable therapy is the use of a GLP-1RA in conjunction with a basal insulin. A recent meta-analysis demonstrated as good glucose control with less hypoglycemia and, in contrast with most insulin therapy, with weight *loss* [81]. In selected individuals, this strategy may be not only successful but also simpler to conduct. Of course, there are substantial cost concerns. See below (Combinations with insulin) for more discussion about this specific combination strategy.

With regard to cardiovascular complications, the role of insulin therapy has been somewhat controversial, with evidence for both benefit and harm. This area is complex, particularly since endogenous hyperinsulinemia, classically apparent in obesity and raised insulin resistance, has been associated with increased cardiovascular events and mortality. From the UKPDS [2] and ORIGIN [114] trials, we have learned that insulin therapy in T2DM is either neutral or mildly beneficial towards macrovascular events. Importantly, however, hypoglycemia, which is itself associated with adverse cardiovascular outcomes, should be avoided as much as possible. Some have proposed that the evidently harmful effects of stringent glucose control in the ACCORD trial, involving older patients with long-standing T2DM at high cardiovascular risk, may have been related to unrecognized hypoglycemia [115, 116].

Minor classes

Beyond the major glucose-lowering drugs for T2DM described above, there are four additional categories that are used uncommonly, predominantely owing to relatively modest HbA_{1c} reductions, the need for frequent administration, lack of robust outcome trials, higher cost, and/or side-effect profile. They are generally used as niche agents, and may be considered in specific scenarios when other more popular agents cannot be used.

Meglitinides (or glinides)

Meglitinides (repaglinide, nateglinide) are rapid-acting insulin secretagogues that are occasionally used in lieu of sulfonylureas [117]. Their rapid onset and resolution of action result in better

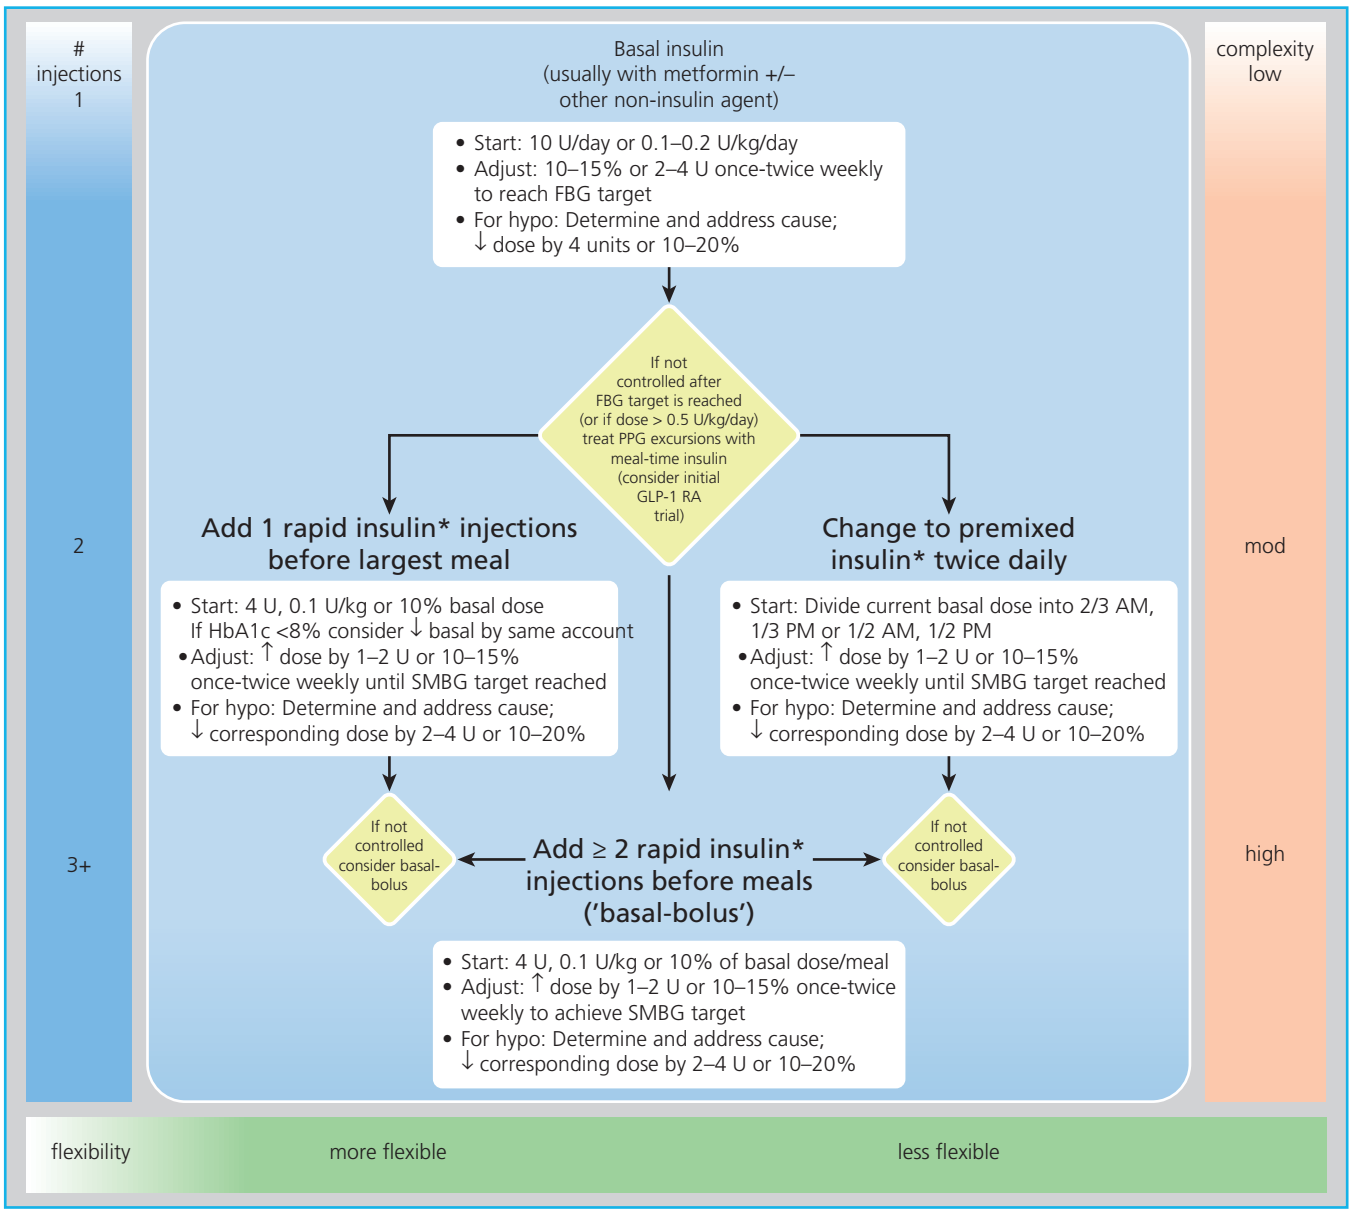

Figure 33.3 Insulin initiation and adjustment recommendations from the 2015 update to the ADA–EASD position statement on management of hyperglycemia in T2DM [34]. Sequential insulin strategies are described, with the number of injections and the relative complexity and flexibility of each stage presented. Basal insulin alone is the most convenient initial regimen, beginning at 10 units or 0.1–0.2 units/kg, depending on the degree of hyperglycemia. It is usually prescribed in conjunction with metformin and possibly one additional non-insulin agent. When basal insulin has been titrated to an acceptable fasting blood glucose but the HbA_{1c} remains above target, consider proceeding to combination injectable therapy (see Figure 33.2) to cover postprandial glucose excursions. Options include adding a GLP-1-RA, adding mealtime insulin, consisting of 1–3 injections of a rapid-acting insulin analog* (lispro, aspart or glulisine) administered just before eating, or switching to twice-daily premixed (or biphasic) insulin analog* (70:30 aspart mix, 75:25 or 50:50 lispro mix). Once any insulin regimen is initiated, dose titration is important, with adjustments made in both mealtime and basal insulins based on the prevailing blood glucose levels, with knowledge of the pharmacodynamic profile of each formulation used. Non-insulin agents may be continued, although sulfonylureas, DPP-4 inhibitors, and GLP-1RA are typically stopped once insulin regimens more complex than basal are utilized. In refractory patients, however, especially in those requiring escalating insulin doses, adjunctive therapy with metformin and pioglitazone or an SGLT-2-inhibitor may be helpful in improving control and reducing the amount of insulin required. Comprehensive education regarding self-monitoring of blood glucose, diet, exercise, and the avoidance of and response to hypoglycemia are very important in any insulin-treated patient. *Regular human insulin and human NPH-Regular premixed formulations (70:30) are less costly alternatives to rapid-acting insulin analogs and premixed insulin analogs, but their pharmacodynamic profiles makes them suboptimal for the coverage of postprandial glucose excursions. †A less commonly used and more costly alternative to basal bolus therapy with multiple daily injections is continuous subcutaneous insulin infusion (CSII, insulin pump.) ‡In addition to the suggestions provided for determining the starting dose of mealtime insulin under "basal-bolus," another method consists of adding up the total current daily insulin dose and then providing half of this amount as basal and half as mealtime insulin, the latter split evenly between three meals. Abbreviations: #, number; U, units; FBG, fasting blood glucose; hypo, hypoglycemia; PPG, postprandial glucose; GLP-1RA, GLP-1 receptor agonist; Mod., moderate; SMBG, self-monitoring of blood glucose. postprandial control of blood glucose, but their overall efficacy is similar to that of the more traditional sulfonylureas. Nateglinide is somewhat weaker. These agents are not used commonly because of their need for frequent dosing, higher cost than generic sulfonylureas, and lack of any coherent evidence base. They can be used in a variety of combinations with other agents, having been studied predominantly in combination with metformin [118]. Meglitinides cannot, of course, be used in conjunction with sulfonylureas. They are associated with hypoglycemia and weight gain, but possibly to a lesser extent than the longer-acting sulfonylureas. They might be considered in people with erratic meal schedules.

α-Glucosidase inhibitors

The α-glucosidase inhibitors (acarbose, miglitol, voglibose) retard carbohydrate absorption by inhibiting the breakdown of disaccharides and polysaccharides in the proximal small bowel, thereby damping postprandial glucose excursions [119]. These drugs remain more popular in East Asian countries than in the rest of the world. Particularly at higher doses and during initial drug titration, they are associated with substantial gastrointestinal side effects, such as flatulence and diarrhea. These result from distal colonic delivery of undigested carbohydrates. The α-glucosidase inhibitors do not by themselves increase the risk of hypoglycemia. They have been tested mainly in conjunction with metformin, sulfonylureas, and insulin [120–122]. Their HbA_{1c}-lowering efficacy is generally low, in the 0.5% range. They could be considered in people with very mild hyperglycemia whose glucose profiles indicate predominately postprandial hyperglycemia.

Bile acid sequestrants

Although its mechanism of action on glycemia is poorly understood, colesevelam, an older cholesterol-lowering drug that binds intestinal bile acids, is approved as a glucose-lowering agent [123]. A modest antihyperglycemic effect (HbA_{1c} –0.5%) has been demonstrated. This class has been associated with constipation and may increase circulating triglyceride levels. They have been studied either as monotherapy or in combination with metformin [124]. One additional benefit is a modest reduction in low-density lipoprotein cholesterol (LDL-C). They might be considered in people requiring a small reduction in HbA_{1c} whose LDL-C is in need of additional lowering without other options (e.g. statin intolerant).

Dopamine-2 agonists

A quick-release form of the dopamine-2 agonist bromocriptine is now available as an antihyperglycemic agent [125]. The drug is usually used in people with hyperprolactinemia from pituitary neoplasms. The HbA_{1c}-lowering capacity is in the 0.5% range. It may exert its metabolic effect through the daily resetting of hypothalamic centers that appear to modulate peripheral insulin sensitivity. Side effects include nausea, fatigue, dizziness, and headache. It has not been extensively studied with specific other treatments and is rarely used.

Amylinomimetics

Amylin is an islet-derived peptide that is co-secreted with insulin. Its apparent physiological role is to suppress glucagon secretion and delay gastric emptying. The amylin receptor agonist pramlintide is an injectable pharmacological agent that is used infrequently but mainly in people with T1DM [126]. It is even less commonly employed in those with T2DM. Pramlintide requires dosing three times per day with meals and its glucose-lowering effect is modest, typically in the 0.5% range. Pramlintide is associated with nausea and vomiting but also weight loss. It may be considered in insulin-requiring individuals who cannot otherwise gain control of postprandial glucose levels, especially if gaining weight. It has not been extensively studied in T2DM in combination with other therapies.

Combination therapy: uses and evidence

In people with T2DM, hyperglycemia tends to progress over time, the result of worsening β-cell function and further decrements in insulin secretory capacity. As a result, most people are not able to maintain adequate glucose control with one agent alone. The value of using medications with complementary mechanisms in combination, thereby targeting different aspects of the disease's complex pathogenesis, is now a standard therapeutic approach and serves three practical purposes:

1 to lower blood glucose to a greater extent than with monotherapy;
2 to allow for lower doses of drugs to minimize their side effects;
3 to use the benefits of one drug to counterbalance the adverse effects of another.

The *first* purpose is to lower blood glucose to a greater extent with two (or three) drugs than can be accomplished with a single agent. This additive effect can be demonstrated with either initial combination therapy (i.e. starting with two drugs from the original prescription) or with sequential therapy, a second drug added to the first after initial failure to lower blood glucose to the extent required or after the first agent fails over time to maintain blood glucose in the targeted range [33, 34]. For example, a person with a baseline HbA_{1c} of 7.9% might respond well to metformin initially, with HbA_{1c} decreasing to 6.7%. The HbA_{1c} might subsequently climb above the targeted range (e.g. to 7.4%) over a period of 2 years. In this circumstance, adding a second agent (i.e. sulfonylurea, thiazolidinedione, DPP-4 inhibitor, SGLT-2 inhibitor, GLP-1RA or basal insulin [see Guidelines, below]) would reduce glucose levels, allowing the individual to attain the HbA_{1c} goal once again. A related scenario would involve a person with a starting HbA_{1c} of 9.2%, which was reduced to 7.7% with metformin monotherapy, and who then requires a second agent to achieve an HbA_{1c} of <7%. This individual, of course, could also have been treated with both metformin plus the second agent from the outset (see Initial combination therapy, below.)

The *second* purpose of combination therapy is to allow for lower doses of each component, in an effort to minimize side effects

or to lessen the cost of a more expensive, branded medication. An example would be someone who experiences protracted diarrhea each time they exceed a metformin dose of 1000 mg. With an HbA_{1c} of 7.5%, this person could perhaps achieve glycemic targets with a higher dose of metformin were it to be tolerated. Instead, a second agent could be added to allow the achievement of the glycemic goal. Another example is an individual already on a full dose of metformin (2 g) and a moderate dose of pioglitazone (30 mg) who is close to but not at their target (e.g. last HbA_{1c}, 7.3%). Each time the pioglitazone is increased to 45 mg, the person develops edema. In this circumstance, an alternative strategy would be the addition of a third agent, while maintaining the pioglitazone at the lower dose.

The *third* potential purpose of combination therapy is for one agent to counteract directly the side effects of another. For example, people often gain weight after basal insulin is added to the glucose-lowering regimen. The addition of metformin, a GLP-1RA, or an SGLT-2 inhibitor (with perhaps a concurrent reduction in the insulin dose) might attenuate weight gain [33, 34, 112, 113]. A similar strategy could be considered if weight gain occurred with the addition of a thiazolidinedione. Theoretically, an SGLT-2 inhibitor could also be used to counteract edema from a thiazolidinedione. Of course, the clinician should strive to make the therapeutic regimen as simple and as cost-effective as possible, and simply abandoning the agent that is leading to adverse effects should also be strongly considered.

The evidence basis

Most of the available antihyperglycemic agents for T2DM have been shown to have additional efficacy when used in combination with each other, with the exception of two insulin secretagogues (i.e. sulfonylurea plus meglitinide) and two incretin enhancers (i.e. DPP-4 inhibitor plus GLP-1RA). The most commonly studied combination is that with metformin [27, 48–51, 71, 112, 113], owing to its widely viewed role as foundation pharmacological therapy for this condition. Most glucose-lowering drugs have also been tested in conjunction with sulfonylureas [27–32], thiazolidinediones [48, 71–76], and insulin [32–34, 76, 81, 112, 113]. SGLT-2 inhibitors have also been assessed in conjunction with DPP-4 inhibitors [95]. In the majority of these clinical trials, typically conducted in phase III of drug development, the added benefit on HbA_{1c} is equivalent to or somewhat slightly less than the efficacy of that drug when used as monotherapy. The reader is referred to two excellent reviews on this topic [127, 128].

In the past, few studies examined long-term clinical outcomes of combination therapy, such as durability of glycemic control or the effect on micro- and/or macrovascular complications. Since 2009, however, in an effort to guarantee drug safety, the US Food and Drug Administration (FDA) and the European Medicines Agency (EMA) have mandated large cardiovascular outcome trials before or soon after regulatory drug approval [84, 129]. Their methodologies have focused on ensuring that MACE are not *increased* when the drugs are used on the backdrop of other glucose-lowering therapies. Most, however, have not contrasted MACE between the study drug and another. One exception is the aforementioned CAROLINA, which will assess the relative cardiovascular effects of the DPP-4 inhibitor linagliptin versus glimepiride [101]. A second is GRADE, funded by the US National Institutes of Health [130] (see Future research, below). In summary, there is a paucity of prospective long-term randomized trials that might inform treatment decisions as to which combinations are better than others on issues beyond glucose-lowering efficacy and adverse effects.

This was the conclusion of an important meta-analysis by Bennett et al., who examined 140 randomized clinical trials and 26 observational studies and compared the efficacies and relative side effects of six antihyperglycemic drug classes both in monotherapy and in dual combination regimens in T2DM [131]. The medication categories were metformin, sulfonylureas, meglitinides, thiazolidinediones, DPP-4 inhibitors, and GLP-1RAs. The authors concluded that most of agents lowered HbA_{1c} by ~1% whether used as monotherapy or in two-drug combinations. They found minor differences in efficacy, with metformin having more powerful effects than DPP-4 inhibitors on HbA_{1c}. Metformin therapy also demonstrated a mean difference in body weight of −2.5 kg compared with sulfonylureas or thiazolidinediones. Metformin treatment was also associated with a beneficial effect on LDL-C when compared with pioglitazone, sulfonylureas, and DPP-4 inhibitors. Sulfonylurea therapy was associated with a more than fourfold greater risk of hypoglycemia than metformin. Thiazolidinediones increased the risk of heart failure compared with sulfonylureas and were associated with bone fractures compared with metformin. However, there was insufficient evidence regarding important long-term clinical outcomes such as mortality, CVD, and microvascular complications such as nephropathy and neuropathy.

Combination therapy: specific strategies

Dual combination therapy

Most glucose-lowering drug categories can be combined with any other, owing to their distinct and complementary actions. Dozens of clinical trials have demonstrated HbA_{1c}-reducing benefit from combining agents in dual combinations. In the USA, FDA-approved prescribing labels no longer endorse specific drug combinations, but now provide broader indications for a specific medication "as an adjunct to diet and exercise to improve glycemic control in adults with type 2 diabetes mellitus," the implication being that the drug may be used either as monotherapy or in combination with other glucose-lowering drugs. Certain combinations are widely viewed as particularly effective, such as combinations that target the opposing defects of impaired insulin sensitivity (e.g. metformin, thiazolidinediones) paired with drugs that augment deficient insulin secretion (sulfonylureas, DPP-4 inhibitors, GLP-1RAs). However, even combinations that focus on insulin sensitivity alone (metformin plus a thiazolidinedione)

or insulin secretion (sulfonylurea plus an incretin enhancer) have been shown to be efficacious.

The first major trial to assess the value of dual combination therapy was by DeFronzo and Goodman, who studied 788 participants not adequately controlled with the sulfonylurea glyburide as monotherapy [27]. Study participants were randomized to three arms (continued glyburide alone, switched to metformin monotherapy, or combined glyburide–metformin) and followed for 29 weeks. There was no difference in either fasting glucose or HbA_{1c} between the first two groups. In the combination group, however, a notable decrease in glycemic variables occurred, with a 63 mg/dL decrease in fasting glucose and a 1.7% fall in HbA_{1c}. In a second, much smaller study, Inzucchi et al. tested the effect of combining metformin and troglitazone—an early thiazolidinedione (Figure 33.4) [71]. Whereas the combination of metformin and a sulfonylurea was expected to have greater efficacy than either drug in monotherapy, there was clinical equipoise as to whether combining two drugs that addressed insulin resistance would behave similarly. Both drugs reduced glucose to a similar extent in 29 participants who were withdrawn from their baseline therapy and randomized to one of the two medications. This was mediated through distinct mechanisms, with metformin predominantly reducing hepatic glucose production and troglitazone mainly increasing peripheral glucose disposal. These complementary actions result in a further reduction in HbA_{1c} of 1.2% when the drugs were combined for an additional 3 months. Hence these two insulin-sensitizing drugs appeared to be useful in combination, as had already been demonstrated with metformin and glyburide in the earlier study.

With the advent of the DPP-4 inhibitors, the GLP-1RAs and the SGLT-2 inhibitors, initial clinical trials required for drug approval have routinely tested the agents not only as monotherapy but also in combination with metformin, in addition to, in most cases, sulfonylureas or thiazolidinediones. More recently, the combination of DPP-4 inhibitors with SGLT-2 inhibitors has been studied. Not surprisingly, each combination proved more powerful than either single drug alone.

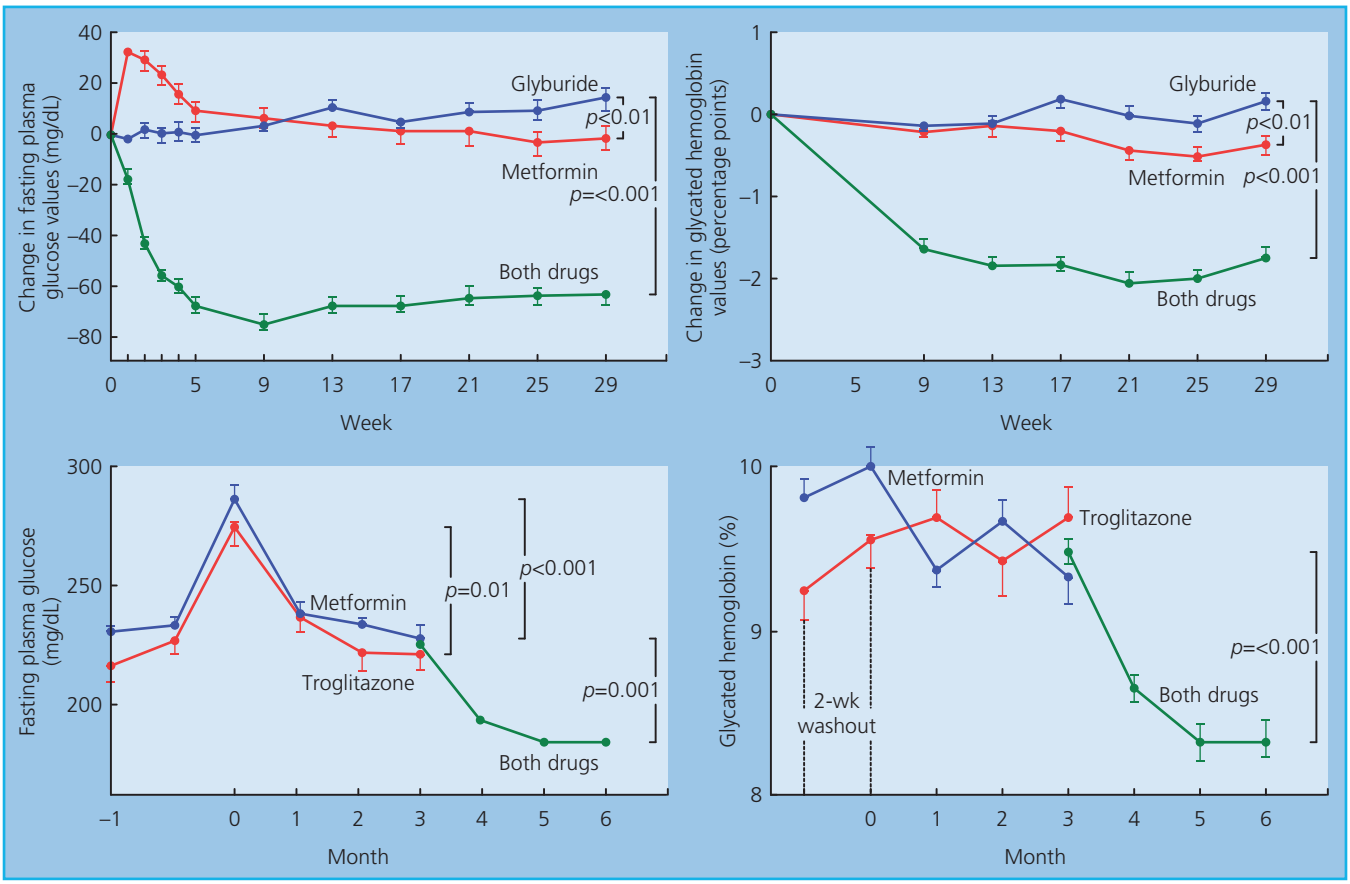

Figure 33.4 Glucose lowering effects from (a,b) adding metformin to baseline glyburide, and (c,d) from combining metformin with a thiazolidedione. (a,b) In people with T2DM who were suboptimally controlled on maximal dose glyburide, continuation of the sulfonylurea resulted in no improvement. Similarly, a switch from glyburide to metformin had no benefit. Instead, when metformin was added to glyburide, patients experience a significant lowering of both fasting glucose and HbA_{1c}. This study exemplifies the general principle that adding agents in combination is preferable to switching one agent for another. Source: Based on Defronzo RA, Goodman AM. *N Engl J Med* 1995; 333:541-549. (c,d) In a small trial, the addition of troglitazone to metformin (and vice-versa) resulted in further significant lowering of fasting glucose and HbA_{1c}. This study underscored the benefits of using drugs with complementary mechanisms of action in combination. Source: Inzucchi et al. 1998 [71]. Copyright 1998 Massachusetts Medical Society. Triple combination therapy

Although the evidence base is not as extensive, several trials have now clearly documented the additional benefit of three drugs in combination versus baseline therapy using two drugs [132–134]. Of course, side effects and cost must be a major consideration as more complex diabetes regimens are contemplated. Therefore, strong consideration at this juncture should be given to the use of insulin, which has less of an efficacy "ceiling" than other drugs.

Combinations with insulin

An older combination strategy dates back to the time before the widespread availability of metformin: insulin injections paired with an sulfonylurea. Although not an intuitively obvious combination, some people with T2DM who had progressed to insulin requirements do maintain a degree of pancreatic β-cell function. It should also be considered that endogenous insulin has the advantage over exogenous insulin of being secreted in the portal vein, thereby allowing for better control of hepatic glucose production. At this time, the concept of "bedtime insulin–daytime SU" had gained popularity in those people who were no longer responding adequately to sulfonylurea monotherapy [135]. The insulin injected at night was of intermediate duration (i.e. insulin NPH or Lente) to control overnight and fasting hyperglycemia, and the secretagogue was administered in the morning in order to control daytime glucose levels. The additional benefit to glucose control was slight, and the strategy was never properly compared with aggressive insulin titration using multiple daily injections. More recent analyses of the sulfonylurea–insulin paired strategy suggest that it is associated with more hypoglycemia than insulin alone [136]. As a result, and with the advent of additional categories of oral agents, this specific combination has become less popular.

Several other combinations with insulin, particularly using a single injection of a basal insulin, have emerged over the past two decades. The most popular is with metformin. The first indication for a thiazolidinedione was in combination with insulin, with trials showing that the addition of a thiazolidinedione to baseline insulin therapy also improved HbA_{1c} and allowed for a reduction in the insulin dose, the latter to a greater extent than with metformin [137]. However, the thiazolidinedione–insulin pairing was also found to increase the likelihood of weight gain and edema and the risk of heart failure. Accordingly, when used, the thiazolidinedione should be started at the lowest dose with careful titration and clinical follow-up. Both DPP-4 and SGLT-2 inhibitors provide a modest additional HbA_{1c} lowering effect when added to insulin [138, 139]. Most drugs, despite not being associated with hypoglycemia as monotherapy, may still increase the risk of hypoglycemia when added to insulin. However, this effect is probably no greater than would be observed had the insulin dose been titrated to the same HbA_{1c} target. Nonetheless, if the HbA_{1c} is close to target, consideration should be given to lowering the insulin dose by 10–20% upon initiation of adjunctive therapy.

A more recent insulin combination gaining in popularity is that with a GLP-1RA. An important meta-analysis by Eng et al. found that this strategy was associated with a mean change in HbA_{1c} of –0.44% (95% CI: –0.60 to –0.29) compared with the comparator groups, in which other drugs were added to achieve glycemic control [81]. Notably, this was achieved with a mean loss of 3.22 kg (95% CI: 4.90–1.54). In addition, a handful of clinical trials had compared the addition of a GLP-1RA to basal insulin with the standard "basal bolus" insulin approach of adding three injections of a mealtime rapid-acting insulin analog. It was found that the HbA_{1c} was slightly lower with the GLP-1RA (0.10%; 95% CI: –0.17 to –0.02), and this was achieved with weight loss instead of weight gain (mean difference –5.66 kg; 95% CI: –9.80 to –1.51 kg) and with less hypoglycemia risk (RR 0.67; 95% CI: 0.56–0.80) [81]. Given the once-daily or even once-weekly injection frequency of most of the GLP-1RAs available and less need for glucose monitoring, using this approach instead of adding multiple daily injections of insulin before meals may be more convenient for patients. Of course, this comes with a higher cost, depending on the insulin dose required.

Is combination therapy synergistic?

Conceptually, two drugs with complementary mechanisms of action could have synergistic effects, that is, resulting in a better glycemic response than the sum of the responses to each drug individually. In fact, when drugs are added, HbA_{1c} reductions tend to be somewhat less robust than one might predict from the reported efficacy with the individual components in monotherapy. This phenomenon may result from the well-described reduced glycemic reduction at lower baseline HbA_{1c} levels [140]. Irrespective of the reason, no drug combination has demonstrated true synergism. Instead, drugs are said to have additive or complementary effects.

Early versus sequential combination therapy

Traditionally, people with T2DM are prescribed a glucose-lowering agent, which is then titrated to the maximally tolerated dose and, if glucose levels are not adequately controlled, a second drug is added. However, some have proposed that, owing to the multiple pathophysiological defects of the disease, two drugs should be prescribed at the initiation of therapy [6, 141]. Several studies have in fact demonstrated the quicker achievement of the HbA_{1c} target using two instead of one drug in drug-naïve individuals over a relatively short term of 3–6 months [142, 143]. It would be fairly likely that the usual sequential approach would achieve an equivalent HbA_{1c} reduction after 1 year as with initial combination therapy. Given the chronic nature of diabetes, the more rapid attainment of a glycemic goal may have little advantage. If the clinician predicts, based on the baseline HbA_{1c} level, that the target is unlikely to be achieved with one drug, initial combination therapy is reasonable. Initial monotherapy, followed by a combination, also has the advantage of being able to discern which potential side effect is attributable to which agent. However, the side effect profiles of glucose-lowering agents are reasonably distinct, so this is rarely a problem with combination therapy.

One controversial strategy that has been proposed is "triple combination" therapy at diagnoses, i.e. treating all people

initially with the combination of metformin, pioglitazone, and a GLP-1RA [6]. The goal is to address each of the fundamental pathophysiological derangements associated with T2DM, namely excess hepatic glucose production (with metformin), decreased insulin sensitivity in skeletal muscle (with pioglitazone), and insufficient insulin secretion and excess glucagon secretion (with the GLP-1RA). In a small, randomized trial that had significant methodological limitations, investigators compared this strategy (metformin–pioglitazone–exenatide) with the conventional approach of metformin followed sequentially by glyburide and insulin glargine in 249 drug-naïve, recently diagnosed individuals [144]. From a baseline of 8.6%, the investigators found that those randomized to triple therapy achieved a significantly better HbA_{1c} (5.95 vs. 6.50% with conventional therapy; $p < 0.001$). Moreover, the treatment goal of HbA_{1c} <6.5% was not achieved in significantly more conventional therapy participants (44 vs. 17% in the triple therapy group; $p = 0.003$.) Triple therapy participants also experienced 7.5 times fewer hypoglycemic events (all mild). Finally, the between-groups weight difference was 5.3 kg in favor of triple therapy. The study, however, had a high dropout rate in both arms, presenting interpretive challenges. Also, the sulfonylurea chosen in this trial was one associated with the greatest risk of hypoglycemia. One conclusion that could be made from this study is that the traditional sequential approach resulted in fairly good glycemic control, albeit at some cost of hypoglycemia and weight gain. Accordingly, it remains unclear if such an initially more complex and expensive triple therapy approach is warranted in such mildly hyperglycemic individuals.

Fixed-dose combinations

For at least 15 years, beginning with metformin–sulfonylurea pairings, two glucose-lowering drugs have been available as so-called "fixed-dose combination" (FDC) tablets. These provide additional convenience for people, who are often on multiple tablets for a variety of other conditions, such as hypertension and dyslipidemia. The combinations may also make drug errors less likely. The clinician should take care to prescribe the most cost-effective medicinal regimens and this may not necessarily be in the form of these FDCs, since generic constituents of these therapies are often available as less expensive products. As with all aspects of diabetes care, individualization is key. The practitioner and office staff must also be cautious during medication reconciliations, since many of the FDC tablets have trade names very similar to those of the parent compounds (see Table 33.2).

Guidelines

Combination therapy played a prominent role in the 2012 ADA–EASD position statement on the management of hyperglycemia in type 2 diabetes, which was updated in 2015 [33, 34]. This statement, as have other sets of recommendations from various professional societies, emphasized the role of lifestyle changes and also the fundamental role of metformin as initial monotherapy. Beyond metformin, if glycemic control remained suboptimal, the statement endorsed the use of one of six potential therapies to be used in combination with metformin (Figure 33.2): sulfonylureas, thiazolidinediones (specifically, pioglitazone), DPP-4 inhibitors, SGLT-2 inhibitors, GLP-1RAs, and basal insulin. The specific choice depends on a variety of factors, including cost, side-effect profile, comorbidities, and anticipated additional benefits in that individual. Reassessment of the quality of glycemic control should be undertaken every 3 months with intensification of therapy made at that interval. After dual combination therapy, if an additional glucose-lowering effect was required, a third agent from one of the aforementioned classes could be used, although basal insulin becomes an increasingly important constituent of the treatment regimen. In those situations where additional glucose-lowering is necessary, the position statement suggested proceeding to combination injectable therapy, either basal bolus insulin or basal insulin with a GLP-1RA (Figure 33.3).

Other published T2DM treatment guidelines that deal with the issue of combination therapy include those from the National Institute for Health and Care Excellence (NICE) in the UK [145], the International Diabetes Federation (IDF) [146], the American College of Physicians (ACP) [147], and the American Association of Clinical Endocrinologists (AACE) [148]. These guidelines differ to some extent based on the intensiveness of glucose control and which specific drugs to add in sequence, but, similarly to the ADA–EASD position statement, generally they focus on several key points:

1 Lifestyle changes are an important component of therapy.
2 Start drug therapy with metformin.
3 Add another oral or injectable agent if metformin monotherapy is insufficient to control glucose.
4 Move towards insulin therapy alone or in combination with other agents if glucose remains controlled.
5 Avoid "glucocentricity": treat blood pressure (favor angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers and lipids (with statins) aggressively, and use antiplatelet therapy where indicated.

Future research needs

There is a paucity of comparative effectiveness research on long-term clinical outcomes with glucose-lowering therapies used in combination in T2DM. Most clinical trials are relatively brief (6–12 months) and focus on glycemic reductions alone after metformin monotherapy. As noted above, since 2009, pharmaceutical companies have been mandated to present cardiovascular safety data prior to or shortly consequent on new drug approval. This necessitates the conduct of large cardiovascular safety trials from which extensive safety data emerge. Unfortunately, the typical methodology of these investigations is to add the compound in question upon a variety of backdrop antihyperglycemic therapies, including a variety of oral agents and insulin. Hence these trials

can determine the safety and potential effectiveness of a strategy involving a particular drug, but cannot in general compare clinical outcomes of that agent with those of another agent of a different class. One exception is CAROLINA, which is assessing cardiovascular and other outcomes between a specific DPP-4 inhibitor and a sulfonylurea [101]. Another major ongoing clinical trial, GRADE, is a comparative effectiveness study, examining the relative effects of four common strategies added to metformin, when the latter is no longer controlling blood glucose adequately: a sulfonylurea (glimepiride), a DPP-4 inhibitor (sitagliptin), a GLP-1RA (liraglutide), or basal insulin (glargine) [148]. The primary outcome is time-to-treatment failure, and so GRADE is essentially a durability study. However, a variety of secondary outcomes are planned, including micro- and macrovascular complications and adverse effects and other safety measures.

Conclusions

Combination therapy is a method commonly used in the management of individuals with T2DM, mainly out of necessity, given the inadequacy of most individual therapies over time. Newer strategies, however, have focused on earlier use of combinations, particularly in those with higher HbA_{1c} values at baseline. There are few data to inform the clinician about the preference for one drug over another after metformin monotherapy, although recently reported cardiovascular benefits with empagliflozin, especially if confirmed with other SGLT-2 inhibitors, may result in a reordering of drug choices, at least for people with established CVD and/or heart failure. The ultimate choice of drug, however, should rely on a comprehensive assessment of expected drug efficacy, side-effect profiles including contraindications, additional benefits, and cost. Recently, the wide availability of fixed-dose combinations has made combination therapy easier for patients. Finally, newer strategies of GLP-1RA plus basal insulin is an emerging strategy in selected individuals with T2DM who would normally require mealtime injections of rapid-acting insulin to attain control.

The future is also likely to yield new devices for improving drug delivery and the long-acting nature of new drugs is likely to transform our approach to therapy. We still cannot reverse β-cell failure, although our developing understanding of the β cell and its pathology may yield a solution even to this, the most pressing of our therapeutic hopes.

34 In-Hospital Treatment and Surgery in People with Diabetes

Ketan Dhatariya[1] and June James[2]

[1] Norfolk and Norwich University Hospitals NHS Foundation Trust, Norwich, UK
[2] University Hospitals of Leicester NHS Trust, Leicester, UK

Key points

- The numbers of inpatients with diabetes continues to increase.
- Hyperglycemia (in particular in those people who were not known to have diabetes prior to hospital admission or those experiencing "stress hyperglycemia") and hypoglycemia are associated with increased levels of harm, using whatever measure is chosen.
- Levels of knowledge among heathcare staff remain poor, and levels of satisfaction among inpatients with diabetes remain low.
- The importance of the early involvement of the diabetes inpatient specialist team is stressed as being an important factor in the education of patients and staff.
- A number of national and international guidelines are now available to help teams manage this increasingly complex cohort of patients, aiming to achieve suitable glycemic control, avoiding symptomatic hyperglycemia or debilitating hypoglycemia.

Introduction

Known diabetes in hospital

The prevalence of diabetes in the general population of Western Europe is in the region of 6–7%, and is expected to rise significantly over the next 20–30 years [1]. The prevalence of diabetes in other parts of the world is much higher; in the United States it is reported to be between 9.3 and 10.9% [1, 2]. It has been recognized that having diabetes more than doubles the risk of being hospitalized for any given condition [3], which is reflected in the high prevalence of diabetes in hospitalized patients. Data from the 2015 UK National Diabetes Inpatient Audit (NaDIA) showed that the prevalence of hospital inpatients with diabetes ranged from 4% to over 35% [4]. Previous work has shown that people with diabetes have a longer length of hospital stay and higher mortality rates than those without the condition [5]. This translates to greater costs. In the United Kingdom, it has been estimated that diabetes accounts for over 10% of the entire budget of the National Health Service (NHS), with the excess costs of inpatients with diabetes equating to between £573 million and £686 million per annum [6]. In the USA, data suggest that in 2012, 20% of the health budget was spent on diabetes, equating to $245 billion, with over 40% of this being attributed to direct inpatient costs [7].

Undiagnosed diabetes and stress hyperglycemia in hospital

In addition to the admissions of people who are known to have diabetes prior to admission, a number of people with hyperglycemia are admitted without a prior diagnosis of diabetes. These include those people not previously known to have diabetes but who continued to have it after they were discharged. However, some patients may develop transient hyperglycemia (a fasting glucose level of >7.0 mmol/L, 126 mg/dL or a random blood glucose level of >11.1 mmol/L, 200 mg/dL) during their inpatient stay that normalizes after discharge—so-called stress hyperglycemia [8, 9]. Taken together, the number of people in hospital with either diabetes or transient hyperglycemia is very large, with observational data indicating a prevalence of between 32 and 38% on general wards [10, 11] and between 28 and 80% of patients with critical illness or undergoing cardiac surgery [11–13].

Pathophysiology of hyperglycemia in acute illness

In healthy individuals who are fasting, glucose levels are usually maintained between 3.9 and 5.6 mmol/L (70 and 100 mg/dL). Levels are finely controlled to match appropriately endogenous glucose production from the liver (and to a lesser extent the

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

kidneys) and glucose utilization by peripheral tissues [14–16]. The glucose levels are controlled by the balance of insulin and the counter-regulatory hormones, glucagon, catecholamines, growth hormone, and cortisol. At relatively low levels, insulin is a potent inhibitor of lipolysis, free fatty acid oxidation, and ketogenesis. As insulin concentrations increase, glucose levels decrease first by inhibiting hepatic gluconeogenesis and glycogenolysis, and then by increasing peripheral glucose uptake and promoting glycogen synthesis. At even higher concentrations, insulin prevents protein breakdown. Finally, at the highest doses, insulin is an anabolic hormone, promoting skeletal muscle formation [17, 18].

Hyperglycemia develops as a result of an imbalance between the glucose-lowering effect of insulin and the counter-regulatory response. Hyperglycemia occurs by three processes: increased gluconeogenesis, accelerated glycogenolysis, and impaired glucose utilization by peripheral tissues [19]. Of these, the first two constitute the major contribution to hyperglycemia. Skeletal muscle breakdown leads to an increased delivery of gluconeogenic precursors in the form of amino acids. Fat breakdown leads to an increased level of free fatty acids delivered to the liver. These effects may be exacerbated by prolonged starvation in the perioperative period. In people without diabetes, a compensatory increase in insulin secretion helps to mediate against these catabolic effects. Without the glucose-lowering effects of insulin, the activity of gluconeogenic enzymes, in particular phosphoenolpyruvate carboxykinase, fructose-1,6-bisphosphatase, and pyruvate carboxylase, is also increased [16, 20]. During times of illness or stress, the increased levels of counter-regulatory hormones alter carbohydrate metabolism by inducing insulin resistance, increasing hepatic glucose production, and reducing peripheral glucose utilization [8, 9]. A major consequence of severe hyperglycemia is osmotic diuresis accompanied by dehydration and electrolyte disturbances (in particular sodium, potassium, magnesium, and phosphate). This increased osmolality leads to a pro-coagulant state. In addition, hyperglycemia results in raised levels of inflammatory cytokines and markers of oxidative stress such as tumor necrosis factor α, interleukin (IL)-6, IL-1β, and IL-8, and C-reactive protein [21, 22]. These pro-inflammatory cytokines have been shown to be associated with the development of insulin resistance by interfering with intracellular pathways, downstream of the insulin receptor [21, 23, 24]. Furthermore, levels fall when the glucose concentrations return to normal [21].

There are other causes of hyperglycemia, which may be more specifically related to the hospital admission [25]. These include co-administered medications such as corticosteroids, although a guideline from the Joint British Diabetes Societies (JBDS) Inpatient Care Group in the UK now exists to help tackle this issue [26].

Evidence of harm from in-hospital hyperglycemia and effect of glucose lowering

Prior to the publication of large, randomized controlled trials in the 1990s, it had been well recognized that poor diabetes control in ambulatory people with either type 1 or type 2 diabetes was associated with poor outcomes. It was only with the publication of the DCCT [27] and UKPDS [28] study results that it was shown that interventions to improve glycemic control maintained over many years were associated with improved outcomes. In the world of inpatient diabetes, there is compelling evidence that high blood glucose levels are associated with higher in-hospital morbidity and mortality, prolonged length of stay, unfavorable post-discharge outcomes, and significant excess healthcare costs in medical and surgical specialities [10, 29–32]. Umpierrez et al. showed that patients with new hyperglycemia had a striking 18-fold increase in in-hospital mortality, whereas patients with known diabetes had a 2.7-fold increase in in-hospital mortality, compared with people with normoglycaemia [10]. In 2004, a joint position statement from the American College of Endocrinology (ACE) and the American Association of Clinical Endocrinologists (AACE) on inpatient diabetes and metabolic control concluded that hyperglycemia in hospitalized patients is a common, serious, and costly healthcare problem. There was a strong recommendation for early detection of hyperglycemia and an aggressive management approach to improve outcomes [3]. In the UK, the JBDS have produced a series of guidelines on managing various aspects of inpatient diabetes care, which also recommend aggressive glucose control [26].

For surgical patients, there are data to show that hyperglycemia in the perioperative period is associated with poor outcomes in several surgical specialities [31–33]. These can be measured as a variety of outcomes, such as length of hospital stay, development of urinary tract infections, surgical site infections, time in the intensive care unit (ICU), and mortality. The reasons for these adverse outcomes are multifactorial, but include failure to identify patients with diabetes and/or hyperglycemia [34, 35]; multiple comorbidities, including microvascular and macrovascular complications [36–42]; complex polypharmacy and insulin prescribing errors [43]; increased perioperative and postoperative infections [32, 44, 45]; associated hypoglycemia and hyperglycemia [32]; lack or inadequate institutional guidelines for management of inpatient diabetes and/or hyperglycemia [32, 46]; and inadequate knowledge of diabetes and hyperglycemia management among staff delivering care [47].

There are also data to show that having a diagnosis of diabetes prior to having surgery is associated with a lowering of risk [31], despite having a high glucose level. Hence the knowledge that a individual has diabetes is somehow protective. It may well be that people with diabetes have more attention paid to them, and thus have more contact with nursing and medical staff, which may mean that postoperative problems are picked up sooner. What remains to be determined is whether it is the high glucose level per se that causes the increased harm, or whether the high glucose is a marker for underlying disease severity.

Whereas there are reasonably robust data showing that high perioperative glucose levels are associated with harm, data showing an association with high preoperative HbA_{1c} are currently lacking [48]. There have been very few good-quality prospective

observational studies in the area of preoperative glycemic control, as measured by HbA_{1c}, as a predictive factor of postoperative morbidity and mortality. Recent work has suggested that risks increase when preoperative HbA_{1c} is >64 mmol/mol (8%), and the UK JBDS guideline also recommends a preoperative level of <69 mmol/mol (8.5%) [33].

Disappointingly, to date, despite the findings that high glucose levels are associated with harm for medical and surgical patients, except for a very few clinical specialities such as cardiac surgery, any convincing evidence to show that achieving good glycemic control while an inpatient is associated with improved outcomes remains to be forthcoming [49].

Glycemic targets for hospitalized inpatients

It has been recognized that hypoglycemia is associated with increased morbidity and mortality [50]. To reduce the impact of hypoglycemia, there is a general consensus that glucose levels should not be allowed to fall below 4.0 mmol/L (72 mg/dL). However, given the lack of robust data showing that aggressive glucose lowering helps reduce the excess morbidity and mortality associated with hyperglycemia, it has been difficult to reach an agreed consensus on what the target glucose levels should be in the hospitalized inpatient. Different targets have been suggested for different categories of patient, e.g. those on the ICU compared with those on a general ward, or those due to undergo surgery.

The intensive care unit (ICU)

A lot of work has been carried out to try to establish the level of glycemic control that is associated with the lowest morbidity and mortality since the first study published in 2001 on patients in the surgical ICU in Belgium [13]. That study compared outcomes in over 1500 patients randomized to a group given "usual care," i.e. glucose levels maintained between 10.0 and 11.1 mmol/L (180–200 mg/dL), or treated with "intensive insulin therapy," i.e. glucose levels maintained between 4.4 and 6.1 mmol/L (80–110 mg/dL) with intravenous insulin given using an infusion pump. The mean glucose concentration in the usual care group was 8.5 mmol/L (153 mg/dL) and the mean concentration in the intensively treated arm was 5.7 mmol/L (103 mg/dL). It was shown that those randomized to the intensive insulin group did significantly better in all outcomes. In particular, their mortality was reduced by 34%, but other measures of outcome were also significantly improved, including less bacteremia, less antibiotic use, shorter length of time on a ventilator, and fewer days on the ICU [13]. The authors then repeated the study in a medical ICU, with a mean glucose concentration in the intensively treated arm of 6.2 mmol/L (111 mg/dL), and showed that intensive insulin therapy was associated with a reduction in overall morbidity and a reduction in mortality if the stay on the ICU was over 3 days [51]. As a result of these two seminal studies, it had been suggested that the target for this cohort of patients should be between 4.4 and 6.1 mmol/L (80 and110 mg/dL). However, subsequent attempts to reproduce these data have proved inconclusive, with most similar studies being unable to achieve similar reductions in morbidity or mortality [52–56], and with some of these studies being stopped early because of the significantly increased risk of harm due to the high frequency of severe hypoglycemia [52, 54, 55]. In a review of the literature in 2013, the lead author of the initial Belgian study concurred that there was still work to be done, and that given the increased mortality in the intensively treated arms of these studies, it remained unclear whether tight glycemic control in the ICU was appropriate [57].

In view of these and other findings, in 2014 a joint statement from the American Diabetes Association (ADA) and the AACE recommended specific glycemic targets in the ICU. They advocated for the initiation of insulin when glucose levels are persistently greater than 10.0 mmol/L (180 mg/dL), aiming for a glucose level between 7.8 and 10.0 mmol/L (140 and 180 mg/dL) [58]. They also suggested that in those centers with more experience in glucose control, a lower target of 6.1–7.8 mmol/L (110–140 mg/dL) may be aimed for provided that there is no increase in the incidence of severe hypoglycemia [58]. The Society of Critical Care Medicine in the USA recommends that glucose-lowering therapy be started once levels rise above 8.3 mmol/L (150 mg/dL), and glucose levels should not be allowed to rise above 10.0 mmol/L (180 mg/dL) or drop below 3.9 mmol/L (70 mg/dL) [59].

General ward patients

There are data from a variety of specialities to show that hyperglycemia in hospitalized patients is associated with poor outcomes [30, 60–63]. Despite this, there remains a paucity of good-quality data on what the ideal target for blood glucose should be in patients on a general ward in hospital, with no data currently available showing if good glycemic control reduces the excess morbidity and mortality seen in hospitalized inpatients with hyperglycemia. The available data are from small cohorts, but show that a lowering of glucose levels is associated with improved outcomes [64]. In the UK, the JBDS has published a series of consensus-based guidelines on a variety of aspects of care for this increasingly large cohort [26]. They advocate that the target glucose level should be between 6.0 and 10.0 mmol/L (108 and180 mg/dL), with a level of 4.0–12.0 mmol/L (72–216 mg/dL) being acceptable for medical patients and for awake surgical patients. These levels are at slight variance with the USA, where the guidelines suggest targets for fasting glucose levels of <7.8 mmol/L (140 mg/dL) and a random glucose target of <10.0 mmol/L (180 mg/dL) [58]. Targets for those who are at the end of life are more relaxed, with the aim of avoiding symptomatic hypoglycemia or hyperglycemia, with levels of 6.0–15.0 mmol/L (108–270 mg/dL) being advocated in the UK [65], and similar but slightly lower levels in the USA [66].

Surgical patients

Several studies have shown that perioperative hyperglycemia is associated with harm [31, 32]. This can be in the form of increased risk of infections of the surgical site or urinary or lower respiratory

tract, increased risk of myocardial infarction and acute kidney injury, time on the ICU or ventilator, and increased risk of mortality. There are data to show that in those individuals who have been previously identified as having diabetes prior to surgery, their risk is significantly lowered, regardless of their glycemic control [31]. This may be because of the increased communication between staff, and if an individual is on an intravenous insulin infusion then it is likely that they will be in contact with nursing staff more frequently (if only to have a capillary glucose measurement taken) than those individuals not previously known to have diabetes. Hence if complications do occur, they may be picked up at an earlier stage. In the UK, the JBDS guideline for the perioperative management of adults with diabetes recommends that the glucose targets for patients undergoing surgery are to keep levels between 6.0 and 10.0 mmol/L (108 and 180 mg/dL), with an acceptable range of 4.0–12.0 mmol/L (72–216 mg/dL) in the awake surgical patient [33]. In those who are asleep, or unable to communicate, the risk of developing hypoglycemia increases at the lower limit, hence the range is recommended to be 6.0–12.0 mmol/L (108–216 mg/dL). The USA and other countries do not yet have similar guidelines, although given the recent evidence that a perioperative HbA_{1c} level of >8.0% (64 mmol/mol) is associated with greater harm, organizations may begin to address this in the future [67, 68].

Given the greatly increased risk of postoperative complications associated with hyperglycemia, it may be necessary for units to adopt a policy to measure a capillary glucose level in at-risk individuals at the preoperative assessment clinic or at the time of acute admission, to ensure that those who have undiagnosed hyperglycemia, either diabetes or stress hyperglycemia, can be identified and appropriately treated.

Surgical patients: potential mechanisms of beneficial effects of glucose lowering in hospital

Although there are few data to show that lowering blood glucose is beneficial, insulin has several beneficial effects on the inflammatory cascade that are independent of its metabolism-regulating effect. These effects include reducing the degree of oxidative stress by its action on free radical production and clearance [69], and also beneficial effects on reducing pro-inflammatory cytokine levels in addition to improving white cell and endothelial function [70–72].

Current recommended standards of care for hospital inpatients with diabetes

Data from the USA in 2012 indicated that 25% of inpatient bed days, accounting for an estimated 43 million days, were attributable to diabetes [7]. In the UK in 2015 people with diabetes occupied between 4 and 35% of hospital beds [73]. Data from NaDIA showed that the majority of patients with diabetes are admitted for reasons other than diabetes, with ~92% admitted as an emergency [74]. In addition, one in four people admitted with heart failure, heart attack, or stroke have diabetes [74].

Professional organizations from different countries publish recommended standards of care for hospital inpatients. The International Diabetes Federation (IDF), an umbrella organization of more than 200 national diabetes associations in over 160 countries, offers a broad perspective on inpatient care relating to people with type 2 diabetes but acknowledges that not all countries have the infrastructure or resources to offer the same care standard for all. They therefore offer three care categories, recommended care, limited care, and comprehensive care, to which member organizations can benchmark [75], as summarized below:

- *Recommended care*. This is evidence-based care that is cost-effective in most nations with a well-developed service base, and with healthcare funding systems consuming a significant part of national wealth. *Recommended care* should be available to all people with diabetes and the aim of any healthcare system should be to achieve this level of care. However, as there are considerable variations in resources throughout the world, other levels of care are described that acknowledge low- and high-resource situations.
- *Limited care*. This is the lowest level of care that anyone with diabetes should receive, as standard medical resources and fully trained health professionals are often unavailable in poorly funded healthcare systems. However, even with limited and cost-effective resources, this level of care aims to achieve a high proportion of what can be achieved by *Recommended care*. Only low-cost or high cost-effectiveness interventions are included at this level.
- *Comprehensive care*. This level of care includes the most up-to-date and complete range of health technologies that can be offered to people with diabetes, with the aim of achieving best possible outcomes. However, the evidence base supporting the use of some of these expensive or new technologies is relatively weak.

This list includes recommendations from other countries including the USA, Australia, Canada, South Africa, and the UK.

Similar themes emerge when reviewing these documents relating to care, including the following:

- A diabetes diagnosis should be clearly identified in the hospital medical case records.
- All people with diabetes admitted to hospital should have their blood glucose level and HbA_{1c} measured, with results available to all members of the healthcare team.
- There should be an emphasis on insulin safety, particularly when using intravenous insulin infusion.
- Recommended blood glucose targets for inpatients should be stated, thereby reducing the risk of hypoglycemia and hyperglycemia.
- Discharge planning should be implemented on admission to hospital.
- Systems and policies should be in place that recognize the specific needs of inpatients with diabetes.
- Each hospital trust should identify a clinical lead for diabetes inpatient care.
- All inpatients with diabetes should have access to a specialist inpatient multidisciplinary diabetes team.
- Staff caring for inpatients with diabetes should be appropriately trained and competent in the management of inpatient diabetes.

The major themes identified in these reports are outlined in the following.

Minimizing length of stay

Reducing excess length of stay is one of the principal aims of good inpatient care. Prolonged length of stay occurs for a multiplicity of reasons, but is often because of diabetes mismanagement secondary to poor staff knowledge and lack of education [47, 76]. Insulin errors are also associated with a longer hospital stay, and although it is recognized that Certified Diabetes Educators (CDEs) and diabetes specialist nurses (DSNs) are effective in reducing length of stay, the majority of diabetes inpatients do not come into contact with these healthcare professionals during admission [77, 78]. The IDF and the ADA are among many institutions that have put discharge planning as a priority at the time of patient admission and not as an afterthought just prior to discharge [75, 79].

Discharge planning defines the agreed management plan for that episode of care, including assessment and prompt referral to the specialist team if necessary, and can aid in anticipating and therefore preventing problems. When possible, this planning should be done in consultation with the patient.

Patient safety

Patient safety for inpatients focuses predominantly on insulin and diabetes management errors and the risks of infection or debilitation associated with extended length of hospital stay. Globally, insulin is one of the five highest risk medications administered [80]. One-third of all inpatient medical errors that cause death within 48 h of the error involve insulin administration. Insulin medication errors can occur at any stage in the process of prescribing, preparing, and delivering the medication to the patient [81]. Errors involving insulin infusion have been highlighted particularly in the last few years [74].

The UK National Patient Safety Agency reviews all medication errors, including those relating to insulin. In 2010, they published a 6-year audit of reported insulin errors described as moderate and severe; 3881 reports were received, and these included inpatient deaths [82]. Following this, a directive was issued stating that all healthcare professionals, including medical staff involved in the prescribing, handling, and administration of insulin, must receive insulin training. In the UK, there is a nationwide initiative to raise the profile of glucose control for inpatients, and also for individual healthcare professionals to take part in a national training program [83, 84]. In recent times there have been a very small number of reports of the development of diabetic ketoacidosis (DKA) in some people with type 1 diabetes, and individuals with type 2 diabetes who are taking SGLT2 inhibitors. In those with type 2 diabetes the blood glucose was only slightly raised. Risk factors for DKA in these people include poor nutrition, reduced insulin, and alcohol abuse. SGLT2 inhibitors should be temporarily discontinued in all patients on admission to hospital for any reason. If the patient is acutely unwell their blood ketones should be tested and they should be assessed for DKA risk.

Diabetes self-management

When not in hospital, people with diabetes are accustomed to managing their own condition. Traditionally, patients are disempowered in the management of their diabetes as soon as they are admitted, and for many people with diabetes, this disempowerment is a negative experience [74, 85]. In 2011, the IDF promoted the need for individuals to be enabled to self-manage their own condition [86]. The USA and UK have set national standards defining the principles of self-management of diabetes, but acknowledge that there is no best practice education program that meets the needs of all people with diabetes [87, 88].

The key principle of self-management is that the person with diabetes has primary responsibility for making the decision about whether they should self-manage their own diabetes. Individuals suitable for self-management in hospital must be competent adults with a stable level of consciousness who successfully manage their diabetes at home. In addition, while in hospital it is advised that these people have the physical skills appropriate to self-administer insulin, be accustomed to performing self-monitoring of blood glucose, and have adequate oral intake. In the event that self-care is deemed unsafe or impossible (e.g. critically ill, post-surgery or unwilling patients), then there must be a governance arrangement to assess patient competency and if necessary supersede patients' right to self-care. Hospitals should have a patient-centered policy for diabetes self-management. Encouraging and supporting individuals to have as much responsibility for their diabetes management as they wish, and their clinical status allows, are likely to enhance the patient experience during a hospital stay [86–88].

Patient satisfaction

Patient experience is important and plays a seminal role when developing local and national guidelines; but there is little in the worldwide literature evaluating inpatient experience. The UK has, however, gathered a large amount of data on patient satisfaction through two sources, as follows.

The Diabetes Inpatient Satisfaction Study was a cross-sectional study measuring inpatient diabetes treatment satisfaction and its relationship to inpatient diabetes care in over 1300 inpatients with insulin-treated diabetes [85]. Patients filled out a validated Diabetes Treatment Satisfaction Questionnaire for Inpatients [89]. Satisfaction with the general diabetes treatment was high, but there were high levels of extreme dissatisfaction with meal choices, meal quality, and lack of similarity of hospital meals to normal domestic choices: 23% would never or rarely have made similar meal choices at home.

Hyperglycemia or hypoglycemia was reported for much of the inpatient stay (20 and 7%, respectively) and 26% reported at least one severe hypoglycemic episode. More frequent inpatient hyperglycemia or hypoglycemia was associated with significantly poorer overall satisfaction scores and negative well-being scores. These groups also had lower satisfaction with the timing of medication in relation to meals. Factors that were significantly associated with the highest levels of satisfaction were the amount

of time spent with a diabetes inpatient specialist nurse (DISN) and self-administration of insulin [85].

Inpatient satisfaction questionnaires were an integral part of the National Diabetes Inpatient Audit, and data were collected over 4 years [74]. In the 2015 audit, 8521 of the 15,229 inpatients included in the audit responded to questionnaires on their inpatient experience, of which 8456 were matched to a corresponding bedside audit form (Box 34.1).

The role of the diabetes specialist team

The patient remains at the heart of the diabetes team. Diabetes specialist inpatient teams are multidisciplinary and should include the consultant in diabetes with a specialist interest in inpatient care, who often is seen at the lead, working closely with DSNs or CDEs, diabetes dieticians, and specialist podiatrists. Extended foot team members should include orthopedic and vascular surgeons, microbiologists, tissue viability nurses, and interventional radiologists. When necessary, rehabilitation teams should also be available. The specialist team should work together by individually contributing their specialist skills to provide a holistic approach to patient care. The success of such team work requires a culture that invests in excellent communication between the person with diabetes, diabetes specialists, and non-specialist teams to activate timely intervention by avoiding glycemic deterioration during the hospital stay.

There is evidence that involvement of the specialist diabetes team, and in particular DISNs and CDEs, significantly reduces length of stay and insulin errors, improves the patient experience, and reduces readmissions [6, 76, 90–92].

A CDE is a health professional in the USA or Canada who possesses comprehensive knowledge of and experience in diabetes management. The role is not exclusive to nursing, but all educators must have a relevant health-related degree and undergo extensive training. They educate and support people affected by diabetes to understand and manage the condition and promote self-management to achieve individualized behavioral and treatment goals that optimize health outcomes. Working in close partnership with social workers, case managers, and home care coordinators, they are able to facilitate a smooth patient pathway from hospital to home at discharge. The DSNs, who work exclusively in diabetes care, and the CDEs are also integral to providing ongoing staff training and may also be prescribers [76, 93]. DSNs deliver patient-centered care wherever required and influence care delivery at every stage of the patient journey, including inpatient care; there is a subgroup of DSNs who specialize in the care of inpatients with diabetes (DISNs). The role of the DISN has evolved in recent times and specifically focuses on supporting inpatients and the ward staff caring for them. Aside from clinical care, DISNs are frequently involved in medical and nursing education. Despite these numerous attributes, almost one-third of UK hospitals do not have a DISN [74]. The same data reveal that the number of hospitals offering inpatient dietetic support is much worse.

Box 34.1 Results from the UK National Diabetes Inpatient Audit 2015.

Patient's ability to self-care

- 27.1% said they had not been able to take control of their own diabetes care in hospital to the extent they would have liked; 17.1% reported they were able to test their own blood glucose levels in hospital. However, the rates of hypoglycemic episodes in those self-testing were higher than in those who did not (27.6% vs. 21.1%).
- 14.2% stated that they were not able to test their own blood glucose levels but would have liked to do so.
- Over half of inpatients (56.5%) taking insulin for their diabetes had been permitted to self-administer insulin while in hospital. The percentage of inpatients who were able to self-administer insulin and who had had one or more hypoglycemic episodes (35.1%) was the same as that among inpatients who were not able to self-administer insulin.
- 9.3% of those taking insulin for their diabetes reported that they were not permitted to self-administer insulin while in hospital but would have liked to do so.
- 30.8% of insulin users stated that they did not want to self-administer while in hospital.
- 23.4% would have liked more involvement in the planning of their diabetes treatment, while 12.5% of inpatients would have preferred to have been less involved in planning their treatment.

Patients' perceptions of ward staff

- 56.4% reported that hospital staff definitely took their treatment preferences into account and 29.5% reported that hospital staff took their treatment preferences into account to some degree
- Inpatients were asked whether they felt the ward staff were knowledgeable about diabetes, 65.7% stated that all or most staff knew enough to meet their needs while they were in hospital. However, 7.7% of inpatients stated that staff did not have sufficient knowledge of diabetes to meet their needs while in hospital; 8.2% of inpatients who had questions about their diabetes reported that hospital staff were not able to answer these questions in a way that they could understand.
- The vast majority of inpatients (84.1%) stated that they were satisfied or very satisfied with the overall care of their diabetes while in hospital.

Staff education

One of the key roles for the specialist diabetes inpatient team is to educate other ward-based generic healthcare professionals. Ward staff may have little or no protected time for education and training other than mandatory training defined by the employing organization. Despite the large numbers of patients with diabetes in

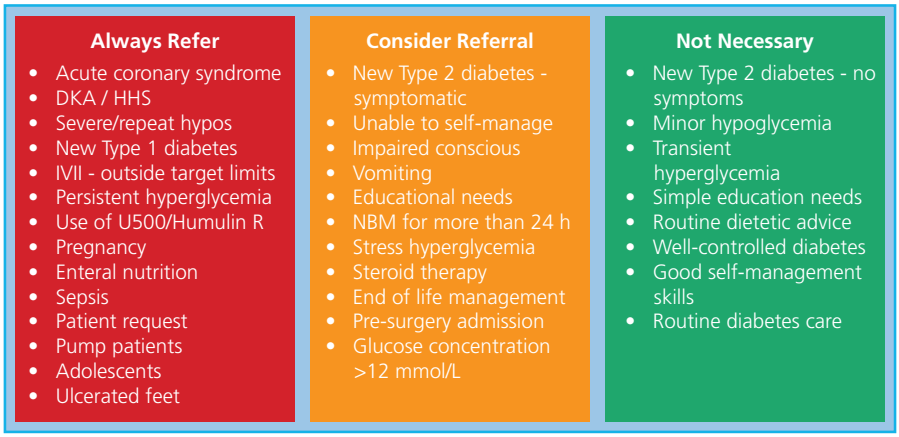

Figure 34.1 Prioritization of patients who should be seen by the diabetes inpatient specialist team. NBM: nil by mouth. Source: Adapted from ThinkGlucose.

hospital, often the only mandatory training in diabetes is in blood glucose monitoring. People with diabetes, who generally have a high level of knowledge about their condition, are therefore frequently being managed by nursing and medical staff who only have only a rudimentary knowledge and training in diabetes care [47, 94]. Hence it is the senior physicians who have the responsibility for educating junior medical staff, whilst the CDE and DSN teams are often best placed to offer education to ward-based staff because they can use the opportunity when reviewing patients to provide education to other non-specialist staff about diabetes management and medication error prevention.

As 10–35% of hospital inpatients have diabetes, it is almost impossible for specialist team members to see every patient on a regular basis. In the UK, specialist teams therefore have drawn up a priority list for which patients should be referred for assessment (Figure 34.1). Ward-based and specialist nursing staff in the UK have to undergo a revalidation process from 2016, which includes ascertaining patient views and demonstrating competency [95].

Management of in-hospital hyperglycemia

"It is as unacceptable for hospitals not to have a glycemic management policy as it is for them not to have an infection control policy" [83]. This statement, from the UK NHS Institute for Innovation and Improvement, echoes similar sentiments from the ADA [58], namely that it is incumbent upon organizations to ensure that diabetes is appropriately managed in the inpatient population.

Hyperglycemia in hospital is a common problem and occurs in around 25% of all hospital inpatients [4]. The majority of people with diabetes are not admitted to hospital to address and treat complications associated with the disease. Control of blood glucose often becomes secondary to the care of the primary diagnosis requiring admission. In people without diabetes who develop hyperglycemia during an acute illness, high or low glucose levels are often ignored or treated inappropriately. Poor glycemic control is common among inpatients with diabetes, for many reasons [4]. Over the last few years, the issue of inpatient diabetes has become a higher priority, with the UK Joint British Diabetes Societies Inpatient Care Group producing a number of different guideline addressing various issues surrounding inpatient glycemic control [26]. In the USA, the PRIDE group has also been set up to address inpatient glycemic control [68].

Medication to manage in-hospital hyperglycemia

For many years, it was thought that it was more straightforward to stop any oral medication that a patient may be taking and to use intravenous insulin because it provided the greatest flexibility in the hospital setting to achieve optimal blood glucose control. However, it has become increasing recognized that the use of insulin is associated with severe hypoglycemia [50, 96]. New strategies are required to manage hyperglycemia, while at the same time keeping the work load of the nursing staff to a minimum, at a reasonable cost. Umpierrez et al. used more flexible insulin regimens either with or without drugs that work by preventing glucose concentrations from rising, with some success in medical and surgical patients [64, 97]. Subcutaneous insulin given as a basal bolus regimen with correction bolus doses have also been used [98]. However, these regimens require a degree of awareness and training among nursing and medical staff. Increasing awareness, such as the use of the ThinkGlucose campaign in the UK, have helped to ensure that nursing staff remain vigilant to the importance of maintaining good glycemic control [83]. Insulin administration errors are very common, and have been classified as a "Never Event" [99]. When incidents occur, they should be regularly audited and staff training put into place as necessary.

Self-management of diabetes in hospital

Self-management describes the whole process of adjusting insulin treatment in response to self-measured capillary glucose values [88]. Although this is an institutional decision, in principle inpatients with diabetes should be given the opportunity to decide whether they wish to self-manage their condition during their admission, provided that they are well enough to do so. Part of this involves institutions providing written information for staff and patients to explain the responsibilities of self-management. For elective surgical patients, this written information may be provided at the time of the preassessment clinic. In addition, for elective admissions, a care plan should be agreed at that time to

establish whether the person with diabetes wishes to self-manage and the circumstances in which this may not be possible should be agreed in advance [88].

At the time of admission, the responsible nurse and the person with diabetes should again agree on the circumstances in which the patient should or should not self-manage. Ideally, an agreement form should be signed by both the person with diabetes and the responsible nurse. People with diabetes should be able to self-monitor their blood glucose but should make the results available to hospital staff. People with diabetes should be allowed to use their own blood glucose monitoring equipment, but ideally this should be quality assessed. In addition, the technique for glucose testing and insulin administration should also be assessed. Once the person with diabetes has administered their own insulin, the dose self-administered should be recorded on the prescription chart, or an entry made on an electronic prescription by a member of staff.

To allow people with diabetes to keep and administer their own insulin, facilities should be available for safe storage of insulin in the ward environment. In addition, the institution should ensure that the timing and content of meals are suitable for the individual with diabetes; this is a common cause of unhappiness and dissatisfaction among inpatients with diabetes [85].

It is important that during the admission, the clinical circumstances should be regularly assessed to ensure that the patient's ability to self-manage has not been compromised by their clinical condition. If there are doubts or disagreements between the person with diabetes and the staff as to whether they can self-manage, then the diabetes specialist team may need to be involved.

Technology

The use of technology to manage inpatient diabetes is still in its infancy, but is likely to play an increasing role in managing glycemic control over the next few years. The use of continuous subcutaneous insulin infusions complemented by implantable real-time glucose sensors has been used successfully in small studies in patients in ICUs [100]. The use of these "closed loops" is likely to become more frequent as the algorithms that they use become more sophisticated, and the cost of the technology falls sufficiently to make it cost-effective to use regularly.

Subcutaneous and intravenous insulin protocols

The use of "sliding-scale" insulin given intravenously or subcutaneously has been soundly discredited, but continues to be used [101, 102]. Umpierrez et al. have published widely on the successful use of subcutaneous insulin to manage glucose levels on the wards in medical and surgical patients [64, 97], and have also shown that the use of the dipeptidyl peptidase inhibitor sitagliptin alone, or in combination with basal insulin, was associated with a lowering of glucose levels in a small, single-center study of 90 general medical and surgical patients [103]. How insulin is given is also a subject of contention. The use of basal bolus or twice-daily mixed subcutaneous insulin regimens has been advocated [3, 104], but to use insulin safely requires a certain level of understanding, and data have shown that among many junior medical staff this is lacking [47]. This may be why there is reluctance among junior medical staff to prescribe subcutaneous insulin earlier, even when glucose levels remain high.

The ideal intravenous or subcutaneous insulin protocol should be safe, understandable, easily ordered, and readily implemented. It should be effective in correcting hyperglycemia quickly and in maintaining glucose levels within a defined target range. If given intravenously, the provision of an easy-to-follow algorithm for making incremental changes to the infusion rate, which can be executed by nursing staff, is likely to improve the efficacy of the protocol. Hypoglycemia is a potential complication of intensified insulin therapy and is associated with poor outcomes. It is for this reason that intravenous insulin infusions should be supported by caloric input when glucose levels drop. In most patients, this is in the form of a simultaneous infusion of dextrose, but calories can be provided by other routes (e.g. enteral, parenteral, or in a dialyzate). The UK JBDS and others have produced comprehensive guidelines on the management of intravenous insulin infusions [98, 105]. It is expected that if the patient was taking a long-acting basal insulin (human or analog) prior to admission, then this should be continued, because continuation of the background insulin prevents rebound hyperglycemia when the intravenous insulin is stopped [106].

Indications for an intravenous insulin infusion

Whether the patient has previously recognized diabetes or not, insulin provides the greatest flexibility to meet rapidly changing requirements in different hospital settings to achieve optimal blood glucose control. Intravenous infusion of insulin is the only insulin treatment strategy specifically developed for use in the hospital setting. The JBDS and the ACE advise that intravenous insulin infusion should be used to control glucose levels in certain circumstances (Box 34.2).

Box 34.2 Indications for an intravenous insulin infusion (variable rate unless stated).

- To treat critical care illness
- Acute coronary syndromes—although owing to the uncertainty here, local guidelines should be followed
- Patients on "nil by mouth" status when more than one meal will be missed
- Type 1 diabetes
- General preoperative, intraoperative and postoperative care
- Stroke
- Hyperglycemia during high-dose corticosteroid therapy
- Labor and delivery
- Other acute illness for which prompt glycemic control is judged important to recovery, such as prevention or treatment of infection
- Diabetes emergencies such as diabetic ketoacidosis or hyperosmolar hyperglycemic syndrome (fixed-rate infusion)

Table 34.1 Insulin infusion table.

Glucose (mmol/L)	Insulin rates (mL/h)[a] (start on standard rate unless otherwise indicated)[b]		
	Reduced rate (for use in insulin sensitive patients, e.g. ≤24 units/day)	Standard rate (first choice in most patients)	Increased rate (for insulin-resistant patients, e.g. ≥100 units/day)
<4.0	0	0	0
4.1–8.0	0.5	1	2
8.1–12.0	1	2	4
12.1–16.0	2	4	6
16.1–20.0	3	5	7
20.1–24.0	4	6	8
>24.1	6	8	10

[a] Using 50 units of human soluble insulin in 49.5 mL of 0.9% sodium chloride solution gives a concentration of 1 unit/mL.
[b] If a patient normally takes basal subcutaneous insulin, continue this alongside the variable rate intravenous insulin infusion.
The scales may be customized as necessary.
Source: George and Stanisstreet 2014 [105].

Preparation and delivery of an intravenous insulin infusion

An intravenous insulin infusion is prepared by adding 50 units of soluble insulin to 49.5 mL of 0.9% sodium chloride solution, which will provide 1 unit of insulin in 1 mL, which is delivered via an infusion pump. This insulin infusion can be piggy-backed into the infusion of dextrose using a three-way connector and a non-return valve. This is most often given as a variable-rate intravenous insulin infusion; it can be given as a fixed-rate intravenous insulin infusion, but this is usually limited to treatment of diabetic ketoacidosis or hyperosmolar hyperglycemic syndrome (Table 34.1). The terms "variable-rate intravenous insulin infusion" (VRIII) and "fixed-rate intravenous insulin infusion" (FRIII), are preferred owing to the potential ambiguity associated with the term "sliding scale."

Transition from intravenous to subcutaneous insulin

Conversion to subcutaneous insulin should only be carried out when the patient is able to eat and drink normally without nausea or emesis. The most appropriate time to switch from intravenous to subcutaneous insulin is at the usual time of the patient's insulin administration, before a meal; however, when possible, this should not be done before the evening meal. People with known type 1 diabetes will become insulin deficient within minutes of the intravenous infusion being stopped because of the short half-life of intravenous insulin. It is therefore good practice to continue the infusion of insulin for 30–60 min after the subcutaneous insulin has been administered to allow time for the insulin to be absorbed [105].

If the patient has been on an established insulin regimen, then this regimen should be restarted, but doses may have to be adjusted depending on the patient's clinical condition. If the patient is new to insulin therapy, then a rough estimation of the total daily dose of insulin can be made from a simple calculation using the hourly rates delivered in the intravenous insulin infusion. Estimation of insulin doses can also be made according to body weight, which is useful in calculating total daily dose requirement in patients who are new to insulin but have not required an insulin infusion (Table 34.2 and Box 34.3).

Avoiding and treating in-hospital hypoglycemia

Hypoglycemia is the commonest side effect of insulin and sulfonylurea treatment, and represents a major barrier to satisfactory long-term glycemic control. The other drug classes, i.e. biguanides, thiazolidinediones, DPP-4 inhibitors, SGLT-2 inhibitors, and GLP-1 receptor agonists, are unlikely to result in hypoglycemia owing to their modes of action, unless co-prescribed with insulin or sulfonylureas. Hypoglycemia should be excluded in any person with diabetes who is acutely unwell, drowsy, unconscious, unable to cooperate, or presenting with aggressive behavior or seizures. In-hospital hypoglycemia is defined as a blood glucose level ≤3.9 mmol/L (70 mg/dL) [58]. There is an increasing body of evidence supporting the widespread occurrence of hypoglycemia in hospitals and poor knowledge of how to detect and manage it [50, 96].

Frequency of hypoglycemia in hospitalized patients

In 2015, the UK National Diabetes Inpatient Audit (NaDIA) data showed 21.8% of inpatients with diabetes experienced one or more hypoglycemic episodes with a blood glucose less than 4.0 mmol/L (72 mg/dL), with 9.3% experiencing one or more hypoglycemic episodes less than 3.0 mmol/L (54 mg/dL) [4].

Farrokhi et al. [107] reported a prevalence of severe hypoglycemia ranging from 5 to 32% in hospital inpatients treated with insulin. In England, the National Diabetes Inpatient Audit data set showed that people with type 1 diabetes had the highest prevalence, with 42.5% experiencing a hypoglycemic episode with a blood glucose less than 4.0 mmol/L (72 mg/dL) and 31.3% experiencing a hypoglycemic episode <3.0 mmol/L (54 mg/dL). Injectable rescue treatment was required by 2.1% of patients [4].

Table 34.2 Transition from intravenous to subcutaneous insulin.

Insulin	Good control, i.e. HbA_{1c} <59 mmol/mol (7.5%)	Suboptimal Control	Monitoring blood glucose for all patients
Basal insulin	Restart usual dose of insulin when it is due (usually with either breakfast or evening meal). Do not stop VRIII until at least 30–60 min after insulin has been given and patient has eaten If it is necessary to stop VRIII but the basal insulin is not due for several hours, give half the usual dose of basal insulin. This will provide background insulin until the usual dose can be recommenced	In addition, discuss with local diabetes inpatient team. Insulin regimen may need adjusting	CBG should be checked 1 h after discontinuing VRIII and at least 4-hourly for the next 24 h, to ensure that there is no rebound hyper- or hypoglycemia
Once- or twice-daily mixed insulin	Restart usual dose of insulin together with a meal (either breakfast or evening meal). Do not stop VRIII until at least 30–60 min after insulin has been given and the patient has eaten If it is necessary to stop VRIII at lunchtime, give half the usual breakfast dose of mixed insulin. This will provide essential background insulin until the usual dose can be recommenced		
Multiple daily insulin injections (MDI or basal bolus)	Restart usual diabetes treatment together with a meal Basal insulin will usually have been continued. Restart bolus dose of insulin together with the next meal. Do not stop VRIII until at least 30–60 min after bolus insulin has been given and the patient has eaten If basal insulin has been stopped, background insulin must be restarted prior to stopping VRIII. Ideally, continue the VRIII until basal insulin is given and a meal is due, and stop at least 30–60 min after basal and bolus insulin is restarted If it is necessary to stop the VRIII, but the basal insulin is not due for several hours, give half the usual daily dose of basal insulin, along with a meal and bolus insulin. This will provide essential background insulin until the usual dose can be recommenced		
Insulin pump (CSII)	Restart usual basal rate via CSII Do not stop VRIII until at least 30 min after insulin has been recommenced via CSII Give bolus insulin according to patient's usual regime. It is not usually necessary to wait until a mealtime to switch back to CSII therapy Avoid restarting CSII at bedtime		

Source: George and Stanisstreet 2014 [105]. CSII, continuous subcutaneous insulin infusion; CBG, capillary blood glucose.

Box 34.3 Converting from intravenous to subcutaneous insulin.

Step 1

Calculate the total daily dose requirement (TDD) using either of two methods: weight based, or using the dose delivered for the last 6 h using a VRIII. The weight-based method suggests that in frail, elderly patients, those with renal failure (CKD stage 4 or 5) or severe hepatic failure, or in those with newly diagnosed type 1 diabetes:

Total daily insulin dose = 0.3 × body weight in kg

All other adult patients:

Total daily insulin dose = 0.5 × body weight in kg

The infusion-based method estimates the daily insulin requirement from the last 6 h of the VRIII as follows:

The total dose of insulin administered in last 6 h of the VRIII is divided by 6 to calculate average hourly dose of insulin. This is then multiplied by 20 (not 24, to reduce risk of hypoglycemia) to estimate the patient's total daily insulin requirement.

Step 2

Using the total daily dose to convert the patient to either a premixed twice daily insulin regimen or a multiple basal bolus dose regimen

For a basal bolus regimen, 50% of the total insulin requirement is usually given as basal insulin, and the remainder as rapid-acting insulin, divided equally between breakfast, lunch, and evening meal

For a twice-daily, premixed insulin regimen, patients usually need 60% of the total insulin requirement at breakfast and the remaining 40% with the evening meal

Source: George and Stanisstreet 2014 [105].

Table 34.3 Potential causes of in-hospital hypoglycemia.

Medical issues	Carbohydrate intake issues
• Inappropriate use of "stat" or "PRN" rapid/short-acting insulin • Acute discontinuation of long-term steroid therapy • Recovery from acute illness/stress • Mobilization after illness • Major amputation of a limb • Incorrect type of insulin or oral hypoglycemic therapy prescribed and administered • Inappropriately timed insulin or oral hypoglycemic therapy in relation to meal or enteral feed • Change of insulin injection site • I.v. insulin infusion with or without glucose infusion • Inadequate mixing of intermediate-acting or mixed insulins • Regular insulin doses or oral hypoglycemia therapy being given in hospital when these are not routinely taken at home	• Missed or delayed meals • Less carbohydrate than normal • Change of the timing of the biggest meal of the day (i.e. main meal at midday rather than evening) • Lack of access to usual between-meal or before-bed snacks • Prolonged starvation time, e.g. "nil by mouth" • Vomiting • Reduced appetite • Reduced carbohydrate intake

Source: Stanisstreet et al. 2013 [119].

The same data showed that the highest proportion of episodes took place overnight (34.3%), between 9 p.m. and 9 a.m., when snack availability was likely to have been lowest; these data have been confirmed elsewhere [108].

The tight glycemic control achieved in ICUs led to much higher reported rates of hypoglycemia, with the incidence of blood glucose ≤2.2 mmol/L (40 mg/dL) ranging from 5 to 18.7% [51, 52, 54, 109].

Causes of in-hospital hypoglycemia

Common causes of inpatient hypoglycemia are listed in Table 34.3. One of the most serious and common causes of inpatient hypoglycemia is insulin prescription errors, including misreading poorly written prescriptions, such as when U is used for units (e.g. 4U becoming 40 units), or confusing the insulin name with the dose (e.g. Humalog Mix25 becoming Humalog 25 units).

Morbidity and mortality associated with in-hospital hypoglycemia

Turchin et al. examined data from 4368 admission episodes for people with diabetes, of whom one-third were on regular insulin therapy [110]. Individuals experiencing inpatient hypoglycemia showed a 66% increased risk of death within 1 year and spent 2.8 days longer in hospital than those not experiencing hypoglycemia. Recent data also suggest increased mortality rates for inpatients on insulin therapy who experienced a blood glucose of <2.8 mmol/L (50 mg/dL) compared with those with no hypoglycemia (20.3% vs. 4.5%) [111]. However, only 41–51% of these participants had diabetes and subgroup analysis of those with diabetes was not performed.

Evidence for treatment options

There is limited evidence regarding the quantity of quick-acting carbohydrate required to treat an episode of hypoglycemia successfully. The initial quantities chosen were the result of expert consensus subsequently backed up with glucose clamp studies [112, 113]. Subsequent work has shown that ~20 g of rapid-acting carbohydrate is often sufficient, with less than 10 g likely to be inadequate [114, 115]. Chocolate- and sucrose-containing foods should be avoided, because the high fat content in chocolate slows gastric emptying, thus delaying absorption, and sucrose needs to be cleaved by intestinal disaccharidases prior to absorption [116, 117]. Fresh fruit juice or glucose-containing tablets or gel remain the most frequently used treatment for hypoglycemia and are an essential component of "Hypoboxes" [113, 118, 119]. The suggested contents of a Hypobox, which are commercially available, can be found in Box 34.4.

Management of in-hospital hypoglycemia

People experiencing hypoglycemia require quick-acting carbohydrate to return their blood glucose levels to the normal range. The quick-acting carbohydrate should be followed up by giving long-acting carbohydrate either as a snack or as part of a planned meal. All patients experiencing hypoglycemia should be treated without delay. When it is safe to do so, a blood glucose measurement should be taken to confirm hypoglycemia (especially if there is any suspicion that the person may be currently under the influence of alcohol or non-prescription drugs). If measurement is difficult (e.g. in a patient having a seizure), then treatment should not be delayed.

Adults who have poor glycemic control may start to experience symptoms of hypoglycemia at blood glucose levels >4.0 mmol/L (72 mg/dL). There is no evidence that the thresholds for cognitive dysfunction are reset upwards; therefore, the only reason for treatment is symptomatic relief. Hence adults who are experiencing hypoglycemia symptoms but have a blood glucose level >4.0 mmol/L (72 mg/dL) should be treated with a small carbohydrate snack only, e.g. one medium banana, a slice of bread, or normal meal if due. All adults with a blood glucose level <4.0 mmol/L (72 mg/dL) with or without symptoms of hypoglycemia should be treated as shown in Figure 34.2.

Box 34.4 Suggested contents of a Hypobox.

- A copy of the locally agreed hypoglycemia algorithm
  - laminated and attached to inside of lid
- 2× 200-mL cartons fruit juice
- 2× packets of dextrose tablets
- 1× mini-pack of biscuits (source of long-acting carbohydrate)
- 3 × tubes (1 box) Glucogel
- 20% glucose i.v. solution (100-mL vial)
- 1× 18G intravenous cannula
- 1× 16G intravenous cannula
- 1× 10-mL sterile syringe
- 3 × 10-mL 0.9% sodium chloride solution ampoules for flush
- 1× 21G sterile needle
- Chlorhexidine spray/alcohol wipes
- 1× dressing cover for the intravenous cannula
- 10% glucose for intravenous infusion (500-mL bag)
- Audit form
- Instructions on where to send audit form and replenish supplies
- 1× glucagon pack: to be kept in the nearest drug refrigerator or labeled with a reduced expiry date of 18 months if it is stored at room temperature

Source: Stanisstreet et al. 2013 [119].

All hypoglycemic events should be documented in the patient's notes. Regular capillary blood glucose monitoring should be continued for 24–48 h. The patient should be told to continue this at home if they are to be discharged. Hypoglycemia education should be given or a referral made to the DISN/CDE.

Surgery in people with diabetes

There have been several studies showing that hyperglycemia in the postoperative period is associated with harm. These include (but are not limited to) general surgery [31, 32], cardiac surgery [120], vascular surgery [121, 122], neurosurgery [123], orthopedic surgery [124, 125], colorectal surgery [126], trauma [127], breast surgery [128], liver transplantation [129], hepatobiliary and pancreatic surgery [130], cholecystectomy [131], and foot and ankle surgery [132]. These harms include wound infection, length of time in hospital, acute kidney injury, myocardial infarction, time spent in an ICU or on a ventilator, and death. The perioperative mortality rate is up to 50% higher than in people without diabetes [32]. Because of these factors, and the data showing that people with diabetes are less likely to be offered day-case surgery and are more likely to have emergency surgery, have longer lengths of stay following admission, and have a higher rate of 28-day readmissions following surgery [133], it would seem sensible to optimize glycemic control prior to surgery and around the time of the operation. However, this optimization would require a great deal of coordination between all the people involved in the care of the person with diabetes.

Primary care

The patient journey for elective surgical patients usually starts with a primary care assessment and referral to the surgeons [33]. It is important that primary care physicians communicate to the surgeons that the person has diabetes when they are referred, ideally indicating the type of diabetes, the duration of diabetes, the most recent HbA_{1c} (ideally taken within the previous 3 months), current treatment, any comorbidities, and who is the usual diabetes care provider. A recent meta-analysis suggested that there was no relationship between HbA_{1c} and outcomes in surgical patients [48]. The current guidelines are effectively pragmatic because it is well recognized that the high-risk surgical patient is often elderly, with multiple coexisting medical conditions, and therefore attempting to attain more aggressive glycemic control may be associated with harm in the form of hypoglycemia. In addition, there has previously been evidence to show that an HbA_{1c} of >64 mmol/mol (8%) has been associated with poor outcomes [67] and the UK National Guidelines suggest that HbA_{1c} should be <69 mmol/mol (8.5%) [33]. Hence it would be incumbent on the primary care provider to optimize glycemic control prior to referral, if possible, or after referral is made, to reduce the risk of (a) the procedure being cancelled or postponed owing to poor glycemic control or (b) the risk of harm postoperatively. The information provided by the primary care team should help the surgeon when they are seen in the surgical outpatient clinic. If the decision is made to operate, then the surgeon should communicate the presence of diabetes to the preoperative assessment team, the anesthetists, and the operating list planners, so that the patient may be placed early on a theater list to minimize starvation time and subsequent metabolic disturbance.

Preoperative assessment

At this stage, the opportunity should be taken to optimize preoperative glycemic control, either by referring back to the primary healthcare team responsible for their diabetes or using a DSN or CDE as necessary [134]. The management of other comorbidities should also be optimized.

There should be good lines of communication between the preassessment team and the surgical team, such that the patient is aware of when they are due to come in, where they are due to go, and what time their surgery is. They should also have very explicitly written instructions on how to manage their diabetes medication. These are shown in Tables 34.4 and Table 34.5. It is important that the preoperative assessment team ensure that the person with diabetes is put first on the morning list to avoid prolonged starvation time and avoid the inappropriate use of a variable-rate intravenous insulin infusion. This would result in the increasing likelihood that they could be same-day admissions. In addition,

Figure 34.2 Algorithm for the treatment of hypoglycemia in adults with diabetes in hospital. Hypoglycemia is defined as a blood glucose level of <4.0 mmol/L (72 mg/dL). If the patient is symptomatic but the blood glucose is >4.0 mmol/L (72 mg/dL) then a small carbohydrate snack should be given for symptom relief. ABC, airway, breathing, circulation; NBM, nil by mouth. Source: [119].

Table 34.4 Guidelines for perioperative adjustment of insulin.

Insulin	Day prior to admission	Day of surgery/while on a VRIII		
		Patient for a.m. surgery	Patient for p.m. surgery	If a VRIII is being used[a]
Once daily (evening) (e.g. Lantus or Levemir, Tresiba, Insulatard, Humulin I, Insuman)	Reduce dose by 20%	Check blood glucose on admission	Check blood glucose on admission	Continue at 80% of the usual dose
Once daily (morning) (Lantus or Levemir, Tresiba Insulatard, Humulin I, Insuman)	Reduce dose by 20%	Reduce dose by 20% Check blood glucose on admission	Reduce dose by 20% Check blood glucose on admission	Continue at 80% of the usual dose
Twice daily (e.g. Novomix 30, Humulin M3, Humalog Mix 25, Humalog Mix 50, Insuman Comb 25, Insuman Comb 50, twice daily Levemir or Lantus)	No dose change	Halve the usual morning dose Check blood glucose on admission Leave the evening meal dose unchanged	Halve the usual morning dose Check blood glucose on admission Leave the evening meal dose unchanged	Stop until eating and drinking normally
Twice daily: separate injections of short acting (e.g. animal neutral, NovoRapid, Humulin S, Apidra) *and intermediate acting* (e.g. animal isophane Insulatard, Humulin I, Insuman)	No dose change	Calculate the total dose of both morning insulins and give half as intermediate acting only in the morning Check blood glucose on admission Leave the evening meal dose unchanged	Calculate the total dose of both morning insulins and give half as intermediate acting only in the morning Check blood glucose on admission Leave the evening meal dose unchanged	Stop until eating and drinking normally
3, 4 or 5 injections daily	No dose change	Basal bolus regimens: omit the morning and lunchtime short-acting insulins. If the dose of long-acting basal insulin is usually taken in the morning then the dose should be reduced by 20%. Keep the basal unchanged[a]. Premixed a.m. insulin: halve the morning dose and omit lunchtime dose Check blood glucose on admission	Take usual morning insulin dose(s). Omit lunchtime dose Check blood glucose on admission	Stop until eating and drinking normally

At the preoperative assessment clinic, all patients should have emergency treatment for hypoglycemia written on their drug chart, i.e. Glucogel, and 20% dextrose. Rapid-acting insulin should also be prescribed.
[a]If the patient requires and ongoing VRIII then the long-acting background insulin should be continued but at 80% of the dose that the patient usually takes when they are well. Normal insulin doses should be recommenced when the patient is eating and drinking normally.
VRIII, variable-rate intravenous insulin infusion.
Source: Dhatariya et al. 2015 [148].

the provision should be made for postoperative admission to critical care, if this is indicated, especially with people who are at high risk and with poor glycemic control.

There are data from the UK to show that many people with diabetes are being inappropriately denied day-case surgery [6]. This means that a large number of people are being unnecessarily admitted to hospital for overnight hospital stay, adding to the cost burden, in the belief that being in hospital will lead to "glycemic optimization." However, this is likely to mean that the patient is admitted to a ward the evening prior to surgery, when there are fewer nursing staff available, and put on a variable-rate intravenous insulin infusion and looked after by one of the most junior members of the medical team, who are known to have poor levels of knowledge of diabetes management [47].

Hospital admission

During the hospital admission, it is important that the individualized care plan is communicated to all staff involved in the care of the patient and that all efforts are made to minimize the metabolic consequences of starvation and surgical stress. At the same time, optimal glycemic control should be achieved using the standard of care for that institution, such as a basal bolus insulin regimen [97, 135].

The principles of the enhanced recovery after surgery program should be put into place, including, for people with type 2 diabetes, the administration of a preoperative carbohydrate load [136].

When the starvation time is short, i.e. less than one missed meal, there would be no need for a variable-rate intravenous insulin infusion; however, if the starvation period is likely to be longer,

Table 34.5 Guidelines for perioperative adjustment of non-insulin medication.

Tablets	Day prior to admission	Day of surgery/while on a VRIII		
		Patient for a.m. surgery	Patient for p.m. surgery	If a VRIII is being used[a]
Acarbose	Take as normal	Omit morning dose if NBM	Give morning dose if eating	Stop until eating and drinking normally
Meglitinide (repaglinide or nateglinide)	Take as normal	Omit morning dose if NBM	Give morning dose if eating	Stop until eating and drinking normally
Metformin (procedure not requiring use of contrast media[b])	Take as normal	If taken once or twice a day take as normal. If taken three times per day, omit lunchtime dose	If taken once or twice a day take as normal. If taken three times per day, omit lunchtime dose	Stop until eating and drinking normally
Sulfonylurea (e.g. glibenclamide, gliclazide, glipizide)	Take as normal	Once daily, omit a.m. Twice daily, omit a.m.	Once daily, omit a.m. Twice daily, omit a.m. and p.m.	Stop until eating and drinking normally
Pioglitazone	Take as normal	Take as normal	Take as normal	Stop until eating and drinking normally
DPP-4 inhibitor (e.g. sitagliptin, vildagliptin, saxagliptin, alogliptin, linagliptin)	Take as normal	Take as normal	Take as normal	Stop until eating and drinking normally
GLP-1 receptor agonist (e.g. exenatide, liraglutide, lixisenatide)	Take as normal	Take as normal	Take as normal	Take as normal
SGLT-2 inhibitor (e.g. dapagliflozin, canagliflozin)	Take as normal	Omit on day of surgery	Omit on day of surgery	Stop until eating and drinking normally

Warn the patient that their blood glucose control may be erratic for a few days after the procedure.
[a]If the patient requires an ongoing VRIII then any long-acting background insulin should be continued but at 80% of the dose that the patient usually takes when they are well. Normal insulin doses should be recommenced when the patient is eating and drinking normally.
[b]If contrast medium is to be used and eGFR <60 mL/min/1.73 m^2, metformin should be omitted on the day of the procedure and for the following 48 h.
eGFR, estimated glomerular filtration rate; NBM, nil by mouth; VRIII, variable-rate intravenous insulin infusion.
Source: Dhatariya et al. 2015 [148].

then one should be *in situ* and the use of long-acting insulin should be continued to prevent rebound hyperglycemia when the intravenous insulin regimen is taken down [106]. During the entire inpatient admission, the patient's pressure areas, including their heels and feet, should be regularly inspected.

While in the operating theater and recovery

While the patient is in theater and in recovery, good glycemic control should be monitored and maintained and normal electrolyte concentration should also be maintained.

The use of multimodal analgesia with an appropriate antiemetic to permit an early return to a normal diet and the usual diabetes regimen is paramount, although the use of dexamethasone in this situation remains a matter for debate [137].

Postoperative period

There are several factors that influence glycemic control in the postoperative period, including a variation in nutritional intake, the discontinuation of the usual blood glucose-lowering medication, the decrease in physical activity, the increase in stress hormones, and the presence of infection or pain. It is therefore important that glycemic control is maintained in addition to fluid and electrolyte balance and that pain and postoperative nausea and vomiting are controlled.

Hospital discharge

Prior to hospital discharge, factors that are likely to delay discharge from hospital should have been identified in the preoperative stage and necessary arrangements should have been made to allow the patient to go back to their usual place of care when they are medically fit. The patient should be made aware that the metabolic and endocrine effects of surgery may last for several days because of ongoing changes in the amount that they eat, their activity levels, and the levels of stress hormones. The patient should be advised that their blood glucose management may need to change for some time postoperatively. The diabetes specialist team or the patient's usual provider of diabetes care should be involved in this discussion.

Emergency surgery

For patients requiring emergency surgery where preoperative glycemic optimization is not possible, then the use of a variable-rate intravenous insulin infusion is likely to be necessary, trying to maintain a blood glucose level between 6.0 and 10.0 mmol/L (108 and 180 mg/dL). This should be continued until the patient is eating and drinking normally. Some patients who are not known to have diabetes may develop transient hyperglycemia (so-called stress hyperglycemia) [8, 9]. These individuals should be treated just as aggressively as people known to have diabetes because

their risk of postoperative complications is far higher than in those who were previously known to have diabetes [31, 32].

Continuous subcutaneous insulin infusions (CSIIs; "pumps")

Manipulation of CSIIs depends on the length of surgery and the length of starvation. If the length of starvation is short, i.e. less and one missed meal, the pump therapy can usually be continued and the patient should remain on their basal rate until they are eating and drinking normally without giving themselves a bolus dose. Regular blood glucose testing is necessary. If, however, the starvation period is likely to be prolonged, then the pump should be discontinued and a variable-rate intravenous insulin infusion started.

If there is a period of post- or perioperative hypotension, then peripheral skin perfusion may be compromised, thus reducing the absorption of insulin given subcutaneously and may necessitate treatment with a variable-rate intravenous insulin infusion, especially if the patient is unable to self-manage.

If the insulin pump has been discontinued and replaced with a variable-rate intravenous insulin infusion, the insulin pump should be restarted once the patient is eating and drinking normally and the variable-rate intravenous insulin infusion should be discontinued 30 min after the first mealtime bolus.

Glucocorticoid use

The prevalence of steroid use in hospital inpatients may be in excess of 10% [138]. The use of steroid treatment in people with pre-existing diabetes is very likely to result in worsening glucose control, which may be termed steroid-induced hyperglycemia. This will warrant temporary additional, and more active, glycemic management. A rise in glucose level may occur in people without a known diagnosis of diabetes, and this may be termed steroid-induced diabetes. It may or may not resolve when the steroids are withdrawn. Short courses of steroids resulting in minimal periods of hyperglycemia may not warrant intervention, although higher dose steroids, for longer periods, may result in significant symptomatic hyperglycemia with the potential for acute complications [139]. Hence addressing the hyperglycemia may reduce these risks.

Steroid therapy: impact on blood glucose

Steroids may be administered by various regimens and at variable doses. A single daily dose of steroid (e.g. prednisolone/prednisone) in the morning is the commonest mode of administration. In susceptible patients, this will often result in a rise in blood glucose by late morning that continues through to the evening. Overnight, the blood glucose generally often falls back to baseline levels by the next morning. Therefore, treatment should be tailored to treating the hyperglycemia, while avoiding nocturnal and early morning hypoglycemia.

Multiple daily doses of steroid, be it intravenous hydrocortisone or oral dexamethasone, can cause a hyperglycemic effect throughout the 24-h period. It may be, however, that a twice-daily premixed or basal bolus regimen may need to be started if oral medication or once-daily insulin proves insufficient to control hyperglycemia. Close attention will therefore need to be paid to blood glucose monitoring and early intervention may be necessary.

Glucose levels in most individuals can be predicted to rise ~4–8 h following the administration of oral steroids, and sooner following the administration of intravenous steroids. Again, capillary blood glucose monitoring is paramount to guide appropriate therapeutic interventions. Conversely, glucose levels may improve to presteroid levels 24 h after intravenous steroids have been discontinued. If oral steroids are weaned down over several weeks, the glucose levels may decline in a dose-dependent fashion, but this may not occur, particularly in those with pre-existing undiagnosed diabetes.

Monitoring

At the commencement of steroid therapy, or for those already on a supraphysiological dose of corticosteroid, capillary blood glucose (CBG) testing should be initiated once daily, perhaps most appropriately prior to or following lunch or the evening meal, when the hyperglycemic effects of a morning dose of steroid is likely to be greatest.

Medication options for people taking once-daily steroid therapy

Non-insulin therapies

Given their mode of action, a short-acting sulfonylurea taken once daily may best manage the glucose excursion associated with a once-daily oral steroid. While monitoring for hypoglycemia, the dose of sulfonylurea may be maximally titrated in the morning. Intuitively, pioglitazone may seem an appropriate choice for the management of steroid-induced hyperglycemia; however, the evidence base for its use is weak [140]. There is currently no evidence to support the use of GLP-1 receptor agonists, DPP-4 inhibitors, or SGLT-2 inhibitors; however, their mode of action may suggest that they would be beneficial in this circumstance.

Insulin therapies

Morning administration of basal human insulin may closely fit the glucose excursion induced by a single morning dose of oral steroid. Basal insulin analogs may be appropriate if hyperglycemia is present for more prolonged periods. However, care should be taken to identify and protect against hypoglycemia overnight and in the early morning if long-acting insulin analogs are used in this context.

Medication options for people taking multiple daily doses of steroid

Non-insulin therapies

Multiple doses of oral or intravenous steroid in at-risk individuals will most likely result in hyperglycemia throughout the day and

night. Administrations of oral hypoglycemic agents are unlikely to be effective in controlling the resultant hyperglycemia. A trial of twice-daily low-dose, short-acting sulfonylurea may be indicated, then with titration as needed. Metformin and pioglitazone are unlikely to be of significant benefit and there is currently no evidence to support the use of other classes of agent.

Insulin therapies

It is likely that subcutaneous insulin using a basal or multiple daily injection regimen will be the most appropriate choice to achieve glycemic control in the event of hyperglycemia for the majority of patients.

Hospital discharge

When a patient is discharged from hospital on steroid therapy, a clear strategy for the management of hyperglycemia or potential hyperglycemia, and the titration of therapy to address the hyperglycemia, should be communicated to the community diabetes team and primary care team. Patients commenced on steroids as an inpatient and discharged after a short stay with the intention of continuing high-dose steroids should receive standard education with regard to diabetes, encompassing the risks associated with hyper- and hypoglycemia.

If steroids are discontinued prior to discharge, and hyperglycemia persists, then CBG testing should be continued on discharge until normoglycemia returns or until a definitive test for diabetes is undertaken (fasting glucose, oral glucose tolerance test, or HbA_{1c}).

If steroid treatment is ceased in hospital and CBG tests are in the normal range, then post-discharge testing is not recommended. A definitive test for diabetes should still be undertaken.

Steroid treatment in end-of-life care

People with diabetes at the end stages of life have a unique set of clinical needs (Chapter 63). Steroid therapy is frequently used in palliative care for symptom control, usually as dexamethasone or prednisolone/prednisone. The hyperglycemia associated with once-daily steroid therapy can often be managed by morning administration of a long-acting sulfonylurea, or morning isophane insulin. However, if steroids are to be given twice daily, it is probable that an alternative approach will be needed. Twice-daily short-acting sulfonylurea or isophane insulin can be effective, but there is a risk of early morning hypoglycemia.

If hypoglycemia is a concern, a once-daily long-acting insulin analog given in the morning may be a safer, less complex regimen, especially for those new to insulin.

Short-term courses (<3 days) of steroids may only require closer CBG testing, but longer courses will require a review of glucose-lowering therapy and may result in a switch from oral agents to insulin. In the latter situation, an isophane insulin given once daily could be considered. In those without a diagnosis of diabetes prior to the commencement of steroids, then CBG testing and patient and carer education should be undertaken.

Blood glucose targets at the end of life may differ from those traditionally given. Glucose levels should be targeted between 6.0 and 15.0 mmol/L (108 and 270 mg/dL), although targets should be individualized.

Foot care

The "diabetic foot" remains the commonest cause for a diabetes-specific acute hospital admission [141], and it has been estimated that that ~£1 in every £150 spent by the NHS in England each year is on diabetes-related foot disease [142], and much of this on in-hospital care (Chapter 48).

It has been well recognized that the presence of a multidisciplinary foot team leads to better outcomes [143]. This should include a specialist podiatrist, diabetologist, vascular and orthopedic surgeon, interventional radiologist, tissue viability nurse, microbiologist, DSN/CDE, and orthotist [144, 145]. Specialist diabetes podiatrists provide the best value when considering admission avoidance, reducing length of hospital stay, and reducing amputation rates [146, 147].

The general principles for foot care in people with diabetes should apply to all admissions, not just those with active foot disease. These measures include taking a specific foot history and an inspection of the feet, looking for evidence of neuropathy, ischemia, ulceration, inflammation, and/or infection, deformity, or Charcot neuroarthropathy. It is important to take the shoes, socks, and any dressings off the feet to inspect any underlying wounds, ensuring that pressure areas are healthy. The feet should be inspected daily during the inpatient stay and new problems that are identified should be managed in conjunction with the specialist diabetic foot multidisciplinary team.

Conclusions

People with diabetes are twice as likely to be admitted to hospital and stay twice as long as those without diabetes. They have worse outcomes and a poorer patient experience than those without diabetes. Given the large numbers of inpatients with diabetes, and the considerable excess costs associated with their care, diabetes inpatient care is now being taken more seriously. However, although there is now a wealth of evidence that specialist inpatient diabetes teams reduce length of stay, reduce errors in prescribing, and improve the patient experience and clinical outcomes, many institutions across the world still lack inpatient specialist teams.

There are now a large number of national and international guidelines available that should make the care of inpatients with diabetes easier to achieve. There remains a lot of work to be done to provide more evidence to substantiate the consensus opinions in many of the guidelines, but as more evidence accrues to show which interventions work, so the excess morbidity and mortality seen in this cohort of patients should reduce to equal those of individuals without diabetes.

Until more evidence is available, it remains incumbent on those delivering the care to ensure that an attitude of nihilism is avoided—"the absence of evidence does not mean the absence of effect." All attempts should be made to achieve suitable glycemic control, avoiding symptomatic hyperglycemia or debilitating hypoglycemia.

35 Hypoglycemia in Diabetes

Philip E. Cryer[1] and Ana María Arbeláez[2]

[1] Division of Endocrinology, Metabolism and Lipid Research, Department of Medicine, Washington University School of Medicine in St. Louis, St. Louis, MO, USA

[2] Division of Endocrinology and Diabetes, Department of Pediatrics, Washington University School of Medicine in St. Louis, St. Louis, MO, USA

Key points

- Iatrogenic hypoglycemia is the limiting factor in the glycemic management of diabetes. It occurs during treatment with a sulfonylurea, a glinide, or insulin.
- The key physiological defenses against falling plasma glucose concentrations are decrements in insulin and increments in glucagon and epinephrine. The behavioral defense is carbohydrate ingestion prompted by symptoms that are largely the result of sympathetic neural activation.
- Hypoglycemia in diabetes is the result of therapeutic hyperinsulinemia. As glucose levels fall, decrements in insulin and increments in glucagon are lost, because of β-cell failure, in type 1 diabetes mellitus (T1DM) and advanced type 2 diabetes mellitus (T2DM). In that setting, attenuated increments in epinephrine cause the syndrome of defective glucose counter-regulation. Attenuated increments in sympathetic neural activity largely bring about the syndrome of hypoglycemia unawareness.
- The concept of hypoglycemia-associated autonomic failure (HAAF) in diabetes posits that recent antecedent hypoglycemia, and also prior exercise or sleep, cause both defective glucose counter-regulation and hypoglycemia unawareness by attenuating the sympathoadrenal response to subsequent hypoglycemia.
- Hypoglycemia unawareness and, in part, the reduced epinephrine component of defective glucose counter-regulation are reversible in 2–3 weeks with scrupulous avoidance of hypoglycemia in most affected individuals.
- The risk factors for hypoglycemia, based on this pathophysiology, include both relative and absolute therapeutic insulin excess and factors indicative of HAAF, which include absolute endogenous insulin deficiency, a history of severe hypoglycemia, hypoglycemia unawareness, or both, in addition to prior exercise or sleep, and aggressive glycemic therapy per se.
- This pathophysiology explains why the incidence of iatrogenic hypoglycemia increases over time in T2DM, approaching that in T1DM. Most episodes of hypoglycemia occur in people with T2DM.
- Minimizing the risk of iatrogenic hypoglycemia requires acknowledging the problem, applying the principles of aggressive glycemic therapy, and considering the risk factors for relative and absolute therapeutic insulin excess and for HAAF.
- A reasonable individualized glycemic goal is the lowest HbA_{1c} that does not cause severe hypoglycemia and preserves awareness of hypoglycemia, preferably with little or no symptomatic or even asymptomatic hypoglycemia, at a given stage in the evolution of the individual's diabetes.
- Maintenance of the greatest degree of glycemic control that can be accomplished safely in a given patient at a given stage of that individual's diabetes is in the person's best interest. Concerns about hypoglycemia should not be an excuse for poor glycemic control.

Overview of the clinical problem

Iatrogenic hypoglycemia is the limiting factor in the glycemic management of diabetes [1, 2]. It causes recurrent morbidity in most people with type 1 diabetes mellitus (T1DM) and many with advanced type 2 diabetes mellitus (T2DM), and is sometimes fatal. It compromises physiological and behavioral defenses against subsequent falling plasma glucose concentrations and thus causes a vicious cycle of recurrent hypoglycemia. It precludes maintenance of euglycemia over a lifetime of diabetes and thus full realization of the vascular benefits of glycemic control.

Hypoglycemia in diabetes is fundamentally iatrogenic, the result of pharmacokinetically imperfect treatments with an insulin secretagogue (e.g. a sulfonylurea or a glinide) or with exogenous insulin that results in episodes of hyperinsulinemia. Nonetheless, hypoglycemia is typically the result of the interplay of relative or absolute therapeutic insulin excess and compromised physiological and behavioral defenses against falling plasma glucose concentrations [1, 2].

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

The problem of hypoglycemia in diabetes has been summarized [1] and reviewed in detail [2]. Our premise is that understanding of the pathophysiology of glucose counter-regulation, the mechanisms that normally prevent or rapidly correct hypoglycemia, leads to insight into the frequency of, risk factors for, and prevention of iatrogenic hypoglycemia. Therefore, the physiology of glucose counter-regulation and its pathophysiology in diabetes are addressed first, followed by a summary of the magnitude of the clinical problem. With that background, a clinical approach to the prevention of iatrogenic hypoglycemia, and if necessary its treatment, is discussed.

Physiology of glucose counter-regulation

Hypoglycemia and the brain

Glucose is an obligate oxidative fuel for the brain under physiological conditions [1–4]. The brain accounts for 20% of whole-body glucose utilization. Because it cannot synthesize glucose, utilize physiological concentrations of circulating non-glucose fuels effectively, or store more than a few minutes' supply as glycogen [1, 2], the brain requires a virtually continuous supply of glucose from the circulation. Because facilitated blood–brain glucose transport is a direct function of the arterial plasma glucose concentration, that requires maintenance of the physiological plasma glucose concentration. Hypoglycemia causes functional brain failure, which is typically reversed after the plasma glucose concentration is raised [4]. Rarely, hypoglycemia causes death [4].

Responses to hypoglycemia

Falling plasma glucose concentrations cause a sequence of responses in individuals without diabetes (Table 35.1) [1, 5–8]. The first physiological response, which occurs as plasma glucose concentrations decline within the postabsorptive plasma glucose concentration range, is a decrease in insulin secretion. The secretion of glucose counter-regulatory (plasma glucose-raising) hormones, including glucagon and epinephrine, increases as plasma glucose concentrations fall just below the physiological range. Lower plasma glucose levels cause a more intense sympathoadrenal, both sympathetic neural and adrenomedullary, response and symptoms. Even lower plasma glucose concentrations cause functional brain failure [4].

Clinical manifestations of hypoglycemia

The symptoms and signs of hypoglycemia are not specific [8, 9]. Thus, clinical hypoglycemia is most convincingly documented by Whipple's triad: symptoms, signs, or both, consistent with hypoglycemia; a low reliably measured plasma glucose concentration; and resolution of those symptoms and signs after the plasma glucose concentration is raised.

Neuroglycopenic symptoms, which are the result of brain glucose deprivation per se, include cognitive impairments, behavioral changes, and psychomotor abnormalities and, at lower plasma glucose concentrations, seizure and coma [1, 2, 4, 8, 9]. Neurogenic (or autonomic) symptoms, which are largely the result of the perception of physiological changes caused by the sympathoadrenal—particularly the sympathetic neural [9]—discharge triggered by hypoglycemia, include both adrenergic (e.g. palpitations, tremulousness, and anxiety/arousal) and cholinergic (e.g. sweating, hunger, and paresthesias) symptoms [8]. Central mechanisms may also be involved in some of the latter symptoms, such as hunger [10]. Awareness of hypoglycemia is largely the result of the perception of neurogenic symptoms [8].

Signs of hypoglycemia include pallor and diaphoresis, the result of adrenergic cutaneous vasoconstriction and cholinergic activation of sweat glands, respectively [1, 2]. Neuroglycopenic manifestations are often observable.

Table 35.1 Physiological responses to decreasing plasma glucose concentrations.

Response	Glycemic threshold[a] (mg/dL) [mmol/L])	Physiological effects	Role in prevention or correction of hypoglycemia (glucose counter-regulation)
↓ Insulin	80–85 [4.4–4.7]	↑ R_a (↓ R_d)	Primary glucose regulatory factor, first defense against hypoglycemia
↑ Glucagon	65–70 [3.6–3.9]	↑ R_a	Primary glucose counter-regulatory factor, second defense against hypoglycemia
↑ Epinephrine	65–70 [3.6–3.9]	↑ R_a, ↓ R_d	Involved, critical when glucagon is deficient, third defense against hypoglycemia
↑ Cortisol and growth hormone	65–70 [3.6–3.9]	↑ R_a, ↓ R_d	Involved but not critical
Symptoms	50–55 [2.8–3.1]	↑ Exogenous glucose	Prompt behavioral defense (food ingestion)
↓ Cognition	<50 [<2.8]	–	Compromises behavioral defense

[a] Arterialized venous, not venous, plasma glucose concentrations.
R_a, rate of glucose appearance, glucose production by the liver and kidneys; R_d, rate of glucose disappearance, glucose utilization by insulin-sensitive tissues such as skeletal muscle (no direct effect on central nervous system glucose utilization).

Maintenance of systemic glucose balance

Because obligatory glucose utilization, largely by the brain, is fixed and exogenous glucose delivery from ingested carbohydrates is intermittent, systemic glucose balance is maintained, and hypoglycemia (and also hyperglycemia) is prevented, by dynamic regulation of endogenous glucose production from the liver (and the kidneys) and of glucose utilization by non-neural tissues such as muscle [1, 11]. Although an array of hormones, neurotransmitters, and metabolic substrates are involved, endogenous glucose production and glucose utilization by non-neural tissues are regulated primarily by insulin (Figure 35.1; Table 35.1) [11].

The first physiological defense against hypoglycemia is a decrease in pancreatic islet β-cell insulin secretion. That occurs as plasma glucose concentrations decline within the physiological range (Table 35.1) and favors increased hepatic (and renal) glucose production with virtual cessation of glucose utilization by insulin-sensitive tissues such as muscle (Figure 35.1). The second physiological defense is an increase in pancreatic islet α-cell glucagon secretion. That occurs as plasma glucose concentrations fall just below the physiological range (Table 35.1) and stimulates hepatic glucose production (largely by stimulating glycogenolysis) (Figure 35.1). Increased glucagon secretion is signaled primarily by a decrease in intra-islet insulin, perhaps among other β-cell secretory products, in the setting of low glucose concentrations [1, 2, 12] and secondarily by increased autonomic nervous system—sympathetic, parasympathetic, and adrenomedullary—inputs [1, 2, 13]. The third physiological defense, which becomes critical when glucagon is deficient, is an increase in adrenomedullary epinephrine secretion [1, 2, 11]. That, too, occurs as plasma

glucose concentrations fall just below the physiological range (Table 35.1). It raises plasma glucose concentrations largely by β_2-adrenergic stimulation of hepatic (and renal) glucose production (Figure 35.1), but the glucose-raising actions of epinephrine also involve limitation of glucose clearance by insulin-sensitive tissues, mobilization of gluconeogenic substrates such as lactate and amino acids from muscle and glycerol from fat, and α_2-adrenergic limitation of insulin secretion [1, 2, 14]. Sympathoadrenal activity, including epinephrine secretion, is regulated in the brain [1, 2, 11]. Circulating epinephrine is almost exclusively derived from the adrenal medullae [9]; while circulating norepinephrine is largely derived from sympathetic nerves under resting and many stimulated (e.g. exercise) conditions, the plasma norepinephrine response to hypoglycemia is also largely adrenomedullary in origin [9].

If these physiological defenses fail to abort an episode of developing hypoglycemia, lower plasma glucose concentrations cause a more intense sympathoadrenal response that causes neurogenic symptoms (Figure 35.1) [1, 2, 11]. Those symptoms cause awareness of hypoglycemia that prompts the behavioral defense of ingestion of carbohydrates [1, 2, 11].

All of these defenses against hypoglycemia, not just insulin secretion, are typically compromised in people with T1DM and those with advanced (i.e. absolutely endogenous insulin-deficient) T2DM (Figure 35.1) [1, 2].

Pathophysiology of glucose counter-regulation in diabetes

Insulin excess

Although substantial insulin excess alone can cause hypoglycemia, the integrity of the defenses against falling plasma glucose concentrations determines whether a typical episode of therapeutic hyperinsulinemia results in clinical hypoglycemia [1, 2]. Thus, iatrogenic hypoglycemia is typically the result of the interplay of relative or absolute therapeutic hyperinsulinemia and compromised physiological and behavioral defenses against falling plasma glucose concentrations (Figure 35.1; Table 35.2) [1, 2, 15, 16].

Table 35.2 Responses to falling plasma glucose concentrations in humans.

Plasma glucose	Individuals	Plasma		
		Insulin	Glucagon	Epinephrine
↓	Non-diabetic	↓	↑	↑
↓	T1DM[a]	No ↓	No ↑	Attenuated ↑
↓	Early T2DM	↓	↑	↑
↓	Late T2DM[a]	No ↓	No ↑	Attenuated ↑

[a]These alterations account for the appearance of defective glucose counter-regulation and hypoglycemia unawareness in T1DM and late T2DM.

Defective glucose counter-regulation and hypoglycemia unawareness

In fully developed (i.e. C-peptide-negative) T1DM, circulating insulin concentrations cannot decrease as plasma glucose concentrations fall in response to therapeutic (exogenous) hyperinsulinemia (Table 35.2) [1, 2, 15]. That is the result of β-cell failure, which also causes loss of the increase in circulating glucagon concentrations (Figure 35.2; Table 35.2) [1, 2, 12, 15]. The latter conclusion is based on the finding that indirect reciprocal β-cell-mediated signaling normally predominates over direct α-cell signaling in the regulation of glucagon secretion in humans [1, 2, 12]. Thus, the absence of a decrease in intra-islet insulin, perhaps among other β-cell secretory products, in concert with low glucose levels, plausibly explains loss of the glucagon response [1, 2, 12]. Therefore, both the first and second physiological defenses against hypoglycemia are lost. Furthermore, the increase in circulating epinephrine, the third physiological defense, is typically attenuated (Figure 35.2; Table 35.2) [1, 15]. In the setting of absent insulin and glucagon responses, the attenuated epinephrine response causes the clinical syndrome of defective glucose counter-regulation (Table 35.2) [1, 2, 15–18], which is associated with a 25-fold [18] or greater [17] increased risk of severe iatrogenic hypoglycemia in T1DM. In addition, the attenuated epinephrine response is a marker for an attenuated sympathoadrenal, including sympathetic neural, response (Table 35.2), which is largely responsible for reduced neurogenic symptom responses and therefore the clinical syndrome of hypoglycemia unawareness [1, 2, 9] which is associated with a sixfold increased risk of severe iatrogenic hypoglycemia in T1DM [19]. Attenuated sympathoadrenal responses to falling plasma glucose concentrations can be caused by recent antecedent hypoglycemia (Figures 35.3 and 35.4) [1, 2, 15, 16, 20], prior exercise [1, 2, 21–23], or sleep [1, 2, 24–26].

Although hypoglycemia unawareness is largely the result of reduced release of the neurotransmitters norepinephrine and acetylcholine [1, 9], there is evidence of decreased β-adrenergic sensitivity, specifically reduced cardiac chronotropic sensitivity to isoproterenol, in affected individuals [27, 28]. However, vascular sensitivity to β_2-adrenergic agonism was not found to be reduced in people with unawareness [29]; reduced sensitivity to β-adrenergic signaling of neurogenic symptoms remains to be demonstrated in those with unawareness, and it would be necessary to postulate decreased cholinergic sensitivity to explain reduced cholinergic symptoms such as sweating.

The pathophysiology of glucose counter-regulation is the same in T1DM and advanced (i.e. absolutely endogenous insulin-deficient) T2DM, albeit with different time courses (Table 35.2) [1, 2, 15, 16]. The pathogenesis of an episode of iatrogenic hypoglycemia involves therapeutic hyperinsulinemia resulting in falling plasma glucose concentrations and loss of the appropriate decrements in insulin and increments in glucagon. The hypoglycemia, in turn, reduces the sympathoadrenal responses to subsequent hypoglycemia. Because β-cell failure, which causes loss of both the insulin and glucagon responses [1, 2, 15, 16], occurs rapidly in T1DM but slowly in T2DM, the syndromes

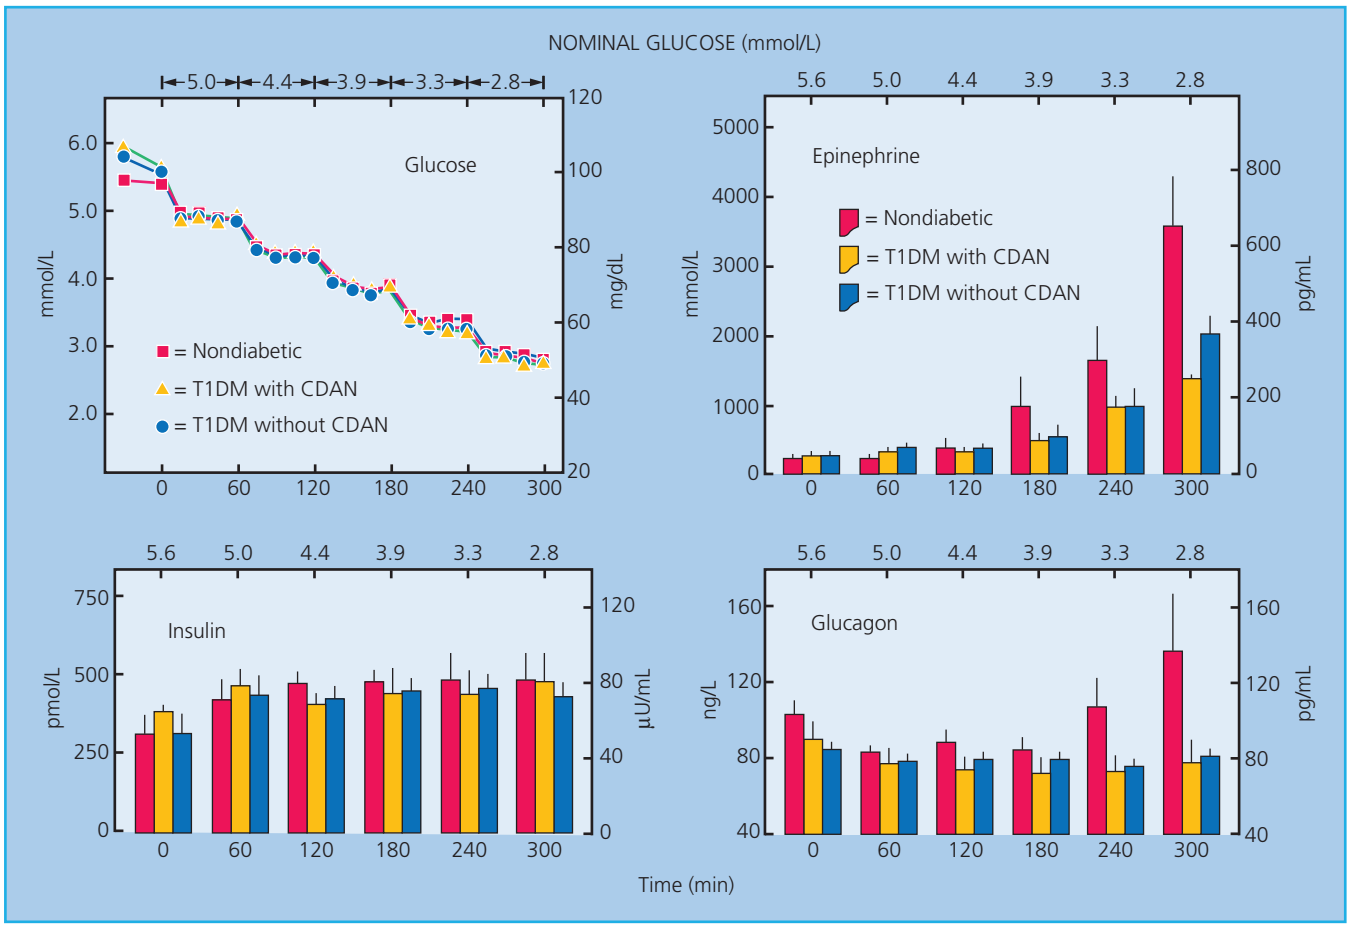

Figure 35.2 Mean (± SE) plasma glucose, insulin, epinephrine, and glucagon concentrations during hyperinsulinemic stepped hypoglycemic glucose clamps in individuals without diabetes (red squares and columns), people with type 1 diabetes (T1DM) with classic diabetic autonomic neuropathy (CDAN) (yellow triangles and columns), and people with type 1 diabetes without CDAN (blue circles and columns). Source: Dagogo-Jack et al. 1993 [15]. Reproduced with permission from the American Society for Clinical Investigation.

of defective glucose counter-regulation and hypoglycemia unawareness develop early in T1DM but later in T2DM. This temporal pattern of compromised glycemic defenses explains why iatrogenic hypoglycemia becomes progressively more frequent as individuals approach the insulin-deficient end of the spectrum of T2DM, as discussed later.

Hypoglycemia-associated autonomic failure

The concept of hypoglycemia-associated autonomic failure (HAAF) in diabetes posits that recent antecedent hypoglycemia (Figures 35.3 and 35.4) [1, 2, 15, 16, 20]—and also prior exercise [1, 2, 21–23] or sleep [1, 2, 24–26]—causes both defective glucose counter-regulation (by attenuating the epinephrine responses to subsequent hypoglycemia in the setting of absent decrements in insulin and absent increments in glucagon) and hypoglycemia unawareness (by attenuating the sympathoadrenal, including the sympathetic neural, and resulting neurogenic symptom responses to subsequent hypoglycemia). It therefore leads to a vicious cycle of recurrent iatrogenic hypoglycemia (Figure 35.5). Thus, HAAF is, at least in large part, a dynamic functional disorder that is distinct from classic diabetic autonomic neuropathy [1, 2]. Nonetheless, the key feature of HAAF, an attenuated sympathoadrenal response to a given level of hypoglycemia, is more prominent in people with diabetic autonomic neuropathy (Figure 35.2) [30, 31].

The clinical impact of HAAF is well established in T1DM [1, 2, 15, 32–37]. Recent antecedent hypoglycemia, even asymptomatic nocturnal hypoglycemia, reduces epinephrine, symptomatic, and cognitive dysfunction responses to a given level of subsequent hypoglycemia [36], reduces detection of hypoglycemia in the clinical setting [37], and reduces defense against hyperinsulinemia [15] in T1DM. Perhaps the most compelling support for the concept of HAAF is the finding, initially by three independent research teams [32–35], that as little as 2–3 weeks of scrupulous avoidance of hypoglycemia reverses hypoglycemia unawareness (Figure 35.6) and improves the attenuated epinephrine component of defective glucose counter-regulation in most affected individuals.

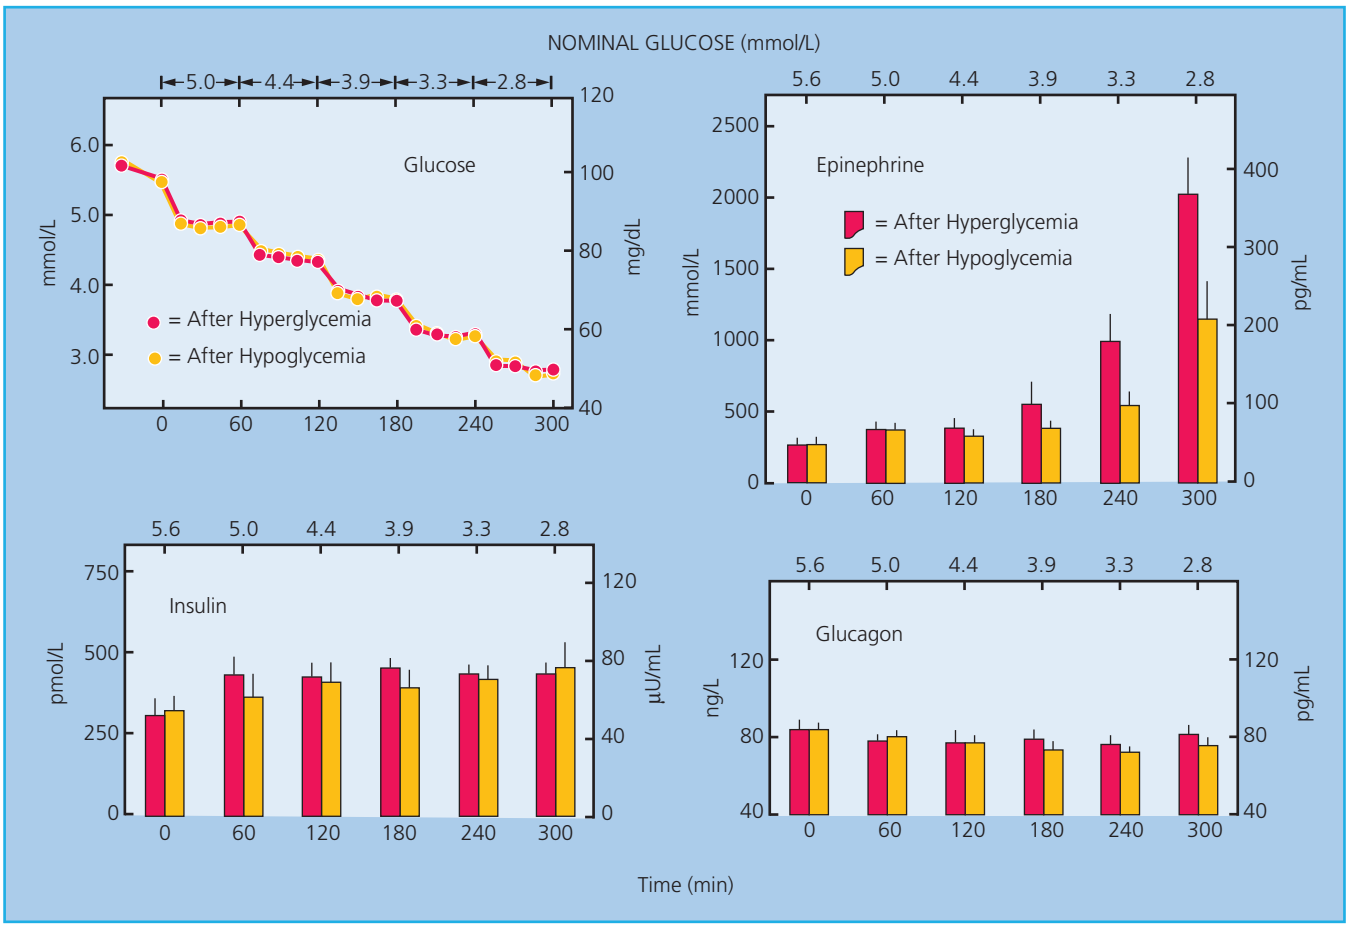

Figure 35.3 Mean (± SE) plasma glucose, insulin, epinephrine, and glucagon concentrations during hyperinsulinemic stepped hypoglycemic glucose clamps in people with type 1 diabetes without classic diabetic autonomic neuropathy on mornings following afternoon hyperglycemia (red circles and columns) and on mornings following afternoon hypoglycemia (yellow circles and columns). Figure 35.4 Mean (± SE) total, neurogenic, and neuroglycopenic symptom scores during hyperinsulinemic stepped hypoglycemic clamps in people with type 1 diabetes without classic diabetic autonomic neuropathy on mornings following afternoon hyperglycemia (red columns) and on mornings following afternoon hypoglycemia (yellow columns). Source: Dagogo-Jack et al. 1993 [15]. Reproduced with permission from the American Society for Clinical Investigation.

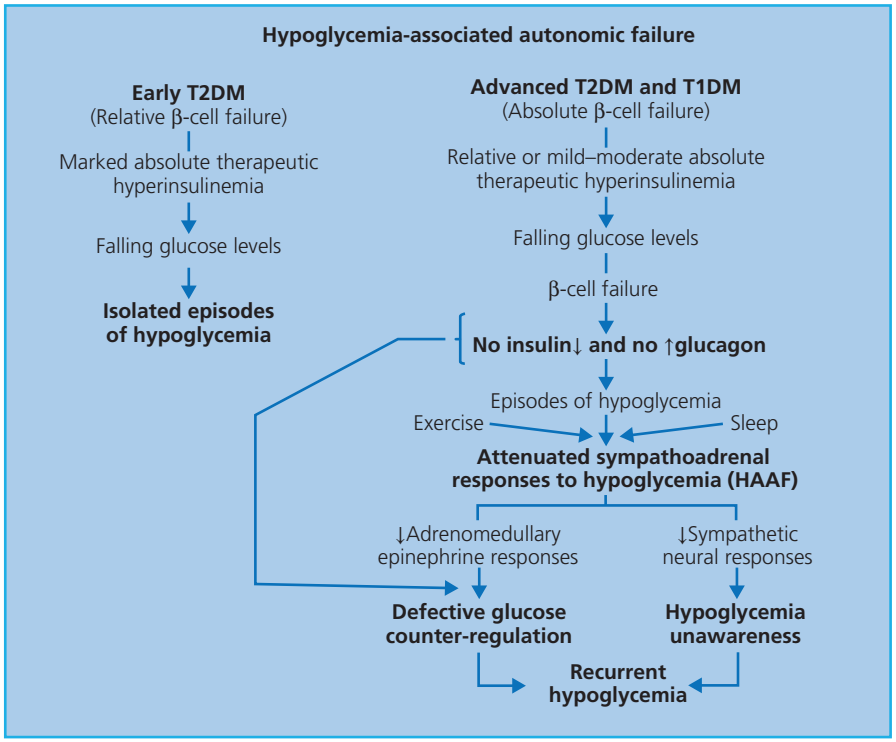

Figure 35.5 Hypoglycemia-associated autonomic failure (HAAF) in the pathogenesis of iatrogenic hypoglycemia in diabetes.

People with advanced T2DM are also at risk for HAAF [1, 2, 16]. Glucagon responses to hypoglycemia are lost [16], as they are in T1DM. Furthermore, the glycemic thresholds for sympathoadrenal and symptomatic (among other) responses to hypoglycemia are shifted to lower plasma glucose concentrations by recent antecedent hypoglycemia [16], as they are in T1DM.

The three recognized causes of HAAF each lead to attenuated sympathoadrenal and symptomatic (among other) responses to a given level of hypoglycemia [1, 2]. Antecedent hypoglycemia-related HAAF [1, 2, 15, 16, 20] led to the concept. Exercise-related HAAF [1, 2, 21–23] is exemplified by late post-exercise hypoglycemia, which typically occurs 6–15 h after strenuous exercise and is often nocturnal [38, 39]. Sleep-related HAAF [1, 2, 24–26] is the result of further attenuation of the sympathoadrenal response to hypoglycemia during sleep. Sleeping patients are therefore much less likely to be awakened by hypoglycemia than individuals without diabetes [24, 26]. There may well be additional, as yet unrecognized, functional, and therefore potentially reversible, causes of HAAF [1, 2]. In addition, there may be a structural component [1, 2].

The mechanisms of HAAF are summarized in Figure 35.7 [1, 2]. Loss of the insulin and glucagon responses to falling plasma glucose concentrations caused by therapeutic hyperinsulinemia is the result of β-cell failure in T1DM and advanced T2DM. Because normal insulin and glucagon responses to low glucose concentrations occur in people with a transplanted (i.e. denervated) pancreas [40] and in dogs with a denervated pancreas [41], and also from the perfused pancreas and perifused pancreatic islets innervation is not required [12].

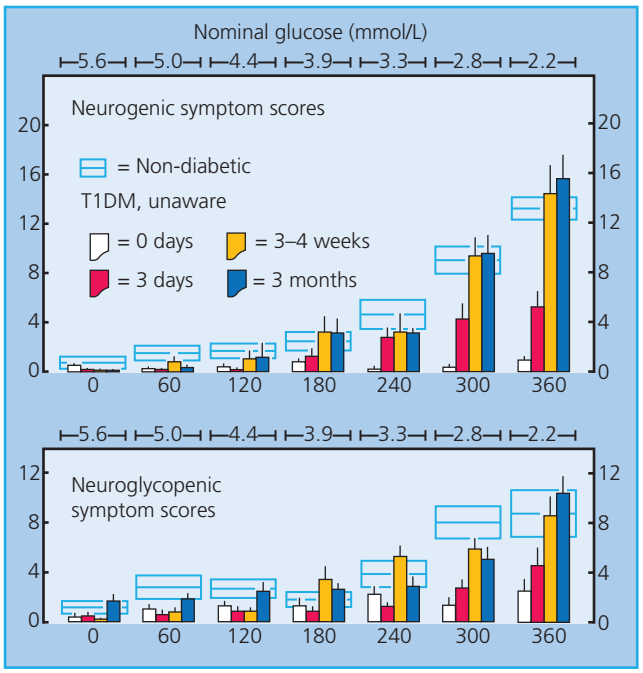

Figure 35.6 Mean (± SE) neurogenic and neuroglycopenic symptom scores during hyperinsulinemic stepped hypoglycemic clamps in individuals without diabetes (open rectangles) and in people with T1DM (columns) at baseline (0 days), after 3 days of inpatient strict avoidance of hypoglycemia, and after 3–4 weeks and 3 months of outpatient scrupulous avoidance of hypoglycemia. Figure 35.7 Pancreatic islet, hypothalamic and cerebral network mechanisms of hypoglycemia-associated autonomic failure (HAAF) in diabetes. Source: Cryer 2008 [1]. Reproduced with permission from the American Diabetes Association.

In the setting of absent insulin and glucagon responses to falling plasma glucose concentrations, attenuated sympathoadrenal responses cause both defective glucose counter-regulation and hypoglycemia unawareness, the two components of HAAF [1, 2]. The mechanism of the attenuated sympathoadrenal response is not known, but it must be at the level of the brain (or the afferent or efferent components of the sympathoadrenal system) (Figure 35.7). The proposed mechanisms include the systemic mediator, brain fuel transport, and brain metabolism hypotheses, all of which have been reviewed [1, 2, 12, 42, 43].

Much of the research into the pathogenesis of HAAF has focused on the hypothalamus, the central integrator of the sympathoadrenal responses to hypoglycemia [43]. While the primary alteration could reside in the hypothalamus, the changes in hypothalamic function could be secondary to those in other brain regions. For example, measurements of regional cerebral blood flow with [^{15}O]water and positron emission tomography (PET) [44] indicate that hypoglycemia activates widespread but interconnected brain regions, including the medial prefrontal cortex, the lateral orbitofrontal cortex, the thalamus, the globus pallidus, and the periaqueductal gray. These studies also show that recent antecedent hypoglycemia both reduces the sympathoadrenal and symptomatic responses (a model of HAAF) and causes a greater increase in synaptic activity in the dorsal midline thalamus during subsequent hypoglycemia [45]. Hence it has been suggested that there may be a cerebral network that results in thalamic inhibition of hypothalamic activity in HAAF (Figure 35.7) [45]. That suggestion is generically consistent with the findings of various patterns of [^{18}F]deoxyglucose uptake in people with T1DM with and without hypoglycemia unawareness [46].

Risk factors for hypoglycemia in diabetes

The risk factors for hypoglycemia in diabetes follow directly from the pathophysiology of glucose counter-regulation and are based on the principle that iatrogenic hypoglycemia is typically the result of the interplay of relative or absolute therapeutic insulin excess and compromised physiological and behavioral defenses against falling plasma glucose concentrations (i.e. HAAF) in T1DM and advanced T2DM [1, 2, 47].

Absolute or relative insulin excess

The conventional risk factors for hypoglycemia in diabetes are based on the premise that absolute or relative therapeutic insulin excess is the sole determinant of risk (Table 35.3) [1, 2, 47]. Absolute therapeutic insulin excess occurs when insulin secretagogue or insulin doses are excessive, ill-timed, or of the wrong type, or when insulin clearance is reduced as in renal failure. Relative therapeutic insulin excess occurs under a variety of conditions. It occurs when exogenous glucose delivery is decreased (as following missed or low-carbohydrate meals and during the overnight fast), when glucose utilization is increased (as during and shortly after exercise), when endogenous glucose production is decreased (as following alcohol ingestion), and when sensitivity to insulin is increased (as following weight loss or improved glycemic control and in the middle of the night). People with diabetes and their caregivers must consider each of these risk factors when the problem of iatrogenic hypoglycemia is recognized. Overall, however, they explain only a minority of episodes of hypoglycemia [48].

Table 35.3 Risk factors for hypoglycemia in diabetes.

Relative or absolute insulin excess

1. Insulin or insulin secretagogue doses are excessive, ill-timed, or of the wrong type
2. Exogenous glucose delivery is decreased (e.g. following missed meals and during the overnight fast)
3. Glucose utilization is increased (e.g. during and shortly after exercise)
4. Endogenous glucose production is decreased (e.g. following alcohol ingestion)
5. Sensitivity to insulin is increased (e.g. in the middle of the night and following weight loss or improved glycemic control)
6. Insulin clearance is decreased (e.g. with renal failure)

Hypoglycemia-associated autonomic failure

1. Absolute endogenous insulin deficiency
2. A history of severe hypoglycemia, hypoglycemia unawareness, or both, and also recent antecedent hypoglycemia, prior exercise, and sleep
3. Aggressive glycemic therapy per se (lower HbA_{1c} levels, lower glycemic goals)

Compromised defenses against hypoglycemia

The risk factors indicative of HAAF (Table 35.3) [1, 2, 47, 49–55] include absolute endogenous insulin deficiency [1, 2, 47, 49–51, 53, 54], a history of severe iatrogenic hypoglycemia, hypoglycemia unawareness, or both, and also recent antecedent hypoglycemia, prior exercise or sleep [1, 2, 47, 49, 50, 53, 55], and aggressive glycemic therapy per se (i.e. lower HbA_{1c} levels, lower glycemic goals, or both) [1, 2, 47, 49, 50, 52–55]. The degree of endogenous insulin deficiency (i.e. β-cell failure) determines the extent to which insulin levels will not decrease and glucagon levels will not increase as plasma glucose concentrations fall in response to therapeutic hyperinsulinemia. A history of severe hypoglycemia indicates, and that of hypoglycemia unawareness implies, recent antecedent hypoglycemia. The latter causes attenuated sympathoadrenal and symptomatic responses to subsequent hypoglycemia, the key feature of HAAF. In addition, prior exercise and sleep cause that feature of HAAF. Studies of intensive glycemic therapy with a control group treated to a higher HbA_{1c} level consistently report higher rates of hypoglycemia in the group treated to lower HbA_{1c} levels in T1DM [56–58] and T2DM [55, 59, 60]. That does not mean that one cannot both improve glycemic control and minimize the risk of hypoglycemia [1, 2, 47], as discussed below.

Magnitude of the clinical problem of hypoglycemia in diabetes

Diabetes is an increasingly common disease. It has been estimated that its prevalence will rise from 415 million people worldwide in 2015 to 642 million people by 2040 [61]. Iatrogenic hypoglycemia affects most of the minority with T1DM and many of the majority with T2DM [1, 2]. Indeed, because it precludes maintenance of euglycemia over a lifetime of diabetes, the barrier of hypoglycemia ultimately affects virtually all people with diabetes [1, 2].

Frequency of hypoglycemia

Hypoglycemia is a fact of life for people with T1DM (Table 35.4) [1, 2, 49, 52, 62]. The average person has untold numbers of episodes of asymptomatic hypoglycemia and experiences two episodes of symptomatic hypoglycemia per week—thousands of such episodes over a lifetime of diabetes—and one or more episodes of severe, temporarily disabling hypoglycemia, often with seizure or coma, per year. There is little evidence that this problem has abated since it was highlighted by the report of the Diabetes Control and Complications Trial (DCCT) in 1993 [56]. For example, in 2007 the UK Hypoglycaemia Study Group [62] reported an incidence of severe hypoglycemia that was twice that in the DCCT in people with T1DM for <5 years and an incidence fivefold higher than that in the DCCT in those with T1DM for >15 years (Table 35.4). An incidence comparable to the latter was also found in a large observational study [52].

Overall, hypoglycemia is less frequent in T2DM (Table 35.4) [1, 2, 52, 55, 58, 62–77], but for the pathophysiological reasons discussed, hypoglycemia becomes progressively more frequent as people approach the insulin-deficient end of the spectrum of T2DM [1, 2, 62, 70]. Indeed, its frequency has been reported to be similar in those with T2DM and T1DM matched for duration of insulin therapy [70]. When the UK Hypoglycaemia Study Group [62] contrasted people with T2DM treated with insulin for <2 years with those treated with insulin for >5 years, they found severe hypoglycemia prevalences of 7% and 25% and incidences of 10 and 70 episodes per 100 patient-years, respectively. The pattern for self-treated hypoglycemia was similar [62]. Thus, although the incidence of iatrogenic hypoglycemia is relatively low (with current less than euglycemic goals) in the first few years of insulin treatment of T2DM, the risk increases substantially, approaching that in T1DM, in advanced of T2DM.

Because asymptomatic episodes will almost invariably be missed, and symptomatic episodes may not be recognized as the result of hypoglycemia [78] and, even if they are, they are not long remembered [79, 80], estimates of the frequency of iatrogenic hypoglycemia are underestimates. Although they represent only a small fraction of the total hypoglycemic experience, because they are dramatic events that are more likely to be reported (by the patient or an associate) [79, 80], estimates of the frequency of severe hypoglycemia, requiring the assistance of another person, are more reliable, particularly if they are determined in population-based prospective studies that include a focus on hypoglycemia [1, 2].

The prospective population-based data of Donnelly et al. [67] indicate that the overall incidence of hypoglycemia in insulin treated T2DM is approximately one-third of that in T1DM (Table 35.4). The incidence of any and of severe hypoglycemia was ~4300 and 115 episodes per 100 patient-years, respectively, in

Table 35.4 Event rates for severe hypoglycemia (that requiring the assistance of another person), expressed as episodes per 100 patient-years, in insulin-treated diabetes.

T1DM and ~1600 and 35 episodes per 100 patient-years, respectively, in insulin-treated T2DM. In addition, in population-based studies, the incidence of severe hypoglycemia requiring emergency treatment in insulin-treated T2DM was ~40% [71] and ~100% [72] of that in T1DM. Because the prevalence of T2DM is ~20-fold greater than that of T1DM, and most people with T2DM ultimately require treatment with insulin, these data suggest that most episodes of iatrogenic hypoglycemia, including severe hypoglycemia, occur in people with T2DM.

Impact of hypoglycemia

Iatrogenic hypoglycemia causes recurrent physical and psychological morbidity, and some mortality, impairs defenses against subsequent hypoglycemia, and precludes maintenance of euglycemia over a lifetime of diabetes [1, 2]. In the short term, it causes brain fuel deprivation that, if unchecked, results in functional brain failure that is typically corrected after the plasma glucose concentration is raised [4]. Rarely, it causes sudden, presumably cardiac arrhythmic [81, 82], death or, if it is profound and prolonged, brain death [4].

The physical morbidity of an episode of hypoglycemia ranges from unpleasant symptoms to seizure and coma [1, 2, 4]. It can impair judgment, behavior, and performance of physical tasks. Permanent neurological damage is rare. Although there is concern that recurrent hypoglycemia might cause chronic cognitive impairment, long-term follow-up of the participants in the DCCT is reassuring in that regard [83]. Nonetheless, the possibility that it does so in young children remains [84, 85], and there are few corresponding data in the elderly [83]. The psychological morbidity includes fear of hypoglycemia [86], which can be a barrier to glycemic control.

Three early reports indicated that 2–4% of people with diabetes die from hypoglycemia [87–89]. More recent reports indicated that 6% [83], 7% [90], and 10% [91] of deaths of people with T1DM were the result of hypoglycemia. In T2DM, mortality rates of up to 10% during episodes of severe sulfonylurea-induced hypoglycemia have been reported [92]. In one trial of T2DM, between 1 and 9% of evaluable deaths were attributed to hypoglycemia [93].

Excessive mortality during intensive glycemic therapy with increased rates of hypoglycemia was found in randomized controlled trials in patients in the intensive care unit (ICU) [94] and in people with T2DM [59]. Although that might have been the result of some non-glycemic effect of the intensive therapy regimens in the people with T2DM, none was found and the regimens themselves (in contrast to the glycemic targets) were

Table 35.5 American Diabetes Association Workgroup on Hypoglycemia classification of hypoglycemia in people with diabetes [98].

Classification	Definition
Severe hypoglycemia	An event requiring the assistance of another person to administer actively carbohydrate, glucagon, or other resuscitative actions. Plasma glucose measurements may not be available during such an event, but neurological recovery attributable to the restoration of plasma glucose to normal is considered sufficient evidence that the event was induced by a low plasma glucose concentration
Documented symptomatic hypoglycemia	An event during which typical symptoms of hypoglycemia are accompanied by a measured plasma glucose concentrations ≤70 mg/dL (3.9 mmol/L)
Asymptomatic hypoglycemia	An event not accompanied by typical symptoms of hypoglycemia but with a measured plasma glucose concentration ≤70 mg/dL (3.9 mmol/L)
Probable symptomatic hypoglycemia	An event during which symptoms typical of hypoglycemia are not accompanied by a plasma glucose determination but that was presumably caused by a plasma glucose concentration ≤70 mg/dL (3.9 mmol/L)
Relative hypoglycemia	An event during which the person with diabetes reports any of the typical symptoms of hypoglycemia, and interprets those as indicative of hypoglycemia, with a measured plasma glucose concentration >70 mg/dL (3.9 mmol/L) but approaching that level

the same in the intensive and the standard care groups in the patients in the ICU. The fact that increased mortality was consistently associated with severe hypoglycemia in six randomized controlled trials, two in patients in the ICU [94, 95] and four in people with T2DM [59, 60, 96, 97], reduces the probability that these associations were the result of chance.

Clinical definition and classification of hypoglycemia

The American Diabetes Association (ADA) and ADA/Endocrine Society Workgroups on Hypoglycemia [98, 99] defined hypoglycemia in diabetes as "all episodes of abnormally low plasma glucose concentration that expose the individual to potential harm." It is not possible to state a specific plasma glucose concentration that defines clinical hypoglycemia. Although symptoms typically develop at plasma glucose concentrations of ~50–55 mg/dL (2.8–3.1 mmol/L) (Table 35.1) [11] in individuals without diabetes, the glycemic threshold for symptoms (and also those for glucose counter-regulatory and cognitive dysfunction responses) shift to lower plasma glucose concentrations in people with tightly controlled diabetes and recurrent hypoglycemia [100, 101] and to higher plasma glucose concentrations in those with poorly controlled diabetes [100–102].

The Workgroups recommended that people with drug-treated diabetes (implicitly those treated with an insulin secretagogue or insulin) become concerned about the possibility of developing hypoglycemia at a plasma glucose concentration of ≤70 mg/dL (3.9 mmol/L) [98, 99]. Within the error of self-monitoring of blood glucose (or continuous glucose sensing), that conservative alert value approximates the lower limit of the non-diabetic post-absorptive plasma glucose concentration range [11] and the normal glycemic thresholds for activation of physiological glucose counter-regulatory systems [11], and is low enough to reduce glycemic defenses against subsequent hypoglycemia [103] in individuals without diabetes. Indeed, impairment of a complex function, driving, has been demonstrated at plasma glucose levels in this general range in T1DM [104]. It also generally provides some margin for the relative inaccuracy of glucose monitors at low plasma glucose concentrations. The ADA/Endocrine Society Workgroup also recommended a clinical classification of hypoglycemia (Table 35.5) [98, 99].

Prevention and treatment of hypoglycemia in diabetes

Prevention of hypoglycemia: hypoglycemia risk factor reduction

Iatrogenic hypoglycemia is a barrier to glycemic control in people with diabetes [1, 2], but that barrier can be lowered in individuals with diabetes by the practice of hypoglycemia risk factor reduction (Table 35.6) [1, 2, 47]. That involves four steps:

1 Acknowledge the problem.

2 Apply the principles of aggressive glycemic therapy [1, 2, 47, 105–109].

3 Consider the conventional risk factors for hypoglycemia (Table 35.3).

4 Consider the risk factors for hypoglycemia-associated autonomic failure (HAAF) in diabetes (Table 35.3).

Table 35.6 Hypoglycemic risk factor reduction.

1 Acknowledge the problem
2 Apply the principles of aggressive glycemic therapy
- Diabetes self-management (patient education and empowerment)
- Frequent self-monitoring of blood glucose (and in some instances continuous glucose sensing)
- Flexible and appropriate insulin (and other drug) regimens
- Individualized glycemic goals
- Ongoing professional guidance and support

3 Consider the conventional risk factors for hypoglycemia (Table 35.3)
4 Consider the risk factors indicative of hypoglycemia-associated autonomic failure (Table 35.3)

The issue of hypoglycemia should be addressed in every contact with people with diabetes, at least those treated with a sulfonylurea, a glinide, or insulin [1, 2, 47]. Acknowledging the problem allows the caregiver either to move on if hypoglycemia is not an issue or to address it, and keep it in perspective, if hypoglycemia is an issue. Patient concerns about the reality, or even the possibility, of hypoglycemia can be a barrier to glycemic control [110, 111]. It is often helpful also to question close associates of the patient because they may have observed clues to episodes of hypoglycemia not recognized by the person with diabetes. Even if no concerns are expressed, examination of the self-monitoring of blood glucose records (or continuous glucose monitoring data) will often disclose that hypoglycemia is a problem.

If hypoglycemia is an issue, the principles of aggressive glycemic therapy in diabetes [1, 2, 47, 105–109] should be reviewed and applied. These include diabetes self-management based on patient education and empowerment, frequent self-monitoring of blood glucose (and in some instances continuous glucose monitoring), flexible and appropriate insulin (and other drug) regimens, individualized glycemic goals, and ongoing professional guidance and support (Table 35.6).

Patient education and empowerment are fundamentally important. As the therapeutic regimen becomes progressively more complex—early in T1DM and later in T2DM—the success of glycemic management becomes progressively more dependent on the many management decisions and skills of the well-informed person with diabetes. In addition to basic training about diabetes, people with insulin secretagogue or insulin-treated diabetes need to be taught about hypoglycemia [112]. They need to know the common symptoms of hypoglycemia, and their individual most meaningful symptoms, and how to treat (and not overtreat) an episode. Close associates also need to be taught the symptoms and signs of hypoglycemia, and when and how to administer glucagon. Patients need to understand the relevant conventional risk factors for hypoglycemia (Table 35.3), including the effects of the dose and timing of their individual secretagogue or insulin preparation(s) and also the effects of missed meals and the overnight fast, exercise, and alcohol ingestion. They also need to know that episodes of hypoglycemia signal an increased likelihood of future, often more severe, hypoglycemia [49, 50, 53, 55, 112–115]. Finally, patients using an online glucose monitor need to apply those data critically to their attempts to minimize both hypoglycemia and hyperglycemia.

The core approach to virtually all patients in whom iatrogenic hypoglycemia becomes a problem is structured patient education (or often re-education), which has been shown to reduce rates of severe hypoglycemia [116–120], typically coupled with short-term scrupulous avoidance of hypoglycemia, which has been shown to reverse hypoglycemia unawareness in most affected patients [32–35]. The therapeutic objective is to minimize the number and the magnitude of episodes of hypoglycemia, not to promote hyperglycemia. Indeed, it is often possible to lower HbA_{1c} levels.

In people treated with an insulin secretagogue, and particularly those treated with insulin, frequent self-monitoring of blood glucose becomes progressively more key to diabetes self-management as the therapeutic regimen becomes more complex, early in T1DM and later in T2DM. Ideally, patients should estimate their glucose levels whenever they suspect hypoglycemia. That would not only confirm or deny an episode of hypoglycemia, it would also help the individual learn the key symptoms of their hypoglycemic episodes and might lead to regimen adjustments. It is particularly important for people with hypoglycemia unawareness to monitor their glucose level before performing a critical task such as driving. Self-monitoring of blood glucose provides a glucose estimate only at one point in time; it does not indicate whether glucose levels are falling, stable, or rising. That limitation is addressed by evolving technologies for real-time continuous glucose monitoring (CGM) [121–123]. Subcutaneous glucose concentrations lag changes in plasma glucose by 10–15 min and their measurement suffers from some inaccuracy. Nonetheless, CGM has been found to be associated with an HbA_{1c} reduction of 0.4–0.6% in adults with T1DM who generally actually used the device without an increase in detected hypoglycemia [121]. However, in one study, the sensitivity and specificity for the detection of low glucose levels were only 65% and 80%, respectively, and both false-negative and false-positive results were common [123].

Flexible and appropriate drug regimens are key components of hypoglycemia risk factor reduction [1, 2, 47]. Hypoglycemia is typically the result of relative or absolute therapeutic (endogenous or exogenous) insulin excess and compromised defenses against falling plasma glucose concentrations. The relevant treatments include insulin or an insulin secretagogue such as a sulfonylurea (e.g. glibenclamide [glyburide], glipizide, glimepiride, and gliclazide) or a glinide (e.g. repaglinide and nateglinide). Early in the course of T2DM, people may respond to drugs that do not raise insulin levels at low or normal plasma glucose concentrations and therefore should not, and probably do not, cause hypoglycemia [1, 2]. Those include the biguanide metformin, which nonetheless has been reported to cause self-reported hypoglycemia [55], thiazolidinediones, α-glucosidase inhibitors, glucagon-like peptide 1 (GLP-1) receptor agonists, dipeptidyl peptidase 4 (DPP-4) inhibitors, and sodium–glucose co-transporter 2 inhibitors. All of these drugs require endogenous insulin secretion to lower plasma glucose concentrations, and insulin secretion declines appropriately as glucose levels fall into the normal range. That is true even for the GLP-1 receptor agonists and the DPP-4 inhibitors, which enhance glucose-stimulated insulin secretion (among other actions). They do not stimulate insulin secretion at normal or low plasma glucose concentrations (i.e. they increase insulin secretion in a glucose-dependent fashion). However, all five categories of drugs can increase the risk of hypoglycemia if used with an insulin secretagogue or insulin.

Among the commonly used sulfonylureas, the longer acting glibenclamide (glyburide) is more often associated with hypoglycemia than the shorter acting glimepiride [92, 124]. The use of long-acting insulin analogs (e.g. glargine or detemir), rather than

neutral protamine Hagedorn (NPH) insulin, as the basal insulin in a multiple daily injection (MDI) insulin regimen reduces at least the incidence of nocturnal hypoglycemia, and perhaps also that of total, symptomatic, and nocturnal hypoglycemia, in T1DM and T2DM [124–126]. The use of a rapid-acting analog (e.g. lispro, aspart, or glulisine) as the prandial insulin in an MDI regimen reduces the incidence of nocturnal hypoglycemia, at least in T1DM [125–128]. Longer acting basal insulins such as degludec and glargine U300 reduce nocturnal hypoglycemia further.

Because one can vary the basal insulin infusion rate across the day, continuous subcutaneous insulin infusion (CSII) should be superior to MDI, although this has been difficult to establish convincingly [129]. It may reduce HbA_{1c}, the frequency of hypoglycemia, or both, in selected capable and motivated individuals. However, in the HypoCOMPaSS trial [120], neither CSII (compared with MDI) nor CGM (compared with SMPG) reduced severe hypoglycemia or improved awareness of hypoglycemia to a greater extent.

The combination of real-time CGM with CSII—sensor-augmented pump therapy—has been reported to achieve an ~0.5% greater decrease in HbA_{1c} than MDI alone without an increase in hypoglycemia [130, 131]. A sensor-augmented CSII pump that temporarily suspends insulin infusion for up to 2 h when the CGM value falls below a preselected level (a low glucose suspend [LGS] feature) has been reported to reduce the frequency of severe hypoglycemia [132, 133].

Additional approaches to the prevention of nocturnal hypoglycemia include attempts to produce sustained delivery of exogenous carbohydrate or sustained endogenous glucose production throughout the night [134].

Closed-loop insulin replacement (e.g. [135]) or closed-loop insulin and glucagon replacement (e.g. [136]) and also pancreas or islet transplantation (e.g. [137]), when these are shown to be consistently successful, will eliminate hypoglycemia.

Given the evidence that glycemic control partially prevents or delays microvascular complications of diabetes, and may partially prevent or delay macrovascular complications, it follows that a lower HbA_{1c} is in the best interest of people with diabetes if that can be achieved and maintained safely [81]. Thus, a reasonable individualized glycemic goal is the lowest HbA_{1c} that does not cause severe hypoglycemia, preferably with little or no symptomatic or even asymptomatic hypoglycemia, at a given stage in the evolution of the individual's diabetes [81]. That links the selection of a glycemic goal to the risk of hypoglycemia, specifically the use of drugs that can cause hypoglycemia and the type and duration of diabetes, a surrogate for endogenous insulin deficiency. If the therapeutic regimen produces severe hypoglycemia or hypoglycemia unawareness, or an unacceptable number of symptomatic or asymptomatic episodes, hypoglycemia has become a problem that needs to be addressed.

Because the glycemic management of diabetes is empirical, caregivers should work with each individual over time to find the most effective and safest method of glycemic control at a given point in the course of that person's diabetes. Care is best accomplished by a team that includes, in addition to a physician, professionals trained in, and dedicated to, translating the standards of care into the care of individual and making full use of modern communication and computing technologies.

Another step is to consider the conventional risk factors for hypoglycemia, those that result in both relative and absolute therapeutic insulin excess. In addition to insulin secretagogue or insulin doses, timing and type, these include conditions in which exogenous glucose delivery or endogenous glucose production is decreased, glucose utilization or sensitivity to insulin is increased, or insulin clearance is reduced (Table 35.3).

Finally, the risk factors for HAAF need to be considered. Those include the degree of endogenous insulin deficiency, a history of severe hypoglycemia, hypoglycemia unawareness, or both, and also any relationship between hypoglycemic episodes and recent antecedent hypoglycemia, prior exercise or sleep, and lower HbA_{1c} levels (Table 35.3). Unless the cause is easily remediable, a history of severe hypoglycemia should prompt consideration of a fundamental regimen adjustment. Without that, the risk of a subsequent episode of severe hypoglycemia is high [49, 50, 53, 55, 112–115]. Given a history of hypoglycemia unawareness, a 2–3-week period of scrupulous avoidance of hypoglycemia, which may require acceptance of somewhat higher glycemic goals in the short term, is advisable because that can be expected to restore awareness [32–35]. A history of late post-exercise hypoglycemia, nocturnal hypoglycemia, or both, should prompt appropriately timed regimen adjustments (generically, less insulin action, more carbohydrate ingestion, or both) (see Chapter 26).

When prevention fails, treatment of hypoglycemia becomes necessary. Most episodes of asymptomatic hypoglycemia (detected by self-monitoring of blood glucose or continuous glucose sensing) and of mild–moderate symptomatic hypoglycemia are effectively self-treated by ingestion of glucose tablets or carbohydrate-containing juice, soft drinks, candy, other snacks, or a meal [138, 139] A reasonable dose is 20 g of glucose [139]. Clinical improvement should occur in 15–20 min; however, in the setting of ongoing hyperinsulinemia, the glycemic response to oral glucose is transient, typically less than 2 h [139]. Thus, ingestion of a more substantial snack or meal shortly after the plasma glucose concentration is raised is generally advisable.

Parenteral treatment is required when a hypoglycemic patient is unwilling (because of neuroglycopenia) or unable to take carbohydrate orally. Glucagon, injected subcutaneously or intramuscularly (in a usual dose of 1.0 mg in adults) by an associate of the patient, is often used. That can be life-saving, but it often causes substantial, albeit transient, hyperglycemia and it can cause nausea or even vomiting. Smaller doses of glucagon (e.g. 150 mg), repeated if necessary, have been found to be effective without side effects [140]. Because it acts by stimulating hepatic glycogenolysis, glucagon is ineffective in glycogen-depleted individuals (e.g. following a binge of alcohol ingestion).

Although glucagon can be administered intravenously by medical personnel, intravenous glucose is the standard parenteral therapy. A common initial dose is 25 g [138]. The glycemic response to intravenous glucose is, of course, transient in the setting of ongoing hyperinsulinemia.

The duration of an episode of iatrogenic hypoglycemia is a function of its cause. An episode caused by a rapid-acting insulin secretagogue or insulin analog will be relatively brief, that caused by a long-acting sulfonylurea or insulin analog substantially longer. The latter can result in prolonged hypoglycemia requiring hospitalization.

The clinical problem of hypoglycemia in children

Diabetes is one of the most common chronic diseases in childhood, affecting more than 190,000 (1 in 433) youth aged less than 20 years in the United States [141] and its incidence has been increasing worldwide [142, 143]. The ultimate goal of diabetes management is to achieve good glycemic control while avoiding hypoglycemia. However, in this effort, iatrogenic hypoglycemia has become the most common complication of youth living with diabetes [144–146]. It occurs more frequently in children and adolescents with T1DM owing to the inadequacies of insulin replacement therapy and the unique challenges for this group of patients. This somewhat unavoidable complication can result in morbidity and sometimes in death. Moreover, given that these hypoglycemic events are occurring at a time of dynamic changes in brain structure and metabolic demand, it has been hypothesized that exposure to this glycemic extreme during childhood could alter normal brain developmental trajectories depending on the age and severity at which these extremes are experienced [147]. Despite the use of insulin analogs, insulin pumps, and continuous glucose sensors, the problem of hypoglycemia has not been solved. Therefore, it is important that hypoglycemia be recognized as a key component of pediatric diabetes care.

Definition of hypoglycemia in youth

As in adults, hypoglycemia in youth is most convincingly documented by the presence of the Whipple's triad [148]: (1) symptoms consistent with hypoglycemia, (2) a low plasma glucose concentration, and (3) relief of those symptoms when the plasma glucose concentration is raised. Symptoms of hypoglycemia may be unique to each individual, and are likely to be diminished or absent by prior hypoglycemia. They are conventionally attributed either to autonomic nervous system activation (autonomic or neurogenic symptoms), which include, but are not limited to, palpitations, tremor, hunger, and sweating, or to glucose deprivation in the central nervous system (neuroglycopenic symptoms), which include behavioral changes, fatigue, headaches, difficulty thinking, confusion, poor feeding, hypotonia or lethargy in infants, seizure, coma, and even death [8]. However, data suggest that symptoms in children differ from those in adults. Behavioral changes such as irritability, stubbornness, quietness, and tantrums may be their primary features of low blood glucose [149].

The ADA and the Endocrine Society define iatrogenic hypoglycemia in people with diabetes as "all episodes of an abnormally low plasma glucose concentration that expose the individual to potential harm" [98, 99]. According to the International Society for Pediatric and Adolescent Diabetes (ISPAD) Consensus Guidelines, a blood glucose level of <65 mg/dL (3.6 mmol/L) has been often accepted in clinical practice as a level for defining hypoglycemia in children with T1DM. However, a glucose value of ≤70 mg/dL (3.9 mmol/L) is conventionally used as the threshold value for recognizing and initiating treatment for hypoglycemia [98, 99, 144] in diabetes in adults and children, since glucose levels can potentially fall further and cause a life-threatening event. In adults, a severe hypoglycemic episode is defined as an event requiring assistance of another person actively to administer carbohydrates or glucagon or take other corrective actions to allow neurological recovery. However, this definition is problematic in children, as most young children require the assistance of another person to correct even mild hypoglycemia. Hence, in the pediatric population, severe hypoglycemia is generally defined as an event associated with severe neuroglycopenia usually resulting in coma or seizure and requiring parenteral therapy (glucagon or intravenous glucose) [150, 151].

Prevalence and incidence of hypoglycemia in youth

The average person with diabetes has an uncountable number of episodes of asymptomatic and symptomatic hypoglycemia in their lifetime; hypoglycemia is therefore a "fact of life" for people with T1DM [152–154], and more so in children than adults [155]. Changes in clinical practice (e.g. new insulin regimens, more intense glucose monitoring and delivery) have reduced the rates of hypoglycemia over the last 15 years [155–160], but the problem of hypoglycemia has not disappeared. Even though the rates of hypoglycemia can vary between clinical studies around the world, it is estimated that the incidence of hypoglycemia in children ranges between 5 and 60 episodes per 100 patient-years [155, 159, 161–167] and is more common in infants [168, 169]. Nocturnal hypoglycemia is common in childhood, with reported incidences on any given night of between 10 and 55% [170–172]. Symptoms can be subtle and may include nightmares, restless sleep, and behavior changes upon awakening. There is a lack of specific mortality data attributed to severe hypoglycemia in the pediatric population.

Risk factors for hypoglycemia in the pediatric population

Undoubtedly, the most important risk factor for hypoglycemia lies within insulin therapy itself, but managing type 1 diabetes in young children and youth presents unique challenges owing to the young child's developmental level, unpredictability of an infant or toddler's dietary intake, the child's irregular activity level, and the child's emotional maturity (see Chapter 59). These variables may explain why hypoglycemic events are less predictable and occur

without a clear cause in younger children [169]. Perhaps the second most important risk factor for severe hypoglycemia is hypoglycemia unawareness. In the pediatric population, this occurs due to recurrent hypoglycemia, which causes blunting of the autonomic responses, which, together with the child's developmental level, impedes their ability to feel and communicate symptoms of hypoglycemia. Therefore, at times, these patients depend on adults for most, if not all, aspects of their care.

Since publication of the DCCT results in the 1990s [56], diabetes management changed, aiming for tighter glycemic control to minimize vascular complications. However, it was soon noticed that the risk of hypoglycemia increased as HbA_{1c} decreased, particularly in younger children (<6 years old) [158, 159, 173]. Therefore, the ADA cautiously set higher targets for glycated hemoglobin (HbA_{1c}) for young children compared with adolescents and adults. However, recent population-based studies of children with T1DM suggest that there is no longer a significant risk of severe hypoglycemia associated with age <6 years, irrespective of treatment modality [155, 174, 175]. In addition, even though elevated HbA_{1c} levels in those with poorly controlled diabetes, per se, do not seem to protect against severe hypoglycemia [158], the previously close relationship between tight glycemic control [158] and the risk of severe events is now weaker [155, 174, 176]. This change in severe hypoglycemic rates has been attributed to the improvements in intensive treatment regimens over the past 20 years. Therefore, the ADA and ISPAD now recommend a general target HbA_{1c} of <7.5% for all pediatric age groups, while also recognizing that targets should be tailored to the individual child [177, 178].

The non-physiological nature of current insulin replacement regimens makes people with diabetes vulnerable to hypoglycemic events. In youth, conventional (split-mixed) insulin regimens with a fixed daily two-shot insulin schedule, have been shown to denote a higher rate of severe hypoglycemic episodes than intensive (basal bolus) insulin regimens with either MDI or pumps [49]. Intermediate and long-acting insulins used in these conventional insulin regimens peak several hours after administration and, given the erratic eating patterns and usual delay in carbohydrate intake in children, puts them at higher risk for hypoglycemia owing to inadequate carbohydrate availability at the time of peak insulin effect. The incidence of hypoglycemia in children treated with a conventional regimen ranges between 20 and 60 episodes per 100 patient-years [162, 163]. Although some controlled trials of insulin pump therapy in children suggest that it is similar to MDI in achieving glycemic control and avoiding hypoglycemic episodes [179, 180], others suggest that pump therapy significantly reduced the risk of severe hypoglycemia [129, 155, 181–184] compared with MDI therapy.

Exercise-induced hypoglycemia is a major limiting factor in establishing optimal glycemic control in children and adolescents with T1DM [185]. Glucose utilization and insulin sensitivity are increased during physical activity. Thus, when energy supply is inadequate in relation to high ambient insulinemia, hypoglycemia ensues [186]. Frequent bouts of hypoglycemia impair counter-regulatory responses to hypoglycemia in people with insulin-deficient diabetes [1, 2]; therefore, episodes of hypoglycemia during and following exercise in people with diabetes [38], particularly children [187, 188], become frequent clinical complaints and may result in seizures, coma, or death [1, 2]. The Diabetes Research in Children Network (DirecNet) Study Group showed that during moderate-intensity treadmill exercise, more than two-thirds of the children studied decreased their plasma glucose concentrations by >25%, and 30% of those children required treatment for hypoglycemia [39, 189]. Moreover, this group and others have shown that following afternoon exercise, hypoglycemia can occur hours after, or at night [186, 189, 190].

Other modifiable risk factors in youth include sleep [25, 191–193], missed snacks or meals, malabsorption attributable to celiac disease [194], alcohol intake in teens, and acute illnesses altering the timing, frequency, and carbohydrate intake [195]. Non-modifiable risk factors of severe hypoglycemia include, but are not limited to, coexisting autoimmune disorders such as adrenal insufficiency, celiac disease, and thyroiditis; hence these disorders should be excluded in children with recurrent unexplained hypoglycemia. Other non-modifiable risk factors include being a minority [158, 196], being male, having longer duration of diabetes [197], having a lower socioeconomic status [158, 161], having an ACE DD genotype, and C-peptide negativity.

Physiology of counter-regulation in youth with T1DM

Although hypoglycemia in diabetes is typically the result of therapeutic hyperinsulinemia, compromised symptoms and physiological glucose counter-regulatory defenses to hypoglycemia are what leads to the cycle of recurrent hypoglycemia [2]. As blood glucose falls just below the post-absorptive physiological range (~70–110 mg/dL), signals to and from the hypothalamus and other brain regions lead to a cascade of hierarchical physiological (counter-regulatory hormone) and behavioral (hypoglycemic symptoms) responses to maintain euglycemia [2] (previously explained in section Physiology of glucose counter-regulation). These responses are normally so effective that hypoglycemia is an uncommon clinical event in individuals without diabetes. Data suggest that some of the counter-regulatory responses in children are initiated at plasma glucose levels higher than in adults [164]. However, in people with diabetes, the normal physiological counter-regulatory responses are disrupted because exogenously administered insulin cannot be suppressed and the glucagon response to hypoglycemia is blunted [2, 198–201]. The loss of the glucagon response to hypoglycemia is not the result of loss of α cells since the glucagon response to arginine [198, 201] or to a meal is not lost, and indeed may be exaggerated [202]. These alterations in glucose counter-regulation occur early in the course of the disease and are present shortly after diagnosis in children [200, 203–205] and adults [198, 199], even when there is some residual endogenous insulin secretion [200, 204]. In contrast to glucagon, epinephrine responses to acute hypoglycemia in youth [203, 204] and adults [2] are not blunted early in the absence of prior hypoglycemia. This suggests that the mechanisms of attenuation of the glucagon

and epinephrine responses to acute hypoglycemia are different, and more so, that an intact plasma epinephrine response is critical early in the course of T1DM.

Antecedent hypoglycemia in people with T1DM causes both defective glucose counter-regulation (by attenuating the adrenomedullary epinephrine response in the setting of absent insulin and glucagon responses) and hypoglycemia unawareness (by attenuating the sympathoadrenal, largely the sympathetic neural, response) to subsequent hypoglycemia [2, 15, 206]. In addition, a prior episode of hypoglycemia can lower the glucose threshold at which sympathoadrenal responses and symptoms occur, increasing the risk for subsequent severe hypoglycemia. Studies have shown that children with T1DM younger than 8 years old with good glycemic control have lower catecholamine, cortisol, and blunted glucagon responses to hypoglycemia (∼<60 mg/dL) compared with adolescents [207]. In addition, the glycemic threshold for release of epinephrine in youth with T1DM was higher than that in adults with T1DM [164] and more so in those with poorly controlled T1DM (mean HbA_{1c} 15.1%) than in those without diabetes [164]. Moreover, in children with T1DM, as in adults, sleep markedly impairs counter-regulatory responses to hypoglycemia [25, 187]. Further studies in children are needed to clarify the mechanisms that cause the attenuation of these responses and to determine whether these abnormalities can be reversed with intensive diabetes management using continuous glucose monitoring and closed-loop insulin delivery systems.

Effects and consequences of hypoglycemia in youth

Severe hypoglycemia is acutely associated with significant morbidity and mortality, including cardiac arrhythmias, seizures, and, rarely, permanent neurological impairment and death. Owing to these potentially devastating consequences, it frequently frightens not only the person with diabetes but also their relatives and parents, leading to the phenomenon known as "fear of hypoglycemia." In this setting, parents and children tend to keep blood glucose values above recommended targets in an effort to avoid hypoglycemic episodes, which results in poor glycemic control [208–214].

In the long term, T1DM and its associated glycemic extremes (severe hypoglycemia and chronic hyperglycemia) can affect multiple organ systems, including the retina, cardiovascular system, kidneys, the peripheral nervous system and, more recently noted, the central nervous system. The brain derives its energy almost exclusively from glucose and is largely driven by neuronal signaling, biosynthesis, and neuroprotection. The developing human brain has unique nutritional requirements and undergoes maturational changes, including synaptogenesis and synaptic remodeling, throughout childhood [215, 216], with the brain continuing to account for as much as 20% of total body glucose consumption through early adulthood [217]. When faced with fluctuations in glucose supply, the metabolism of the body and brain changes dramatically, largely to conserve resources and, at a cost to other organs, to preserve brain function [147, 218]. However, if the normal physiological mechanisms that prevent these severe glucose fluctuations and maintain homeostasis are impaired during childhood, normal brain developmental trajectories and neuronal function can be affected [8, 148, 149, 219–221].

The effects of long-duration T1DM and its associated glycemic extremes (severe hypoglycemia and chronic hyperglycemia) on brain structure and function have been examined in multiple adult [83, 222–235] and a handful of child cohorts [84, 236–253]. Even though the DCCT [83, 254] and others [255, 256] have reported no association between the frequency of severe hypoglycemia and cognitive function decline in adults with T1DM, the literature on children with T1DM supports that early exposure (<6 years) to severe hypoglycemia may lead to subtle differences in cognitive and academic function, particularly on declarative memory skills, spatial analysis, verbal function, and psychomotor efficiency [84, 233, 237, 246, 247, 251, 257–266].

Magnetic resonance imaging (MRI) techniques have been used to ascertain the impact of hypoglycemia in T1DM on the developmental trajectory of gray and white matter volumes and structure in children [85, 235, 246, 252, 267]. Case reports and imaging studies in adults and children with T1DM have shown that the regions that appear most susceptible to hypoglycemia include total gray matter, left superior temporal gray matter, thalamus, and hippocampus. Although a prospective study in youth found that exposure to severe hypoglycemia inhibited white matter volume development [236], a retrospective study in youth with T1DM found no significant effects of severe hypoglycemia on white matter integrity across the brain [85, 268]. However this does not rule out the possibility that white matter integrity might be affected over time and be found to be abnormal in a longitudinal study. Despite ample evidence suggesting that children with T1DM have differences in cognitive functioning dependent upon their exposure to glycemic extremes, there have been no studies linking these changes to the observed brain structural or functional differences. Hence further research on the effects of hypoglycemia on the brain is needed to understand better the mechanisms that lead to cognitive outcomes and brain regional vulnerability. Moreover, such studies may allow us a better understanding of the mechanisms involved in the development of recurrent hypoglycemia and HAAF.

Even though rates of severe hypoglycemia may have decreased in the last decade and the ADA and ISPAD have lowered glycemic targets in children with T1DM, hypoglycemia continues to be a fact of life for youth with this disease. Owing to the brain's unique energy demands and key neurodevelopmental processes that occur during childhood, hypoglycemia in children with T1DM may lead to acute and permanent neurological complications. Pending prevention and cure of diabetes or better diabetes regimens providing regulated insulin and glucagon replacement, the management plan of childhood-onset T1DM should be tailored to each child's age, cognitive ability, and emotional maturity to avoid severe and recurrent hypoglycemia while achieving good glycemic control.

Perspective on hypoglycemia in diabetes

Glycemic control, a focus of this chapter, is but one aspect of the management of diabetes. It is now possible to drive plasma low-density lipoprotein (LDL) cholesterol concentrations to subphysiological levels and to normalize blood pressure pharmacologically, usually without major side effects, in most people with diabetes. Weight loss and smoking cessation are more challenging. Although it is not possible to maintain euglycemia over a lifetime of diabetes, because of the barrier of hypoglycemia, maintenance of the lowest mean glycemia that can be accomplished safely is in the best interest of people with diabetes.

Despite the difficulty, people with diabetes and their caregivers should keep the problem of iatrogenic hypoglycemia in perspective. Early in the course of T2DM, by far the most common type of diabetes, hyperglycemia may respond to lifestyle changes, specifically weight loss, or to glucose-lowering drugs that do not raise insulin levels and therefore do not cause hypoglycemia. In theory, when such drugs are effective in the absence of side effects, there is no reason not to accelerate their dosing until euglycemia is achieved. Over time, however, as people with T2DM become progressively more insulin deficient, those drugs, even in combination, fail to maintain glycemic control. Insulin secretagogues are also effective early in the course of T2DM, but they cause hyperinsulinemia and therefore introduce the risk of hypoglycemia. Euglycemia is not an appropriate goal during therapy with an insulin secretagogue or with insulin. Nonetheless, as discussed earlier, the frequency of hypoglycemia is relatively low (with current less than euglycemic goals) during treatment with an insulin secretagogue or even with insulin early in the course of T2DM when glycemic defenses against falling plasma glucose concentrations are still intact. Therefore, over much of the course of the most common type of diabetes, it is possible to maintain a meaningful degree of glycemic control with a relatively low risk of hypoglycemia.

The challenge is greater in people with advanced T2DM and T1DM caused by compromised defenses against falling plasma glucose concentrations and the resulting higher barrier of iatrogenic hypoglycemia. In such individuals, therapy with insulin is demonstrably effective, but it is not demonstrably safe. Nonetheless, concerns about hypoglycemia should not be used as an excuse for poor glycemic control. It should be recalled that the DCCT data [56, 269] document that the relationship between microvascular complications and mean glycemia is curvilinear; some degree of glycemic control puts the person with diabetes at substantially lower risk than little or no glycemic control.

Diabetes will someday be cured and prevented. Pending that, elimination of hypoglycemia from the lives of people with diabetes will likely be accomplished by new treatment methods that provide plasma glucose-regulated insulin replacement or secretion. In the meantime, innovative research is needed if we are to improve the lives of all people affected by diabetes by lowering the barrier of iatrogenic hypoglycemia.

Acknowledgments

The authors' original work cited was supported, in part, by US Public Health Service, National Institutes of Health grants R37 DK27085, MO1 RR00036 (now UL1 RR24992), P60 DK20579, and T32 DK07120 and by a fellowship award from the American Diabetes Association. The senior author is grateful for the contributions of the postdoctoral fellows who did the bulk of the work and made the work better by their conceptual input, and the skilled nursing, technical, dietary and data management/statistical assistance of the staff of the Washington University General Clinical Research Center. Ms. Janet Dedeke, our administrative assistant, prepared the manuscript.

This chapter was written shortly after completion of the second edition of *Hypoglycemia in Diabetes: Pathophysiology, Prevalence and Prevention* [2]. Therefore, much of the factual and interpretive content here is the same, as is no small part of the phraseology.

Disclosures

Dr. Cryer has served as a consultant to several pharmaceutical firms, including Boehringer-Ingelheim/Lilly, Calibrium, Merck and Co., Novo Nordisk A/S, and Pfizer, in recent years. Dr. Arbeláez has no disclosures.

36 Acute Metabolic Complications of Diabetes: Diabetic Ketoacidosis and the Hyperosmolar Hyperglycemic State

Niels Møller
Medical Department MEA (Endocrinology and Diabetes), Aarhus University Hospital, Aarhus, Denmark

Key points

Diabetic ketoacidosis

- Lack of insulin is the culprit in diabetic ketoacidosis.
- The most common precipitating cause is infection.
- The classic signs include polyuria and polydipsia, rapid weight loss, weakness, Kussmaul respiration, drowsiness, and, rarely, coma.
- The cornerstones of treatment are rehydration, intravenous insulin, and potassium supplementation.
- Intravenous insulin administration should continue until the acidosis is normalized (i.e. not merely until euglycemia is achieved).

Hyperosmolar non-ketotic hyperglycemia

- This is characterized by hyperosmolality with progressive hyperglycemia of >35–40 mmol/L and an effective serum osmolality of >320 mOsm/kg.
- It typically affects older people with type 2 diabetes.
- The most common precipitating causes are infection and cardiovascular disease.
- Treatment involves aggressive rehydration and intravenous insulin.

Introduction

Both diabetic ketoacidosis (DKA) and the hyperosmolar non-ketotic hyperglycemic state (HHS) are caused by a lack of insulin, leading to unrestricted flux of stored lipid, carbohydrate, and amino acid nutrients into the blood. These conditions are both acute and life-threatening, and represent the ultimate metabolic consequences of deranged type 1 (T1DM) and type 2 diabetes mellitus (T2DM), respectively [1–3]. The hallmark of DKA is a high-anion-gap metabolic acidosis caused by a rapidly progressive excess of keto acids (3-hydroxybutyrate and acetoacetate—"ketone bodies") whereas severe hyperosmolality caused by hyperglycemia is the most notable feature of HHS. The distinction is not always obvious on clinical grounds; patients with DKA may be very hyperosmolar and ketone body levels are in general somewhat elevated in HHS. Although the clinical picture may vary considerably depending on comorbidities, differential diagnosis seldom poses any major problem and, in the rare cases in which distinction remains difficult, treatment generally follows the same principles, regardless of whether ketosis or hyperglycemia is the most urgent clinical challenge.

Mortality rates have been steadily declining over the past few years [4], but remain close to around 1% for DKA and 10–15% for HHS [2, 5, 6]. The decline in mortality may be a consequence of lower incidence of DKA and HHS, earlier diagnosis, improved treatment, or, more plausibly, all of these effects combined. Improved education schedules and self-monitoring (e.g. blood ketone testing), organization of specialized diabetes clinics, and the use of standardized low-dose insulin regimens have also contributed to this favorable trend [2, 7].

Diabetic ketoacidosis

Definitions

Diabetic ketoacidosis is one of the most common, serious, and demanding medical emergencies within the fields of diabetes and endocrinology. There is no generally accepted definition of DKA and, in particular, very mild cases may be difficult to diagnose. At a minimum, it is reasonable to require that the pH is below the normal range and that the levels of keto acids (ketone bodies) in the blood or urine are markedly elevated. As outlined in

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

Table 36.1 Classification of clinical pictures and diagnostic criteria.

Property	Stress ketosis	Compensated DKA	Diabetic ketoacidosis			Hyperosmolar hyperglycemia
			Mild	Moderate	Severe	
Plasma glucose	Variable	Generally increased	Generally increased	Generally increased	Generally increased	>35–40 mmol/L
Arterial pH	Normal	Normal	Decreased >7.25	7.0–7.25	<7.0	Generally normal
Serum bicarbonate	Normal	Marginally decreased	15–18 mmol/L	10–15 mmol/L	<10 mmol/L	>15 mmol/L
Urine ketones	Increased	Increased	Increased	Increased	Increased	Normal/marginally increased
Blood ketones	Increased	Increased	Increased	Increased	Increased	Normal/marginally increased
Anion gap[a]	Normal/marginally increased	Marginally increased	>10	>12	>12	Variable
Mental status	Normal	Normal	Normal	Normal/drowsy	Drowsy–coma	Drowsy–coma

[a] Anion gap can be calculated as $[Na^+] - ([Cl^-] + [HCO_3^-])$.
DKA, diabetic ketoacidosis.

Table 36.1, there is a continuous deterioration from clinically insignificant "stress" ketosis to full-blown severe ketoacidosis. In the US population, it has been estimated that 2–8% of hospital admissions in children with diabetes are a result of DKA and that the annual incidence rate of DKA in children is around 5 per 1000 patients [1].

Pathogenesis and pathophysiology

Insulin deficiency

DKA is caused by insulin deficiency. Insulin deficiency may be relative (e.g. in the setting of severe infection) where normal amounts of insulin are insufficient, or absolute when insulin therapy is neglected. Lack of insulin leads to uncontrolled lipolysis and ketogenesis and increased plasma glucose. Although often disregarded, it should also be borne in mind that insulin deficiency, most particularly when long-standing, causes increased breakdown of body protein, as evidenced by the extreme sarcopenia and cachexia of people with T1DM prior to the insulin era. Excessive protein breakdown and ensuing release of ketogenic and gluconeogenic amino acids may contribute to ketosis and hyperglycemia.

Stress hormones and cytokines

At some stage, insulin deficiency becomes coupled with excess "counter-regulatory" or "stress" hormones and cytokines [8, 9]. Release of stress hormones may in part be triggered by cytokines and in part by general stress, such as dehydration, hypotension, and hypoperfusion. It has been shown that both endotoxin and tumor necrosis factor (TNF) mimic all metabolic responses to infection, including hyperthermia and stress hormone release [10, 11]. The traditional stress hormones include glucagon, epinephrine, growth hormone (GH), and cortisol, all of which have well-described metabolic actions. Glucagon and epinephrine have a rapid onset of action, whereas GH and cortisol act with a latency of hours.

Cytokine levels are elevated in DKA, even in the absence of infection. The metabolic actions of cytokines are in general not so well understood and it is plausible that many of these actions are mediated by hypothalamo-pituitary activation and subsequent stress hormone release. Certain cytokines, such as TNF-α, may impair insulin sensitivity in peripheral tissues [12, 13] and a vicious circle may thus be initiated with self-perpetual increments in blood glucose and cytokine levels. Insulin has anti-inflammatory properties in critically ill patients [14], and administration of exogenous insulin may in itself increase insulin sensitivity [15], conceivably to some extent by breaking this vicious circle but also because glucotoxicity and lipotoxicity wane.

Lipid metabolism

Contrary to popular belief, deranged lipid—not carbohydrate—metabolism is the main cause of DKA. In essence, DKA is brought about by uncontrolled lipolysis in adipose tissue and uncontrolled ketogenesis in liver.

Adipose tissue is present in regional depots such as subcutaneous upper and lower body and visceral fat [16]. Apart from these classic depots, fat is present in most other tissues (e.g. connective tissue, bone marrow, liver, and muscle). The picture is further complicated by the fact that within each tissue, fat is distributed in compartments. In muscle, for instance, fat is present intramyocellularly, intermyocellularly, and intermuscularly. Under physiological conditions, lipolysis is tightly controlled by lipases. Hormone-sensitive lipase and probably also adipose triglyceride lipase stimulate the release of free fatty acids and glycerol into the circulation. This process is inhibited by insulin, and low insulin levels increase lipolysis swiftly. The stress hormones, such as epinephrine, growth hormone, and cortisol, stimulate lipolysis. It

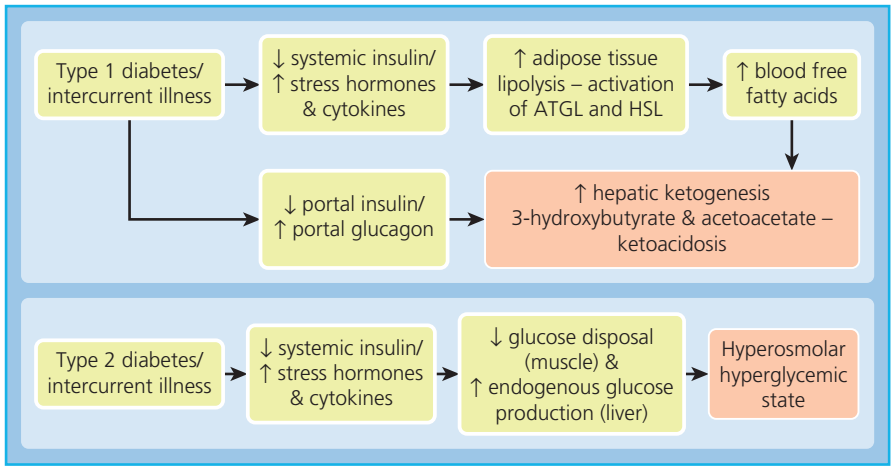

Figure 36.1 Simplistic diagram of the pathogenesis of diabetic ketoacidosis and hyperosmolar non-ketotic hyperglycemic state ATGL: adipose triglyceride lipase, HSL: hormone sensitive lipase.

is plausible that dehydration per se also participates in the stimulation of lipolysis [17]. These events take place in the course of hours and may rapidly triple or quadruple blood concentrations of free fatty acids.

Ketogenesis occurs in the liver by oxidation of free fatty acids to keto acids or ketone bodies (Figure 36.1). Ketone bodies, in particular 3-hydroxybutyrate, are phylogenetically ancient fuel compounds, which are present and prominent in very primitive species [18], suggesting that they have had an important role throughout evolution for the past 2–3 billion years. Physiologically, ketone bodies provide important fuel energy for the brain and other tissues under fasting, prolonged exercise, and other conditions of fuel shortage. In DKA, ketogenesis becomes uncontrolled and circulating levels of ketone bodies rise rapidly and excessively. This occurs because of both an increased supply of fatty acids to the liver and because low levels of insulin and high levels of glucagon in the liver promote ketogenesis [19]. In normal individuals, this unrestrained process is prevented by compensatory rises in insulin secretion, but this does not occur in those with T1DM.

Glucose metabolism

Hyperglycemia is usually present in DKA, but it is important to stress that DKA not infrequently presents with normal or modestly elevated glucose concentrations [20]. This may particularly be the case during caloric deprivation caused by gastrointestinal disease, for example. Recently, euglycemic DKA has been reported during treatment with SGLT-2 inhibitiors. Hyperglycemia is caused by a combination of lack of insulin and an excess of stress hormones, leading to insulin resistance. In the liver, this increases gluconeogenesis and hepatic glucose production. The kidney is unlikely to have any significant role in the initial stages of DKA [21]. The ensuing high glucose levels generate a high flux state with increased peripheral glucose disposal, but the increased mass action of glucose is generally insufficient to compensate fully. Muscle glucose metabolism is characterized by insulin resistance because of high levels of stress hormones, high levels of free fatty acids, and varying degrees of dehydration.

Precipitating factors

In people with known diabetes, DKA is usually precipitated by a coexisting illness or by omission of insulin therapy. The most common factor is infection, ranging from trivial viral infections to full-blown septicemia. Other precipitating factors include cardiovascular events (myocardial infarction, stroke), gastrointestinal disease, inflammatory diseases, pancreatitis, trauma and major surgery, alcohol abuse, and drugs, especially glucocorticoids. All of these factors induce insulin resistance because of the stress hormone responses. Furthermore, poor appetite and food deprivation will often lead the patient to take less insulin. In this context, gastrointestinal disease with nausea and vomiting pose a specific problem and it may be necessary to admit such patients to hospital for intravenous glucose and insulin therapy. Diabetes ketoacidosis may be a presenting feature of new onset T1DM (see Chapter 22).

Psychological factors also play an important part. Poor adherence is commonly seen in younger people with T1DM, those with psychiatric illnesses, and in minority groups who unfortunately may have a poor understanding of diabetes care principles for linguistic or cultural reasons.

Diagnosis and clinical presentation

DKA usually develops over a short period of time, generally in less than 24 h. There may have been some antecedent days with general malaise and poor metabolic control. Depending on the degree of hyperglycemia, the history will include symptoms of polydipsia and polyuria (Box 36.1). Specific symptoms depend on the precipitating factors and other comorbidities that might be present. Physical examination may reveal poor skin turgor, hyperventilation (Kussmaul respirations), hypotension, tachycardia, and impairment of mental state. Many patients have infections but often with normothermia or even hypothermia, caused by peripheral vasodilatation brought about by the acidemia.

Box 36.1 Common clinical features of diabetic ketoacidosis.

Polyuria, polydipsia
Rapid weight loss
Muscular weakness
Visual disturbance
Air hunger with Kussmaul respiration, dry lips
Abdominal pain, leg cramps
Nausea, vomiting
Confusion, drowsiness, coma

Prompt diagnosis and initial treatment rests on:

1 careful clinical examination;
2 determination of plasma glucose;
3 measurement of ketones in blood or urine;
4 measurement of plasma potassium and other electrolytes; and
5 assessment of acidemia.

If glucose is high and blood or urine ketones are markedly elevated, DKA is likely and fluid and insulin therapy should usually be initiated, unless the patient is severely hypokalemic (<3.5 mmol/L). If potassium is very low, supplementation must be given prior to insulin therapy; however, rehydration should not be delayed while waiting for a potassium measurement.

The next diagnostic steps usually include arterial blood gas analysis, blood electrolytes (including anion gap), serum lactate (if there is doubt about the cause of the acidemia), complete blood cell count, biochemical assessment of liver and renal function, blood and urine cultures, myocardial biomarkers (if there is suspicion of a myocardial infarction), electrocardiogram (ECG) and chest X-ray. In this context, it is advantageous that most modern gas analyzers also readily provide potassium concentrations. Another recent advantage is the advent of bedside ketone body monitors. Hence it is now possible to have a quick and reliable measure of 3-hydroxybutyrate concentrations in blood, as opposed to unreliable measurements of acetoacetate in urine or the time-consuming conventional laboratory methods used in the past [22]. The diagnostic criteria are given in Table 36.1.

Despite total body potassium depletion, serum potassium is typically either normal or elevated because of water deficiency and an intracellular to extracellular shift caused by insulin deficiency and acidemia. Patients with potassium in the low range have a severe total body potassium deficiency and should receive vigorous replacement therapy together with cardiac monitoring. Sodium concentrations can be normal or low, as a result of osmotic shifts. It can be calculated that for every 3 mmol/L rise in plasma glucose, the plasma sodium falls by 1 mmol/L. Hence there is often a real hypernatremia with sodium levels rising as the glucose is brought under control. A majority of patients will have a leukocytosis, which correlates with ketone body levels rather than with the presence of infection. There is also a water deficit of around 10% of body weight. Non-specific elevations of amylase and liver enzymes are also common.

Differential diagnoses include all other causes of acidosis. Note that many acute medical conditions induce a stress ketosis and may be associated with acidosis. DKA is a metabolic acidosis characterized by a high anion gap and varying degrees of respiratory compensation. Hence it is crucial to obtain measures of ketone body concentrations and perform an arterial gas analysis. If there is a major discrepancy between the extent of the ketonemia and the acidemia, then lactate measurements are warranted. Starvation ketosis and alcoholic ketoacidosis can usually be identified by clinical history. Other conditions causing metabolic acidosis include lactic acidosis and intoxication with salicylate, methanol, ethylene glycol (antifreeze), and paraldehyde. The clinical picture may be blurred whenever the acidosis is aggravated by renal failure or respiratory failure. In addition, DKA may imitate other diseases. High levels of potassium may also cause ECG changes suggestive of myocardial infarction and elevation of myocardial enzymes and biomarkers may occur in the absence of a clinical myocardial infarction [23]. DKA may also mimic an acute abdomen, particularly in younger patients.

Management

Management and treatment of DKA rests on four pillars:

1 fluid and electrolyte therapy;
2 intravenous (i.v.) insulin therapy;
3 treatment of comorbidities; and
4 careful monitoring of the clinical course.

It is particularly important that treatment is initiated without delay and that the patient is monitored frequently and carefully, preferably in a highly specialized unit. Severe cases should be treated and monitored in an intensive care unit where possible. Useful algorithms for treatment are available from many sources, including the American Diabetes Association. In general, the overall goal is a controlled, gradual correction of metabolic abnormalities and fluid and electrolyte deficiencies in the course of ~24 h.

Treatment of DKA in children and young adolescents follows slightly different guidelines than those presented below (see Chapter 59) [24]. It is recommended that in children insulin is given continuously intravenously (0.1 IU/kg body weight/h) after initiation of fluid and electrolyte therapy in order to minimize the risk of cerebral edema. Otherwise, children are in general treated with weight-reduced doses as indicated below.

Fluid/saline therapy

The first priority is to start to replace fluids. Water and sodium deficits typically are ~10% of body weight and 10 mmol/kg and isotonic saline (0.154 mmol/L; 0.9% NaCl) is given at a rate of ~15–20 mL/kg/h or 1 L/h initially, followed by 250 mL/h after the first 2–3 h depending on the state of dehydration. Depending on prevailing sodium concentrations and hydration, hypotonic saline may also be used, but this is rarely necessary. Urine production and also cardiovascular, renal, and mental performance should be monitored frequently.

Insulin

Lack of insulin is the culprit in DKA and insulin treatment is mandatory. Insulin therapy in adults is given by infusion of 0.1 IU/kg body weight/h or more simply as 6–8 units/h. An i.v. bolus of 0.15 IU/kg body weight (or 10 IU) of regular insulin can be given initially but is not really required, as most of the initial improvement in metabolic status is brought about by rehydration. Alternatively, a bolus of 0.15 IU/kg body weight (or 10 IU) may be given every hour or a 20-unit bolus i.m. followed by 6 units every hour. If the patient is very insulin resistant, as assessed by daily insulin requirements, dosage can be increased, and vice versa if the patient is insulin sensitive. Considering the short half-life of i.v.-administered insulin, it is imperative that insulin is given at least every hour, regardless of the prevailing blood glucose.

Insulin therapy may be adjusted based on hourly measurements of blood glucose and, if possible, blood ketones, with the overall aim being a gradual decline in both. However, recent guidelines now advocate a fixed rate intravenous infusion as being safer and more effective in normalizing the ketonemia. The initial decline is to a large extent caused by rehydration and expansion of the extracellular volume. Repeated analysis of arterial blood gases may be indicated but only in those patients with very low pH values and/or poor clinical condition. Measurement of ketone levels in urine is in general unreliable in this phase; these methods measure acetoacetate, which is quantitatively of minor importance compared with 3-hydroxybutyrate, and acetoacetate in urine may exhibit a paradoxical initial increase because of increasing blood concentrations (and low urine production), despite successful treatment. In particular, acetone is also measured by standard urine dipstick methods and may continue to be excreted for up to 48 h after the onset of treatment as it is fat soluble and leaches out slowly during treatment.

When glucose concentrations are 10–15 mmol/L, glucose is given i.v. and/or orally to avoid hypoglycemia. It may be possible to taper i.v. insulin treatment when 3-hydroxybutyrate concentrations are well below 3 mmol/L. For i.v. replacement 10% glucose should be used as this provides some extra anabolic substrate. If the patient is still dehydrated, then the saline infusion should be continued.

Potassium, bicarbonate, and phosphate

Potassium

Even though the body is potassium depleted, with a typical deficit of around 5 mmol/kg, initial potassium values are usually normal or elevated. Insulin therapy, rehydration, and correction of acidosis all cause a rapid decrease in serum potassium and 20–30 mmol potassium/h should be administered once potassium levels are below 5.0 mmol/L, provided that renal function is intact. Subsequent potassium administration is guided by frequent concentration measurements; adjuvant oral administration may be used in very mild cases of DKA. It is a frequent practical problem that there may be some delay before values are available from the laboratory; gas analyzers that provide instant bedside potassium concentrations greatly facilitate this process.

Bicarbonate

Bicarbonate use in DKA is a matter of controversy [25], but it is empirically recommended that 25–50 mmol sodium bicarbonate is given hourly for 1–2 h if the pH is below 7.0.

Phosphate

Phosphate deficiency of around 1 mmol/kg is typically present in DKA, but there is no evidence that phosphate supplementation should be given routinely. In patients with severe hypophosphatemia and/or cardiac and skeletal or respiratory muscle weakness, 20–30 mmol potassium phosphate can be given hourly for 1–2 h.

Comorbidity

Coexisting diseases precipitate DKA and DKA precipitates coexisting disease. Most often, people with DKA have infectious disease, and signs of infection should be vigorously sought and treatment should be instituted as appropriate. Other prominent comorbidities include cardiovascular events (myocardial infarction, stroke, thrombophlebitis, pulmonary embolism), acute gastrointestinal disorders, and a variety of intoxications.

Complications

Iatrogenic hypoglycemia and hypokalemia are common and preventable, provided that there is access to rapid analysis of glucose and potassium and—not less important—a competent and experienced medical team. Another frequent complication is recurrence of DKA or unnecessary protraction of the course, typically caused by insufficient insulin therapy. Thrombotic events are also not uncommon, although more often in HHS than DKA.

Cerebral edema is a rare, but often fatal, complication preponderant in children and adolescents. The pathophysiology is poorly understood, but may relate to overly aggressive therapy, the use of hypotonic replacement fluids, local cerebral overhydration, and abnormalities of vasogenic function [24]. Symptoms frequently develop 4–12 h after initiation of therapy and include headache, altered mental status, specific neurological deficits, and signs of increased intracranial pressure. Treatment with mannitol or hypertonic saline may be beneficial in this condition.

In some patients, the high anion-gap ketoacidosis may be further complicated by the appearance of a non-anion-gap hyperchloremic acidosis during treatment with insulin and saline infusions [26]. This is because of loss of alkali in the form of ketoanions with sodium or potassium in the urine. This component often results in protracted acidosis, which can confuse clinical assessment. Some of these patients may benefit from bicarbonate therapy.

Prevention

Implementation of self-care and shared-care principles is crucial. People with T1DM should learn about the symptoms of DKA and be able to measure ketones in blood or urine when they feel ill or if their blood glucose is high. A common lapse is the omission or reduction of insulin during episodes with impaired well-being and poor appetite. Persistent ketosis should be treated with extra insulin, fluid, and carbohydrate, when necessary. Furthermore, it is very important that the individual patient has ready, 24 h/day access to diabetological expertise, preferably in a specialized diabetes center.

Hyperosmolar hyperglycemic state

The HHS is generally the fulminant result of poorly treated T2DM or delayed diagnosis of previously unknown T2DM. HHS is less frequent than DKA, but mortality is higher and remains close to 15% in many centers [2, 27]. As implied, hyperosmolality is the primary clinical problem accompanied by hyperglycemia of >35–40 mmol/L and an effective serum osmolality of >320 mOsm/kg (Table 36.1). HHS most often occurs in frail patients in combination with other potentially fatal conditions. Strict differentiation between DKA and HHS can be difficult, because some degree of ketosis may be present in HHS and because lactic acidosis and respiratory and renal failure may also be present. In practice, this dilemma is mainly ornamental, because diagnostic and therapeutic efforts follow the same principles.

In line with DKA, HHS is most often precipitated by infectious diseases or cardiovascular events and symptoms of hyperglycemia usually have been present for some days. Hyperglycemia is caused by a vicious cycle, in which relative insulin deficiency and high levels of stress hormones lead to increased endogenous glucose production and decreased peripheral glucose utilization; hyperglycemia in turn induces hyperosmolality and dehydration, which amplifies the stress hormone response and further impairs insulin secretion, and vice versa.

At presentation, the patient's clinical condition is poor, with severe dehydration, poor skin turgor, and often an altered level of consciousness (ranging from drowsiness to coma) and signs of hypovolemic shock. In general, the diagnostic procedures are similar to those for DKA. Typically, there will be a water deficit of 10–20% of body weight together with sodium, chloride, and potassium deficits of 5–10 mmol/kg body weight.

Treatment of HHS in general follows the same guidelines as for DKA, the main aim being a controlled correction of hyperglycemia, hyperosmolality, and water and electrolyte deficits over 24 h. Patients are generally more sensitive to insulin and an infusion of 0.1 IU/kg body weight/h is more than adequate in most cases. Repeated hourly boluses of 0.15 IU/kg body weight (or 10 IU) may also be used. As with DKA, the dosage should be adjusted according to normal daily insulin needs and depending on the therapeutic response. Usually 1 L of isotonic saline is infused in the first hour but after that slower rehydration is advisable. Hemodynamic performance should be monitored carefully and it should be borne in mind that many of the patients have pre- or coexisting cardiac disease. The use of a central venous pressure line is helpful. It should be noted that a significant proportion of HHS patients are hypernatremic. In this case, hypotonic saline can be used, but more slowly. Potassium is administered along the same lines as with DKA and it is often prudent to monitor the patient in the intensive care unit.

7 Microvascular Complications in Diabetes

37 Pathogenesis of Microvascular Complications

Allan Flyvbjerg
Steno Diabetes Center Copenhagen (SDCC), The Capital Region of Denmark and Department of Clinical Medicine, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark

Key points

- Microvascular complications affect the capillaries and arterioles in the retina (retinopathy), the kidney (nephropathy), and nerves (neuropathy).
- Microvascular complications are caused by prolonged exposure to hyperglycemia.
- Microvascular complications are best prevented by strict metabolic control.
- Hyperglycemia damages cell types that cannot downregulate glucose uptake, causing intracellular hyperglycemia.
- Persistent consequences of hyperglycemia-induced mitochondrial superoxide production may also explain the continuing progression of tissue damage after improvement of glycemic levels ("hyperglycemic memory" or "legacy effect").
- Different individual susceptibilities to microvascular complications have been linked to genetic polymorphisms.
- A number of proven and potential pathogenic factors linking hyperglycemia to the development of microvascular complications may be categorized into five groups: metabolic factors, hemodynamic factors, growth factors/cytokines, intracellular factors, and the complement system.

Diabetic angiopathy: definition and clinical features

Diabetic angiopathy is characterized by functional and structural organ damage as a result of changes in the vascular system. Diabetic angiopathy is divided into *microangiopathy*, which affects the capillaries and arterioles in the retina (retinopathy), the kidney (nephropathy), and nerves (neuropathy), and *macroangiopathy*, which affects arteries in the brain (cerebrovascular disease), heart (ischemic heart disease and congestive heart failure), and the lower extremities (peripheral arterial disease) (Figure 37.1). The consequences of diabetic angiopathy are late diabetic complications, which have a significant impact on the prognosis, life expectancy, and quality of life of people with diabetes. Late diabetic complications may occur both in type 1 diabetes mellitus (T1DM) and type 2 diabetes mellitus (T2DM), which is the reason why all people with diabetes should be examined regularly in an appropriate screening program. Microvascular complications are quantitatively dominant in T1DM, whereas macroangiopathy dominates the clinical appearance in T2DM. In the treatment priorities in the prevention of diabetic angiopathy, microvascular complications are best avoided by strict metabolic control of blood glucose, whereas macrovascular complications are best avoided by strict treatment of dyslipidemia, hypertension, and other risk factors for cardiovascular disease (CVD) (Figure 37.2).

The pathogenesis of macrovascular complications, including atherosclerosis in diabetes, is described in Chapter 41, cardiovascular risk factors in diabetes in Chapters 42 and 43, ischemic heart disease in Chapter 44, congestive heart failure in Chapter 45, cerebrovascular disease in Chapter 46, and peripheral arterial disease in Chapter 47. The pathogenesis of microvascular complications is described in this chapter, followed by a description of diabetic retinopathy in Chapter 38, diabetic nephropathy in Chapter 39 and diabetic peripheral neuropathy in Chapter 40.

A classical morphological feature of diabetic microvascular complications (i.e. microangiopathy) is a thickening of the basement membrane in the capillaries and arterioles in the retina, kidney, and nerves. The magnitude of the thickening increases with the duration of diabetes. The thickening of the basement membrane is seen in virtually all people with diabetes, but clinically symptomatic organ damage is far less frequent. However, much of the impact of chronic diabetes falls on the microcirculation [1, 2]. With long-standing disease, there is progressive narrowing and eventual occlusion of vascular lumina, resulting in impaired perfusion, ischemia, and dysfunction of the affected tissues. Several processes contribute to microvascular occlusion. One of the earliest is increased vascular permeability, allowing extravasation of plasma proteins that accumulate as periodic acid–Schiff

(PAS)-positive deposits in the vessel walls. In addition, extracellular matrix production by perivascular cells such as pericytes (retina) and mesangial cells (glomerulus) is increased, brought about by changes in synthesis and turnover of its component proteins and glycosaminoglycans. As a result, the basement membrane is thickened in many tissues, including retinal capillaries and the vasa nervorum, along with mesangial matrix in the renal glomerulus. Hypertrophy and hyperplasia of endothelial, mesangial, and arteriolar smooth muscle cells also contribute to vessel wall thickening. Finally, increased coagulability and adhesion of platelets and leukocytes to the endothelial surface lead to microthrombus formation and luminal occlusion.

The progressive narrowing and blockage of diabetic microvascular lumina are accompanied by loss of microvascular cells. In the retina, diabetes induces apoptosis of Müller cells and ganglion cells [3], pericytes, and endothelial cells [4]. In the glomerulus, widespread capillary occlusion and declining renal function are associated with podocyte loss. In the vasa nervorum of diabetic nerves, endothelial cell and pericyte degeneration occur [5] and appear to precede functional abnormalities of peripheral nerves [6]. Increased apoptosis of cells in the retina, renal glomerulus, and peripheral neurons is a prominent feature of diabetic microvascular tissue damage [7–11] and may also damage adjacent cells.

Pathogenesis of microvascular complication: the role of hyperglycemia

Overall, diabetic microvascular complications are caused by prolonged exposure to high glucose levels. This has been established by large-scale prospective studies for both T1DM by the Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications Study (DCCT/EDIC) [12] and for T2DM by the UK Prospective Diabetes Study (UKPDS) [13]. Similar T2DM data have been reported by the Steno-2 study [14].

In this section, the potential mechanisms of differences in cell response to hyperglycemia, the phenomenon of glycemic memory, and determinants of individual susceptibility to hyperglycemia-induced damage are described.

Differences in cell response to hyperglycemia

As every cell in the body of individuals with diabetes is exposed to abnormally high glucose concentrations, it may be asked why hyperglycemia selectively damages some cell types whereas others are unaffected. The targeting of specific cell types by generalized hyperglycemia reflects the failure of those cells to downregulate their uptake of glucose when extracellular glucose concentrations are elevated. Cells that are not directly susceptible to direct hyperglycemic damage, such as vascular smooth muscle, show an inverse relationship between extracellular glucose concentrations and glucose transport. In contrast, vascular endothelial cells, a major target of hyperglycemic damage, show no significant change in glucose transport rate when the glucose

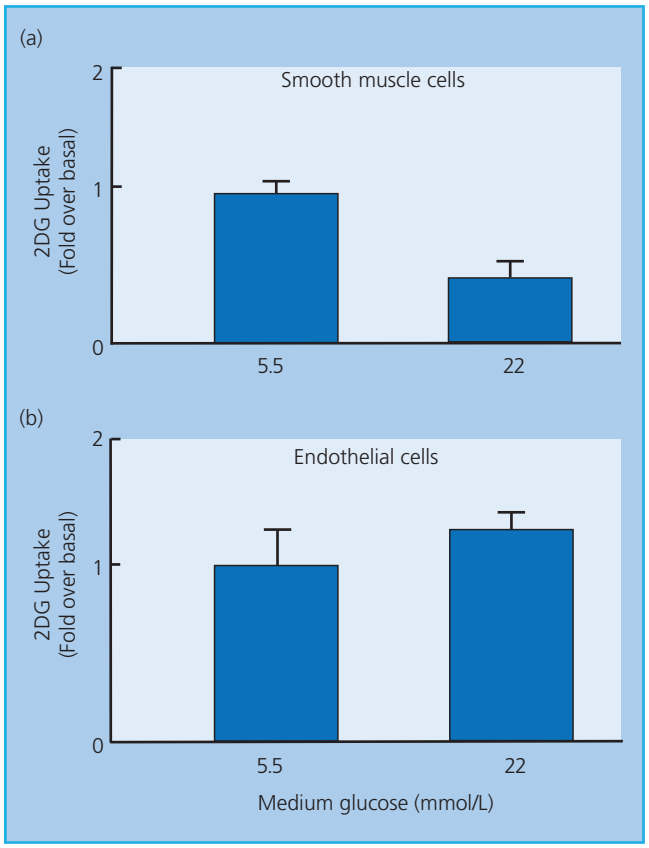

Figure 37.3 Lack of downregulation of glucose transport by hyperglycemia in cells affected by diabetic complications. (a) 2-Deoxyglucose uptake in vascular smooth muscle cells pre-exposed to 5.5 or 22 mmol/L glucose; (b) 2-deoxyglucose uptake in aortic endothelial cells pre-exposed to 5.5 or 22 mmol/L glucose. concentration is elevated, resulting in intracellular hyperglycemia (Figure 37.3) [15]. These differences are caused in part by tissue-specific differences in expression and function of different glucose transporter (GLUT) proteins [16].

Glycemic memory or legacy effect

In 1993, the results of the landmark DCCT study showed that, in people with short-duration T1DM, intensive glycemic control dramatically reduced the occurrence and severity of diabetic microvascular complications. After the announcement of the DCCT results, many participants who had been in the standard therapy group adopted more intensive therapeutic regimens, and their level of glycemic control improved, as measured by HbA_{1c}. At the same time, the mean level of HbA_{1c} worsened for those who had been in the intensive therapy group. The post-DCCT HbA_{1c} values for both groups became statistically identical for the following 14 years of the EDIC Study.

Surprisingly, however, the effects of a 6.5-year difference in HbA_{1c} during the DCCT on the incidence of retinopathy and nephropathy persisted and became greater over the subsequent 14 years of follow-up. People in the standard therapy group continued to have a higher incidence of complications, even with an improvement in glycemic control during the 14 years of EDIC, whereas people in the intensive therapy group continued to have a lower incidence of complications, even with deterioration in glycemic control during the EDIC years. This phenomenon has been given the name *glycemic memory* or *legacy effect* (Figure 37.4). More recent data indicate that glycemic memory also occurs in people with T2DM. The tight glucose control group from the UKPDS demonstrated a continued reduction in microvascular risk and emergent risk reductions for acute myocardial infarction and death from any cause, despite an early loss of glycemic differences. A continued benefit was evident during the 10-year post-trial follow-up among overweight participants [17–19]. Glycemic memory has several important clinical implications and recommendations:

1 Early and tight metabolic control is very important.

2 Tight metabolic control after long-term metabolic dysregulation may not prevent subsequent development of diabetic microvascular complications.

3 There is a need for the development of novel therapies that reverse hyperglycemic memory.

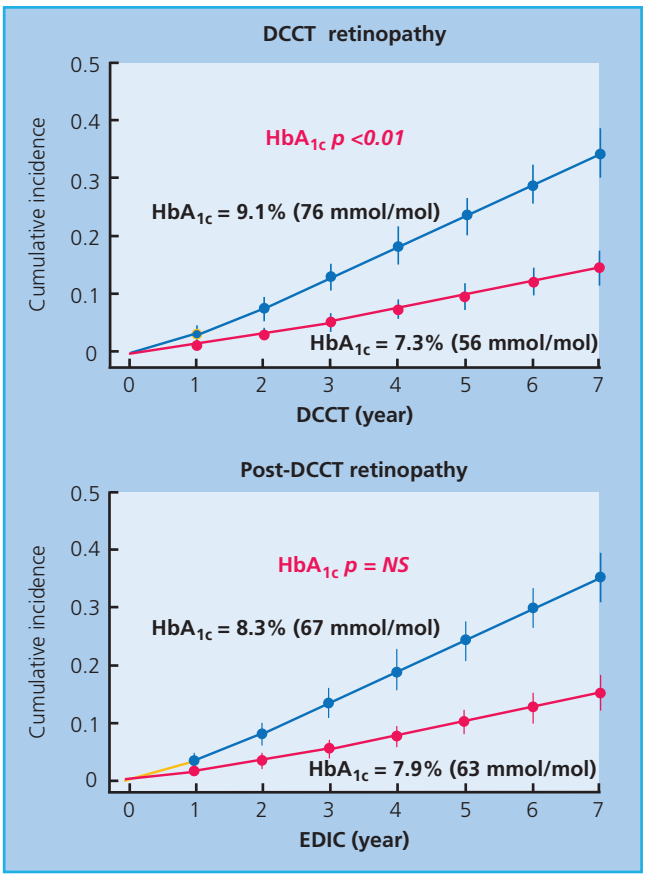

Figure 37.4 Hyperglycemic memory. Previous higher blood glucose levels make people with diabetes more susceptible to damage despite subsequent lower blood glucose exposure. After the end of the Diabetes Control and Complications Trial (DCCT) study, the group who had been poorly controlled on conventional insulin therapy continued to have a higher incidence of diabetic retinopathy than the tightly controlled group given intensive therapy, even though post-trial HbA_{1c} levels were comparable in the two groups. Reported HbA_{1c} is the mean in each group. EDIC, Epidemiology of Diabetes Interventions and Complications Study.

Hyperglycemia-induced mitochondrial superoxide production may provide an explanation for the continuing progression of tissue damage after the correction of hyperglycemia (*hyperglycemic memory*). Post-translational modifications of histones cause chromatin remodeling and changes in levels of gene expression [20–22]. Because these modifications do not involve differences in DNA sequence, they are called *epigenetic* (Figure 37.5a). Transient hyperglycemia has been shown to induce long-lasting activating epigenetic changes in the promoter of the Fib-subunit p65 in human aortic endothelial cells (16 h exposure) and in aortic cells *in vivo* in non-diabetic mice (6 h exposure), which cause sustained increases in p65 gene expression (Figure 37.5b) and in the expression of p65-dependent pro-inflammatory genes. Both the epigenetic changes and the gene expression changes persist for at least 6 days of subsequent normal glycemia. Hyperglycemia-induced epigenetic changes and increased p65 expression are prevented by normalizing mitochondrial superoxide production or superoxide-induced methylglyoxal (Figure 37.5b and c) [23]. These results highlight the dramatic and long-lasting effects that short-term hyperglycemic spikes can have on vascular cells and suggest that transient spikes of hyperglycemia may be an HbA_{1c}-independent risk factor for diabetic complications. Demethylation of another histone lysine residue, H3K9, is also induced by hyperglycemia-induced overproduction of reactive oxygen species (ROS). This reduces inhibition of p65 gene expression, and thus acts synergistically with the activating methylation of histone 3 lysine 4 [24]. Consistent with these observations, others have shown similar epigenetic changes in lymphocytes

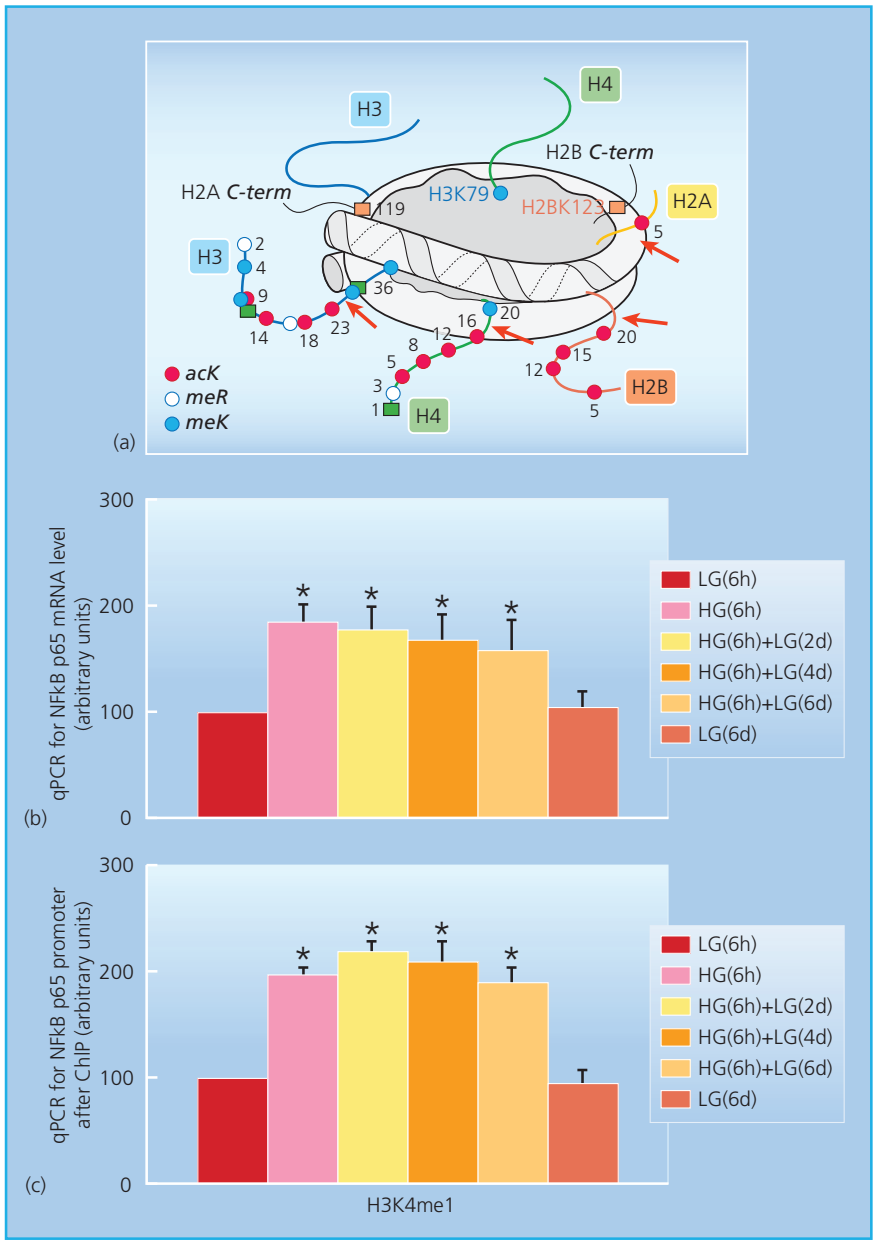

Figure 37.5 Transient hyperglycemia causes persistent epigenetic changes and altered gene expression during subsequent normoglycemia. (a) Schematic representation of several histone modifications (acK, acetylated lysine; meK, methylated lysine; meR, methylated arginine). from people with T1DM [25] and in vascular smooth muscle cells derived from an experimental mouse model of T2DM [26].

Determinants of individual susceptibility to hyperglycemia-induced damage

As with all complex diseases, the occurrence and progression of diabetic complications vary markedly among people with diabetes. Some have T1DM for over 50 years with minimal complications, whereas others manifest severe disease or death within 15 years after diagnosis. The control of blood glucose, and also blood pressure and blood lipid profiles, are important factors in predicting the risk of complications, but they only partially explain the risk of complications for an individual. Therefore, genetic factors have been investigated for their influence on the risk of developing complications. An understanding of the genes involved in the susceptibility to or protection from diabetic complications can lead both to a better understanding of the pathophysiological mechanisms and to new biomarkers and molecular targets for drug development. Familial clustering studies strongly support a role for genetic determinants of susceptibility to hyperglycemic damage.

In two studies of families that have two or more siblings with T1DM, if one sibling had advanced diabetic nephropathy, the other sibling with diabetes had a nephropathy risk of 72–83%. By contrast, the risk was only 17–22% if the index sibling did not have diabetic nephropathy [27, 28]. Numerous associations have been made between various genetic polymorphisms and the risk of various diabetic complications. These include the HLA-DQB10201/0302 alleles [29], polymorphisms of the aldose reductase gene [30], the sorbitol dehydrogenase gene [31], and the promoter of erythropoietin gene [32]. A positive linkage and association with diabetic nephropathy of simple tandem repeat polymorphisms and single nucleotide polymorphisms in 20 genes have been demonstrated in families of people with T1DM of white European descent [33]. Three genes code for growth factors or growth factor receptors, five genes code for intracellular factors, three genes code for components of the extracellular matrix, and two genes are involved in its degradation. The remaining genes are likely to be important in kidney function [33]. The DCCT/EDIC trial also reported familial clustering and association with gene polymorphisms. In those with diabetes, the odds ratio for risk of severe retinopathy was 5.4-fold higher in family members of participants with retinopathy than in those without; coronary artery calcification also showed familial clustering [34]. In the same cohort, an association of multiple superoxide dismutase 1 variants was associated with the development and progression of diabetic nephropathy [35].

In the future, the challenge will be to identify specific genes involved in the varying clinical severity of diabetic complications. Recent emphasis in human disease genetics has been on so-called modifying genes, i.e. genetic variants that are distinct from disease susceptibility genes but modify the phenotypic and clinical expression of the disease genes. Studies show that genetic modifiers can be *tipping point* genes. This means that one gene changes the whole phenotype in an all-or-nothing fashion, in contrast with the incremental effects seen with changes in a large number of non-modifier genes. Many examples of modifier genes are known in model organisms, and several have been identified in humans [36, 37].

Pathogenesis of microvascular complication: beyond hyperglycemia

During recent decades, it has become increasingly evident that a number of different pathways may play a role as mediators between elevated and fluctuating blood glucose levels, thereby leading to the development of diabetic microvascular complications. The number of systems and interactions between these factors are complex, but as described in a review article dealing with the pathogenesis of diabetic kidney disease, four important groups of mediators are metabolic factors, hemodynamic factors, growth factors/cytokines, and intracellular factors [38]. Further, an increasing amount of evidence for an important role of the innate immune system has been published in recent years. In Figure 37.6, a schematic depiction of the potential hierarchy and interactions between metabolic, hemodynamic, growth factors/cytokines, intracellular factors, and the innate immune system in the pathogenesis of diabetic microvascular complications is proposed. In the following section, the five systems and the evidence for their role are described in more detail.

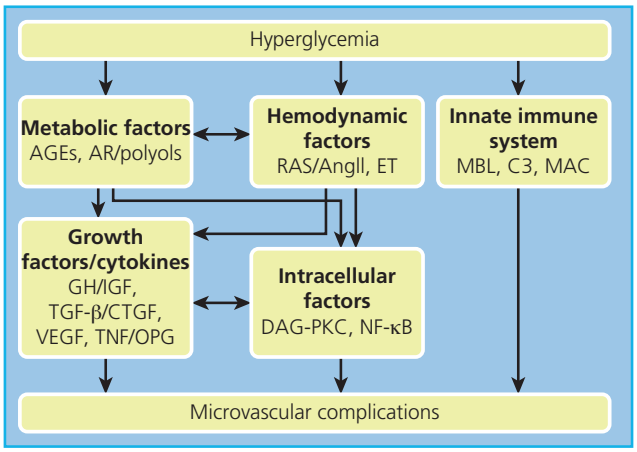

Figure 37.6 Schematic depiction of pathogenetic factors in diabetic microvascular complications. The potential hierarchy and interactions between metabolic, hemodynamic, growth factors/cytokines, intracellular factors, and the innate immune system in the pathogenesis of diabetic microvascular complications. AGEs, advanced glycation end-products; AR/polyols, aldose reductase/polyols; RAS, renin–angiotensin system; AngII, angiotensin II; ET, endothelin; GH, growth hormone; IGF, insulin-like growth factor; TGF-β, transforming growth factor β; CTGF, connective tissue growth factor; VEGF, vascular endothelial growth factor; TNF, tumor necrosis factor; OPG, osteoprotegerin; DAG–PKC, diacylglycerol–protein kinase C; NFκB, nuclear factor κB; MBL, mannose binding lectin; C3, complement C3; MAC, membrane attack complex.

Metabolic factors

Among the different metabolic pathways that impact the development of diabetic microvascular complications, the role of advanced glycation end-products (AGEs) and the aldose reductase (AR)/polyol pathway have been studied in detail.

Advanced glycation end-products (AGEs)

Amadori products are formed when glucose and other reactive carbonyl compounds react non-enzymatically with proteins, lipids, or nucleic acids and Schiff bases. Additional rearrangements and modifications lead to the generation of various forms of AGEs, such as carboxymethyllysine (CML), pentosidine, imidazolone, and pyrraline [39, 40]. AGEs interact with specific receptors [39–41]. p60 (OST-48, AGE-R1), p90 (80K-H, AGE-R2), galectin-3 (AGE-R3), the macrophage scavenger receptor type II (ScR-II), and CD36 all regulate the uptake and clearance of AGEs [39, 41]. The best-characterized receptor is receptor for AGEs (RAGE) [39]. AGEs can also act in a receptor-independent way by cross-linking proteins [39, 40]. AGEs alter the structure and function of intra- and extracellular molecules, increase oxidative stress, and modulate cell activation, signal transduction, and the expression of cytokines and growth factors through receptor-dependent and -independent pathways [39–41].

Preclinical data in support of a role for AGEs in diabetic microvascular complications come from studies in diabetic animal models [38, 42]. Renal AGE levels are increased in long-term experimental diabetes [43, 44]. Furthermore, in models of T1DM and T2DM, the intake of food-derived AGEs accelerates renal changes whereas a low-AGE diet provides protection against kidney damage [45]. In diabetic animal models of both T1DM [46, 47] and T2DM, elevated RAGE glomerular podocyte staining has been reported, compared with non-diabetic controls [48]. Finally, diabetic transgenic mice overexpressing human RAGE present with kidney and glomerular hypertrophy, increased albuminuria, mesangial expansion, advanced glomerulosclerosis, and increased impaired kidney function, compared with controls [49]. In clinical studies, AGEs have been shown to be elevated in both T1DM and T2DM [50, 51]. It is important to note, however, that studies indicate that AGEs at the concentrations found in diabetic sera are not the major ligand for RAGE. Rather, several pro-inflammatory protein ligands have been identified that activate RAGE at low concentrations. These include several members of the S100 calgranulin family and high-mobility group box 1 (HMGB1), all of which are increased by diabetic hyperglycemia. Binding of these ligands with RAGE causes cooperative interaction with the innate immune system signaling molecule toll-like receptor 4 (TLR-4) [52, 53].

During the last two decades, various agents have been examined in attempts to interfere with AGE formation or the cross-linking of proteins by AGEs. Agents that block AGE formation by scavenging reactive carbonyl intermediates include aminoguanidine, pyridoxamine, 2,3-diaminophenazine, OPB-9195, and tenilsetam. ALT-711 is an example of an AGE cross-link breaker. Further, ways to block the signal transduction through the RAGE can be achieved by the use of RAGE antibodies, antisense oligodeoxynucleotides (AS-ODNs), or soluble RAGE [38, 42]. A number of clinical trials have been performed aimed at exploring the clinical effects of pyridoxamine in both T1DM and T2DM [54, 55]. In one study, of mild to moderate renal impairment, the intervention reduced the slope of creatinine change without having an influence on urinary albumin excretion (UAE) [54]. In another study of more severe diabetic renal impairment, there was no effect of the treatment, indicating that treatment should be administered before the onset of significant pathological organ changes [55].

Aldose reductase/polyol pathway

The polyol pathway is based on a family of aldoketoreductase enzymes, which can utilize a wide variety of sugar-derived carbonyl compounds as substrates and reduce these by nicotinamide adenine dinucleotide phosphate (NADPH) to their respective sugar alcohols (polyols). The classic representation holds that glucose is converted to sorbitol, and galactose to galactitol. Sorbitol is then oxidized to fructose by the enzyme sorbitol dehydrogenase (SDH), with NAD^+ being reduced to NADH. The first and rate-limiting step of the polyol pathway is regulated by aldose reductase, which is found in tissues such as nerve, retina, lens, glomerulus, and blood vessel wall. In these tissues, glucose uptake is mediated by GLUT proteins other than GLUT-4 and so does not require insulin; intracellular glucose concentrations therefore rise in parallel with hyperglycemia. Several mechanisms have been proposed to explain how hyperglycemia-induced increases in polyol pathway flux could damage the tissues involved. These include sorbitol-induced osmotic stress, decreased cytosolic Na/K^+-ATPase activity, increased cytosolic $NADH/NAD^+$, and decreased cytosolic NADPH. It was originally suggested that intracellular accumulation of sorbitol, which does not diffuse easily across cell membranes, could result in osmotic damage, but it is now clear that sorbitol levels in diabetic vessels and nerves are far too low to do this. Another early suggestion was that increased flux through the polyol pathway led to decreased phosphatidylinositol synthesis, and that this inhibited Na/K^+-ATPase activity. The latter abnormality occurs in diabetes, but has subsequently been shown to result from hyperglycemia-induced activation of protein kinase C (PKC), which increases the production of two inhibitors of Na/K^+-ATPase, arachidonate and prostaglandin E2 [56].

It has also been suggested that the reduction of glucose to sorbitol by NADPH consumes the latter. NADPH is a cofactor required to regenerate reduced glutathione (GSH); as GSH is an important scavenger of ROS, this could induce or exacerbate intracellular oxidative stress. Indeed, overexpression of human AR increased atherosclerosis in diabetic mice and reduced the expression of genes that regulate regeneration of GSH [57]. Reduced GSH is depleted in the lens of transgenic mice that overexpress AR and in diabetic rat lens compared with non-diabetic lens [58, 59]. It has also been demonstrated that decreased glutathiolation of

cellular proteins is related to decreased nitric oxide (NO) availability in diabetic rats, which would decrease *S*-nitrosoglutathione. Restoring the NO levels in experimental animal models of diabetes increases glutathiolation of cellular proteins, inhibits AR activity, and prevents sorbitol accumulation. Moreover, hyperglycemia can also inhibit glucose-6-phosphate dehydrogenase, the major source of NADPH regeneration, which may further reduce the NADPH concentration in some vascular cells and neurons [60]. In diabetic vascular cells, however, glucose does not appear to be the substrate for AR, because the Michaelis constant (K_m) of aldose reductase for glucose is 100 mmol/L, whereas the intracellular concentration of glucose in the diabetic retina is 0.15 mmol/L [61, 62]. Glycolytic metabolites of glucose such as glyceraldehyde-3-phosphate, for which AR has much higher affinity, may be the physiologically relevant substrate.

In recent decades, a number of AR inhibitors have been developed and studied in experimental and clinical studies for their potential effect on diabetic microvascular complications [63]. Unfortunately, these drugs have not so far shown convincing clinical effects [63].

Hemodynamic factors

Tight control of blood pressure delays the progression of retinopathy and nephropathy, whereas elevated blood pressure accelerates the onset of nephropathy and its progression [64–66]. Blockade of the renin–angiotensin system (RAS), and thereby the effects of the vasoconstrictor angiotensin II (AngII), is gold-standard treatment and a cornerstone in the secondary and tertiary treatment of incipient or overt diabetic microvascular complications, in particular diabetic retinopathy (see Chapter 38) and diabetic nephropathy (see Chapter 39). In addition to the well-known systemic and locally hemodynamic effects, RAS and the endothelin (ET) system may exert non-hemodynamic effects through autocrine and paracrine actions. In the following section, the ET system and its role in diabetic microvascular complications are addressed.

Endothelin

The ET system embraces ET-1–3 and two receptors. ET-1 is the most potent vasoconstrictor of the three [67, 68]. In mammals, two receptors, ET_A and ET_B, exert their signal mainly through activation of G-proteins. The ET_A receptor is mainly involved in vasoconstriction and cell proliferation, whereas the ET_B receptor induces NO release and vasodilation [67, 68]. ETs acts through paracrine and autocrine actions.

The effects of ETs can be blocked by the administration of non-selective ET receptor antagonists (e.g. bosentan), selective ET_A antagonists (e.g. avosentan, atrasentan), or ET_B antagonists. As summarized in a recent review [69], ET receptor blockade, in particular by the use of selective ET_A blockers, has shown renal protective effects in experimental animal models of diabetes, by lowering UAE, podocyte loss, and inflammation. In human diabetes, some renoprotective effects have been reported with bosentan treatment [70] or treatment with selective ET_A blockers [71, 72]. However, fluid retention has been a challenge in most studies, which may reduce the future potential for this class of drugs in the treatment of diabetic microvascular complications [69].

Growth factors/cytokines

Of the many known growth factors and cytokines, growth hormone (GH) and insulin-like growth factor I (IGF-I) were the first to be implicated in the development of diabetic microangiopathy [73–75]. The evidence for a role of GH/IGF-I in the pathogenesis is reviewed elsewhere [38]. So far, no drugs with regulatory effects on this axis have yet made it to a clinical use. Transforming growth factor β (TGF-β), connective tissue growth factor (CTGF), and vascular endothelial growth factor (VEGF) have been studied intensively over several decades as significant pathogenic factors for diabetic microangiopathy. In recent years, the role of the tumor necrosis factor (TNF) superfamily has been increasingly associated with a pathogenic role in diabetic microvascular complications.

Transforming growth factor/connective tissue growth factor

The TGF-β superfamily consists of multifunctional cytokines, where TGF-β1, TGF-β2, and TGF-β3 are involved in ECM synthesis [76]. The biologically active isoforms are generated after proteolytic activation [76]. Three TGF-β receptors have been identified and TGF-β signal transduction involves at least three subclasses of SMAD proteins [76–78]. CTGF has been identified as a downstream mediator of TGF-β [38]. There is a huge amount of preclinical and clinical evidence that the TGF-β superfamily, including CTGF, may be involved in the pathogenesis of particular diabetic nephropathy and retinopathy [38, 79, 80].

Accordingly, a number of clinical studies have been conducted in recent years in order to examine the effects of TGF-β or CTGF blockade. A phase II clinical study has been performed with the application of a TGF-β antibody in people with T1DM and diabetic nephropathy, showing a minor effect on the rise in serum creatinine [81]. Pirfenidone, a compound that blocks TGF-β promoter activity, has been trialed in people with T1DM and T2DM and diabetic kidney disease, already on RAS blockade, and demonstrated a beneficial effect on estimated glomerular filtration rate (eGFR) compared with placebo; however, there was a high dropout rate in the pirfenidone-treated participants [82]. In addition to a series of preclinical diabetic studies showing positive results on kidney variables by blocking the CTGF axis, a single clinical trial has been performed with the application of a human monoclonal antibody to CTGF (FG-3019) in people with diabetic nephropathy [83]. The treatment was generally well tolerated and reduced UAE [83].

Although the promising renoprotective results from preclinical studies have facilitated the first clinical studies in people with diabetic renal impairment, the safety and efficacy of using TGF-β and CTGF blockers in the clinical management of diabetic microvascular complications are still uncertain.

VEGF

The VEGF family embraces a number of different isoforms and exists in a number of homodimeric glycoproteins [84, 85]. VEGF increases vascular permeability and has a stimulatory effect on endothelial cell differentiation and proliferation [85]. The two well-described VEGF receptors (VEGFR-1 and VEGFR-2) are high-affinity transmembrane tyrosine kinase receptors [85]. The production of VEGF is regulated by a number of other growth factors and cytokines, including IGF-I [84, 85].

Numerous preclinical and clinical studies have been published in the last two decades, indication a pathogenic role of VEGF in both diabetic nephropathy [38, 86] and diabetic retinopathy [87]. Further, several VEGF/VEGFR antagonists have been developed, including agents that directly block the VEGF peptide, such as an anti-VEGF aptamer (pegaptanib), a monoclonal antibody fragment (ranibizumab), and a full-length VEGF antibody (bevacizumab). Other agents include a soluble VEGF receptor analog (VEGF-Trap) and small interfering RNA drugs (bevasiranib and rapamycin). Although anti-VEGF treatment has been shown to halt the development of diabetic renal changes in experimental models of T1DM and T2DM [38], anti-VEGF treatment have not yet been introduced in the clinic. By contrast, local application of anti-VEGF agents in the eye is a widely used procedure in the management of proliferative diabetic retinopathy (PDR), macular edema, and their associated complications [86, 87]. See also Chapter 38.

The TNF superfamily

The TNF superfamily and its relation to diabetic microvascular complications have been described in detail [88]. In brief, the TNF superfamily consists of structurally related proteins involved in processes such as regulation of immune response, inflammation, and cell death. TNF-related apoptosis-inducing ligand (TRAIL; also called TNF ligand superfamily member 10) was initially identified as a third member of the TNF superfamily to induce apoptosis [89, 89]. In contrast to other members of the TNF superfamily, TRAIL binds to a complex system of TRAIL receptors. Different TRAIL receptors have been described in humans, four of which are membrane bound, that is, TRAIL receptor 1 (TRAIL-R1) to TRAIL-R4 [88, 89]. A fifth receptor is osteoprotegerin (OPG). In addition to being a stimulator of the various TRAIL receptors, TRAIL is also an inhibitor of OPG. OPG was originally known as an inhibitor of bone resorption binding to RANKL (the receptor activator of nuclear factor κB ligand) [89–91]. OPG acts as a soluble inhibitor of the interaction between RANKL and RANK and also of osteoclastogenesis. Therefore, OPG acts as an inhibitor of both TRAIL and RANKL, and the delicate balance between these three components is important both in normal physiology and in pathophysiology [92].

Research on the role of TRAIL in diabetic microvascular complications is in its initial phase [88], while an increasing number of studies have been carried out on the role of OPG. It has become increasingly clear that OPG may play an important role in vascular dysfunction in diabetes, although it was originally identified as a bone molecule, with a inhibitory effect on osteoclast formation [89, 90]. Some studies, on the one hand, indicate that OPG may be involved in the development of vascular calcifications [93–95]. Thus, OPG has also been suggested to be a survival factor for endothelial cells [96]. In addition, OPG knockout (KO) mice develop vascular calcifications [97]. However, most studies are in support of a pro-atherosclerotic role for OPG in the vasculature, which may be particularly pronounced in diabetes. Accordingly, increased circulating levels of OPG have been demonstrated in a studies of experimental diabetes [98, 99] and microarray studies in human diabetes specimens have shown upregulation of OPG mRNA levels in kidney samples [100, 101]. Plasma OPG levels have been shown to correlate with the presence of renal dysfunction or CVD in T1DM and T2DM [88], and further plasma OPG levels are associated with vascular endothelial dysfunction [102]. A number of prospective studies have focused on circulating OPG levels as a putative predictor of progression of end-stage renal disease. Accordingly, in people with T1DM and nephropathy, plasma OPG is a powerful and independent predictor of progression to end-stage renal disease, cardiovascular, and all-cause mortality [103].

Intracellular factors

Among many different intracellular factors, there has been particular focus on the potential role of the activation of the diacylglycerol–protein kinase C (DAG–PKC) pathway in the development of diabetic microvascular complications.

DAG–PKC

PKC is an important intracellular pathway that can be activated by many upstream factors in the development of diabetic microvascular lesions, including metabolic, hemodynamic, and growth factor/cytokine factors. PKC can then be a stimulus for the initiation of several growth factors and cytokines. The group of PKCs comprises at least 11 isoforms that are widely distributed in mammalian tissues. The activity of the classic isoforms is dependent on both Ca^{2+} ions and phosphatidylserine and is greatly enhanced by DAG. Persistent and excessive activation of several PKC isoforms might also operate as a third common pathway mediating tissue injury induced by hyperglycemia and associated biochemical and metabolic abnormalities. This results primarily from enhanced *de novo* synthesis of DAG from glucose via triose phosphates, whose availability is increased because raised intracellular glucose levels enhance glucose flux through the glycolytic pathway [104–107]. Finally, evidence suggests that the enhanced activity of PKC isoforms could also result from the interaction between AGEs and their cell-surface receptors [108]. Hyperglycemia primarily activates the β and δ isoforms of PKC, both in cultured vascular cells [109–111] and in the retina and glomeruli of diabetic animals [106–108], but increases in other isoforms have also been found, such as PKC-α and PKC-ε isoforms in the retina [104] and PKC-α and PKC-δ in the glomerulus of diabetic rats [112, 113].

In early experimental diabetes, activation of PKC-β isoforms was shown to mediate the diabetes-related decreases in retinal

and renal blood flow [114], perhaps by depressing the production of the vasodilator NO and/or increasing ET-1, a potent vasoconstrictor. Overactivity of PKC has been implicated in the decreased NO production by the glomerulus in experimental diabetes [115] and by smooth muscle cells in the presence of high glucose levels [116], and inhibits insulin-stimulated expression of endothelial NO synthase (eNOS) in cultured endothelial cells [102]. Hyperglycemia increases the ability of endothelin-1 to stimulate mitogen-activated protein kinase (MAPK) activity in glomerular mesangial cells, and this occurs by activating PKC isoforms [117]. The increased endothelial cell permeability induced by high glucose levels in cultured cells is mediated by activation of PKC-a [118]; activation of PKC by high glucose also induces expression of the permeability-enhancing factor VEGF in smooth muscle cells [119]. In addition to mediating hyperglycemia-induced abnormalities of blood flow and permeability, activation of PKC may contribute to the accumulation of microvascular matrix protein by inducing expression of TGF-β1, fibronectin and type IV collagen in both cultured mesangial cells [120, 121] and in glomeruli of diabetic rats [112]. This effect also appears to be mediated through the inhibition of NO production by PKC [122]. Hyperglycemia-induced activation of PKC has also been implicated in the overexpression of the fibrinolytic inhibitor plasminogen activator inhibitor 1 (PAI-1) [123], and in the activation of nuclear factor κB (NFκB) in cultured endothelial cells and vascular smooth muscle cells [124].

Over the last few decades, a number of PKC inhibitors have been developed and examined in an attempt to lower PKC activity. Ruboxistaurin mesylate, which is a highly specific blocker of PKCβ isoforms, and the most widely studied specific PKC inhibitor, has been examined in diabetic animal models and a few pilot studies in humans [125]. These studies showed some beneficial effects on the development of diabetic renal changes in animals, but studies in humans have predominantly been inconclusive [125]. Therefore, the clinical effects of lowering PKC activity in the prevention of diabetic microvascular complications remain unclear at present.

The innate immune system

The innate immune or complement system and its relation to diabetic microvascular complications have been described in detail previously [88]. In brief, activation of the complement system takes place through three different pathways: the mannose-binding lectin (MBL), the classical, and the alternative pathways. All three pathways merge to stimulate the formation of a complement C3 convertase. When cleaved by a complement C3 convertase into pro-inflammatory and proteolytic subforms, the zymogens are activated, with subsequent downstream effects that include recruitment of inflammatory cells, tagging and subsequent clearing of immunocomplexes, and the generation of the membrane attack complex (MAC). A number of experimental studies have shown an association between the MBL and diabetic microvascular changes. In a mouse model of T1DM, diabetic MBL KO mice were protected from diabetic kidney damage, as indicated by diminished renal hypertrophy, urinary albumin excretion, and renal collagen IV expression and a tendency to reduced mesangial expansion and basement membrane thickness compared with diabetic wild-type mice [126]. In people with T1DM, high levels of circulating MBL and high MBL genotypes are associated with the development of diabetic nephropathy and increased mortality [127]. In addition, elevated MBL levels were found in people with T1DM with micro- and macroalbuminuria compared with people with normoalbuminuria in the FinnDiane study [128]. Further, serum MBL levels, measured at the onset of diabetes in a cohort of 270 people with T1DM, were predictive for the development of microalbuminuria during an 18-year follow-up period [129]. Finally, serum MBL is a significant predictor of both the development of albuminuria and overall mortality in people with T2DM, as shown in a group without classical risk factors for nephropathy [130]. In this study, the combination of high MBL and high hsCRP (high-sensitivity C-reactive protein) levels at baseline were predicted for an increased risk of developing microalbuminuria or macroalbuminuria compared with those with low levels of both proteins. In addition, high levels of MBL and hsCRP were predictive for mortality in people with T2DM with and without nephropathy [130]. A recent meta-analysis concluded that high expression of MBL is correlated with a significantly increased risk of vascular complications in diabetes and that measurements of MBL levels in diabetes is an effective and feasible method to predict high risk of microvascular complications [131].

In addition to MBL, other studies suggest that downstream complement components may be involved in microvascular complications. Accordingly, the magnitude of renal deposition of C3 has been studied in various preclinical diabetes models. In one study, C3 deposition was localized in glomerular capillaries of mice with T2DM [132]. In an experimental model of T1DM, enhanced glomerular and tubular C3 staining normalized in response to transplantation of pancreatic islets [133, 134]. In addition, renal transplantation from the rats with T1DM into non-diabetic animals normalized the renal C3 staining, whereas transplantation of kidneys from non-diabetic rats to rats with T1DM enhanced kidney C3 staining [135]. Clinical data are also in support of a role of downstream components of the complement system. In people with T1DM and varying degrees of diabetic nephropathy, MAC deposits were found to be localized to the glomerular basement membrane, the tubular basement membrane, and Bowman's capsular membrane. These are locations that correlate with mesangial expansion, which suggests that MAC has a role in the pathogenesis of diabetic nephropathy [136].

Conclusion

Beyond any doubt, hyperglycemia is the main driver in the development of microvascular complications in people with T1DM and T2DM. Accordingly, strict metabolic control is a cornerstone in the primary prevention of the diabetic microvascular complications retinopathy, nephropathy, and neuropathy. Further, a number of effective treatments of manifest microvascular disease have

been developed, in particular against diabetic retinopathy and diabetic nephropathy; see Chapters 38–40 for further descriptions.

Although many pharmaceutical and technical interventions are available today that effectively prevent or delay the development of microvascular complications in diabetes, there is an ongoing need for the development of new biomarkers and new therapeutic treatments for these complications.

Acknowledgments

Part of this chapter is an updated version of Chapter 35 in the Fourth Edition of this book. Dr. Ferdinando Giacco and Professor Michael Brownlee, the authors of that chapter, are thanked for their contributions.

38 Diabetic Retinopathy

Toke Bek
Department of Ophthalmology, Aarhus University Hospital and Department of Clinical Medicine, Faculty of Health, Aarhus University, Aarhus, Denmark

Key points

- Diabetic retinopathy is a frequent cause of blindness in the Western world.
- The pathophysiology of the disease is unknown, but the morphological lesions characterizing the disease indicate that disturbances in retinal vascular function are involved in the disease pathogenesis.
- The early stages of diabetic retinopathy are not accompanied by any subjective symptoms, but the disease can be detected by screening with inspection of the ocular fundus.
- The early changes may develop into one or both of two vision-threatening complications, proliferative diabetic retinopathy and diabetic maculopathy, each with a different epidemiology, clinical appearance, and location in the retina.
- Diabetic retinopathy can be treated by retinal photocoagulation, and recently the advent of intravitreal angiostatic treatment has added to the therapeutic armamentarium for cases where photocoagulation is not suitable or sufficient.
- Countries with effective population screening and timely treatment of diabetic retinopathy have managed to reduce the incidence of low vision and blindness secondary to the disease to a negligible level.

Introduction

Diabetes mellitus is a disease of intermediary metabolism that may lead to complications in all parts of the body, including the eye [1]. The ocular complications include sudden palsies of external eye muscles resulting in diplopia that normally disappears spontaneously within a few weeks. Individuals with diabetes also have reduced motility of the pupil secondary to autonomic neuropathy, and diabetes may lead to the development of cataract at a much earlier age than in the normal population [2]. However, this condition can be treated by surgery with a low complication rate.

The diabetic complication developing in the retina, diabetic retinopathy, is a potentially much more serious condition and constitutes one of the most frequent causes of blindness in the Western world [3]. The disease is characterized by morphological lesions in the retina related to disturbances in retinal blood flow [4]. The initial signs of the disease are microaneurysms and hemorrhages in the macular area (Figure 38.1) that may progress to one or both of the two vision-threatening complications, diabetic maculopathy and proliferative diabetic retinopathy. In diabetic maculopathy, the early changes progress with breakdown of the blood–retina barrier, exudation of plasma proteins, and formation of retinal edema that may expand to include the foveal region with a resulting destructive effect on central vision. Proliferative diabetic retinopathy is initiated by occlusion of capillaries in the retinal periphery. The consequent ischemia and hypoxia stimulate the release of growth factors that diffuse to the nearest venule with an angiogenic potential and initiate a neovascular response.

Nomenclature

The nomenclature of diabetic retinopathy dates back to the initial descriptions of retinopathy in persons with type 1 diabetes mellitus (T1DM), where it was important to distinguish the early changes without visual loss termed simplex, background (inside the retinal background), or non-proliferative diabetic retinopathy from proliferative diabetic retinopathy where neovascularizations grow pre-retinally and lead to vitreous hemorrhage and blindness if untreated [5]. The grading of retinopathy on this scale was supplemented with a notification of whether edema and/or exudates in the macular area (maculopathy) was present or not, since such changes would threaten central vision by mechanisms other than those related to proliferative diabetic retinopathy. However, the comprehension of diabetic retinopathy should reflect the fact that early retinopathy changes can develop into one or both of the two vision-threatening complications, diabetic maculopathy and proliferative diabetic retinopathy, with different sites of development in the retina, different epidemiologies, and different pathophysiologies (Table 38.1).

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

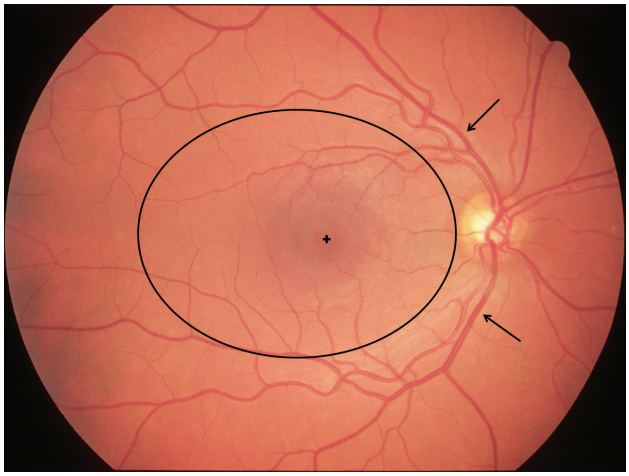

Figure 38.1 Fundus photograph from a normal person. The retinal vascular tree branches from the optic nerve to the right. Arrows indicate the temporal vascular arcades. The ellipse delimits the temporal vascular arcades and the cross in the center indicates the fovea.

Pathophysiology

The coupling between diabetic metabolic disturbances and the development of the morphological changes that characterize diabetic retinopathy is not known in detail [6]. Consequently, diabetic retinopathy has been studied from a number of different perspectives, and over the years a number of different hypotheses have been proposed to explain the development of the disease. One of the most productive hypotheses was the proposal of Michaelson that proliferative diabetic retinopathy is due to the release of growth factors from ischemic and hypoxic areas in the retinal periphery [7], which formed the rational basis for the development of angiostatic treatment for diabetic retinopathy.

Table 38.1 The nomenclature used to describe diabetic retinopathy.

Feature	Nomenclature for diabetic retinopathy	
Early changes without vision loss	• Simplex retinopathy Older notation that has largely been abandoned • Background retinopathy • Non-proliferative diabetic retinopathy Newer notation that is somewhat misleading as it does not indicate that these changes also precede diabetic maculopathy	
Transition towards vision-threatening retinopathy	Preproliferative diabetic retinopathy	Diabetic maculopathy without center involvement
Vision-threatening diabetic retinopathy	Proliferative diabetic retinopathy	Diabetic maculopathy with involvement of the area in and around the fovea

Later hypotheses emphasized metabolic disturbances in the retina, such as hyperglycemia leading to non-enzymatic glycosylation, shunting via aldose reductase, or activation of protein kinase C [8]. Other hypotheses have focused on specific anatomical elements as key factors in the pathogenesis of the disease, such as leukocytes, vascular pericytes, basement membranes, endothelial cells, the blood–retina barrier, neuroglia, and elements involved in neurovascular coupling [9–13]. Finally, some hypotheses have emphasized the involvement of specific reaction types such as inflammation in the development of the disease [14]. All these hypotheses can explain the pathophysiology of the disease in part, but have not individually or together been able to explain fully the development of the disease.

It is a particular feature of the retina that the inner vascular supply is devoid of autonomic nerves. This implies that retinal blood flow is autoregulated, and it has been shown that the vascular changes in diabetic retinopathy may be related to impairment of this autoregulation [15]. The disturbances affect both pressure autoregulation, so that retinal resistance vessels contract insufficiently when the systemic blood pressure is increased [16], and metabolic autoregulation, implying a reduction in the normal dilation of retinal arterioles when the retinal metabolism is increased, such as during exposure to flickering light [17]. Therefore, one of the key issues in the exploration of diabetic retinopathy is to understand the connection between diabetic metabolic dysregulation and disturbances in the regulation of retinal blood flow.

Development

Early changes with no vision loss

The initial morphological changes in diabetic retinopathy are red dots in the macular area representing capillary microaneurysms and dot hemorrhages. These two lesion types often have a similar funduscopic appearance, presenting as small, round, reddish lesions [18]. A differentiation of microaneurysms from hemorrhages requires fluorescein angiography, where microaneurysms are hyperfluorescent and hemorrhages appear as dark spots [19]. Therefore, the idea of counting microaneurysms alone in fundus photographs is meaningless. However, in clinical practice the distinction between microaneurysms and dot hemorrhages is conceptual, and the two lesion types should be considered together in the grading of retinopathy, just referred to as red dots.

The initial lesions typically develop in the area temporal from the fovea (Figure 38.2), probably because the intraluminal pressure is particularly high in this area where the capillaries are supplied by dilated arterioles from both the upper and the lower temporal vascular arcades [20]. The presence of up to a few red dots implies the same risk of progression of the disease, whereas the risk of progression to a vision-threatening condition is proportionate with higher numbers of red dots [21]. Retinal hemorrhages may also assume shapes other than circular when the extravasated blood distributes around the anatomical structures in the retina. One of the most striking examples is the stripe-shaped

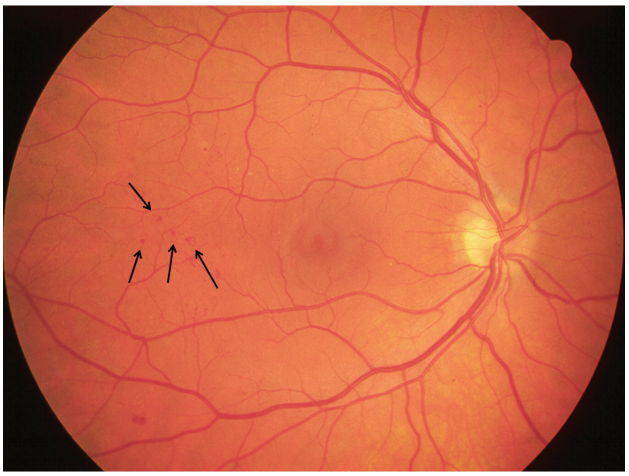

Figure 38.2 Early diabetic retinopathy with red dots (arrows) predominantly located temporally in the macular area.

hemorrhages that may develop in the retinal nerve fiber layer. Microaneurysms and hemorrhages show a highly dynamic pattern of development with continuous new formation and resolution of lesions occurring within days to weeks [22, 23]. Therefore, the progression of the disease with an increase in the total number of lesions over months to years is due to a change in this balance where the number of newly formed lesions is higher than the number of lesions that are resolved.

The progression of diabetic retinopathy (Figure 38.3) implies an increase in the number of red dots and the occurrence of blot hemorrhages, defined as lesions with a diameter larger than that of the vascular arcades at the crossing of the border of the optic disk [19]. Hemorrhages developing around the larger vascular arcades may indicate that impaired autoregulation has resulted in a higher than normal arterial blood pressure being transmitted to the smaller retinal vessels, resulting in damage to the capillary system adjacent to these arcades [24].

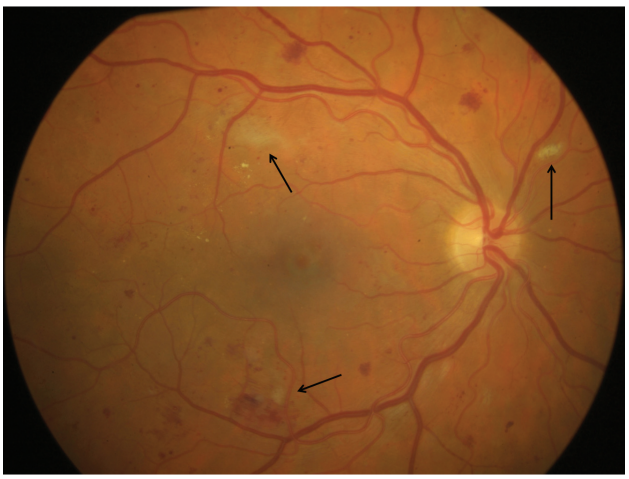

Figure 38.3 Moderate diabetic retinopathy with red dots, larger blot hemorrhages, and cotton-wool spots (arrows).

Figure 38.4 Severe diabetic retinopathy with many whitish cotton-wool spots developing during a period with poor metabolic control.

Diabetic retinopathy may also lead to the development of cotton-wool spots, which are localized whitish lesions about the size of one-third disk diameter located at the inner surface of the retina (Figure 38.4). The lesions represent swelling of the retinal nerve fibers because the axoplasmic transport has been arrested in a focal area with a consequent intracellular accumulation of the organelles transported to the site of the lesion [25]. Therefore, cotton-wool spots are most frequently located in the arcuate areas, where the retinal nerve fiber layer is thick, and never in the foveal area or the retinal periphery, which are devoid of retinal nerve fibers. The lesions reflect a response potential to disturbed axoplasmic transport in the retinal nerve fiber layer, but do not point to a specific cause of this disturbance. Therefore, it is erroneous to refer to the lesions per se as retinal infarctions, although this may be the background for the lesions in some cases. Cotton-wool spots have a dynamic cycle of development and disappearance lasting weeks to months and only rarely affect visual function [26]. The development of a single cotton-wool spot without any other retinopathy lesions does not imply a risk of progression of the disease, but the development of many cotton-wool spots in people with other retinopathy changes (Figure 38.4) may be an indication of unstable regulation of the blood glucose levels and of imminent progression to vision-threatening diabetic retinopathy [27].

Vision-threatening diabetic retinopathy

The early retinopathy changes may progress to one or both of the two vision-threatening complications, proliferative diabetic retinopathy and diabetic maculopathy, each preceded by transition forms.

Proliferative diabetic retinopathy

Mechanism of development

This complication is assumed to be initiated by occlusion of the capillaries in the retinal periphery. The resulting ischemia and

hypoxia stimulate the release of growth factors such as vascular endothelial growth factor (VEGF) that diffuse to the nearest retinal venule with an angiogenic potential and eventually initiate neovascularization [18]. This response reflects the normal angiogenesis during fetal development, where the retinal microcirculation is formed by vascular outgrowth from the retinal venules to reach the arterioles and complete the circulation. The vascular occlusion preceding neovascularization is not directly visible by inspection of the ocular fundus. However, retinal ischemia should be suspected when the retinal fundus has a more yellowish appearance than normal and other causes such as cataract with pronounced nuclear sclerosis that absorbs short-wavelength light have been ruled out. Retinal capillary occlusion can be demonstrated by fluorescein angiography, where the lesions appear as uniform dark areas, probably due to diffusion of the choroidal vascular pattern from fluid accumulated between the photoreceptor outer segments and the pigment epithelium [28]. Fluorescein angiography may also show localized areas of capillary occlusion at earlier stages, and it has been hypothesized that these changes could be involved in the early development of the disease [29].

The peripheral capillary occlusion and the consequent release of angiogenic factors progress to initiate growth of new vessels from the larger retinal venules. This neovascularization requires the presence of both an angiogenic stimulus and viable vessels with an angiogenic potential that is present in the larger venules proximal to areas of capillary occlusion. The proliferating new vessels are unable to grow inside the mature retina and therefore cannot replace the occluded vessels. Alternatively, the vessels grow along the posterior hyaloid membrane to expand preretinally. Therefore, the new vessels never reach an arteriole to complete the circulation, but are recursive back to the site of origin. Since there is no difference between the intravascular pressure of the legs at the origin of the neovascularization there is no blood flow through the vessel. The lack of contact between the new vessel and the retinal tissue precludes normal development of the vessels, which remain immature and fragile, eventually resulting in rupture and spontaneous hemorrhages into the vitreous body. The new vessels developing from venules at the optic nerve head are accompanied with a higher risk of progression to visual loss than neovascularizations located elsewhere [36], but the background for this difference is unknown. The clinical observation of proliferative diabetic retinopathy as a chronically progressive condition may give the impression that the disease process is irreversible, but the fact that retinal neovascularizations may disappear a few days after anti-VEGF therapy, and even under certain conditions spontaneously [31], suggests that the growth of these lesions depends on a continuous stimulation by growth factors.

Clinical presentation

The presence of preproliferative changes with capillary occlusion in the retinal periphery can be suspected when one or more of the following signs (Figure 38.5) are observed [19, 32]:

- The occurrence of many blot hemorrhages temporal in the macular area. These hemorrhages may develop in the foveal region with a consequent reduction in visual acuity, which is one of the few signs of severe diabetic retinopathy that can be noticed subjectively by the person with diabetes [33].
- Intraretinal microvascular abnormalities (IRMAs) that represent dilations of existing vessels from the retinal microcirculation. On fluorescein angiograms, these lesions are located at the border of areas of capillary occlusion and are therefore assumed to represent shunt formations to bypass the areas of capillary occlusion.
- Many cotton-wool spots, probably representing an aggravation of disturbances in blood flow and metabolism.
- Abundant reflexes from the posterior hyaloid membrane visible in younger persons where the optical media are clear. The reflections originate from the vertex of local swellings of the retina, probably reflecting localized areas of subclinical retinal edema.
- Caliber changes of the larger retinal venules that may develop to resemble beads on a string, so-called venous beading. Under normal conditions, the diameter of retinal vessels decreases with increasing distance from the optic disk, and therefore a localized increase in the diameter can be considered to be abnormal. The background for this manifestation of diabetic retinopathy is unknown, but may be related to metabolic acidosis or stagnant retinal blood flow.

Figure 38.5 Preproliferative diabetic retinopathy with blot hemorrhages temporal in the macular area, cotton-wool spots, venous beading (upper arrows), IRMA vessels (lower arrows), and vivid reflexes from the posterior hyaloid membrane in the macular area.

The occurrence of neovascularizations (Figure 38.6) is a pivotal event since this prompts the initiation of treatment. In clinical practice, it is important to differentiate neovascularizations from shunt vessels, which can almost always be done on the basis of the following criteria [34] (Table 38.2):

- Retinal neovascularization is initiated by proliferation of retinal endothelial cells that penetrate the vascular wall to grow out of the vessel. However, endothelial cell proliferation may also develop inside retinal venules. These proliferations lead to occlusion of the venule of origin, which is slow enough to allow the development of shunt vessels to bypass the site of occlusion. These shunt

Figure 38.6 Proliferative diabetic retinopathy with new vessels blurring the optic disk. A neovascularization at the upper temporal arcade has given rise to a preretinal hemorrhage extending close to the fovea.

vessels may have the appearance of an omega loop or reduplicated bypass channels (Figure 38.7). When these changes are observed, the patient will usually already have developed preretinal neovascularizations and the condition should therefore be handled as any other case of proliferative diabetic retinopathy [35, 36].

- Retinal neovascularizations will in most cases become sites of origin of spontaneous hemorrhages, either as preretinal hemorrhages located behind the posterior hyaloid membrane resulting in a localized scotoma in the visual field, or will break through to the vitreous body. This progression of the hemorrhage results in a severe reduction in visual acuity, typically to hand movements, and a severely blurred view to the retinal fundus. If untreated, the vitreous hemorrhage may organize and together with traction from connective tissue in the new vessels the course may result in retinal detachment and total blindness.

Diabetic maculopathy

Mechanism of development

The progression of early diabetic retinopathy may result in the development of retinal edema and/or exudates representing precipitations of plasma proteins predominantly in the macular area. These changes are due to breakdown of the blood–retina barrier

Table 38.2 The differences between neovascularizations and shunt vessels.

Neovascularizations	Shunt vessels
Grow preretinally	Develop intraretinally
Develop from venules and are recursive back to the site of origin	Connect a venule with an arteriole
Many branchings	Few branchings, but often tortuous
May cross feeder vessel	Do not cross feeder vessel
May contain connective tissue	Do not contain connective tissue

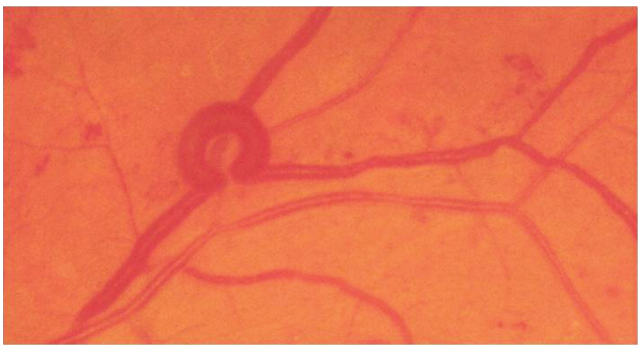

Figure 38.7 A segment of the upper vascular arcade. An omega loop represents a shunt formed to bypass an occlusion of a larger venule because of intravascular proliferation of endothelial cells. The venule extending peripheral from the loop displays changing caliber.

secondary to structural changes in the retinal vessels and impaired autoregulation so that a higher than normal blood pressure is transmitted to the capillary system [37, 38]. These factors compromise the tight junctions between the vascular endothelial cells and cause the exudation of plasma proteins that precipitate as hard exudates.

Clinical presentation

Diabetic maculopathy can be observed in the macular area and a short distance beyond the temporal vascular arcades and nasal from the optic disk, but not in the retinal periphery. Hard exudates may develop in circular precipitation lines around focal points of leakage or more randomly in the macular area when points of leakage are more distributed (Figure 38.8). Retinal edema has been categorized according to whether it is focal or diffuse [39], which may be an indication of the severity of the condition, but the practical significance of this distinction is disputed [40].

Retinal exudates and/or edema can progress and potentially threaten central vision as clinically significant macular edema when exudates and/or retinal edema either (Figure 38.9) (1)

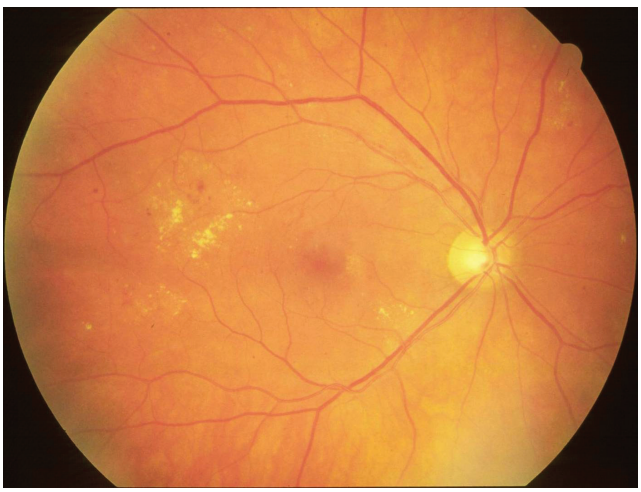

Figure 38.8 Diabetic maculopathy with exudates located temporally in the macular area.

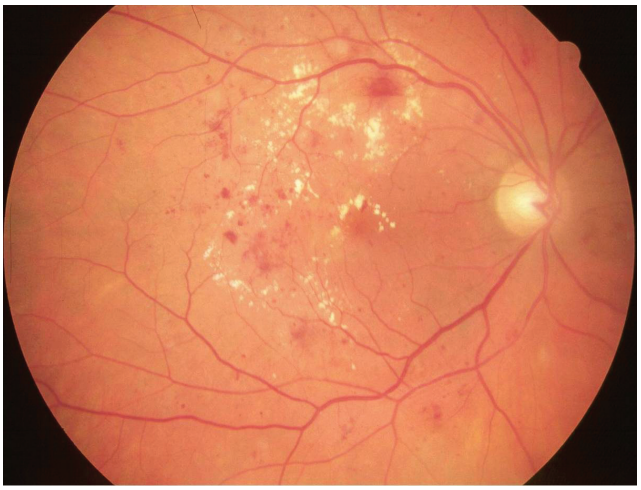

Figure 38.9 Diabetic maculopathy with clinically significant macular edema. Exudates extend over a larger part of the macular area and involving the foveal region.

extend over an area larger than one disk diameter of which a part is located within one disk diameter from the fovea, and/or (2) are located within half a disk diameter from the fovea [41]. Retinal edema together with exudates is termed exudative maculopathy and is the most common type of diabetic maculopathy. However, on rare occasions, macular edema may be due to an extension of capillary occlusion from the retinal periphery to the macular area [42]. The resulting macular ischemia is accompanied by edema that appears yellowish in the retinal fundus with many hemorrhages, but with no exudates. The two types of maculopathy can be differentiated by fluorescein angiography that can identify leakage and capillary occlusion.

Epidemiology

Diabetes mellitus is assumed to affect ~415 million people worldwide, of whom one-third have retinopathy and one-tenth have vision-threatening retinopathy [43]. However, these estimates cover ethnic, socioeconomic, and genetic variations. The pattern of development of diabetic retinopathy differs in the two diabetes types and is influenced by the success of the prevention, detection, and therapy of the disease. Thus, in countries with limited access to antidiabetes medication and lack of systematic population screening, retinopathy changes may develop after a few years' duration of diabetes and may be detected by the occurrence of vision-threatening changes. Therefore, the incidence and prevalence of diabetic retinopathy vary considerably, and estimates of the occurrence of the disease refer to countries with organized population-based screening and management of diabetic retinopathy.

In type 1 diabetes mellitus (T1DM), a few microaneurysms and/or dot hemorrhages may occur at the time of onset of the disease, but these lesions disappear so that the initial signs of diabetic retinopathy in progression appear after ~10 years' duration of diabetes [44]. The prevalence of diabetic retinopathy subsequently increases gradually until ~20 years' duration of diabetes, when almost all people with diabetes have some retinopathy [45]. The incidence of vision-threatening diabetic retinopathy gradually increases until ~25 years' duration of diabetes, after which it declines. This suggests the existence of constitutional risk factors that affect the risk of developing vision-threatening retinopathy within the first decades' duration of diabetes that overlie the risk of disease progression related to the cumulated exposure to metabolic dysregulation. In populations with comprehensive and organized screening and treatment programs, half of all individuals with T1DM develop vision-threatening retinopathy, of whom two-thirds develop proliferative diabetic retinopathy and one-third develop diabetic maculopathy [46].

In type 2 diabetes mellitus (T2DM), the onset of the disease is gradual, and although a large part of the population will remain undiagnosed in the early stages [44], the occurrence of retinopathy in this group is negligable [47]. At the time of diagnosis of T2DM, retinopathy can be observed in a considerable number of individuals, some of whom have already developed vision-threatening retinopathy [48]. After the time of diagnosis, the annual incidence of vision-threatening diabetic retinopathy is constant, and less than 10% of the individuals reach one of the treatment-requiring conditions, proliferative diabetic retinopathy and diabetic maculopathy. Since the number of persons with T2DM is larger than the number of those with T1DM, the absolute number of individuals developing vision-threatening retinopathy is approximately the same in the two groups.

Prevention

The occurrence and development of diabetic retinopathy are influenced by a number of modifiable or non-modifiable risk factors. Studies of non-modifiable risk factors such as ethnicity [49], actual age, and age at onset of diabetes [50] have provided important information about the pathophysiology of the disease. However, modifiable risk factors have received much more attention because of the potential for clinical intervention. Thus, it has been shown that the development of diabetic retinopathy correlates with glycemic control [51], and that intervention to improve this reduces the risk of progression of the disease in both T1DM [52] and T2DM [53]. Similarly, it has been documented that the development of diabetic retinopathy correlates with the systemic blood pressure [54], and that lowering blood pressure can reduce the progression of retinopathy changes in both T2DM [54] and T1DM [55]. Close monitoring of blood glucose and blood pressure can halt the progression of diabetic retinopathy, and are especially relevant during pregnancy where lifestyle and metabolism may be difficult to maintain at a stable level.

Recent evidence suggests that the formation of hard exudates may be related to the cholesterol level in the plasma [43], but clinical intervention studies are lacking to document that a reduction in plasma cholesterol can reduce the risk of diabetic maculopathy.

The development of diabetic retinopathy also depends on the type of diabetes and several studies have reported a higher frequency of retinopathy in men than in women, which may be due to men paying less attention to lifestyle [56].

Screening

Diabetic retinopathy is suitable for screening because the disease fulfills all of the following criteria [57]:

- *The development and early progression of the disease are not detected by the individual with retinopathy.* Since diabetic retinopathy initially develops and progresses outside the foveal area, the individual will not have subjective symptoms until at late stages when damage to central vision has started. Therefore, a screening examination with inspection of the ocular fundus is needed in order to detect early retinopathy lesions before they become a threat to central vision.
- *The disease is frequent.* The frequency of diabetes is increasing, but does not justify screening for diabetic retinopathy in the general population. However, diabetic retinopathy is frequent among the individuals in whom diabetes has been diagnosed and therefore justifies screening for diabetic retinopathy in this population [58, 59].
- *The disease can be detected.* Diabetic retinopathy can be detected by inspection of the ocular fundus, which is achievable in all persons unless impeded by cataract or other media opacities.
- *The disease can be treated.* A number of studies have confirmed the beneficial effect of retinal photocoagulation, intravitreal angiostatic pharmacotherapy, and vitrectomy for the treatment of diabetic retinopathy. This implies that therapeutic consquences can be taken from the detection of diabetic retinopathy.
- *Screening is cost-efficient.* A number of health economic analyses have documented that in addition to the beneficial effects for individuals screened for diabetic retinopathy, the procedure is also highly cost-efficient for society [60].

Screening for diabetic retinopathy consists of inspection of the ocular fundus, which may be supplemented with a measurement of visual acuity in order to assess the consequences of the disease for central vision [61]. It is recommended that the funduscopic appearance is documented by photography, which (1) gives an overview of lesions in all parts of the fundus background, (2) allows retinopathy lesions to be reviewed in order to obtain second opinions, and (3) allows a detailed evaluation of changes in the morphological appearance of the disease over time.

It has been a matter of debate whether screening examinations should be performed without dilation of the pupil (nonmydriatically) in order to allow a faster and more feasible examination procedure for the patient, and the availability of cameras for imaging of the retina through small pupils has facilitated this approach. The disadvantage of this photographic procedure is a reduced quality of images from the retinal periphery.

A single fundus photograph only provides indirect information about depth relations in the retina, which can be inferred from differences in focus. However, the examination can be supplemented with stereo fundus photography, where duplicate fundus photographs are recorded with the camera moved sligthly to each side and the light path tangential to the left and right pupil margins. The resulting images have different disparities and when studied binocularly the grader will obtain a stereoscopic view of the retina, which can be used to diagnose macular edema. However, the evaluation of depth relations in the retina by stereopsis is subjective, and nowadays the evaluation of macular edema should be performed by optical coherence tomography (OCT) scanning [62].

Fundus photography should cover retinal areas where relevant retinopathy changes can be detected, which can be achieved by seven photographic fields using a 30° field of view as in the United States standard [63] or by two 60° images as in the European standard [61]. Grading of retinopathy is performed by comparing the pattern of retinopathy with a set of standard images representing the different stages of the disease, and is designed so that at all levels of retinopathy the risk of progression from one level to the next is the same. This semiquantitative grading method considers the type, overall severity, and location of lesions in different quadrants and in relation to the fovea, but there is considerable morphological information that is not used, such as the number, shape, size, detailed location, and dynamics of the lesions. In order to include this information in the evaluation, initiatives have been taken to develop computer algorithms for quantitative analysis of diabetic retinopathy lesions. This work has been challenged by the lack of gold standards for lesion detection. Hence the interpretation of findings in the retina depends on image quality, and even experienced clinicians may disagree about the identification of retinal lesions [64].

The immense task of evaluating fundus photographs obtained during population screening for diabetic retinopathy has stimulated the training and certification of non-academic graders to manage this task. The grading of diabetic retinopathy should result in answers to the following two questions: (1) what is the time interval to the next screening examination? or (2) should the patient be referred for further diagnostic evaluation or treatment? The time interval to the next screening examination is generally determined by rule-based decision algorithms. On the basis of the diabetes type, diabetes duration, and retinopathy grade, a standard interval is recommended so that the disease will not progress undetected to a vision-threatening stage, even in persons with the fastest disease progression [65]. However, this conservative approach implies that the individuals in whom disease progression is slow will experience a number of superfluous examinations because the disease has not progressed by the time of the next screening examination. Therefore, new algorithms are being developed with the aim of individualizing the control interval and optimizing screening by reducing the number of superfluous examinations. These algorithms consider individual risk factors in order to prolong the control interval as much as possible while ensuring that the condition does not progress to vision-threatening retinopathy [66–68]. However, individualized control intervals may be difficult to remember for both the person

with diabetes and the doctors and other personnel involved in patient care, which is further complicated if optimized retinopathy screening implies that the examinations are not synchronized with visits for metabolic regulation and screening examinations for other late diabetic complications.

Overall, screening for diabetic retinopathy is a complex challenge that involves ophthalmological, technical, and organizational elements, and should therefore be adapted to the local healthcare system in each country. The potentials of such efforts have been proved in countries where screening for diabetic retinopathy has reduced the occurrence of blindness secondary to diabetic retinopathy to a negligible level [69].

Diagnosis

Diabetic retinopathy is defined and diagnosed by inspection of the ocular fundus to identify the typical morphological lesions of disease. Observation of the retina in red-free light may increase the contrast to improve the detection of lesions, but a detailed evaluation of the disease requires information about colors in order to distinguish red lesions from pigmentation. When diabetic retinopathy has progressed to a stage where treatment should be considered, supplementation with other imaging techniques may be required.

Fluorescein angiography (Figure 38.10) is a photographic recording of retinal morphology after intravenous injection of fluorescein, where the fluorescent dye is distributed in the systemic circulation and reaches the eye. In order to detect fluorescein in the retina, an excitation filter that transmits short-wavelength light is inserted into the light path that illuminates the retina, and a barrier filter that transmits longer wavelengths is inserted in front of the photographic film. Previously, the method was used routinely for the diagnosis of diabetic retinopathy but has to a large extent been replaced by less invasive techniques, and at present fluorescein angiography is restricted to special diagnostic cases. The method can detect (1) leakage of fluorescein from the retinal vessels as an indication of breakdown of the blood–retina barrier [70] and (2) capillary occlusion that appears as well-delimited and uniformly black areas [42]. The method plays a particular role in the differentiation of exudative macular edema from ischemic macular edema, which should be managed differently.

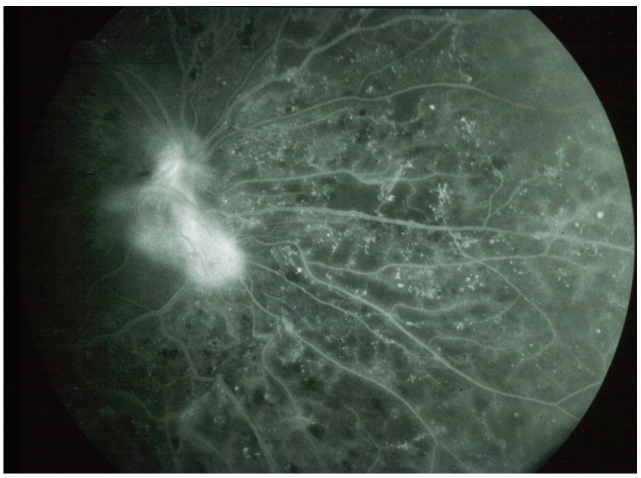

Figure 38.10 Fluorescein angiogram showing focal areas of capillary occlusion and leakage from bordering vessels. Microaneurysms are seen to fill with fluorescein. The hyperfluorescent area to the left represents a neovascularization.

OCT scanning records the latency of light pulses reflected from different retinal layers, which is translated to a measure of distance in the retina (Figure 38.11). The method can determine the location of individual layers in the retina with an accuracy of less than 10 µm and is therefore suitable for detecting pathological lesions in the retina not visible by clinical inspection [71] and for quantifying retinal edema in diabetic maculopathy [72]. This allows the monitoring of the effect of treatment of retinal edema, but the method is also suitable for differentiating diabetic macular edema from other causes of retinal swelling, such as traction from the posterior hyaloid.

A number of other techniques are used for the study of vascular changes in diabetic retinopathy, such as vessel analysis, oximetry, adaptive optics imaging, and flow measurement [73–76]. However, these techniques are research tools and do not at present have a role in daily clinical practice.

Treatment

Retinal photocoagulation

Retinal photocoagulation was the first available treatment with a documented effect on diabetic retinopathy [77]. The treatment is typically applied through a contact lens as localized laser burns with a width of 200–500 µm arranged in a grid pattern with a spacing corresponding to the width of one burn. The adverse effects of the treatment are related to the destructive effects on retinal tissue. At the beginning of a treatment session, the patient will have a strong feeling of glare, which often disappears after adaptation to the intense light. During the treatment, the applications may induce a distinct feeling of pain, especially when applied in the retinal periphery corresponding to the horizontal and the vertical meridians. After treatment, the patient will need a few minutes to adapt to ambient light conditions, and during the following days or weeks may experience blurred vision and flashes in the visual field corresponding to the laser applications. The treatment will induce permanent shrinkage of the visual field and reduce dark adaptation, but in most cases the patient will adapt to this new situation, especially when both eyes have been treated and the visual impression is comparable in the two eyes.

In proliferative diabetic retinopathy, the treatment is applied outside the macular area extending to the retinal periphery, and the beneficial effect is assumed to be related to the elimination of ischemic and hypoxic retinal tissue with a reduction in the release of the growth factors that stimulate neovascularization. The treatment typically requires 2000–3000 applications and is

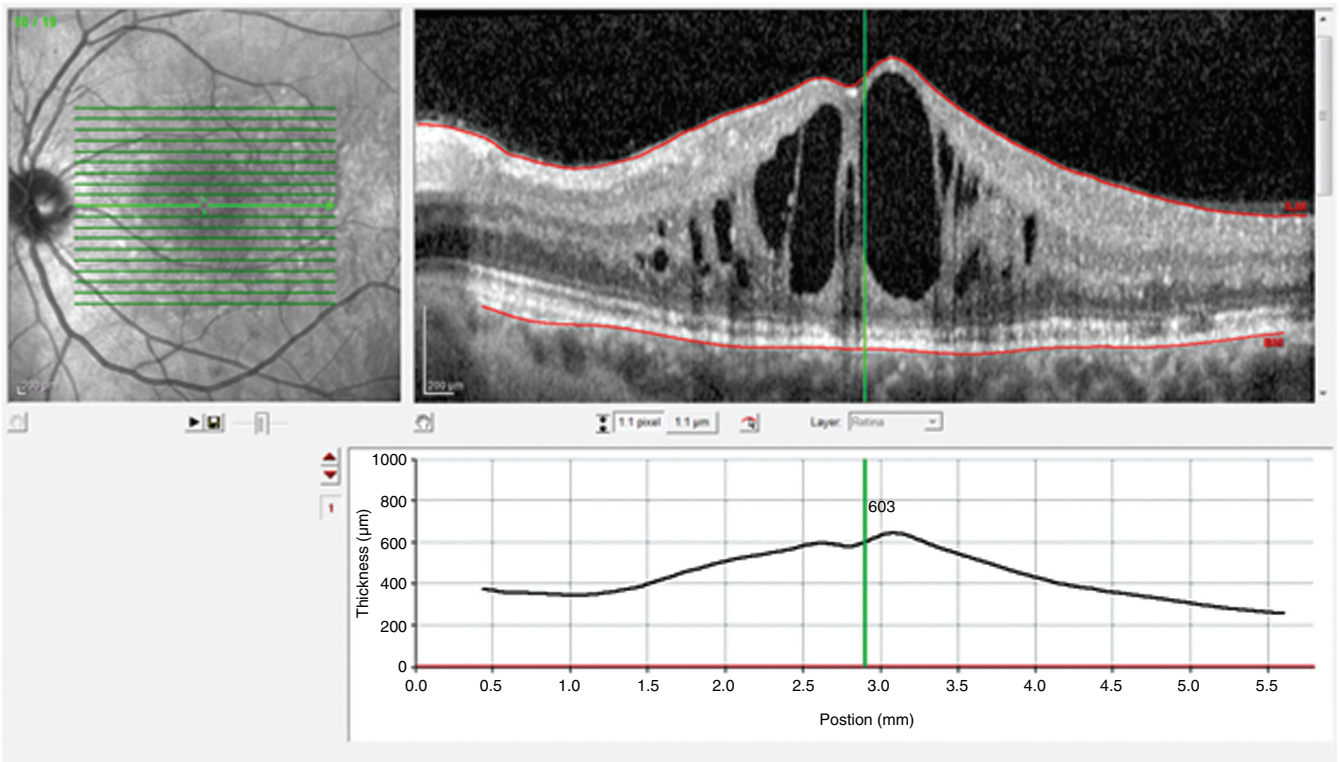

Figure 38.11 In the top left image, horizontal green lines represent the optical coherence tomography (OCT) scanning lines in the macular area from a person with diabetes mellitus. In the top right image, the OCT scan through the fovea shows cystic macular edema secondary to diabetic maculopathy. The graph represents the profile of the retinal surface along the OCT scan.

performed in several sessions until the intended clinical response has been obtained (Figure 38.12). The visual prognosis depends on age and visual acuity before treatment, whereas the number of laser applications necessary to halt the disease has no influence on the visual prognosis [78].

Figure 38.12 Fundus photograph 1 year after panretinal photocoagulation of the case shown in Figure 38.6. The hyperpigmented laser scars extend to the retinal periphery beyond the borders of the image.

Proliferative diabetic retinopathy may lead to vitreous hemorrhage, which can be the initial sign of retinopathy if progression to this stage has not been detected otherwise, but may also occur in individuals who have received photocoagulation and in whom retinal neovascularizations have not regressed. Vitreous hemorrhage leads to a sudden reduction in visual acuity and therefore the patient is generally referred to an ophthalmologist. If the patient has not received photocoagulation it is important to perform ultrasound B-scan examination to rule out retinal detachment. Generally, spontaneous resolution of the vitreous hemorrhage should be awaited for a few weeks to allow inspection and/or treatment of the retina [79]. If the hemorrhage does not resolve spontaneously, the treatment of choice is vitrectomy with surgical removal of the vitreous opacities [80]. The clearing of the vitreous body may at the same time establish a clear view to the retina to allow retinal photocoagulation. The visual prognosis depends on the damage to the retina induced by the diabetic retinopathy changes before treatment. Interestingly, vitrectomy has also been suggested for the treatment of diabetic maculopathy, since the replacement of the vitreous body with saline can improve diffusion and thereby facilitate the exchange of oxygen and other metabolites to the retina [69]. Retinal photocoagulation and vitrectomy will also often lead to regression of new vessels in the iris and the anterior chamber angle of the eye, but if this regression is insufficient the patient may need treatment for neovascular glaucoma.

In diabetic maculopathy, retinal photocoagulation is assumed to facilitate diffusion of oxygen and other nutrients from the choroid, and the elimination of metabolically active tissue induces a contraction of the pathologically dilated retinal vessels [81]. It is a general misconception that focal treatment of microaneurysms is effective. Owing to the fast turnover, the lesions disappear spontaneously whether treated or not [23]. However, focal treatment in other areas of leakage may reduce permeability of the retinal vessels and result in regression of hard exudates that have precipitated in circles around the leaking point [82]. The treatment is applied corresponding to areas with retinal edema, but sparing the papillomacular bundle and a zone within 500 µm from the fovea, which can often be achieved by a few hundred applications. Persons with reduced visual acuity may have extrafoveal points of fixation, and care should be taken not to photocoagulate these areas. Visual acuity may also be reduced in ischemic maculopathy with occlusion of perifoveal capillaries so that the foveal avascular zone is enlarged. In these cases, retinal photocoagulation may reduce central vision further and is therefore not recommended.

Intravitreal angiostatic treatment

Recently, several new approaches for intravitreal medication have been introduced for the treatment of diabetic retinopathy and other retinal vascular diseases. Thus, intravitreal injection with triamcinolone has been shown to reduce diabetic macular edema, which supports the hypothesis that inflammation is involved in the disease process. The effect of the treatment is transient, but may provide a time window for the initiation of other therapies with a more permanent effect. However, the treatment is also accompanied by the risk of adverse effects such as glaucoma and cataract, which should be included in the considerations about which treatment strategy to follow [843].

The introduction of intravitreal treatment with anti-VEGF medication has significantly improved the visual prognosis of diabetic retinopathy [84]. Thus, the treatment has beneficial effects on diabetic macular edema [85–87] and can reduce neovascularization in proliferative diabetic retinopathy [88]. The advantage of the treatment is that it is not accompanied by destruction of retinal tissue, but the treatment should often be repeated with an interval of months with accumulation of the risk of adverse effects such as infection, glaucoma, cataract, and retinal detachment. Therefore, the prospects of life-long repeated intravitreal injections are less attractive in younger people. The treatment consists of a loading phase with three injections separated by 1 month, followed by regular controls where the treatment can be repeated depending on the clinical response. The treatment is the first choice in persons with diabetic maculopathy where the retinal edema is mainly located in the foveal area centrally from the zone that is accessible for retinal photocoagulation (Figure 38.13), and also in those in whom macular photocoagulation has not had a sufficient effect.

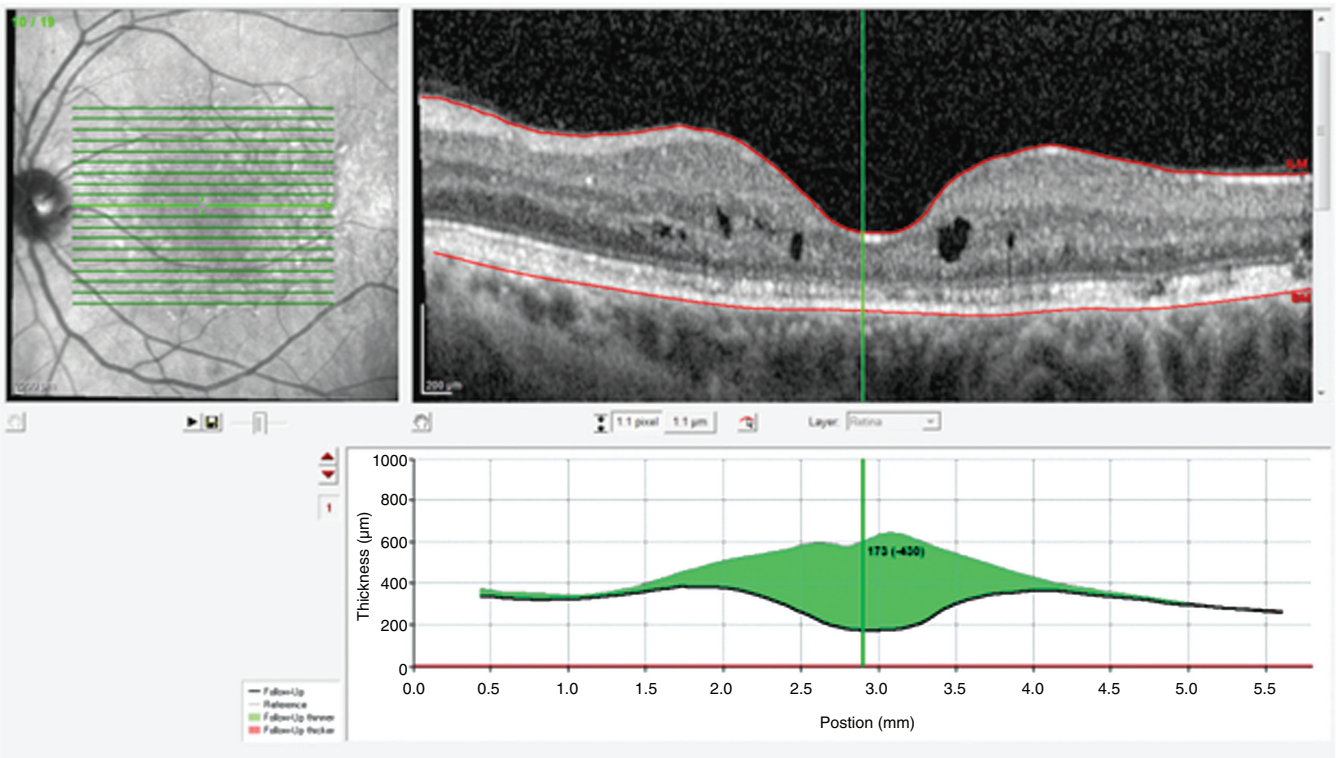

Figure 38.13 In the top left image, horizontal green lines represent the OCT scanning lines in the patient shown in Figure 38.11 and recorded 3 months after intravitreal injections of VEGF inhibitor. In the top right image, the OCT scan through the fovea shows that the retinal swelling has been reduced to a few cysts and the fovea has been restituted. The graph represents the retinal profile along the OCT scan before and after treatment. The green area represents the reduction in retinal thickness along the scan.

Additionally, the treatment may lead to regression of retinal neovascularizations and thereby reduce the risks to vision after photocoagulation or vitrectomy in proliferative diabetic retinopathy.

Exploration of diabetic retinopathy

During the past 50 years, immense research efforts have been invested in exploring diabetic retinopathy, and several developments have significantly shifted the understanding and management of the disease. In the 1960s, the beneficial effect of retinal photocoagulation was discovered by serendipity and once fluorescein angiography was accepted by the ophthalmological community, this diagnostic method added significantly to the diagnosis and understanding of the disease. In the 1980s, the introduction of vitrectomy was refined for the treatment of severe proliferative diabetic retinopathy, and systematic screening programs for diabetic retinopathy were initiated worldwide. In the 2000s, intravitreal angiostatic treatment was introduced, based on the discovery of VEGF as a key compound involved in increasing vascular permeability and stimulating neovascularization.

However, there is still a lack of understanding of how the diabetic metabolic dysregulation triggers the processes in the retina that initiate and accelerate diabetic retinopathy. Vascular changes resembling early diabetic retinopathy have been induced in small rodents, and more advanced diabetic retinopathy-like changes have been induced in diabetic dogs, pigs, and monkeys, but the full spectrum of lesions observed in human diabetic retinopathy has not been reproduced in these models, which is a major barrier for studying the pathophysiology of the disease. This lack of direction has opened up numerous working hypotheses and studies of diabetic retinopathy viewed from a number of different perspectives, depending considerably on the interests and opinions of individual researchers rather than firm knowledge. Being a systemic disease, diabetes affects all elements of the eye, and almost any working hypothesis suggesting a change in a measurement in the eyes of persons with diabetes can be confirmed. This implies that the research field of diabetic retinopathy is productive, but it is uncertain which research direction will contribute to the next breakthrough in the understanding and management of this condition. The art of research in diabetic retinopathy is to make the right choices for such experimental strategies.

[2] Steno Diabetes Center Copenhagen (SDCC), The Capital Region of Denmark and Department of Clinical Medicine, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark

Key points

- Classically, diabetic nephropathy is characterized by gradually increasing urine albumin excretion over many years, accompanied by slowing rising blood pressure and declining glomerular filtration rate (GFR).
- A small number of individuals with type 1 diabetes and about 30% of those with type 2 diabetes who develop chronic kidney disease have a progressive fall in GFR with no or minimal albuminuria. This may be a different form of kidney disease.
- Individuals with nephropathy are at greatly increased risk of other microvascular and macrovascular complications of diabetes.
- The risk of cardiovascular disease (CVD) increases as albuminuria increases and independently as GFR decreases.
- Approximately 30–50% of white European individuals with diabetes will develop albuminuria grade A2; the prevalence is higher in non-Caucasian people.
- One-third of people with diabetes will progress to albuminuria grade A3 and be at high risk of end-stage renal disease.
- Factors most closely associated with progression of nephropathy are poor glucose and blood pressure control and baseline albuminuria.
- Screening for diabetic kidney disease should be done annually, by measuring the urine albumin : creatinine ratio and estimated GFR (eGFR).
- Good blood glucose and blood pressure control are key to the prevention of nephropathy.
- If albuminuria grade A2 or greater is present, an inhibitor of the renin–angiotensin system (RAS) should be commenced and titrated up to the maximum tolerated dose.
- Maintaining blood pressure at 120–130/75 mmHg, with the addition of other antihypertensive agents as necessary, will reduce the rate of decline of GFR from 10–12 to 3–5 mL/min/1.73 m^2.
- Reducing dietary protein intake to 0.7–1.0 g/kg body weight per day may slow the deterioration in renal function.
- Aggressive management of other cardiovascular risk factors and prescription of aspirin reduce the incidence of cardiovascular events and of progression to nephropathy by ~60%.
- Renal failure due to diabetes is the commonest single cause of entry to renal replacement programs worldwide; the majority of patients have type 2 diabetes plus major comorbidities.
- People with end-stage renal disease and significant comorbidities should be offered dialysis. Fitter individuals benefit from kidney or kidney–pancreas transplantation, but need full cardiovascular assessment and if necessary treatment before transplantation.

Introduction

Worldwide, chronic kidney disease (CKD) remains an important, common complication of diabetes. End-stage renal disease (ESRD) is devastating to the individual and of enormous financial and social consequences to society. The proportion of individuals commencing renal replacement therapy in 2012 because of diabetes varied enormously, ranging from 12% in Ukraine to 66% in Singapore [1]. In the United States, incidence rates of ESRD in diabetes increased by 50% between 1996 and 2006, but have fallen slowly since then, and in 2012 it was ~150 per million per year [1]. The incidence of ESRD in type 1 diabetes mellitus (T1DM) remained stable or declined over the last decade, but increased in type 2 diabetes mellitus (T2DM) [2–4]. Most people with diabetes on renal replacement therapy have T2DM.

Definitions

Diabetic nephropathy refers to the chronic condition developing over many years, characterized by gradually increasing urinary albumin excretion (UAE), blood pressure and cardiovascular risk, falling glomerular filtration rate (GFR) and eventual ESRD. The clinical syndrome is associated with characteristic histopathological features [5]. A small proportion of individuals with T1DM [6, 7], and ~50% of those with T2DM [8] with progressively declining GFR have no or minimal albuminuria. We will refer

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

Table 39.1 Glomerular filtration rate (GFR) categories in chronic kidney disease.

GFR category	GFR (mL/min/1.73 m^2)	Description
G1	≥90	Normal or high
G2	60–89	Mildly decreased[a]
G3a	45–59	Mildly to moderately decreased
G3b	30–44	Moderately to severely decreased
G4	15–29	Severely decreased
G5	<15	Kidney failure

[a]Relative to young adult level.

to this clinical phenotype as non-classical diabetic nephropathy. "Diabetic kidney disease" refers to both classical and non-classical diabetic nephropathy. Chronic kidney disease (CKD) refers to kidney disease of any etiology, including non-diabetes-related causes.

Screening for and classification of chronic kidney disease

Guidelines suggest systematic screening, as part of the "annual review." Albuminuria and GFR should be measured, allowing identification of proteinuric and non-proteinuric disease. Screening should be undertaken when the person is free from acute illness and in stable glucose control, because many acute illnesses and acute hyperglycemia increase albuminuria temporarily.

As albuminuria may increase in the upright posture and with exercise, measurements are best made in an early-morning urine sample; however, a spot urine sample is acceptable if there is no alternative. Both urine albumin and creatinine are measured and the albumin : creatinine ratio (ACR) is calculated. Because of the high day-to-day variation in UAE, if the first sample is positive, further samples should be obtained, ideally within 1–3 months. At least two out of three measurements should be abnormal before a diagnosis of albuminuria is made.

Serum creatinine should be measured annually, using an accredited assay standardized to the recommended isotope dilution mass spectrometry reference method. Most laboratories calculate the estimated GFR (eGFR) using the four-variable Modification of Diet in Renal Disease (MDRD) equation, adjusting for age, sex, and ethnicity [9]. This equation provides more reliable information than serum creatinine and is sufficiently accurate for clinical use when eGFR is <60 mL/min/1.73 m^2 [10, 11]. However, the MDRD equation underestimates GFR at higher levels and is not a good indicator of hyperfiltration [12, 13]. The CKD-EPI equation uses the same variables as the MDRD equation, but estimates measured GFR more accurately, particularly at higher levels of GFR [14]. The CKD-EPI equation also categorizes risk of mortality and ESRD more accurately than the MDRD equation in a wide range of populations, including those with diabetes [15, 16]. Hence recent guidelines advocate using the CKD-EPI rather than MDRD equation to estimate eGFR [17].

The 2012 Kidney Disease: Improving Global Outcomes (KDIGO) Clinical Practice Guideline for the Evaluation and Management of CKD advocates that final screening status should indicate both the GFR and UAE status, as in Tables 39.1 and 39.2, along with the cause of the kidney disease [17, 18]. The information can then be used as a measure of renal prognosis (Figure 39.1).

There is no agreement that cystatin C-based estimates of GFR are superior to creatinine-based estimates [19, 20]. KDIGO guidelines recommend calculating cystatin-based eGFR in adults whose creatinine-based eGFR is 45–59 mL/min/1.73 m^2 without other markers of kidney disease [17]. However, we do not know that this approach improves the identification of individuals with progressive CKD compared with frequent measures of creatinine-based eGFR.

Natural history and histopathology

Classical diabetic nephropathy

Gradually increasing UAE over many years is the hallmark of classical diabetic nephropathy (Figure 39.2). At presentation of T1DM, albuminuria grade 2 or 3 may be present. As glycemia is controlled, albuminuria returns to normal. In those who will never develop nephropathy, UAE remains normal, except during periods of particularly poor glucose control, or during acute intercurrent illness, when a transient increase in UAE may occur.

Table 39.2 Albuminuria categories in chronic kidney disease.

		ACR (approximate equivalent)			
Category	AER (mg/24 h)	mg/mmol	mg/g	Description	Previous terminology
A1	<30	<3	<30	Normal to mildly increased	Normal
A2	30–300	3–30	30–300	Moderately increased[a]	Microalbuminuria
A3	>300	>30	>300	Severely increased[b]	Proteinuria

[a]Relative to young adult level.
[b]Including nephrotic syndrome.
ACR, urine albumin : creatinine ratio; AER, albumin excretion rate.

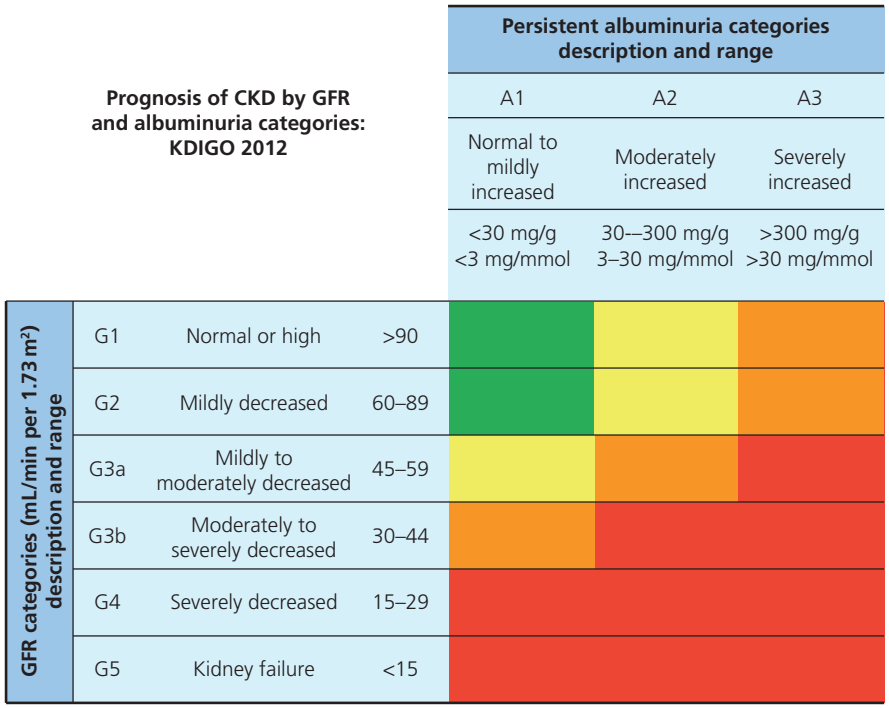

Figure 39.1 Prognosis of chronic kidney disease by estimated glomerular filtration rate and albuminuria. Source: Reprinted by permission from Macmillan Publishers Ltd: *Kidney International*, Levin A, Stevens PE [18], copyright 2014.

In those who will develop diabetic nephropathy, UAE increases gradually, with albuminuria grade A2 usually appearing within 5–15 years of diabetes. Untreated, the mean increase in UAE is 20% per year. In people with T1DM, ~1.5–2.5% per annum develop albuminuria grade A2 [21, 22], and 50% develop persistent grade A2 at some point [23, 24]. Approximately one-third with albuminuria grade A2 progress gradually over a further 5–15 years to albuminuria grade A3, one-third will remain at grade A2, and one-third will revert to grade A1 [25, 26]. In the short term, reversion from albuminuria grade A2 to grade 1 appears common, one study reporting regression in 58% of participants over 6 years [27]. Short-duration grade A2 albuminuria, and lower HbA_{1c}, systolic blood pressure, total cholesterol, and triglycerides were all independently associated with regression. The eventual outcome in those who regress, or who do not initially progress, remains unclear. However, they probably remain at increased risk of nephropathy compared with individuals who have never had albuminuria grade A2.

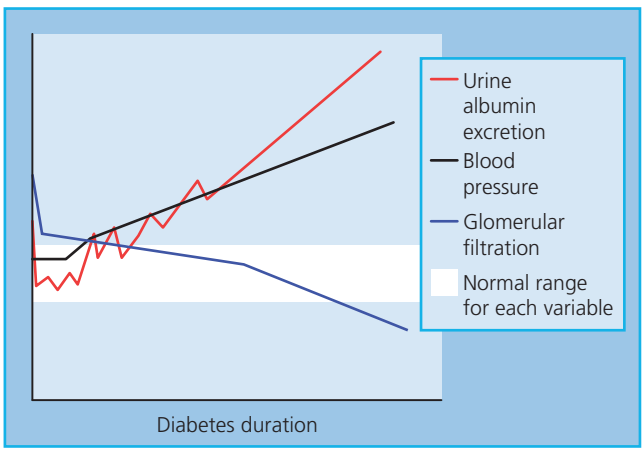

Figure 39.2 Natural history of classical diabetic nephropathy. The white bar represents the normal range for each variable.

Almost all people with T1DM and albuminuria grade A3 eventually progress to ESRD. The use of eGFR rather than serum creatinine has unmasked a decline in eGFR within the normal range in individuals with progressive albuminuria grade A2, but eGFR <60 mL/min/1.73 m^2 is rare at this stage. However, in albuminuria grade A3, the mean annual rate of decline of GFR is 10–12 mL/min/1.73 m^2 untreated.

One group has suggested that GFR falls before the onset of albuminuria in T1DM [7]. Using serial estimates of eGFR derived from serum creatinine and cystatin C, they reported a median annual decline in eGFR of 1.5% per year in individuals with albuminuria grade A1 and 2.2% in those with grade A2. They argued that albuminuria is therefore not a good guide to diabetic nephropathy [28]. Alternative explanations are suppression of albuminuria by renin–angiotensin system (RAS) inhibitors or that kidney disease with and without albuminuria are different pathological processes, as discussed below.

The natural history of diabetic nephropathy is generally similar in T2DM. Albuminuria grade A2 or A3 may be present at diagnosis, and may persist in individuals who have had undiagnosed diabetes for some years. GFR is usually >60 mL/min/1.73 m^2 at onset of albuminuria grade A2, only declining to CKD stage 3 or more when albuminuria grade A3 develops [29, 30].

The characteristic structural changes of classical diabetic nephropathy include basement membrane thickening,

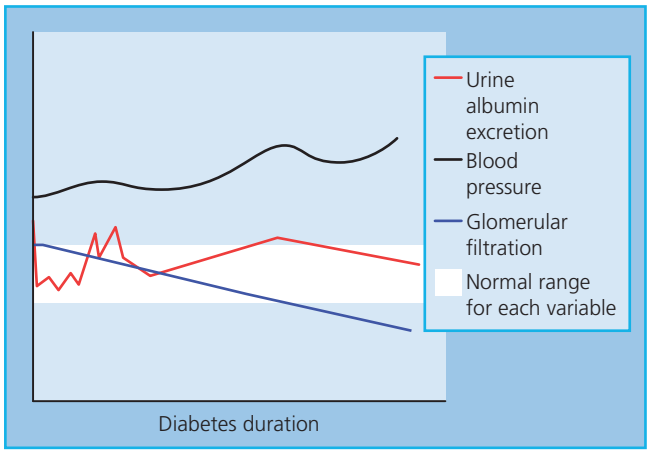

Figure 39.3 Natural history of non-classical diabetic nephropathy. The white bar represents the normal range for each variable.

progressive mesangial expansion, alteration and loss of podocytes, and tubulo-interstitial fibrosis, eventually leading to glomerulosclerosis [5].

Non-classical diabetic kidney disease

Some 7–22% of individuals with T1DM [6, 31] and 50% of those with T2DM [8, 32] who develop progressive CKD do not have preceding albuminuria (Figure 39.3). Identification of people with non-diabetic renal changes on the basis of clinical features, including the absence of diabetic retinopathy [33], is difficult. Individuals with T2DM and CKD stage 3 or more plus albuminuria grade A2 or 3 are very likely to have histological features of diabetic glomerulosclerosis, whereas those with albuminuria grade A1 are much more likely to have arteriosclerosis [34]. The underlying disease process in non-classical diabetic CKD probably reflects a combination of aging, hypertension, and atherosclerotic vascular disease in addition to diabetes. Obesity, with ectopic lipid accumulation in the kidney, may also be important [35].

The rate of progression of CKD in the absence of significant albuminuria is slower than in those with albuminuria in both T1DM [7] and T2DM [36, 37]. Low eGFR and albuminuria synergistically increase the risk of ESRD.

Changing epidemiology of kidney disease in diabetes

T1DM

Recent data suggest that in T1DM, albuminuria grade A2 and A3 and ESRD may be less common than previously, at least in some countries [38].

Older studies suggested a lifetime risk of developing albuminuria grade A2 of ~50%, appearing generally between 10 and 20 years' duration of T1DM. In the Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications (DCCT/EDIC) cohort, the cumulative incidence of persistent albuminuria grade A2 was 38% after 30 years in the conventional group and 25% in the intensive group [39]. The incidence appeared to plateau in both groups after 25–30 years. Grade A2 albuminuria developed most frequently in the second decade of diabetes in the conventional group, the incidence being blunted particularly during this time in the intensive group.

Older data suggest that the cumulative incidence of albuminuria grade A3 is ~40% after 40 years' duration of T1DM. In the DCCT, after 30 years' duration, 25% of the conventional group and 9% of the intensively managed group had albuminuria grade A3 [40]. Several Scandinavian studies also reported low rates of ~13% after 20–25 years' duration [41, 42]. However, in the Pittsburgh cohort, the incidence has remained relatively steady at 32% after 25 years [43].

Several European countries report a current incidence of ESRD in T1DM of 2.5–7.8% after 30 years of diabetes [44, 45]. The Pittsburgh Epidemiology of Diabetes Complications Study [46] and the WESDR cohort [47] suggested a declining incidence in those diagnosed after 1970. Survival with ESRD may also have improved.

Hence the incidence of all stages of diabetic nephropathy in T1DM may be declining, at least in some centers. However, in the United Kingdom, in the Golden Years cohort of individuals with duration of T1DM >50 years, 36% had albuminuria grade A2 or A3 [48]. In a similar cohort in the USA, the prevalence of albuminuria, defined using a higher cut-off than in the UK cohort, was 13.1% [49]. Thus the observed decline in incidence of nephropathy may be delay rather than true prevention.

T2DM

A widely varying prevalence of albuminuria grade A2, from 10 to 42%, has been reported. Longitudinal studies suggested that the rate of progression from albuminuria grade A1 to A2 is 3–4% per annum. One older study demonstrated equivalent cumulative incidence of albuminuria grade A3 in T1DM and T2DM after 25 years' duration of diabetes [50]. In the Pima Indians, the incidence of ESRD has declined since 1990 [51]. National US survey data reported a prevalence of chronic kidney disease (eGFR <60 mL/min/1.73 m^2 or UAE >30 mg/g) of 43.5% in the overall T2DM population and 61.0% in those aged ≥65 years [52]. In the UK, using a similar definition, the prevalence was 42.3% [53]. The increasing number of individuals with diabetes commencing renal replacement therapy in many countries is due mainly to persons with T2DM [1] and is accounted for in part by an increased acceptance of older, sicker individuals and improved cardiovascular survival.

Risk factors and markers for chronic kidney disease in diabetes

Many factors are associated with CKD in diabetes (Figure 39.4). Some are associated with both classical and non-classical kidney disease, and some with one but not the other phenotype [54]. Associations may be with both albuminuria and GFR or with one measurement only. Some factors influence initial development of

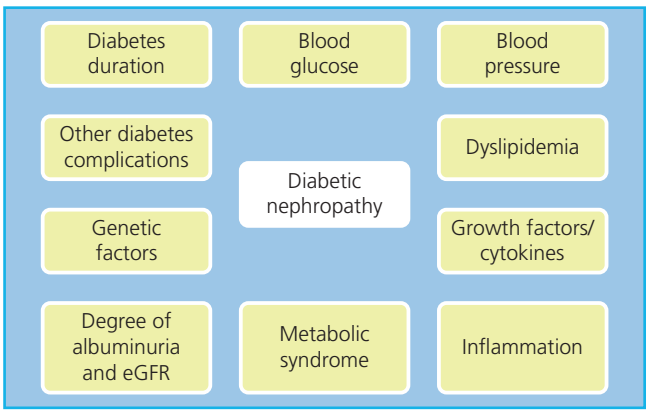

Figure 39.4 Clustering of risk factors and markers for classical diabetic nephropathy.

kidney disease and others progression of disease. Duration of diabetes is one of the strongest risks factors for diabetic nephropathy, particularly in T1DM.

Glucose control

Recent studies reinforce the importance of glucose control in the development and progression of diabetic nephropathy. An unselected Swedish cohort of individuals with T1DM was followed from diagnosis for 20–24 years [55]. No individuals with a long-term weighted mean HbA_{1c} < 60 mmol/mol (7.6%) developed albuminuria grade A2. In contrast, 23% of those with mean HbA_{1c} >80 mmol/mol (9.5%) did so. There is a strong, graded positive association between HbA_{1c} and incident eGFR <60 mL/min/1.73 m^2, independent of other risk factors and present even in the absence of albuminuria [56]. Greater variability in HbA_{1c} is associated independently with albuminuria and diabetic nephropathy [57, 58]. In the DCCT, stimulated C-peptide was associated inversely with albuminuria [59]. Whether the protection afforded by preservation of C-peptide secretion is through improved blood glucose control or by a direct effect is unclear.

Blood pressure

Blood pressure is critical in the development and progression of diabetic kidney disease. The excess prevalence of hypertension in T1DM is confined to those with nephropathy [60]. In young people with albuminuria grade A2, changes in blood pressure are subtle, perhaps manifesting only as reduced nocturnal diastolic blood pressure dipping [61]. Once albuminuria grade A3 is present, frank hypertension is present in 80% of patients, and is almost universal in ESRD. Variability in systolic and diastolic blood pressure independently predicts the development of albuminuria in T1DM [62].

In T2DM, the link between hypertension and renal disease is less striking, because hypertension is so common. Almost all with albuminuria grade A2 or worse have hypertension. In people with diabetic nephropathy, variability in systolic blood pressure is independently associated with the development of ESRD [63].

Other metabolic factors

Blood lipids, including triglycerides [48], contribute to the development and progression of nephropathy, although the lipid phenotype alters as nephropathy progresses [64, 65]. Current smoking predicts the development of albuminuria [66]. Insulin resistance increases the risk of albuminuria and a rapid decline in eGFR in T1DM [67] and of albuminuria in T2DM [68]. Uric acid predicts the development of albuminuria grade A3 [69, 70]. Individuals with T1DM or T2DM and nephropathy are more likely to have the metabolic syndrome [71–73].

Hyperfiltration

Hyperfiltration is common at onset of T1DM and is also present in some individuals at diagnosis of T2DM. In the majority, GFR returns to normal as glucose is controlled, but in some individuals, hyperfiltration persists. The hypothesis that individuals with persistent hyperfiltration are most at risk of subsequent diabetic nephropathy remains controversial [74–76].

Genetic factors

Genetic factors influence susceptibility to diabetic nephropathy [77]. If one sibling with T1DM has nephropathy, the risk to a second sibling is increased 4–8-fold compared with siblings where neither has nephropathy [78]. The clustering of conventional cardiovascular risk factors and CVD in people with diabetic nephropathy also occurs in their parents [79]. This suggests that the genetic susceptibility to nephropathy also influences the associated CVD. Multiple genes are involved, either protective or deleterious. Different loci may influence albuminuria and GFR separately [80]. Epigenetic modification may also be important [81].

Ethnicity

Albuminuria and CKD stages 4 and 5 are more common in UK Afro-Caribbean and South Asian individuals than white European people [82, 83]. The prevalence of early CKD (defined as albuminuria grade A2 or greater and eGFR<60 mL/min/1.73 m^2) is higher in Latino and African American individuals than white people [84]. Albuminuria and CKD are also more common in Pima Indians [85] and in Māoris and Pacific Islanders [86, 87] than white Europeans. Reasons for this varying prevalence may include differing genetic influences and altered response to, or poorer access to, treatments.

T2DM developing in young people

Individuals who develop T2DM in youth have a high prevalence of hypertension and albuminuria grade A2 [88]. ESRD and death are particularly common in young people from ethnic minorities [89–91]. However, in some of these populations, there is a high prevalence of non-diabetic kidney disease [92].

Albuminuria and GFR

Baseline albuminuria and eGFR independently influence the development and rate of progression of CKD [93]. Baseline albuminuria strongly predicts ESRD [94]. Higher levels of

albuminuria grade A1 [95] and lower eGFR [96] predict a faster decline in eGFR.

Other risk factors

Other risk factors for nephropathy include pre-eclampsia [97], inflammatory markers [98, 99], cytokines and growth factors [100], periodontitis [101], and serum bilirubin levels [102, 103]. Obstructive sleep apnea [104] and non-alcoholic fatty liver disease are both independently associated with diabetic nephropathy [105, 106]. Circulating levels of tumor necrosis factor-α receptor 1 are independently associated with the cumulative risk of ESRD in T1DM and T2DM [107–109].

Association of diabetic kidney disease with cardiovascular disease

The prognosis for people with diabetes and CKD is much poorer than for those without CKD. Both albuminuria (Figure 39.5) and eGFR <60 mL/min/1.73 m^2 (Figure 39.6) contribute independently and synergistically to the increased all-cause and cardiovascular risk [37, 110–112].

Type 1 diabetes

In T1DM, the relative risk of premature mortality is 2–3-fold higher in grade A2 albuminuria, 9-fold in grade A3, and 18-fold in ESRD compared with the non-diabetic population (Figure 39.7) [113]. Individuals with T1DM and grade A1 albuminuria do not have a higher risk of premature death [113, 114]. CVD is 1.2-fold more common in people with grade A2 albuminuria [115] and 10-fold higher in those with albuminuria grade A3 compared with those with grade A1 [116]. The cumulative incidence of CVD by the age of 40 years is 43% in people with T1DM and albuminuria grade A3, compared with 7% in individuals with albuminuria grade A1, with a 10-fold risk of coronary heart disease and stroke. In ESRD, the risk of CVD is even higher. Median survival on renal replacement therapy is 3.84 years [117].

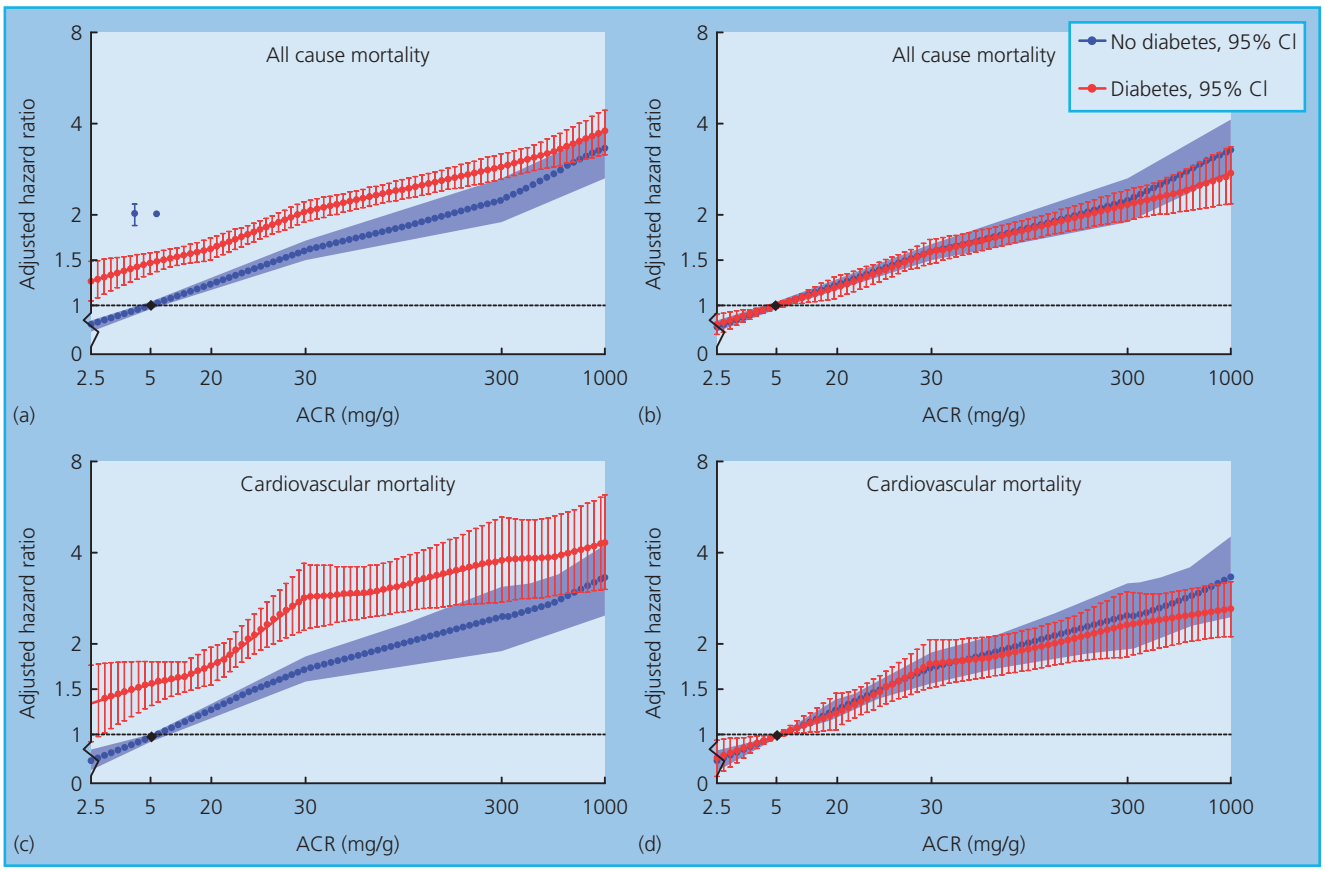

Figure 39.5 Hazard ratios for all-cause and cardiovascular mortality in the combined general and high-risk populations according to urine albumin : creatinine ratio (ACR) in participants with and without diabetes. (a, b) All-cause mortality; (c, d) cardiovascular mortality. Panels (a) and (c) use one reference point (diamond, ACR of 5 mg/g in the no diabetes group), for both individuals with and without hypertension to show the main effect of diabetes on risk. Panels (b) and (d) use separate references (diamonds) in the diabetes and no diabetes groups to assess interaction with diabetes specifically. Hazard ratios were adjusted for age, sex, race, smoking, history of cardiovascular disease, serum total cholesterol concentration, body mass index, and estimated glomerular filtration rate. Blue and red circles denote $p < 0.05$ compared with the reference (diamond). Significant interaction between diabetes and ACR is shown by × signs. Type 2 diabetes

In T2DM, CVD risk is increased 2–4-fold with grade A2 albuminuria [118] and 9-fold in grade A3 [119]. Once serum creatinine is outwith the normal range, cardiovascular risk increases exponentially [120]. Median survival from initiation of renal replacement therapy is 2.16 years [117].

Microvascular complications

People with diabetic nephropathy invariably also have other microvascular complications. Significant retinopathy is almost always present in people with T1DM and albuminuria grade A2 or more. Progression of retinopathy and development of nephropathy each increases the risk for the other, supporting the notion of a common etiology [121]. In people with T2DM, the relationship is less clear-cut [122]. Those with classical nephropathy and progressively increasing albuminuria usually have significant retinopathy, and indeed albuminuria grade A2 predicts the development and progression of retinopathy in T2DM [123, 124]. In those with non-classical disease, retinopathy may be absent.

Peripheral neuropathy is also more common in diabetic nephropathy, associating with both albuminuria and declining GFR [125]. Autonomic neuropathy, reflected in loss of nocturnal blood pressure dipping, occurs frequently [126] and predicts renal function decline [127].

Investigation of kidney disease in diabetes

Excluding other treatable causes of kidney disease

It is uncommon to find a specific treatable cause of chronic kidney disease if the natural history is classical. However, if there is doubt, ultrasound of the renal tract, measurement of autoantibodies and immunoglobulins, and renal biopsy may help.

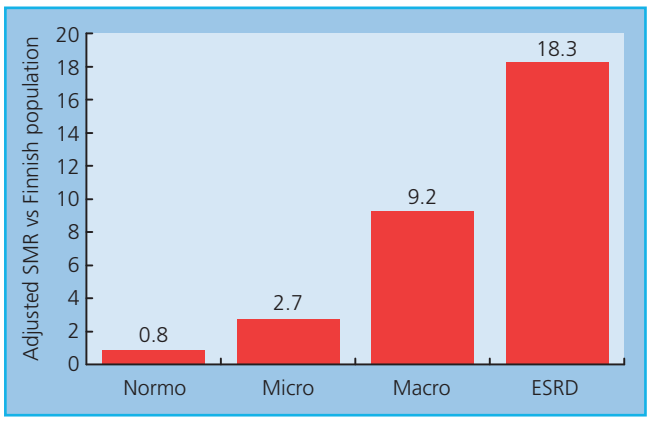

Figure 39.7 Risk of mortality in individuals with T1DM from the FinnDiane study associated with each level of albuminuria and end-stage renal disease (ESRD). Adjusted SMRs are provided standardized against the age- and sex-matched Finnish general population (arbitrary value of 1.0). Source: Based on Groop et al. 2009 [113].

Monitoring kidney disease

Once UAE is abnormal, the ACR should be measured every 3 months and eGFR 3–6 monthly, depending on the stage of CKD. There is a linear relationship with time and eGFR, which is useful in assessing changes in response to therapy and in predicting when an individual will reach ESRD.

Prevention and management of diabetic kidney disease

Prevention of kidney disease is crucial. Although much can be done to slow progression, it may not be possible to avoid ESRD. The risk of developing diabetic nephropathy is particularly reduced by good blood glucose and blood pressure control.

Glucose control

Glucose control in T1DM

Among the participants in the DCCT who initially had albuminuria grade A1, the relative risk reduction for development of albuminuria grade A2 was 39% and for grade A3 54% in those allocated to the intensively treated group compared with those in the conventionally managed group over the 6.5-year study [128]. Mean achieved HbA_{1c} was 52 mmol/mol (7.0%) and 76 mmol/mol (9.1%), respectively. There is no HbA_{1c} threshold below which risk is not reduced [129].

In the open follow-up of the DCCT cohort, HbA_{1c} in the previously intensively and conventionally managed groups became similar, ~64 mmol/mol (8.0%). Despite this, the incidence of albuminuria grades A2 and A3 [130], eGFR <60 mL/min/1.73 m^2, and ESRD [131] were significantly reduced in those who had previously received intensive management, as summarized in Table 39.3. These results are supported by an observational study of individuals with T1DM and CKD stages 1–3 with albuminuria grade A3 at baseline [132]. The cumulative risk of ESRD after 15 years was significantly lower in those whose HbA_{1c} improved compared with those whose HbA_{1c} remained stable or deteriorated. Hence improving glucose control significantly reduces the risk of development and progression of all stages of diabetic nephropathy in T1DM. The beneficial effects extend far beyond the actual period of good glucose control, a phenomenon termed "metabolic memory." In highly selected patients undergoing serial renal biopsies after successful pancreas transplantation, renal structural changes regressed after 10 but not 5 years [133]. Thus, prolonged periods of "normoglycemia" are necessary to reverse renal structural changes.

Table 39.3 Renal benefits of intensive insulin therapy demonstrated by the Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications Cohort.

Parameter	Duration of observation (years)	Conventional insulin therapy	Intensive insulin therapy
Albuminuria grade A2	8	15.8%	6.8%
Albuminuria grade A3	8	9.4%	1.4%
eGFR <60 mL/min/1.73 m^2	22	46 (*n*)	24 (*n*)
ESRD	22	16 (*n*)	8 (*n*)

n, Number.
eGFR estimated glomerular filtration rate; ESRD, end-stage renal disease.

Glucose control in T2DM

In the UKPDS, although the mean achieved HbA_{1c} in the intensively managed group was 53 mmol/mol (7.0%) compared with 63 mmol/mol (7.9%) in the less strictly managed group, there was a reduction in the relative risk of developing albuminuria grades A2 and A3 of 30% after 9–12 years [134]. No threshold of HbA_{1c} and risk was observed, suggesting that the lower the HbA_{1c}, the lower is the risk of nephropathy [135]. In the open follow-up of the UKPDS cohort, HbA_{1c} was similar in the previously intensively and conventionally managed groups after 1 year [136]. Despite this, microvascular risk remained lower, confirming the "metabolic memory" seen in the DCCT/EDIC study. In the ADVANCE study, the HbA_{1c} achieved in the intensively managed group was 48 mmol/mol (6.5%), compared with 56 mmol/mol (7.3%) in the standard care group [137]. In the intensive group there was a 9% relative risk reduction in new-onset albuminuria grade A2, a 30% reduction in the development of albuminuria grade A3, and a 65% reduction in ESRD over 5 years [138]. The ACCORD study also demonstrated significant reductions in new-onset albuminuria grades A2 and A3 and of ESRD with intensive glucose management [139]. Progression of albuminuria was reduced and regression increased. However, in those with CKD at baseline, the risk of all-cause and cardiovascular mortality was

significantly increased in the intensive glucose management group [140]. Hence the renal benefits of extremely tight glucose control are outweighed by the excess mortality. A less tight HbA_{1c} target in individuals with T2DM and duration >10 years seems sensible.

Dipeptidyl peptidase 4 inhibitors and sodium–glucose cotransporter 2 inhibitors may have added renal benefits beyond glucose lowering [141, 142].

Glucose control in ESRD

Most [143–145] but not all [146] observational studies have demonstrated increasing all-cause and cardiovascular mortality with increasing HbA_{1c} in people with diabetes on renal replacement therapy. Some also showed a U-shaped relationship, with mortality increasing at low HbA_{1c} levels [144, 145]. However, there have been no studies that demonstrated improved survival with improving glucose control.

Blood pressure control

Rigorous blood pressure control improves the prognosis in diabetic nephropathy dramatically. Conservative estimates suggest that good blood pressure management doubles the time taken from first appearance of albuminuria grade A3 to need for renal replacement therapy, from a mean of 9 to 18 years. Improved management in albuminuria grade A2 may prevent progression and promote regression to grade A1. Blood pressure and blood glucose lowering effects are independent of one another, but have synergistic effects [147, 148]. In contrast to glucose "metabolic memory," the benefits of blood pressure reduction are lost rapidly when control deteriorates [149]. The effects of angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs) are broadly similar [150].

T1DM

RAS inhibitors do not prevent albuminuria grade A2 in normotensive people with T1DM [151–153]. There is also no evidence that control of hypertension in T1DM and grade 1 albuminuria prevents progression of albuminuria and renal decline. However, it seems highly likely.

Once albuminuria grade A2 or A3 is present, inhibition of the RAS is the backbone of therapy, because it reduces intraglomerular pressure. A meta-analysis summarized the effects of ACE inhibitors in people with T1DM and grade A2 albuminuria [154]. The odds ratio for progression to albuminuria A3 was reduced by ACE inhibition to 0.35, and for regression to albuminuria grade A1 it increased to 3.07, compared with placebo treatment. After 2 years of treatment, the mean reduction in albumin excretion was 50.5% with ACE inhibition, and was greatest in those with highest baseline levels. However, the response to treatment plateaued with time, suggesting that treatment delays, rather than prevents, progression.

Addition of an ACE inhibitor to non-ACE inhibitor antihypertensive therapy reduced the risk of a doubling of the serum creatinine by 48% and the composite end-point of death, need for dialysis or renal transplantation, by 50%, in people with T1DM and with albuminuria grade A3 and hypertension [155]. Both benefits were independent of blood pressure. In short-term studies, the effects of ARBs on blood pressure and UAE were similar to those of ACE inhibitors in T1DM and grade A3 albuminuria [156].

For a similar reduction in blood pressure, there is a greater reduction in protein excretion using ACE inhibitors compared with other classes of antihypertensive agents [157]. This may be beneficial, as the passage of protein across the glomerular filtration barrier may accelerate the progression of nephropathy [158]. Animal data show that this is due to preferential reduction in intraglomerular pressure with ACE inhibitors [159].

RAS inhibitors should be offered to all individuals with T1DM and albuminuria, regardless of blood pressure. The dose should be titrated up to the maximum recommended or tolerated, to obtain maximal antiproteinuric effect. If blood pressure remains >125/75 mmHg on maximum dose of RAS inhibitor, antihypertensive therapy should be intensified. Lower blood pressure reduces the rate of decline of GFR from 10–12 mL/min/year untreated to <5 mL/min/year [160]. Regression from albuminuria grade A3 to A2 can be achieved, with the fall in GFR reduced to <1 mL/min/year [161]. The choice of agent should be made on an individual basis, as there is no evidence in T1DM that any one add-on agent is better than any other. Often multiple agents are needed in CKD stage 3 and beyond.

T2DM

Control of hypertension reduces the risk of developing albuminuria grade A2 or A3 [162–165]. There may be a particular benefit of RAS inhibition in prevention of nephropathy [166, 167], but lowering blood pressure sufficiently is the key. Achieved blood pressure in these studies was generally ~140/80 mmHg, but most guidelines now suggest a blood pressure target of 130/80 mmHg in T2DM.

As with T1DM, there is good evidence in T2DM that inhibition of the RAS should be the backbone of therapy if albuminuria grade A2 or A3 is present. RAS blockade reduces progression of albuminuria grade A2 to A3 [163, 168] and increases regression to grade A1 [168]. The benefits are at least partly independent of blood pressure lowering. In more advanced diabetic nephropathy, RAS inhibition with ARB reduces progression, defined as doubling of serum creatinine, ESRD, or death [169, 170]. Hence people with T2DM and albuminuria grade A2 or A3 should be prescribed a RAS inhibitor, titrated to the maximum tolerated dose [171]. Hyperkalemia is common in individuals with T2DM and nephropathy taking an ARB and is associated with increased risk of renal failure [172]. Introduction of a RAS inhibitor often leads to an acute decline in GFR, which then stabilizes. Individuals with the greatest initial fall in GFR have the slowest subsequent decline in renal function [173].

Most people with T2DM and albuminuria will require additional antihypertensive therapy. The choice of additional agents

should be made on an individual basis, with diuretics and calcium channel blockers often being appropriate.

In the UKPDS, there was no blood pressure level below which risk of developing albuminuria grade A2 or beyond increased, i.e. no "J" shape [174]. The ADVANCE study explored the effects of reduction of blood pressure below the currently recommended targets of 130/80 mmHg in individuals with albuminuria grade A1 or A2 and 125/75 mmHg in those with grade A3 [175]. Over 4 years, the risk of renal events was reduced by 21%, mainly because of reduced risk of developing albuminuria grade A2 or A3. However, an achieved systolic blood pressure below 120–130 mmHg was associated with increased mortality and ESRD [176]. Therefore, extremely tight blood pressure control should be avoided.

Dual blockade of the RAS

Addition of an ARB to an ACE inhibitor [177, 178] or of the direct renin inhibitor aliskiren to an ARB [179] reduces blood pressure and albuminuria more than each agent individually. However, in the longer term, dual blockade increases the risk of hyperkalemia, hypotension, and acute, irreversible renal failure [180–183]. Hence dual blockade is not recommended.

Sodium intake

Short-term dietary sodium restriction (target sodium intake 50 mmol Na^+ per day), added to RAS blockade, reduces albuminuria [184]. The treatment effects of ARB are greater in patients with lower rather than higher dietary sodium intake [185]. Hence dietary counseling to reduce sodium intake is essential.

Non-classical diabetic kidney disease

There is no specific evidence for the use of RAS inhibition in individuals without albuminuria. However, control of blood pressure remains crucial to slow progression.

Low-protein diet

A meta-analysis concluded that such a diet significantly improves GFR but not albuminuria, across all subtypes of diabetes and stages of nephropathy [186]. Protein intake should not be restricted to less than 0.7 g protein/kg body weight/day because of concerns about malnutrition in ESRD.

Lipids

There is some evidence that lipid-lowering agents are beneficial to the kidney. In a post hoc analysis of the Collaborative Atorvastatin Diabetes Study, the rate of decline of eGFR was significantly less in those individuals taking atorvastatin 10 mg daily compared with placebo [187]. Fibrates also reduce albuminuria, although they reversibly increase serum creatinine [188].

Cardiovascular risk—other factors

There have been no good trials of smoking cessation and use of aspirin in diabetic kidney disease. However, smoking cessation should clearly be encouraged, and the use of aspirin considered.

Weight loss

In a trial comparing intensive lifestyle intervention with diabetes support and education in T2DM, individuals randomized to intensive lifestyle modification were less likely to develop CKD over 8 years [189]. The effect was partly attributable to reductions in body weight, HbA_{1c}, and systolic blood pressure. Low-carbohydrate, Mediterranean, and low-fat diets have similar beneficial effects on change in eGFR and albuminuria over 2 years [190]. In individuals with T2DM who have undergone bariatric surgery, albuminuria grades A2 and A3 regresses to grade A1 [191].

Further management of chronic kidney disease stage 3 or poorer

Monitoring anemia and bone chemistry

In progressive CKD from stage 3 onwards, bone chemistry, full blood count, and iron stores should be assessed 3–6 monthly.

Monitoring glucose control

Red blood cell and protein turnover are abnormal in CKD, making the interpretation of HbA_{1c}, glycated albumin, and fructosamine results difficult. Thus, more reliance should be placed on self-monitoring of blood glucose and continuous glucose monitoring.

Glucose-lowering agents (Table 39.4)

Metformin and its metabolites are excreted mainly by the kidney. In renal failure, they accumulate and inhibit lactate oxidation. Metformin should therefore be used cautiously in those with eGFR <40 mL/min/1.73 m^2, and stopped completely when eGFR <30 mL/min/1.73 m^2.

The sulfonylureas glibenclamide, gliclazide, and tolbutamide are excreted predominantly renally and accumulate in CKD. Their dose, and indeed the dose of any sulfonylurea, may need to be reduced as CKD progresses. Only ~10% of the meglitinides repaglinide and nateglinide is renally excreted, making them suitable alternative agents. The thiazolidinediones rosiglitazone and pioglitazone are predominantly metabolized in the liver. However, their use in ESRD may be limited by fluid retention.

Insulin is also excreted by the kidney so that reduced dosage, and perhaps a switch to shorter acting preparations, may be required.

The dose of some but not all DPP-4 inhibitors and GLP-1 receptor agonists may need to be reduced as renal function deteriorates. The SGLT-2 inhibitors become less effective as GFR falls.

Table 39.4 Glucose-lowering agents in chronic kidney disease.

Drug	Comment
Metformin	Risk of accumulation and possibly lactic acidosis Caution when eGFR <40 mL/min/1.73 m^2 Stop when eGFR <30 mL/min/1.73 m^2
Sulfonylureas	Glibenclamide, gliclazide, and tolbutamide predominantly renally excreted; may need to reduce dose
Meglitinides	~10% excreted via kidney; usually safe
Thiazolidinediones	Predominantly hepatic metabolism; use may be limited by fluid retention
Dipeptidyl peptidase IV inhibitors	Probably safe. Dose may need to be reduced in some agents
Glucagon-like peptide-1 receptor agonists	Few data when eGFR <45 mL/min/1.73 m^2
Sodium–glucose co-transporter 2 inhibitors	Ineffective at eGFR <45 mL/min/1.73 m^2
Insulin	Excreted by kidney; may need to reduce dose and/or switch to shorter-acting preparations

eGFR, estimated glomerular filtration rate.

Anemia

Anemia is common in people with diabetes and CKD stage 3 or poorer [192]. Full investigation of iron deficiency anemia may be needed to exclude a non-renal cause. Those with anemia have a higher mortality, higher rates of hospital admission with heart failure, and poorer quality of life. Iron stores should be repleted, with oral or parenteral iron as necessary, and erythropoietin replacement commenced if indicated.

When to refer to nephrology

Patients who begin dialysis as an emergency do less well than those in whom treatment is planned [193]. Referral to nephrology should be made when serum creatinine is 150–200 μmol/L or eGFR <45 mL/min/1.73 m^2. This allows structured physical and psychological preparation for renal replacement therapy. Earlier referral may be necessary in particular circumstances (Box 39.1). The need for renal replacement therapy should be discussed with all patients and those who wish it should have access. People without significant comorbidities will usually be offered transplantation. Full cardiovascular assessment and treatment are essential before transplantation.

Organization of care

Structured care, delivered by trained specialists working to clear protocols with specific, multiple treatment goals for all the variables described above, reduces the incidence of albuminuria grade A2 [194] and provides greater renal and cardiovascular benefits than routine care for individuals with T2DM and CKD [195, 196]. Progression to ESRD or death, need for laser therapy, and cardiovascular endpoints are all reduced by such multifactorial intervention.

Box 39.1 Indications for referral to nephrology.

Diagnosis uncertain
Hypertension difficult to control
Fluid overload
Anemia unresponsive to oral iron
Abnormal bone chemistry
eGFR 30–45 mL/min/1.73 m^2
Nephrotic syndrome
eGFR fall >5 mL/min/1.73 m^2 per year

Pregnancy in women with diabetes and chronic kidney disease

Women with diabetic nephropathy have poor pregnancy outcomes [197]. They remain at increased risk of hypertension, pre-eclampsia, abnormal fetal growth, and preterm delivery [198]. In a recent series, the prevalence of diabetic nephropathy and albuminuria grade A2 in early pregnancy was similar in women with T1DM or T2DM, and pregnancy outcomes were comparable regardless of the type of diabetes [199]. Women with any evidence of CKD therefore should be counseled pre-pregnancy. RAS inhibitors should be stopped and therapies safe in pregnancy, such as methyldopa, labetolol, and nifedipine, substituted. In women with T1DM, maintenance of BP <135/85 mmHg and proteinuria <300 mg/24 h with methyldopa improves outcomes [200].

40 Diabetic Peripheral and Autonomic Neuropathy

Dan Ziegler

Institute for Clinical Diabetology, German Diabetes Center at Heinrich Heine University, Leibniz Center for Diabetes Research; Department of Endocrinology and Diabetology. Medical Faculty, Heinrich Heine University, Düsseldorf, Germany

Key points

- Approximately one in three individuals with diabetes is affected by diabetic sensorimotor polyneuropathy (DSPN) which represents a major health problem, as it may present with excruciating neuropathic pain and is responsible for substantial morbidity, increased mortality, and impaired quality of life.
- Neuropathic pain exerts a substantial impact on the quality of life, particularly by causing considerable interference with sleep, daily activities, and enjoyment of life.
- Treatment is based on four cornerstones: (1) intensive diabetes therapy and multifactorial risk intervention, (2) treatment based on pathogenetic mechanisms, (3) symptomatic treatment, and (4) avoidance of risk factors and complications.
- Recent experimental studies suggest a multifactorial pathogenesis of diabetic neuropathy. From the clinical point of view, it is important to note that, based on these pathogenetic mechanisms, therapeutic approaches could be derived, some of which are currently being evaluated in clinical trials.
- Management of chronic painful DSPN remains a challenge for the physician who should consider the following practical rules: the appropriate and effective drug has to be tried and identified in each patient by carefully titrating the dose based on efficacy and side effects. Lack of efficacy should be judged only after 2–4 weeks of treatment using an adequate dose. Analgesic combination therapy may be useful, and potential drug interactions have to be considered given the frequent polypharmacy in people with diabetes.
- Epidemiological data indicate that not only increased alcohol consumption but also the traditional cardiovascular risk factors such as prediabetes, visceral obesity, hypertension, hyperlipidemia, and smoking play a role in the development and progression of diabetic neuropathy and hence need to be prevented or treated.
- The manifestations of diabetic autonomic neuropathy cause multiple symptoms and involve:
  - Cardiovascular system: resting tachycardia, reduced heart rate variability and circadian rhythm of heart rate and blood pressure, painless myocardial ischemia/infarction, orthostatic hypotension, exercise intolerance, perioperative instability, sudden death.
  - Respiratory system: reduced ventilatory drive to hypercapnia/hypoxemia, sleep apnea.
  - Gastrointestinal tract: esophageal motor dysfunction, diabetic gastroparesis, gallbladder atony, diabetic enteropathy, colonic hypomotility, anorectal dysfunction.
  - Urogenital system: diabetic cystopathy, erectile dysfunction, female sexual dysfunction.

Diabetic peripheral neuropathy

Classification, epidemiology, and clinical impact

Diabetic neuropathy has been defined as a demonstrable disorder, either clinically evident or subclinical, that occurs in the setting of diabetes mellitus without other causes for peripheral neuropathy. It includes manifestations in the somatic and/or autonomic parts of the peripheral nervous system [1], which are classified along clinical criteria. However, owing to the variety of the clinical syndromes with possible overlaps, there is no universally accepted classification. The most widely used classification of diabetic neuropathy, proposed by Thomas [2], has subsequently been modified [3]. This proposal differentiates between rapidly reversible, persistent symmetric polyneuropathies, and focal or multifocal neuropathies (Table 40.1). Diabetic distal symmetrical sensory or sensorimotor polyneuropathy (DSPN) represents the most relevant clinical manifestation, affecting ~30% of hospital-based populations with diabetes and 20% of community-based individuals with diabetes [4]. There is emerging evidence to suggest that prediabetes is associated with an increased risk of DSPN. In the general population (Augsburg region, southern Germany), the prevalence of polyneuropathy was 28.0% in people with diabetes, 13.0% in those with impaired glucose tolerance

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

Table 40.1 Classification of diabetic neuropathies.

Type	Neuropathy
Rapidly reversible	Hyperglycemic neuropathy
Persistent symmetric polyneuropathies	Distal somatic sensory/motor polyneuropathies involving predominantly large fibers
	Autonomic neuropathies
	Small-fiber neuropathies
Focal/multifocal neuropathies	Cranial neuropathies
	Thoracoabdominal radiculopathies
	Focal limb neuropathies
	Proximal neuropathies
	Compression and entrapment neuropathies

Source: Adapted from Sima et al. 1997 [3].

(IGT), 11.3% in those with impaired fasting glucose (IFG), and 7.4% in those with normal glucose tolerance (NGT) [5]. The incidence of DSPN is ~2% per year [4].

The most important etiological factors that have been associated with DSPN are poor glycemic control, visceral obesity, diabetes duration, height, hypertension, age, smoking, hypoinsulinemia, and dyslipidemia [4]. DSPN is related to both lower extremity impairments such as diminished position sense and functional limitations such as walking ability [6]. Measures of polyneuropathy such as nerve conduction velocity and vibration perception threshold predict mortality in people with diabetes [7, 8]. Elevated vibration perception threshold also predicts the development of neuropathic foot ulceration, one of the most common causes for hospital admission and lower limb amputations among people with diabetes [9]. Three more recent studies underline the major impact of DSPN on cardiovascular morbidity and mortality. In the DIAD study [10], both sensory deficits and neuropathic pain were independent predictors of cardiac death or non-fatal myocardial infarction. In a community-based study in the United Kingdom, reduced touch or pressure sensation predicted cardiovascular morbidity [11]. History of neuropathy was the most important predictor for increased mortality in people with type 2 diabetes (T2DM) allocated to very intensive diabetes therapy aimed at HbA_{1c} <6.0% in the ACCORD trial [12].

However, the impact of DSPN is still being underestimated by both physicians and people with diabetes. In a German population-based survey, 77% of the cases with DSPN were unaware of having the disorder, defined as answering "no" to the question, "Has a physician ever told you that you are suffering from nerve damage, neuropathy, polyneuropathy, or diabetic foot?" Approximately one-quarter of the participants with known diabetes had never undergone a foot examination. Even among individuals with known diabetes who reported having had their feet examined by a physician, 72% of those with DSPN were unaware of having DSPN. Hence there is still a high prevalence of unawareness of having clinical DSPN among persons with diabetes and an insufficient frequency of professional foot examinations, suggesting inadequate attention to diabetic foot prevention practice [13].

Pain is a subjective symptom of major clinical importance as it is often this complaint that motivates people to seek healthcare. Pain associated with diabetic neuropathy exerts a substantial impact on the quality of life, particularly by causing considerable interference in sleep and enjoyment of life [14]. However, in one UK survey, only 65% of people with diabetes received treatment for their neuropathic pain, although 96% had reported the pain to their physician [15]. Pain treatment consisted of antidepressants in 43.5% of the cases, anticonvulsants in 17.4%, opiates in 39%, and alternative treatments in 30%. Although 77% of the patients reported persistent pain over 5 years, 23% were pain free over at least 1 year [15]. Hence neuropathic pain persists in the majority of individuals with diabetes over periods of several years.

Chronic painful neuropathy is present in up to 26% of people with diabetes [4, 16, 17]. In the general population (Augsburg region, southern Germany), the prevalence of painful neuropathy was 13.3% in the people with diabetes, 8.7% in those with IGT, 4.2% in those with IFG, and 1.2% in those with NGT [16]. Among survivors of myocardial infarction from the Augsburg Myocardial Infarction Registry, the prevalence of neuropathic pain was 21.0% in the individuals with diabetes, 14.8% in those with IGT, 5.7% in those with IFG, and 3.7% in those with NGT [17]. Thus, people with macrovascular disease appear to be prone to neuropathic pain. The most important risk factors of polyneuropathy and neuropathic pain in these surveys were age, obesity, and low physical activity, and the predominant comorbidity was peripheral arterial disease, highlighting the paramount role of cardiovascular risk factors and diseases in prevalent DSPN.

Clinical manifestations

Diabetic sensorimotor polyneuropathy

DSPN is a symmetrical, length-dependent sensorimotor polyneuropathy attributable to metabolic and microvessel alterations as a result of chronic hyperglycemia exposure (diabetes) and cardiovascular risk covariates [18]. It is commonly associated with autonomic involvement. Its onset is insidious and, in the absence of intervention, the course is chronic and progressive. It seems that the longer axons to the lower limbs are more vulnerable towards the nerve lesions induced by diabetes (length-related distribution). This notion is supported by the correlation found between the presence of DSPN and height. DSPN typically develops as a dying-back neuropathy, affecting the most distal extremities (toes) first. The neuropathic process then extends proximally up the limbs and later it may also affect the anterior abdominal wall and then spread laterally around the trunk. Occasionally the upper limbs are involved, with the fingertips being affected first (glove-and-stocking distribution) (Figure 40.1). Variants including painful small-fiber or pseudosyringomyelic syndromes and an atactic syndrome (diabetic pseudotabes) have been described. Small-fiber unmyelinated (C) and thinly myelinated (Aδ) fibers and also large-fiber myelinated (Aα, Aβ) neurons are

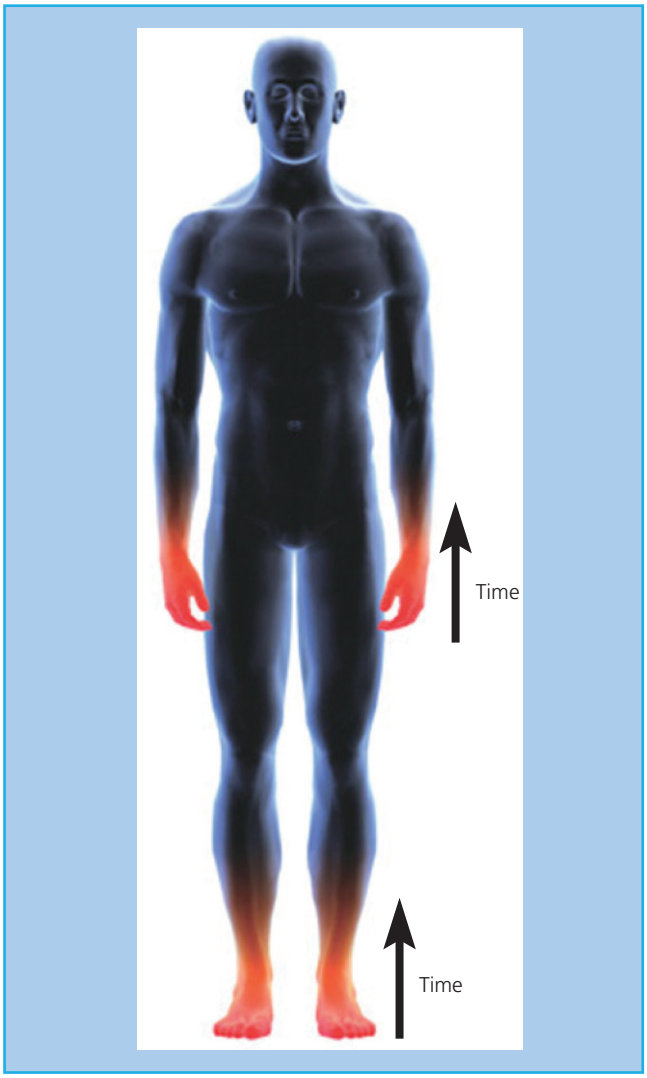

Figure 40.1 The typical glove-and-stocking distribution of diabetic distal symmetric sensory or sensorimotor polyneuropathy (DSPN).

Figure 40.2 A typical example of the distribution of sensory deficits (dots, reduced thermal sensation; lines, reduced pain sensation; crossed lines, reduced touch sensation) in a person with distal symmetric sensory or sensorimotor polyneuropathy (DSPN).

typically involved. However, it is as yet uncertain whether the various fiber-type damage develops following a regular sequence, with small fibers being affected first, followed by larger fibers, or whether the small-fiber or large-fiber involvement reflects either side of a continuous spectrum of fiber damage. However, there is evidence suggesting that small-fiber neuropathy may occur early, often presenting with pain and hyperalgesia before sensory deficits or nerve conduction slowing can be detected [2]. The reduction or loss of small-fiber-mediated sensation results in loss of pain sensation (heat pain, pin-prick) and temperature perception to cold (Aδ) and warm (C) stimuli. Large-fiber involvement leads to nerve conduction slowing and reduction or loss of touch, pressure, two-point discrimination, and vibration sensation, which may lead to sensory ataxia (atactic gait) in severe cases. A typical example of the distribution of sensory deficits is shown in Figure 40.2. Sensory fiber involvement causes "positive" sensory symptoms such as paresthesia, dysesthesia, numbness, and pain, in addition to "negative" symptoms such as reduced sensation.

Persistent or episodic pain that typically may worsen at night and improve during walking is localized predominantly in the feet. The pain is often described as a deep-seated aching but there may be superimposed lancinating stabs or it may have a burning thermal quality. In a clinical survey of 105 people with painful polyneuropathy, the following locations of pain were most frequent: 96% feet, 69% balls of feet, 67% toes, 54% dorsum of foot, 39% hands, 37% plantum of foot, 37% calves, and 32% heels. The pain was most often described as "burning/hot," "electric," "sharp," "achy," and "tingling," and was worse at night-time and when tired or stressed [14]. The average pain intensity was moderate, ~5.75/10 on a 0–10 scale, with the "least" and "most" pain being 3.6 and 6.9/10, respectively. Allodynia (pain due to a stimulus that does not normally cause pain, e.g. stroking) may occur. The symptoms may be accompanied by sensory loss, while those

with severe pain may have few clinical signs. Pain may persist over several years [15, 19], causing considerable disability and impaired quality of life in some individuals [14], whereas it remits partially or completely in others, despite further deterioration in small-fiber function [20]. Pain remission tends to be associated with sudden metabolic change, short duration of pain or diabetes, preceding weight loss, and less severe sensory loss [20].

Compared with the sensory deficits, motor involvement is usually less prominent and restricted to the distal lower limbs, resulting in muscle atrophy and weakness at the toes and foot. Ankle reflexes are frequently reduced or absent. At the foot level, the loss of the protective sensation (painless feet), motor dysfunction, and reduced sweat production resulting in dry and chapped skin due to autonomic involvement increase the risk of callus and foot ulcers. Hence the person with neuropathy is at high risk for developing severe and potentially life-threatening foot complications such as ulceration, osteoarthropathy (Charcot foot), and osteomyelitis, and also medial arterial calcification and neuropathic edema. Because DSPN is the major contributory factor for diabetic foot ulcers and the lower limb amputation rates in people with diabetes are 15 times higher than those without diabetes, an early detection of DSPN by screening is of paramount importance [9]. This is even more imperative because many people with DSPN are asymptomatic or have only mild symptoms. In view of these causal pathways, the majority of amputations should potentially be preventable if appropriate screening and preventive measures are adopted.

Acute painful neuropathy

Acute painful neuropathy has been described as a separate clinical entity [21]. It is encountered infrequently in both people with type 1 diabetes mellitus (T1DM) and T2DM, presenting with continuous burning pain particularly in the soles ("like walking on burning sand") with nocturnal exacerbation. A characteristic feature is cutaneous contact discomfort with clothes and sheets, which can be objectified as hypersensitivity to tactile (allodynia) and painful stimuli (hyperalgesia). Motor function is preserved, and sensory loss may be only slight, being greater for thermal than vibration sensation. The onset is associated with and preceded by precipitous and severe weight loss. Depression and erectile dysfunction are common associated features. The weight loss responds to adequate glycemic control, and the severe manifestations subside within 10 months in all cases. No recurrences were observed after follow-up periods of up to 6 years [21]. The syndrome of acute painful neuropathy seems to be equivalent to "diabetic cachexia" as described by Ellenberg [22].

The term *insulin neuritis* was used by Caravati [23] to describe a case with precipitation of acute painful neuropathy several weeks following the institution of insulin treatment. In the most recent series, the term treatment-induced neuropathy in diabetes (TIND) has been used to describe this relatively rare iatrogenic small-fiber neuropathy with neuropathic pain and autonomic involvement caused by an abrupt improvement in glycemic control in the setting of chronic hyperglycemia. With a decrease in HbA_{1c} of 2–3% over 3 months, there was a 20% absolute risk of developing TIND, and with a decrease in HbA_{1c} of >4% over 3 months this risk exceeded 80% [24]. In another series, painful symptoms gradually improved in all patients, allowing discontinuation of analgesic therapy within 3–8 months. Hence careful correction of glucose levels should be considered in individuals with long-standing uncontrolled diabetes [25]. Sural nerve biopsy shows signs of chronic neuropathy with prominent regenerative activity [26] and also epineurial arteriovenous shunting and a fine network of vessels, resembling the new vessels of the retina, which may lead to a steal effect rendering the endoneurium ischemic [27]. This may be analogous with the transient deterioration of a pre-existing retinopathy following rapid improvement in glycemic control.

Focal and multifocal neuropathies

Most of the focal and multifocal neuropathies tend to occur in people with long-term diabetes who are middle aged or older. The outlook for most of them is for recovery, either partial or complete, and for eventual resolution of the associated pain [28]. With this in mind, physicians should always maintain an optimistic outlook when dealing with patients with these afflictions.

Cranial neuropathy

Palsies of the third cranial nerve (diabetic ophthalmoplegia) are painful in about 50% of cases. The onset is usually abrupt. The pain is felt behind and above the eye, and at times precedes the ptosis and diplopia (with pupillary dysfunction in 14–18% of cases) by several days. Oculomotor findings reach their nadir within a day or at most a few days, persist for several weeks, and then begin gradually to improve. Full resolution is the rule and generally takes place within 3–5 months. The fourth, sixth, and seventh cranial nerves are next in frequency [28].

Mononeuropathy of the limbs

Focal lesions affecting the limb nerves, most commonly the ulnar, median, radial, and peroneal, may be painful, particularly if of acute onset, as may entrapment neuropathies such as the carpal tunnel syndrome that is associated with painful paresthesia [28].

Diabetic truncal neuropathy

Mononeuropathy of the trunk (thoracoabdominal neuropathy or radiculopathy) presents with an abrupt onset, with pain or dysesthesias being the heralding feature, sometimes accompanied by cutaneous sensory impairment or hyperesthesia. Pain has been described as deep, aching, or boring, but the descriptors jabbing, burning, sensitive skin, and tearing have also been used. The neuropathy is almost always unilateral or predominantly so. As a result, the pain felt in the chest or the abdomen may be confused with pain of pulmonary, cardiac, or gastrointestinal origin. Sometimes it may have a radicular or girdling quality, half encircling the trunk in a root-like distribution. Pain may be felt in one or several dermatomal distributions and, almost universally, it is worst

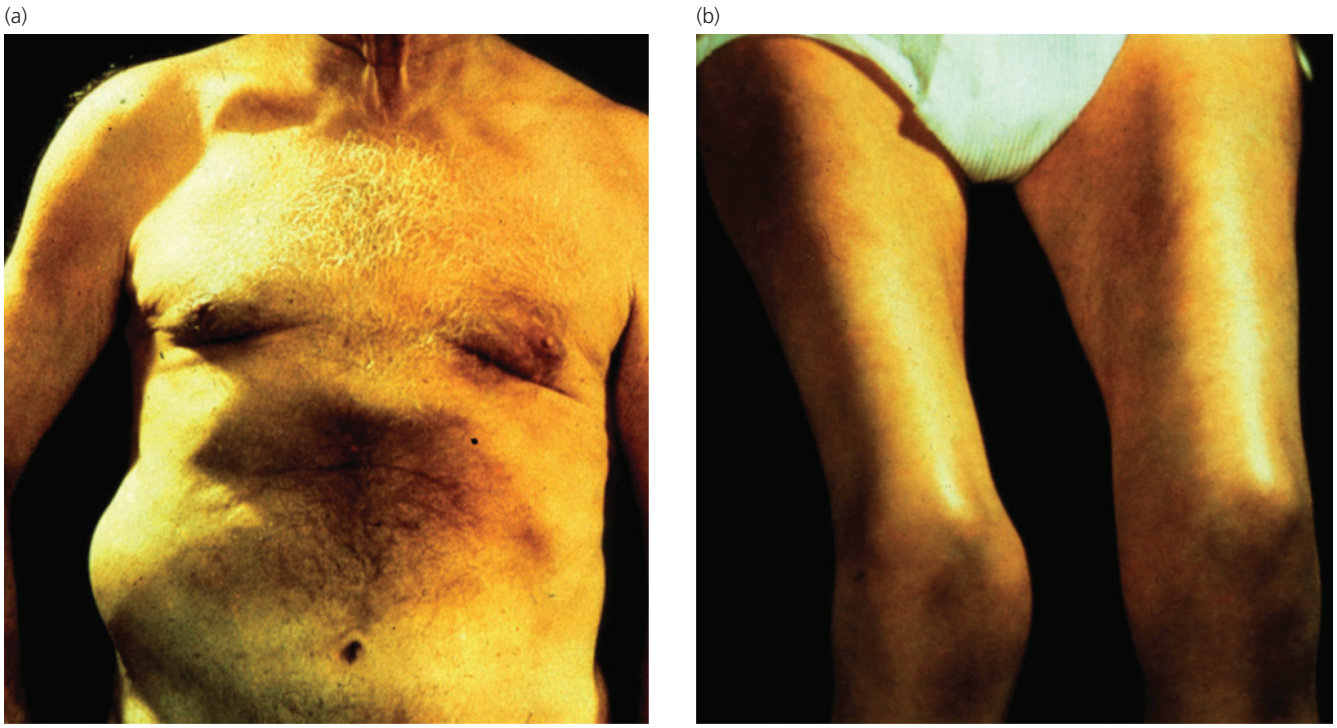

Figure 40.3 (a) Diabetic truncal neuropathy (thoracoabdominal neuropathy or radiculopathy) leading to herniation of the oblique abdominal muscle. (b) Diabetic amyotrophy (proximal neuropathy): pronounced bilateral atrophy and paresis of the quadriceps muscle.

at night. Rarely, abdominal muscle herniation may occur predominantly in middle-aged men, involving 3–5 adjacent nerve roots between T6 and T12 (Figure 40.3a).The time from first symptom to the peak of the pain syndrome is often just a few days, although occasionally spread of the pain to adjacent dermatomes may continue for weeks or even months. Weight loss of 7–18 kg occurs in >50% of the cases. The course of truncal neuropathy is favorable, and pain subsides within months with a maximum of 1.5–2 years [28].

Diabetic amyotrophy

Asymmetric or symmetric proximal muscle weakness and muscle wasting (iliopsoas, obturator, and adductor muscles) are easily recognized clinically in the syndrome of lower limb proximal motor neuropathy (synonyms: Bruns–Garland syndrome, diabetic amyotrophy, proximal diabetic neuropathy, diabetic lumbosacral plexopathy, ischemic mononeuropathy multiplex, femoral–sciatic neuropathy, femoral neuropathy). Pronounced bilateral atrophy and paresis of the quadriceps muscle are shown in Figure 40.3b. Pain is nearly universal in this syndrome. Characteristically, it is deep, aching, constant, and severe, invariably worse at night, and may have a burning, raw quality. It is usually not frankly dysesthetic and cutaneous. Frequently, pain is first experienced in the lower back or buttock on the affected side, or may be felt as extending from hip to knee. Although severe and tenacious, the pain of proximal motor neuropathy has a good prognosis. Concurrent distal sensory polyneuropathy is frequently present. Weight loss is also a frequently associated feature and may be as much as 15–18 kg. The weight is generally regained during the recovery phase [29, 30].

Central nervous system dysfunction

Relatively little attention has been directed towards impairment of the central nervous system (CNS) in people with diabetes with DSPN. Previous autopsy studies in people with diabetes have demonstrated diffuse degenerative lesions in the CNS including demyelination and loss of axon cylinders in the posterior columns [31, 32], degeneration of cortical neurons [33], and abnormalities in the midbrain and cerebellum [33, 34], which have been described as "diabetic myelopathy" [32] and "diabetic encephalopathy" [34].

Studies that evaluated CNS function in people with diabetes using evoked potentials in response to stimulation of peripheral nerves, event-related potentials, and neuropsychological tests have yielded variable results as to the existence of spinal or supraspinal (central) conduction deficits or cognitive dysfunction. However, we have shown that the degree of dysfunction along the somatosensory afferent pathways in persons with T1DM depends on the stage of peripheral neuropathy, is not related to the duration of diabetes or glycemic control, and can be characterized by an alteration of the cortical sensory complex and peripheral rather than spinal or supraspinal conduction deficits [35]. Magnetic resonance imaging showed an increased frequency of subcortical and brainstem lesions in people with T1DM with DSPN [36]. Moreover, individuals with DSPN showed a smaller cross-sectional chord area at C4/5 and T3/4 [37]. Using positron emission

tomography (PET) and [^{18}F]-2-deoxy-2-fluoro-D-glucose (FDG), we have demonstrated reduced cerebral glucose metabolism in people with T1DM with DSPN compared with people with newly diagnosed diabetes and healthy people without diabetes [38]. Spectroscopic measurement of brain metabolites such as *N*-acetyl aspartate (NAA) in the thalamus revealed a lower NAA : creatine ratio, suggesting thalamic neuronal dysfunction in DSPN [39]. Hence there is accumulating evidence suggesting that neuropathic involvement at central and spinal levels is a feature of DSPN, but it is not clear whether these are primary or secondary events.

Pathogenetic mechanisms

Recent experimental studies suggest a multifactorial pathogenesis of diabetic neuropathy [40, 41]. Most data have been generated in the diabetic rat model, on the basis of which two approaches have been chosen to contribute to the clarification of the pathogenesis of diabetic neuropathy. First, attempts have been made to characterize the pathophysiological, pathobiochemical, and structural abnormalities that result in experimental diabetic neuropathy. Second, specific therapeutic interventions have been employed to prevent the development of these alterations, to halt their progression, or to induce their regression despite concomitant hyperglycemia. At present, the following six pathogenetic mechanisms are under discussion, but, in contrast to earlier years, they are no longer regarded as separate hypotheses but mainly as a complex interplay with multiple interactions between metabolic and vascular factors:

1 Increased flux through the polyol pathway that leads to accumulation of sorbitol and fructose, *myo*-inositol depletion, and reduction in Na^+K^+-ATPase activity.

2 Disturbances in n-6 essential fatty acid and prostaglandin metabolism that result in alterations of nerve membrane structure and microvascular and hemorrheological abnormalities.

3 Endoneural microvascular deficits with subsequent ischemia and hypoxia, generation of reactive oxygen species (oxidative stress), activation of the redox-sensitive transcription factor NF-κB, and increased activity of protein kinase C (PKC).

4 Deficits in neurotrophism leading to reduced expression and depletion of neurotrophic factors such as nerve growth factor (NGF), neurotrophin-3 (NT-3), and insulin-like growth factor (IGF) and alterations in axonal transport.

5 Accumulation of non-enzymatic advanced glycation end-products (AGEs) on nerve and/or vessel proteins.

6 Immunological processes with autoantibodies to vagal nerve, sympathetic ganglia, and adrenal medulla in addition to inflammatory changes.

From the clinical point of view, it is important to note that, based on these pathogenetic mechanisms, therapeutic approaches could be derived, some of which have been evaluated in randomized clinical trials (see Treatment section).

Diagnostic assessment

Owing to the increasing recognition of diabetic neuropathy as a major contributor to morbidity and the recent expansion of clinical trials in this field on the one hand, but the lack of agreement on the definition and diagnostic assessment of neuropathy on the other, several consensus conferences were convened to overcome current problems. The Consensus Development Conference on Standardized Measures in Diabetic Neuropathy [42] recommended the following five measures to be employed in the diagnosis of diabetic neuropathy:

1 clinical measures;
2 morphological and biochemical analyses;
3 electrodiagnostic assessment;
4 quantitative sensory testing;
5 autonomic nervous system testing.

Clinical measures

Clinical measures include the following:

1 general medical history and neurological history;
2 neurological examination which consists of:
  a sensory (pain, light touch, vibration, position);
  b motor (graded as normal = 0, weak = 1–4 [25–100%]);
  c reflex (present or absent);
  d autonomic examination (bedside tests including heart rate variation during deep breathing and postural blood pressure response).

The basic neurological assessment comprises the general medical and neurological history, inspection of the feet, and neurological examination of sensation using simple semiquantitative bedside instruments such as the 10 g Semmes–Weinstein monofilament, the Neuropen (Figure 40.4a) [43] (touch), NeuroQuick (Figure 40.4b) [44], or Tiptherm [45] (temperature), calibrated Rydel—Seiffer tuning fork (Figure 40.4a) (vibration), pin-prick (pain), and tendon reflexes (knee and ankle). In addition, assessment of joint-position and motor power may be indicated. The normal range for the tuning fork on the dorsal distal joint of the great toe is ≥5/8 scale units in persons 21–40 years of age, ≥4.5/8 in those aged 41–60 years, ≥4/8 in those aged 61–71 years, and ≥3.5/8 scale units in those aged 72–82 years [46]. An indicator test for the detection of sudomotor dysfunction is the Neuropad, which assesses plantar sweat production by means of a color change from blue to pink. The patch contains the salt anhydrous cobalt(II) chloride. In the presence of water, this salt absorbs water molecules, normally changing its color from blue to pink. If the patch remains completely or partially blue within 10 min, the result is considered abnormal (Figure 40.4b) [47].

Clinical assessment should be standardized using validated scores for both the severity of symptoms and the degree of neuropathic deficits such as the Michigan Neuropathy Screening Instrument (MNSI) [48], Neuropathy Symptom Score (NSS) for neuropathic symptoms and Neuropathy Disability (NDS) for neuropathic deficits (impairments) [49].

The Toronto Consensus [18] has defined the following minimal criteria for the diagnosis of DSPN: (1) possible DSPN: the presence of symptoms or signs of DSPN; (2) probable DSPN: the presence of a combination of symptoms and signs of neuropathy including any two or more of the following: neuropathic

Figure 40.4 Bedside tests for the assessment of (a) large-fiber function and (b) small-fiber function.

symptoms, decreased distal sensation, or unequivocally decreased or absent ankle reflexes; (3) confirmed DSPN: the presence of an abnormality of nerve conduction and a symptom or symptoms or a sign or signs of neuropathy. If nerve conduction is normal, a validated measure of small-fiber neuropathy may be used; (4) subclinical DSPN: the presence of no signs or symptoms of neuropathy are confirmed with abnormal nerve conduction velocity or a validated measure of small-fiber neuropathy. It was recommended that definition 1, 2, or 3 be used for clinical practice and definition 3 or 4 for research studies [18].

Small-fiber neuropathy should be graded as follows: (1) possible: the presence of length-dependent symptoms and/or clinical signs of small-fiber damage; (2) probable: the presence of length-dependent symptoms, clinical signs of small-fiber damage, and normal sural nerve conduction; and (3) definite: the presence of length-dependent symptoms, clinical signs of small-fiber damage, normal sural nerve conduction, and altered intra-epidermal nerve fiber density at the ankle and/or abnormal thermal thresholds at the foot [18].

The intensity (severity) of neuropathic pain and its course should be assessed using an 11-point numerical rating scale (Likert scale) or a visual analog scale. Various screening tools (with or without limited bedside testing) have been developed to identify neuropathic pain such as the PainDetect, LANSS, NPQ, DN-4, and ID-Pain. These questionnaires use verbal descriptors and pain qualities as a basis for distinguishing neuropathic pain from other types of chronic pain such as nociceptive pain [50].

The following findings should alert the physician to consider causes for DSPN other than diabetes and referral for a detailed neurological work-up [51]:

- pronounced asymmetry of the neurological deficits;
- predominant motor deficits, mononeuropathy, cranial nerve involvement;
- rapid development or progression of the neuropathic impairments;
- progression of the neuropathy despite optimal glycemic control;
- development of symptoms and deficits only in the upper limbs;
- family history of non-diabetic neuropathy;
- diagnosis of DSPN cannot be ascertained by clinical examination.

The most important differential diagnoses include neuropathies caused by alcohol abuse, uremia, hypothyroidism, vitamin B_{12} deficiency, peripheral arterial disease, cancer, inflammatory and infectious diseases, and neurotoxic drugs [51].

Positive symptoms may reflect different pathophysiology than deficits, i.e. pain or paresthesia may be related to the degree of compensatory regeneration rather than to the degree of nerve fiber damage. Hence it has been suggested that symptom or pain scores should not be used to evaluate overall presence or progression of diabetic neuropathy but only to assess pain severity [42].

Electrodiagnostic measures

Electrophysiological techniques have the advantage of being the most objective, sensitive, specific, and reproducible methods that are available in many neurophysiological laboratories worldwide (Figure 40.5a).

Electrodiagnostic measures have also limitations inasmuch as they:

1 measure only function in the largest, fastest conducting myelinated fibers;
2 have relatively low specificity in detecting diabetic neuropathy;
3 show relatively high intra-individual variability for certain parameters (amplitudes);
4 are vulnerable to external factors such as electrode locations or limb temperature;
5 provide only indirect information about symptoms and deficits [42].

Quantitative sensory testing

Quantitative sensory testing (QST) is a psychophysical method used to quantify somatosensory function in response to controlled stimuli [52]. In clinical practice, the NeuPSIG Consensus [52] recommended the use of QST for screening for small- and large-fiber neuropathies, monitoring of somatosensory deficits, and monitoring of evoked pains, allodynia, and hyperalgesia. For the conduct of QST, it was recommended to use predefined standardized stimuli and instructions, validated algorithms of testing, and reference values corrected for anatomical site, age, and gender. Interpretation of results should always take into account the clinical context, and individuals with language and cognitive difficulties, anxiety, or litigation should not be considered eligible for QST [52]. Detection thresholds of touch-pressure, vibration, coolness, warmth, heat pain, cold pain, and mechanical pain can be used to characterize cutaneous sensation (Figure 40.5b).

The procedures that are being used for QST include the following:

1 the method of limits (continuous increase or decrease in intensity to appearance or disappearance threshold);
2 threshold tracking (combination of appearance or disappearance threshold);
3 titration method (graded steps to appearance and disappearance threshold);
4 the two-alternative forced-choice method (pairs of stimulus and null-stimulus phases) [52].

Morphological assessment

Sural nerve biopsy

Sural nerve biopsy does not represent a routine method in the diagnosis of diabetic neuropathy. It may be used to establish the diagnosis when the etiology of the neuropathy is in doubt. The limitations to this technique are that the information from the biopsy is of no direct benefit to the patient and that the procedure is associated with a certain morbidity and may result in complications [42].

Skin biopsy

Skin biopsy has become a widely used tool to investigate intra-epidermal nerve fiber density, dermal myelinated nerve fibers,

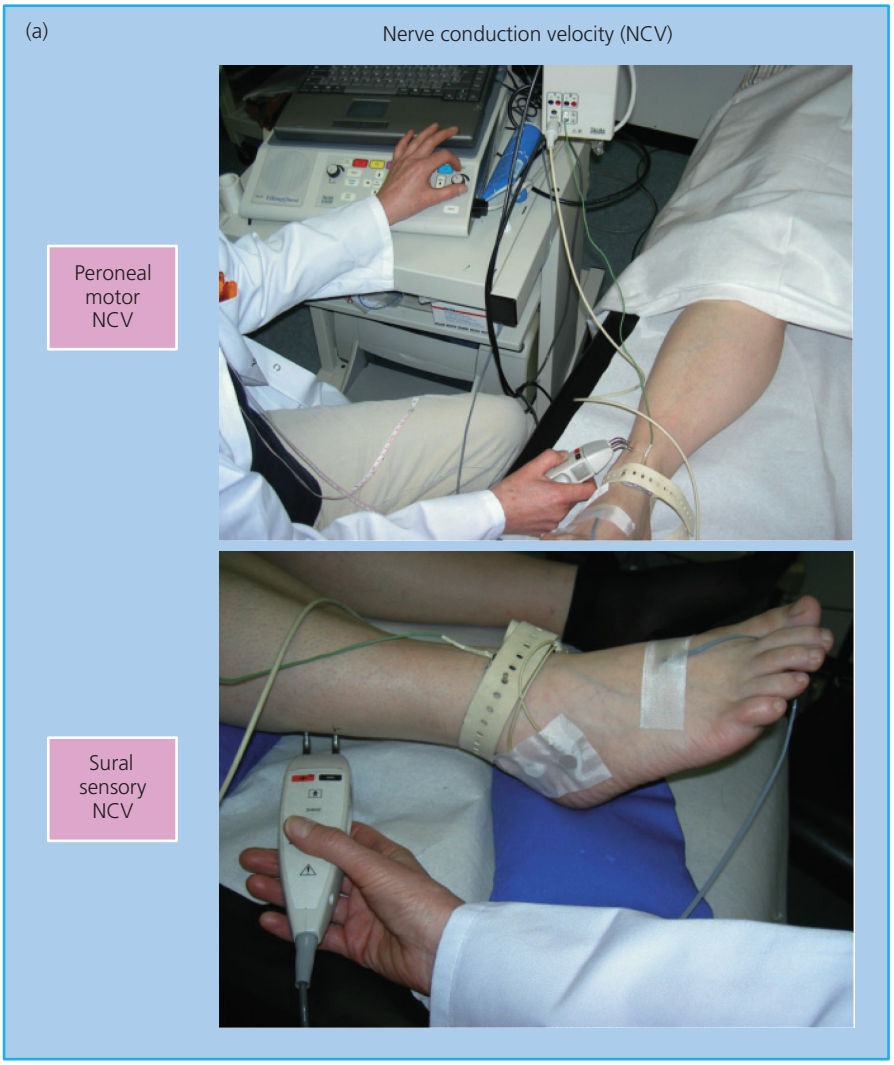

Figure 40.5 (a) Measurement of motor and sensory nerve conduction velocity. (b) Quantitative sensory testing.

and autonomic nerve fibers in peripheral neuropathies and other conditions (Figure 40.6). Different techniques for tissue processing and nerve fiber evaluation have been used. A Task Force of the European Federation of Neurological Societies (EFNS) updated the guideline on the use of skin biopsy in the diagnosis of peripheral neuropathies [53]. For diagnostic purposes in peripheral neuropathies, the guideline recommends performing a 3-mm punch skin biopsy at the distal leg and quantifying the linear density of intra-epidermal nerve fiber in at least three 50-µm thick sections per biopsy, fixed in 2% PLP or Zamboni's solution, by bright-field immunohistochemistry or immunofluorescence with anti-protein gene product 9.5 antibodies (PGP 9.5) (level A recommendation). Quantification of intra-epidermal nerve fiber density closely correlated with warm- and heat-pain threshold, and appeared more sensitive than sensory nerve conduction study and sural nerve biopsy in diagnosing small-fiber sensory neuropathy. The diagnostic efficiency and predictive values of this technique were very high (level A recommendation). Longitudinal studies of intra-epidermal nerve fiber density and regeneration rate are warranted to correlate neuropathological changes with progression of neuropathy and to assess the potential usefulness of skin biopsy as an outcome measure in peripheral neuropathy trials (level B recommendation). In conclusion, punch skin biopsy is a safe and reliable technique (level A recommendation) [53]. Age-dependent limits for normal intra-epidermal nerve fiber density are available [54].

Corneal confocal microscopy

The cornea of the human eye harbors a multitude of nerve fibers originating from the ophthalmic division of the trigeminal nerve and organized in three main groups: the sub-basal plexus, the sub-epithelial plexus, and the stromal nerves. *In vivo* laser-scanning corneal confocal microscopy (CCM), a non-invasive modality for the study of human cornea, has emerged as a promising technique for the detection of small-nerve fiber alterations [55]. CCM is being used to assess the corneal sub-basal nerve plexus lying between the basal epithelium and Bowman's membrane. CCM has good reproducibility and may contribute to the

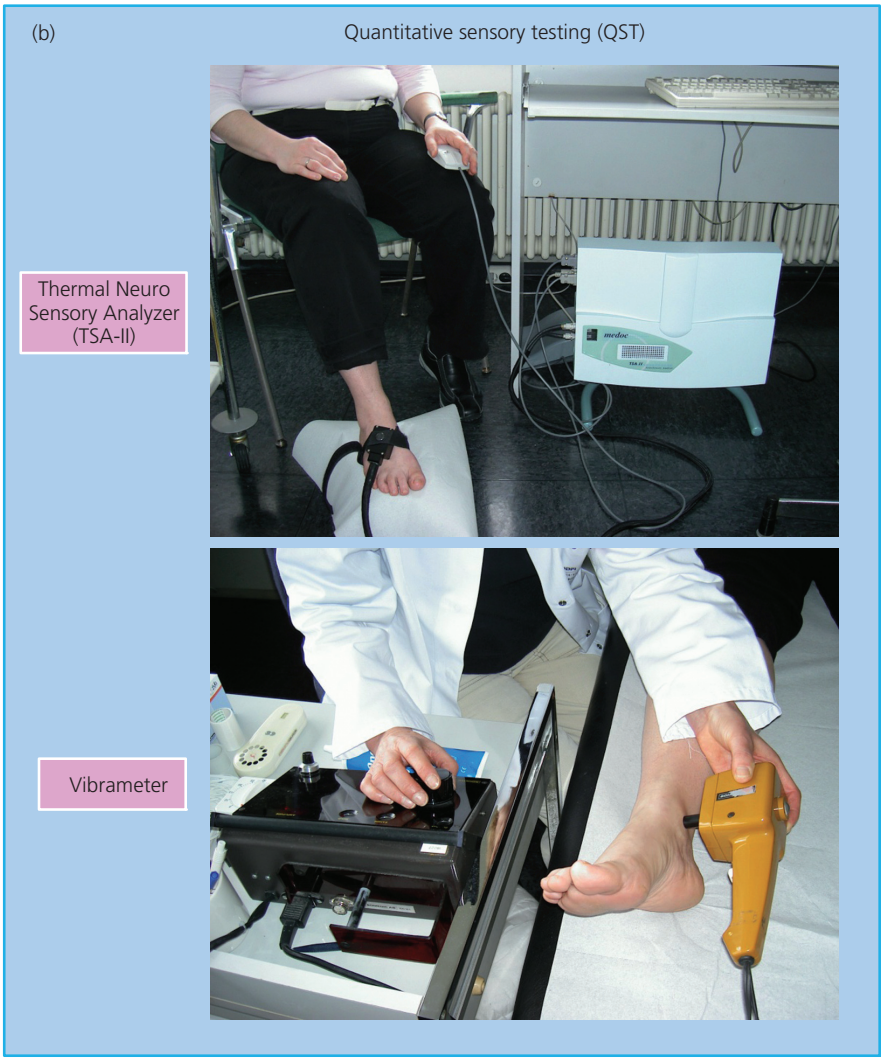

Figure 40.5 (*Continued*).

early diagnosis of diabetic polyneuropathy. It may also be useful to document favorable changes in nerve fiber structure early after therapeutic intervention [56]. Corneal nerve pathology is more pronounced in people with diabetic polyneuropathy and is associated with its clinical severity. The sensitivity and specificity of CCM for the diagnosis of polyneuropathy are moderate to high. Corneal nerve fiber loss by about 20% has been demonstrated in individuals with recent-onset T2DM despite good glycemic

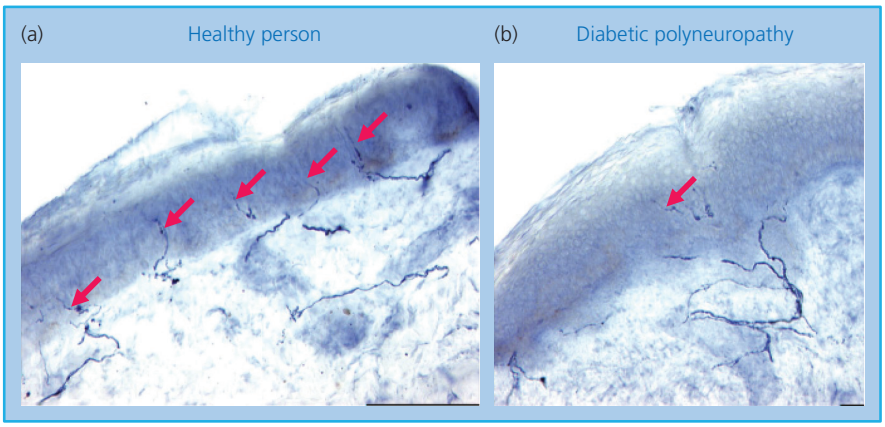

Figure 40.6 Loss of intra-epidermal nerve fibers in skin biopsy from the lateral lower leg in a person with diabetes with polyneuropathy (a) compared with a healthy person without diabetes (b) (red arrows indicate intra-epidermal nerve fiber). Bright-field immunohistochemistry with anti-protein gene product 9.5 antibodies (PGP 9.5).

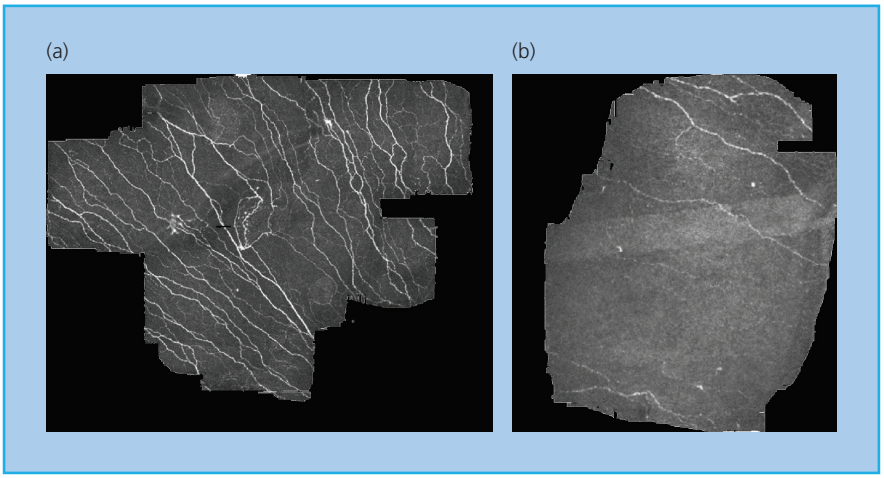

Figure 40.7 Corneal confocal microscopy showing the sub-basal nerve plexus. (a) Normal structure of corneal nerve fibers in a healthy individual; (b) loss of corneal nerve fibers in a person recently diagnosed with T2DM.

control [57]. Figure 40.7 shows CCM images of the sub-basal nerve plexus with normal appearance in a healthy individual (a) and corneal nerve fiber loss in a person recently diagnosed with T2DM (b). CCM now merits further use in large longitudinal studies to provide more information on the natural history of diabetic neuropathy and effects of treatment on corneal nerve regeneration [56].

Treatment

Role of intensive diabetes therapy in treatment and prevention of diabetic neuropathy

Several long-term prospective studies that assessed the effects intensive diabetes therapy on the prevention and progression of chronic diabetic complications have been published. The large randomized trials such as the Diabetes Control and Complications Trial (DCCT) and UK Prospective Diabetes Study (UKPDS) were not designed to evaluate the effects of intensive diabetes therapy on DSPN, but rather to study the influence of such treatment on the development and progression of the chronic diabetic complications [52, 53] Hence only a minority of the individuals enrolled in these studies had symptomatic polyneuropathy at entry.

Studies in persons with T1DM showed that intensive diabetes therapy retards but does not completely prevent the development of DSPN [58, 59]. In contrast, in those with T2DM, there is no evidence that intensive diabetes therapy or a target-driven intensified intervention aimed at multiple risk factors favorably influences the development or progression of DSPN in persons with T2DM [60, 61].

Treatment based on pathogenetic concepts

Recent experimental studies suggest a multifactorial pathogenesis of diabetic neuropathy. From the clinical point of view, it is important to note that, based on the various pathogenetic mechanisms, therapeutic approaches could be derived, some of which have been evaluated in randomized clinical trials, including aldose reductase inhibitors (alrestatin, sorbinil, ponalrestat, tolrestat, epalrestat, zopolrestat, zenarestat, fidarestat, ranirestat), the antioxidant α-lipoic acid (thioctic acid), essential fatty acid (γ-linolenic acid), ACE inhibitors (trandolapril), prostacyclin (PGI_2) analogs (iloprost, beraprost), prostaglandin derivatives (PGE_1.αCD), nerve growth factor (NGF), PKC β inhibitor (ruboxistaurin), C-peptide, vascular endothelial growth factor (VEGF), and benfotiamine (vitamin B_1 derivative) [62, 63]. These drugs have been designed to influence the underlying neuropathic process favorably rather than for symptomatic pain treatment. Since in the foreseeable future normoglycemia will not be achievable in the majority of persons with diabetes, the advantage of the aforementioned treatment approaches is that they may exert their effects despite prevailing hyperglycemia. Experimental studies of low-dose combined drug treatment suggest enhanced drug efficacy mediated by facilitatory interactions between drugs. Although considerable improvements in the quality of controlled trials has recently been made, no major breakthrough in slowing the progression of diabetic neuropathy in the long run has been achieved with drugs used on the basis of current pathogenetic concepts. Some of the newer drugs have shown promising results in phase II trials that require confirmation from large phase III trials. It is conceivable that drugs interfering with the pathogenesis of diabetic neuropathy may be most effective in terms of prevention, rather than intervention.

For clinical use only the antioxidant α-lipoic acid [64–68], the deproteinized hemo derivative of calf blood actovegin [69], and the lipid-soluble vitamin B_1 derivative benfotiamine [70] are licensed and used for treatment of symptomatic DSPN in several countries, and epalrestat is marketed in Japan and India. According to several meta-analyses, intravenous infusions of α-lipoic acid (600 mg/day) ameliorated neuropathic symptoms and deficits after 3 weeks [64–66]. Moreover, treatment for 5 weeks using 600 mg of α-lipoic acid orally once daily reduced the main symptoms of diabetic polyneuropathy including pain, paresthesia, numbness, and numbness to a clinically meaningful degree [65, 66]. In a multicenter, randomized, double-masked, parallel-group clinical trial (NATHAN 1), 460 people with diabetes with mild to moderate largely asymptomatic DSPN were randomly assigned to oral treatment with α-lipoic acid 600 mg once daily

($n = 233$) or placebo ($n = 227$) for 4 years. After 4 years, neuropathic deficits and symptoms, but not nerve conduction velocity, were improved, and the drug was well tolerated throughout the trial [67]. Clinical and post-marketing surveillance studies revealed a highly favorable safety profile [68].

Symptomatic treatment of painful neuropathy

Painful symptoms in diabetic polyneuropathy may constitute a considerable management problem. The efficacy of a single therapeutic agent is not the rule, and simple analgesics are usually inadequate to control the pain. There is agreement that patients should be offered the available therapies in a stepwise fashion [71–73]. Effective pain treatment considers a favorable balance between pain relief and side effects without implying a maximum effect. The following general considerations in the pharmacotherapy of neuropathic pain require attention:

- The appropriate and effective drug has to be tried and identified in each person by carefully titrating the dose based on efficacy and side effects.
- Lack of efficacy should be judged only after 2–4 weeks of treatment using an adequate dose.
- Because the evidence from clinical trials suggests only a maximum response of ~50% for any monotherapy, analgesic combinations may be useful.
- Potential drug interactions have to be considered given the frequent use of polypharmacy in individuals with diabetes.

A rational treatment algorithm including the various causal and symptomatic options is summarized in Table 40.2. Certain antidepressants (tricyclic drugs, duloxetine) and anticonvulsants (pregabalin, gabapentin) are considered as first-line treatments, and opioids are recommended as second-line options [72–74]. The advantages and disadvantages of the various drugs and drug classes used for treatment of painful diabetic neuropathy under consideration of the various comorbidities and complications associated with diabetes are summarized in Table 40.3. Prior to any decision regarding the appropriate treatment, the diagnosis of the underlying neuropathic manifestation allowing the estimation of its natural history should be established. In contrast to the agents that have been derived from the pathogenetic mechanisms

Table 40.2 Treatment options for painful diabetic neuropathy.

Approach	Compound/measure	Dose per day	Remarks	NNT (95% CI)
Optimal diabetes control	Lifestyle modification, OAD, insulin	Individual adaptation	Aim: HbA_{1c} ≤6.5–7%	–
Pathogenesis-oriented treatment	α-Lipoic acid (thioctic acid)[a]	600 mg i.v. infusion	RCT duration: 3 weeks	6.3[b]
		600–1800 mg orally	FSP; RCT duration: 4 yr	2.8–4.2[b]
	Actovegin[a]	2 g i.v., 1.8 g orally	FSP; RCT duration: 6 mo	8.3[b]
	Benfotiamine[a]	600 mg orally	FSP; RCT duration: 6 wk	?
Symptomatic treatment	*Tricyclic antidepressants*			3.6 (3.0–4.4)[c]
	Amitriptyline	(10–)25–150 mg	NNMH: 15	
	Desipramine	(10–)25–150 mg	NNMH: 24	
	Imipramine	(10–)25–150 mg	CRR	
	Clomipramine	(10–)25–150 mg	NNMH: 8.7	
	Nortriptyline	(10–)25–150 mg		
	SNRIs			6.4 (5.2–8.4)[c]
	Duloxetine	60–120 mg	Effective dose: 60 mg	
	α2–δ ligands			
	Gabapentin	900–3600 mg	Long titration	7.2 (5.9–9.1)[c]
	Pregabalin	300–600 mg	Dose-dependent effect	7.7 (6.5–9.4)[c]
	Weak opioids			
	Tramadol	50–400 mg	NNMH: 7.8	4.7 (3.6–6.7)[c]
	Local treatment			
	Capsaicin (0.025%) cream	q.i.d. topically	Max. duration: 6–8 weeks	5.7
	Capsaicin 8%	One time 179 mg topically	3-month repeat intervals as needed	10.6 (7.4–18.8)[c]
	Strong opioids			4.3 (3.4–5.8)[c]
Pain resistant to standard pharmacotherapy	Oxycodone, tapentadol		Add-on treatment	
	Electrical spinal cord stimulation		Invasive, specialist required	

[a] Available only in some countries.
[b] ≥50% symptom relief after 3 and 5 weeks.

of diabetic neuropathy, those used for symptomatic therapy were designed to modulate the pain, without favorably influencing the underlying neuropathy.

The relative benefit of an active treatment over a control in clinical trials is usually expressed as the relative risk, the relative risk reduction, or the odds ratio (OR). However, to estimate the extent of a therapeutic effect (i.e. pain relief) that can be translated into clinical practice, it is useful to apply a simple measure that serves the physician to select the appropriate treatment for the individual patient. Such a practical measure is the "number needed to treat" (NNT), i.e. the number of people that need to be treated with a particular therapy to observe a clinically relevant effect or adverse event in one patient. This measure is expressed as the reciprocal of the absolute risk reduction, i.e. the difference between the proportion of events in the control group (P_c) and the proportion of events in the intervention group (P_i): $\text{NNT} = 1/(P_c - P_i)$. The 95% confidence interval (CI) of NNT can be obtained from the reciprocal value of the 95% CI for the absolute risk reduction. The NNT and NNH (number needed to harm) for the individual agents used in the treatment of painful diabetic neuropathy are given in Table 40.2.

Oral treatments

Tricyclic antidepressants

Psychotropic agents, among which tricyclic antidepressants have been evaluated most extensively, have constituted an important component in the treatment of chronic pain syndromes for more than 30 years. Putative mechanisms of pain relief by antidepressants include the inhibition of norepinephrine and/or serotonin reuptake at synapses of central descending pain control systems and the antagonism of *N*-methyl D-aspartate receptor that mediate hyperalgesia and allodynia. Imipramine, amitriptyline, and clomipramine induce a balanced reuptake inhibition of both norepinephrine and serotonin, while desipramine is a relatively selective norepinephrine inhibitor. The NNT for a ≥50% relief of neuropathic pain by tricyclic antidepressants is 3.6 (95% CI: 3.0–4.4) [72]. The most frequent adverse events of tricyclic antidepressants include tiredness and dry mouth. The starting dose should be 25 mg (10 mg in frail patients) and taken as a single nighttime dose 1 h before sleep. It should be increased by 25 mg at weekly intervals until pain relief is achieved or adverse events occur. The maximum dose is usually 150 mg/day. Tricyclic antidepressants are contraindicated in people with orthostatic hypotension, unstable angina, recent (<6 months) myocardial infarction, heart failure, history of ventricular arrhythmias, significant conduction system disease, and long QT syndrome.

Selective serotonin reuptake inhibitors (SSRIs)

Because of the relative high rates of adverse effects and several contraindications of tricyclic antidepressants, it has been reasoned whether people who do not tolerate them could alternatively be treated with SSRIs. These specifically inhibit presynaptic reuptake of serotonin but not norepinephrine, and unlike the tricyclic antidepressants they lack the postsynaptic receptor blocking effects and quinidine-like membrane stabilization. However, only weak or no effects on neuropathic pain were observed after treatment with fluoxetine, paroxetine, citalopram, and escitalopram [75]. Because of these limited efficacy data, SSRIs have not been licensed for the treatment of neuropathic pain.

Serotonin noradrenaline reuptake inhibitors (SNRIs)

Because SSRIs have been found to be less effective than tricyclic antidepressants, recent interest has focused on antidepressants with dual selective inhibition of serotonin and noradrenaline, such as duloxetine and venlafaxine. The efficacy and safety of duloxetine were evaluated in three controlled studies using doses of 60 and 120 mg/day over 12 weeks [76]. In all three studies, the average 24-h pain intensity was significantly reduced with both doses compared with placebo treatment, the difference between active and placebo achieving statistical significance after 1 week. The response rates, defined as ≥50% pain reduction, were 48.2%

(120 mg/day), 47.2% (60 mg/day), and 27.9% (placebo), giving an NNT of 4.9 (95% CI: 3.6–7.6) for 120 mg/day and 5.3 (95% CI: 3.8–8.3) for 60 mg/day. Pain severity but not variables related to diabetes or neuropathy predicts the effects of duloxetine in diabetic peripheral neuropathic pain. People with higher pain intensity tend to respond better than those with lower pain levels [77]. The most frequent side effects of duloxetine (60/120 mg/day) include nausea (16.7/27.4%), somnolence (20.2/28.3%), dizziness (9.6/23%), constipation 14.9/10.6%), dry mouth (7.1/15%), and reduced appetite (2.6/12.4%). These adverse events are usually mild to moderate and transient. To minimize them, the starting dose should be 30 mg/day for 4–5 days. In contrast to tricyclic antidepressants and some anticonvulsants, duloxetine does not cause weight gain, but a small increase in fasting blood glucose may occur.

In a 6-week trial comprising 244 participants, the analgesic response rates were 56, 39, and 34% in those given 150–225 mg venlafaxine, 75 mg venlafaxine, and placebo, respectively. Because people with depression were excluded, the effect of venlafaxine (150–225 mg) was attributed to an analgesic, rather than antidepressant, effect. The most common adverse events were tiredness and nausea [78]. Duloxetine but not venlafaxine has been licensed for the treatment of painful diabetic neuropathy.

Anticonvulsants

Calcium channel modulators (α2–δ ligands)

Gabapentin is an anticonvulsant structurally related to γ-aminobutyric acid (GABA), a neurotransmitter that plays a role in pain transmission and modulation. The exact mechanisms of action of this drug in neuropathic pain have not been fully elucidated. Among others, they involve an interaction with the system L-amino acid transporter and high-affinity binding to the α2–δ subunit of voltage-activated calcium channels. In an 8-week multicenter dose-escalation trial including 165 participants with diabetes and painful neuropathy, 60% of those on gabapentin (3600 mg/day achieved in 67%) had at least moderate pain relief compared with 33% on placebo. Dizziness and somnolence were the most frequent adverse events in ∼23% of both groups [79]. Pregabalin is a more specific α2–δ ligand with a sixfold higher binding affinity than gabapentin. The efficacy and safety of pregabalin were reported in a pooled analysis of six studies over 5–11 weeks in 1346 people with diabetes with painful neuropathy. The response rates, defined as ≥50% pain reduction, were 46% (600 mg/day), 39% (300 mg/day), 27% (150 mg/day), and 22% (placebo), giving NNTs of 4.2, 5.9, and 20.0 [33]. The most frequent side effects for 150–600 mg/day were dizziness (22.0%), somnolence (12.1%), peripheral edema (10.0%), headache (7.2%), and weight gain (5.4%) [80]. The evidence supporting a favorable effect in painful diabetic neuropathy is more solid and dose titration is considerably easier for pregabalin than gabapentin.

Sodium channel blockers

Although carbamazepine has been widely used for treating neuropathic pain, it cannot be recommended in painful diabetic neuropathy owing to very limited data. Its successor drug, oxcarbazepine [81], and also other sodium channel blockers such as valproate, mexiletine, topiramate [82], and lamotrigine [83], showed only marginal efficacy and have not been licensed for the treatment of painful diabetic neuropathy.

A single intravenous infusion of lidocaine (5 mg/kg body weight over 30 min during continuous ECG monitoring) resulted in a significant pain relief after 1 and 8 days in a controlled study of 15 people with diabetes and chronic painful neuropathy. [84].

Lacosamide

Lacosamide is an anticonvulsant that selectively enhances the slow inactivation of voltage-dependent sodium channels but, in contrast to the aforementioned sodium channel blockers, does not influence the fast sodium channel inactivation. Its second putative mechanism is an interaction with a neuronal cytosolic protein, the collapsin response mediator protein 2 (CRMP-2), which plays an important role in nerve sprouting and excitotoxicity [85]. Lacosamide has been evaluated in several studies in painful diabetic neuropathy. However, owing to insufficient efficacy, the drug was not approved by the FDA and EMEA for painful diabetic neuropathy.

Opioids

Tramadol acts directly via opioid receptors and indirectly via monoaminergic receptor systems. Because the development of tolerance and dependence during long-term tramadol treatment is uncommon and its abuse liability appears to be low, it is an alternative to strong opioids in neuropathic pain. In painful diabetic neuropathy, tramadol (up to 400 mg/day orally, mean dose 210 mg/day orally) was studied in a 6-week multicenter trial including 131 participants [86]. Pain relief was 44% on tramadol versus 12% on placebo. The most frequent adverse events were nausea and constipation. The NNH of 7.8 for dropouts due to adverse events was relatively low, indicating significant toxicity. Since tramadol has SNRI properties, it should not be combined with serotonergic drugs (*cave*: serotonin syndrome).

The most severe pain requires administration of strong opioids such as oxycodone or tapentadol. Although there are few data available on combination treatment, combinations of different substance classes have to be used in people with pain resistant to monotherapy. Several add-on trials have demonstrated significant pain relief and improvement in quality of life following treatment with controlled-release oxycodone, a pure mu-agonist in people with painful DSPN whose pain was not adequately controlled by standard treatment with antidepressants and anticonvulsants [87, 88]. As expected, adverse events were frequent and typical of opioid-related side effects. The results of these studies suggest that opioids should be included among the therapeutic options for painful DSPN, provided that careful selection of those unresponsive to standard treatments, regular monitoring, appropriate dose titration, and management of possible opioid-specific problems

(analgesic misuse or addiction, tolerance, opioid-induced hyperalgesia) are ensured. Recent recommendations have emphasized the need for clinical skills in risk assessment and management as a prerequisite to safe and effective opioid prescribing [71]. Treatment of painful DSPN with opioid agonists should generally be reserved for those who have failed to respond to or cannot tolerate the first-line medications.

Tapentadol is a novel centrally active analgesic with a dual mode of action: mu-opioid receptor agonist and norepinephrine-reuptake inhibitor. Recent phase III, randomized-withdrawal, placebo-controlled trials evaluated the safety and efficacy of tapentadol extended release (ER) in painful diabetic DSPN. Participants with at least a ≥1-point reduction in pain intensity at the end of a 3-week open-label titration phase were randomized to receive placebo or the optimal fixed dose over 12 weeks. Compared with placebo, tapentadol ER 100–250 mg twice daily was associated with a statistically significant difference in the maintenance of the initial improvement and was well tolerated [89, 90].

Topical agents

Capsaicin

Capsaicin (*trans*-8-methyl-*N*-vanillyl-6-nonenamide) is a selective transient receptor potential vanilloid 1 (TRPV1) agonist and the most pungent ingredient in the red pepper. It depletes tissues of substance P and reduces neurogenic plasma extravasation, the flare response, and chemically induced pain. Substance P is present in afferent neurones innervating skin, mainly in polymodal nociceptors, and is considered the primary neurotransmitter of painful stimuli from the periphery to the CNS. Several studies have demonstrated significant pain reduction and improvement in quality of life in people with diabetes with painful neuropathy after 8 weeks of treatment with capsaicin cream 0.075% [91]. The high concentration 8% adhesive capsaicin patch (Qutenza) is effective in several neuropathic pain conditions [92], and has recently been approved for treatment of painful diabetic neuropathy. The patch is applied for 30 min to the most painful areas, and this procedure may be repeated as needed every 3 months. In people with painful DSPN, a single 30-min application of the capsaicin 8% patch significantly improved pain relief and sleep quality compared to placebo over 12 weeks. In a 52-week, randomized trial, up to seven consecutive 30-min treatments with the capsaicin 8% patch as add-on to standard care was associated with sustained pain relief without adverse effects on sensory function.

Lidocaine

The topical lidocaine patch 5% (Lidoderm), a targeted peripheral analgesic, was associated with relief of pain and tactile allodynia with a minimal risk of systemic adverse effects or drug–drug interactions in people with post-herpetic neuralgia [93]. Controlled clinical trials in people with DSPN are under way.

Botulinum toxin A

Recent experimental evidence suggests that botulinum toxin type A (BTX-A) may not only inhibit the release of acetylcholine at the neuromuscular junctions, but also modulate afferent sensory fiber firing, thereby relieving neuropathic pain. In a recent randomized, double-blind, placebo-controlled trial, two administrations of botulinum toxin A 12 weeks apart, each of which comprised several injections, had a sustained analgesic effect against peripheral neuropathic pain of mixed origin [94]. Large scale studies are required to confirm this finding specifically in people with painful DSPN.

Combination pharmacotherapy

The response rates to analgesic monotherapy in painful diabetic DSPN are only ~50%. Therefore, combination pharmacotherapy is required in individuals who have only partial response or in whom the drug cannot be further titrated owing to intolerable side effects. Synergistic interactions of drug combinations might provide superior analgesia and fewer side effects than monotherapy by targeting of multiple mechanisms. In some trials, combined treatment showed superiority over monotherapy, but in others improved benefit or tolerability was not seen [95]. A crossover study examined the maximum tolerable dose of a combination treatment of gabapentin and morphine compared with monotherapy with each drug. The maximum tolerable dose was significantly lower and efficacy was better with combination therapy than with monotherapy, suggesting an additive interaction between the two drugs [96]. Other trials also showed that the combinations of antidepressants with α2–δ ligands [97, 98] and opioids with antidepressants [99] at the maximum tolerated dose were more effective than either monotherapy. In contrast, in people responding only partially to standard doses of duloxetine or pregabalin, combining both medications was not superior to increasing each drug in monotherapy to its maximum recommended dose. However, duloxetine at a dose of 60 mg/day was more effective than pregabalin at a dose of 300 mg/day [100].

Although several novel analgesic drugs have recently been introduced into clinical practice, the pharmacological treatment of chronic painful diabetic neuropathy remains a challenge for the physician. Individual tolerability remains a major aspect in any treatment decision. Little information is available from controlled trials on long-term analgesic efficacy and head-to-head comparisons of individual analgesics, and only a few studies have used drug combinations. Combination drug use or the addition of a new drug to a therapeutic regimen may lead to increased efficacy. In the future, drug combinations may also include those aimed at symptomatic pain relief and quality of life on the one hand, and improvement or slowing of the progression of the underlying neuropathic process on the other.

Non-pharmacological treatment

Because there is no entirely satisfactory pharmacotherapy of painful diabetic neuropathy, non-pharmacological treatment

options should always be considered. As for the pharmacological treatment, considerable efforts must also be made to develop effective non-pharmacological approaches. A systematic review assessed the evidence from rigorous clinical trials and meta-analyses of complementary and alternative therapies for treating neuropathic and neuralgic pain [101]. Data on the following complementary and alternative medicine treatments were identified: acupuncture, electrostimulation, herbal medicine, magnets, dietary supplements, imagery, and spiritual healing. The conclusion was that the evidence is not fully convincing for most complementary and alternative medicine modalities in relieving neuropathic or neuralgic pain. The evidence can be classified as encouraging and warrants further study for cannabis extract, magnets, carnitine, and electrostimulation.

Psychological support

A psychological component to pain should not be underestimated. Hence an explanation to the patient that even severe pain may remit, particularly in people with poorly controlled diabetes and acute painful neuropathy or in those with painful symptoms precipitated by intensive insulin treatment. Hence an emphatic approach addressing the concerns and anxieties of those with neuropathic pain is essential for their successful management [102].

Physical measures

The temperature of the painful neuropathic foot may be increased owing to arteriovenous shunting. Immersion in cold water may reduce shunt flow and relieve pain. Allodynia may be relieved by wearing silk pyjamas or the use of a bed cradle. Patients who describe painful symptoms on walking, likened to walking on pebbles, may benefit from the use of comfortable footwear [102].

Acupuncture

In a 10-week uncontrolled study in people with diabetes on standard pain therapy, 77% showed significant pain relief after up to six courses of traditional Chinese acupuncture without any side effects. During a follow-up period of 18–52 weeks, 67% were able to stop or significantly reduce their medications and only 24% required further acupuncture treatment [103]. Controlled studies using placebo needles should be performed to confirm these findings.

Transcutaneous electrical nerve stimulation (TENS)

TENS influences neuronal afferent transmission and conduction velocity, increases the nociceptive flexion reflex threshold, and changes the somatosensory evoked potentials. In a recent meta-analysis, reductions in the mean pain score were significantly greater with TENS than with sham treatment [104]. Hence TENS may be used as an adjunctive modality combined with pharmacotherapy to augment pain relief.

External muscle stimulation (high-tone therapy)

One randomized controlled study showed a better effect of mid-frequency external muscle stimulation than TENS on neuropathic symptoms after 1 week [105], but longer term controlled studies are not available.

Frequency-modulated electromagnetic nerve stimulation (FREMS)

FREMS applied during 10 sessions over 3 weeks resulted in significant pain reduction compared with placebo stimulation [106, 107].

Electrical spinal cord stimulation

It is generally agreed that electrical stimulation is effective in neurogenic forms of pain. Experiments indicate that electrical stimulation is followed by a decrease in the excitatory amino acid derivatives glutamate and aspartate in the dorsal horn. This effect is mediated by a GABAergic mechanism. In people with refractory painful diabetic neuropathy, spinal cord stimulation therapy over 6 months significantly reduced pain and improved quality of life [108]. This invasive treatment option should be reserved for those who do not respond to analgesic pharmacotherapy.

Surgical decompression

Surgical decompression at the site of anatomic narrowing has been promoted as an alternative treatment for people with symptomatic DSPN. A systematic review of the literature revealed only Class IV studies concerning the utility of this therapeutic approach. Given the current evidence available, this treatment alternative should be considered unproven (Level U). Prospective randomized controlled trials with standard definitions and outcome measures are necessary to determine the value of this therapeutic intervention [109, 110].

Diabetic autonomic neuropathy

Clinical impact

Diabetic autonomic neuropathy may affect any organ innervated by the autonomic nervous system. Although diabetic autonomic neuropathy has been appreciated as a clinical entity since the classical report by Rundles [111], in the past it has received less attention than peripheral sensorimotor neuropathy. This was because the onset of clinical features is insidious and severe clinical symptoms usually occur relatively late in the course of diabetes. Furthermore, non-invasive quantitative and reliable methods for assessment of diabetic autonomic neuropathy have been available only for the last two decades. Asymptomatic involvement of the autonomic nervous system can be widespread, but remains undetected without careful examination. Alternatively, severe symptoms confined to a single organ may result in extensive diagnostic evaluation and intense therapeutic efforts. The late stages of diabetic autonomic neuropathy are associated with considerable

Table 40.4 Clinical manifestations of diabetic autonomic neuropathy.

System	Manifestation
Cardiovascular system	Resting tachycardia, orthostatic hypotension
	Sudden death, malignant arrhythmia (?)
Respiratory system	Reduced ventilatory drive to hypercapnia/hypoxemia
	Sleep apnea, respiratory arrest (?)
Pupillary system	Pupillary reflex dysfunction, reduced dark adaptation
Gastrointestinal tract	Esophageal motor dysfunction
	Diabetic gastroparesis (gastropathy)
	Gallbladder dysfunction
	Diabetic enteropathy (diarrhea)
	Colonic hypomotility (constipation)
	Anorectal dysfunction (fecal incontinence)
Urogenital system	Diabetic cystopathy (neurogenic vesical dysfunction)
	Erectile dysfunction, female sexual dysfunction
Thermoregulation	Sudomotor dysfunction: distal hypohydrosis/anhidrosis, gustatory sweating
	Vasomotor dysfunction: vasodilatation, arteriovenous shunting, peripheral edema
Neuroendocrine system	Hypoglycemia-associated autonomic failure (HAAF):
	Defective counter-regulation, hypoglycemia unawareness
	Reduced hormonal responses to orthostatic changes/exercise

morbidity and increased mortality, hence early detection aimed at prevention of advanced symptomatic stages of this complication is essential. Since the clinical symptoms of autonomic neuropathy may be ambiguous and asymptomatic stages elude clinical examination, reliable, specific, and sensitive diagnostic methods are postulated. The clinical manifestations of diabetic autonomic neuropathy are summarized in Table 40.4.

There are no suitable test procedures available to screen for autonomic neuropathy. However, the following symptoms can serve as an indication, albeit with low specificity and sensitivity: resting tachycardia, gastrointestinal symptoms (dyspepsia, constipation, diarrhea, fecal incontinence), disorders of bladder function, sexual dysfunction, hypoglycemia unawareness, disordered sweat secretion, and blood glucose fluctuations that cannot be explained otherwise [51]. The Survey of Autonomic Symptoms (SAS), a simple questionnaire that consists of 11 items for women and 12 for men, has recently been validated. Each item is rated by an impact score ranging from 1 (least severe) to 5 (most severe). The SAS shows a high sensitivity and specificity (area under the receiver operating characteristic curve 0.828) that compares favorably with the detailed Autonomic Symptom Profile [112].

Cardiovascular autonomic neuropathy

Cardiovascular autonomic neuropathy (CAN) is a serious complication of diabetes that is associated with a poor prognosis and may result in severe postural hypotension, exercise intolerance, enhanced intraoperative instability, and increased incidence of silent myocardial infarction or ischemia, and may even predict the development of stroke. According to a meta-analysis, the overall mortality rates over periods up to 10 years were 30.4% in people with diabetes and CAN detected by reduced heart rate variability (HRV) compared with 13.4% in those without evidence of CAN. The relative risk of mortality from 15 studies ($n = 2900$) was increased in people with CAN by 2.14 (95% CI: 1.83–2.51) [113]. In the population-based KORA Augsburg Cohort Study, low HRV and prolonged QTc interval were independent predictors of all-cause and cardiovascular mortality in people with diabetes and in the general population [114, 115].

After cardiovascular reflex tests based on changes in HRV and blood pressure regulation had been introduced into clinical routine, it became evident that CAN may frequently be detected at early stages in asymptomatic people with diabetes. CAN can be divided into (1) subclinical, which is diagnosed only by tests, and (2) clinical, which presents with symptoms or signs [116]. The main clinical features of CAN are given in Table 40.5 [51]. In the population-based KORA S4 survey, the prevalence of CAN diagnosed by reduced HRV was 18% in people with known diabetes, 12% in those with newly detected diabetes, 11% in those with combined IFG/IGT, 8% in those with isolated IFG, 6% in those with isolated IGT, and 4.5% in those with NGT [115]. The presence of CAN is associated not only with the duration of diabetes and degree of glycemic control but also with smoking and the various components of the metabolic syndrome, including cardiovascular risk factors such as obesity, hyperlipidemia, hypertension, and albuminuria [117, 118].

It has long been recognized that resting tachycardia and fixed heart rate are characteristic findings in individuals with diabetes with advanced CAN. However, heart rate may decline with increasing severity of CAN and therefore does not provide a reliable diagnostic criterion. The hallmark and earliest indicator of, and the most frequent finding in, subclinical and symptomatic cardiac autonomic dysfunction is a reduced HRV, i.e. the magnitude of heart rate fluctuations around the mean heart rate, which can be detected using various non-invasive autonomic reflex tests described below. Postural hypotension is recognized as the clinical hallmark of CAN in persons with diabetes. It is characterized by weakness, faintness, dizziness, visual impairment, and even syncope following the change from the lying to the standing posture. In some cases this complication may become disabling, but the blood pressure fall may also be asymptomatic. It is generally agreed among diabetologists that postural hypotension is defined by a decrease in systolic blood pressure upon standing of 30 mmHg or more. It is important to note that orthostatic symptoms can be misjudged as hypoglycemia and be aggravated by a number of drugs, including vasodilators, diuretics, phenothiazines, and in particular tricyclic antidepressants and insulin [116, 119].

Silent ischemia

Several clinical studies have examined the possible relationship between CAN and silent myocardial ischemia. In a survey from the National Registry of Myocardial Infarction 2 (NRMI-2) among 434,877 individuals with myocardial infarction, 33% did not have

Table 40.5 Diabetic autonomic neuropathy of the cardiovascular, respiratory, neuroendocrine, sudomotor, vasomotor, and pupillomotor systems: clinical features, diagnostic work-up, and specific treatment.

Organ manifestations/clinical features	Diagnostic procedures	Treatment
Cardiovascular system		
Resting sinus tachycardia Reduced heart rate variability (HRV), fixed heart rate Orthostatic hypotension Exercise intolerance (inadequate increase in heart rate and blood pressure during physical activity) Perioperative instability with frequent drops in blood pressure and heart rate Reduced or absent perception of myocardial ischemia during physical activity Reduced left ventricular diastolic filling/ejection fraction Silent myocardial infarction Prolonged QT interval Sudden cardiac death	*Basic diagnostic work-up* HRV during deep breathing HRV after standing up Orthostatic test *Extended diagnostic work-up* Autonomic function tests: Resting HRV (time and frequency domain) E/I ratio during deep breathing; max./min. 30:15 ratio Valsalva ratio (Valsalva maneuver) Orthostatic test 24-h HRV, syncope work-up	*Cardiovascular autonomic neuropathy* In general, no specific treatment necessary (important: diagnosis and therapy of coronary heart disease and heart failure) For sinus tachycardia: cardioselective β-receptor blockers *Orthostatic hypotension* General measures: liberal salt intake, physical training, compression stockings, avoidance of hypotensive drugs Midodrine (α_1-adrenergic agonist) Fludrocortisone (9α-fluorohydrocortisone)
Respiratory system		
Central respiratory dysregulation with reduced respiratory drive in response to hypercapnia or hypoxia Sleep apnea syndrome Respiratory arrest	Sleep laboratory, as applicable	CPAP therapy, as applicable
Neuroendocrine system (endocrine dysfunction)		
Hypoglycemia-associated autonomic dysfunction Blunted or absent hormonal counter-regulation Hypoglycemia unawareness Increased glucose threshold for hypoglycemic symptoms at blood glucose lowering Decreased catecholamine secretion when standing or upon physical exertion	Optimal blood glucose control (in particular self-control), including during the night	Avoidance of symptomatic and asymptomatic (often nocturnal) hypoglycemia Hypoglycemia awareness training (blood glucose awareness training)
Sudomotor and vasomotor systems		
Dyshidrosis, anhidrosis ("dry feet") Gustatory sweating	Sweat tests: QSART: quantitative sudomotor axon reflex test TST: thermoregulatory sweat test SSI: Silastic sweat imprint ACHSST: acetylcholine sweatspot test Neuropad: indicator plaster	Topical agents containing fat or urea Avoidance of exposure to intense heat Prophylaxis in case of identified cause of sweating (dietary component) Anticholinergic drugs, clonidine (low dose) Topical glycopyrrolate cream In focal hyperhidrosis, botulinum toxin can be tried
Pupillomotor system		
Myosis Defective pupillary reflexes Reduced dark adaptation	Clinical examination Infrared pupillography (constriction rate, dilation rate, latency of pupillary light reflex)	Advise patient of impaired adaptation to dark and danger of night blindness Danger of glaucoma (check intraocular pressure)

chest pain on presentation. The rates in people with diabetes were 32.6% among those presenting without chest pain versus 25.4% in the group with chest pain [120]. In the DIAD study, the prevalence of silent ischemia was 22% among persons with T2DM. CAN rather than traditional and emerging cardiovascular risk factors was a strong predictor of silent ischemia [121], and CAN also predicted incident cardiovascular morbidity [10]. A meta-analysis covering 12 studies (n = 1468) revealed an increased risk of silent myocardial ischemia during exercise by 1.96 (95% CI: 1.53–2.51) in people with diabetes with CAN compared with those without CAN [122]. In asymptomatic individuals with diabetes, the risk of major cardiac events was highest in those with both CAN and silent myocardial ischemia, but the latter was a weaker predictor of these events than CAN [122]. In persons with diabetes with exertional chest pain, a prolonged anginal perceptual threshold, i.e. the time from onset of 0.1 mV ST

depression to the onset of angina pectoris during exercise ECG, has been demonstrated compared with those without diabetes. This delay was associated with the presence of CAN [123]. Hence people with CAN and CAD are in jeopardy, because the longer threshold permits them to continue exercising despite increasing ischemia.

Diagnostic assessment

Cardiovascular autonomic reflex tests

During the past quarter of a century, several non-invasive cardiovascular reflex tests for computer-assisted assessment of abnormalities in HRV and blood pressure regulation have been described [124]. It is generally accepted that the diagnosis of CAN should be based on the results of a battery of autonomic tests rather than a single test [125]. HRV can be assessed either by calculation of indices based on statistical analysis of R–R intervals (time domain analysis) or by spectral analysis (frequency domain analysis) of an array of R–R intervals. Commercially available computer programs are usually employed to assess autonomic nerve function, but conventional ECG equipment can also be used. We previously validated a combination of autonomic function tests based on standard, spectral, and vector analysis of HRV [126, 127]. This test battery included measurement of the following indices: (1) Coefficient of variation (CV) of R–R intervals at rest, (2) spectral power in the very low-frequency band and (3) the low-frequency band, (4) HRV during deep breathing, including mean circular resultant of vector analysis or expiration/inspiration (E/I) ratio, (5) maximum–minimum 30:15 ratio, (6) Valsalva ratio, and (7) postural change in systolic blood pressure. The age-related normal ranges of these seven indices that have been selected following specific criteria (different physiological basis, independence of heart rate, and relatively high sensitivity and reproducibility) have been reported [128]. We suggested that definite CAN be defined as the presence of three or more abnormalities among these seven variables (specificity: 100%). Borderline or incipient CAN is assumed when two or more abnormal findings are present (specificity: 98%).

According to the Toronto Consensus [125], diagnosis of CAN should be based on the use of heart rate response to deep breathing, standing, and Valsalva maneuver, and blood pressure response to standing. For the diagnosis and monitoring of CAN, more than one heart rate test and the orthostatic hypotension test are required. The following criteria for the diagnosis and staging of CAN were proposed: (1) the presence of one abnormal cardiovagal test result identifies the condition of possible or early CAN, to be confirmed over time; (2) two or more abnormal cardiovagal test results are required for a definite or confirmed diagnosis of CAN; and (3) the presence of orthostatic hypotension in addition to abnormal HRV identifies severe or advanced CAN. The diagnostic work-up for CAN is presented in Table 40.5 [51]. Because of the potential risk of inducing retinal or vitreous hemorrhage, the Valsalva maneuver should not be performed in those with advanced diabetic retinopathy.

24-hour heart rate variability

Evidence has accumulated indicating a circadian variation in the frequency of acute cardiovascular events, with an increased incidence in the early morning hours. Neural activities represent typical examples of circadian rhythms, i.e. the day–night cycle, and it is well known that circulatory changes follow a similar circadian cycle. This highlights the importance of continuous 24-h monitoring of heart rate and blood pressure changes in studying the neural control of circulation in people with and without diabetes [129].

Cardiac radionuclide imaging

Radionuclide techniques for cardiac mapping have recently been used to quantify directly cardiac sympathetic innervation in various diseases including CAN. The non-metabolized norepinephrine analog *m*-iodobenzylguanidine (MIBG) participates in norepinephrine uptake in postganglionic sympathetic neurons. Several studies have demonstrated decreased myocardial MIBG uptake in persons with CAN as assessed by autonomic reflex tests [119, 130]. These defects in MIBG uptake usually remain unchanged over several years [131]. An example of reduced MIBG uptake in the left ventricular posterior wall in a person with long-term T1DM and renal failure before undergoing combined pancreas/kidney transplantation (P/KX) is shown in Figure 40.8a (white arrow). Eight years following successful P/KX, stable MIBG uptake was observed with the defect in MIBG uptake still visible in the left ventricular posterior wall (Figure 40.8b, white arrows). There is evidence to suggest that scintigraphic assessment using MIBG and single photon emission computed tomography (SPECT) using the norepinephrine analog [^{11}C]hydroxyephedrine is more sensitive in detecting CAN than indirect autonomic reflex testing, since MIBG uptake was reduced in people with normal autonomic tests [119, 130]. However, cardiac radionuclide imaging constitutes a research tool that is not available in the routine clinical setting.

Management

Causal treatment

In general, elimination of hyperglycemia, which is considered the permissive pathogenetic factor, is the primary approach of a causal treatment of any stage and manifestation of diabetic neuropathy. However, similarly to DSPN, studies in individuals with T1DM have shown that the progression of CAN may be delayed during long-term near-normoglycemia, whereas the majority of studies in those with T2DM could not convincingly demonstrate a favorable effect [132]. Interestingly, a multifactorial cardiovascular risk intervention aimed at improvements in glycemic control, weight loss, lipids, and hypertension in the Steno 2 study resulted in a slowing of progression of CAN but not DSPN [133].

Treatment based on pathogenetic concepts

A variety of experimental studies have provided new insights into the putative mechanisms implicated in the pathogenesis

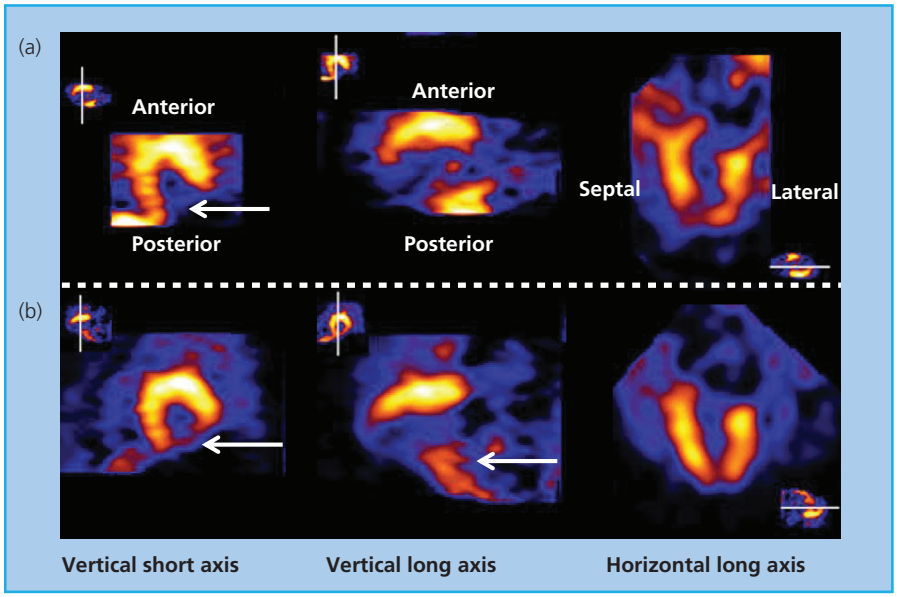

Figure 40.8 (a) Reduced MIBG uptake in the left ventricular posterior wall in a person with long-term T1DM and renal failure before undergoing combined pancreas/kidney transplantation (P/KX) (white arrow). (b) Eight years following successful P/KX, stable MIBG uptake with persisting defect in MIBG uptake in the left ventricular posterior wall (white arrows).

of diabetic neuropathy [40, 41]. Several experimental treatment approaches have been developed on the basis of pathogenetic concepts. From the clinical viewpoint, only limited data regarding these agents are available in persons with diabetes with CAN. Favorable effects on parasympathetic activity in people with diabetes have been shown in randomized controlled trials using the antioxidant α-lipoic acid (800 mg/day orally) after 4 months (DEKAN Study) [134], vitamin E (600 mg/day) after 4 months [135], and also ACE inhibitors, AT1 blockers and β-blockers [119, 136]. Further long-term studies are needed to confirm these findings.

Modulation of autonomic tone

Changes in autonomic nervous system activity play an important role in the genesis of cardiac arrhythmias. In general, parasympathetic withdrawal or sympathetic activation facilitate the formation of ventricular arrhythmias [137]. Drugs that adversely affect the autonomic tone by reducing HRV include class Ic antiarrhythmic agents (e.g. flecainide), β-blockers with intrinsic sympathomimetic activity (e.g. pindolol), clonidine, diltiazem, and tricyclic antidepressants (e.g. amitriptyline, imipramine, desipramine). An increase in HRV has been described for ACE inhibitors, cardioselective β-blockers without intrinsic sympathomimetic activity (e.g. metoprolol), digoxin, and verapamil. No consistent effect on HRV has been shown for longer acting dihydropyridine calcium channel blockers (e.g. nifedipine), amiodarone, and SSRIs (e.g. paroxetine, fluvoxamine) [119, 136]. Autonomic imbalance and high post-infarction morbidity and mortality are frequently observed in people with diabetes. As β-blockers without intrinsic sympathomimetic activity reduce both recurrent myocardial infarction and mortality post-infarction to a greater extent in people with diabetes than in those without diabetes, it has been suggested that this high-risk group could particularly benefit from these agents [137].

Symptomatic treatment

At present, the therapeutic strategies that are available in the routine clinical setting are limited to symptomatic treatment of CAN. Resting tachycardia usually does not require drug treatment, but in severe cases low-dose cardioselective β-blockers may be tried. In a considerable number of individuals with diabetes, postural hypotension remains asymptomatic and does not require any treatment. On the other hand, in severe cases it is the most disabling symptom of diabetic autonomic neuropathy. Drug treatment of symptomatic postural hypotension in people with diabetes and CAN may be difficult, because the goal of increasing blood pressure on standing has to be thoroughly balanced with the avoidance of a marked increase in supine blood pressure. This problem is particularly marked in those who develop arterial hypertension due to diabetic nephropathy, since the latter is commonly associated with CAN.

The first therapeutic approach should be an attempt to increase the venous return to the heart with mechanical measures such as an elasticized garment reaching from the metatarsals to the costal margin, careful and mild physical exercise such as swimming, head-up bed position during sleeping, and sitting on the edge of the bed before standing up. Simple physical maneuvers including leg crossing and squatting produce circulatory effects associated with an increase in blood pressure and improvement of orthostatic symptoms in persons with autonomic failure. In the absence of contraindications, salt intake may be increased by 2–6 g/day. Administration of psychotropic and diuretic drugs which may result in similar symptoms should be avoided, and electrolyte imbalance or volume depletion are to be excluded. When insulin

has been identified as a source aggravating postural hypotension, changing the timing of injections should be considered [115].

The efficacy of pharmacological treatment has been adequately substantiated for only a few drugs, is limited for others, particularly in people with advanced disease, and significant adverse reactions are frequent. Therefore, before any symptomatic treatment is initiated, its potential risk should be thoroughly weighed against its possible benefit. As first-line treatment the α_1-adrenergic agonist midodrine can be administered [138]. Another effective drug for treatment of orthostatic hypotension is the mineralocorticoid hormone fludrocortisone (9α-fluorohydrocortisone). This compound leads to an increase in systolic and diastolic blood pressure on standing and to improvement of orthostatic symptoms [139] (Table 40.5).

Gustatory sweating

Clinical features

Gustatory sweating refers to facial sweating, often accompanied by a flush, that follows the ingestion of food or drink. The prevalence of diabetic gustatory sweating is unknown, but it occurs particularly in individuals with either diabetic nephropathy or neuropathy [140]. Diabetic gustatory sweating is believed to be triggered by the taste buds by chewing inert substances, thinking of food, and smelling it; placing foods or alcohol in the stomach by a gastric tube does not evoke it. The tongue is the most sensitive area, and even cocainization fails to inhibit gustatory sweating completely. The etiology of diabetic gustatory sweating is uncertain. It has been assumed that it is a physiological response reflecting a compensatory mechanism to anhidrosis induced by diabetic autonomic neuropathy.

Management

Since sweating is controlled by sympathetic cholinergic pathways, oral anticholinergic drugs such as propantheline have been suggested for the treatment of diabetic gustatory sweating. However, these agents have a high side-effect profile and therefore are frequently unacceptable. A controlled trial using a 0.5% glycopyrrolate cream applied to affected areas on alternate days showed efficacy in reducing both the severity and frequency of diabetic gustatory sweating [140]. As it is not possible to apply this topical antimuscarinic agent beyond the hairline, it is limited to persons who do not experience sweating on the scalp. More recently, after intracutaneous injections of botulinum toxin type A into the affected facial skin areas, sweating ceased within 4 days, with the maximal follow-up time lasting 24 weeks [141] (Table 40.5).

Gastrointestinal dysfunction

Autonomic neuropathy may involve the esophagus, stomach, gallbladder, pancreas, small intestine, and large intestine (See Chapter 50). Abnormalities include both motor function with generally hypotonic and poorly contractile smooth muscle and regulation of gastrointestinal hormone secretion. The clinical features, diagnostic work-up, and specific treatment of diabetic autonomic neuropathy involving the gastrointestinal tract are listed in Table 40.6.

Esophageal dysfunction

Esophageal motility disturbances are frequently demonstrable using scintigraphic techniques, but symptoms including dysphagia, retrosternal discomfort, and heartburn are uncommon. People who complain about these symptoms should undergo endoscopy to exclude an obstructive lesion [51]. Manometric studies show diminished pharyngeal and esophageal contractions and reduced lower sphincter tone. Prokinetic drugs can be tried empirically. Since people with reduced esophageal motility may be at risk of delayed transit and hold-up of tablets, potentially leading to localized mucosal ulceration and delayed drug absorption, they always should drink after taking their medication.

Gallbladder dysfunction

The gallbladder may become atonic in association with autonomic neuropathy, which increases the gallbladder volume by retention of bile [51]. It is unknown whether these changes result in symptoms. Possibly biliary stasis explains the increased risk of gallstones, as shown by recent epidemiological data.

Diabetic gastroparesis

The speed of stomach emptying is important in the regulation of glucose homeostasis. Severe gastroparesis is an uncommon diabetic complication but is very difficult to manage. The rate of gastric emptying depends on the physicochemical composition of food (carbohydrates leave the stomach most rapidly, proteins less so, and fats remain longest, while liquids empty much more quickly than solids), its consistency (large chunks of meat remain in the stomach longer than small pieces), motor activity of the stomach, and the interaction of stomach and duodenum, including involvement of gastrointestinal hormones. The stomach receives nerve impulses from sympathetic and parasympathetic fibers and its movements are coordinated so that chyme (the food/gastric secretion mixture) is transported from the fundus, through the antrum to the pylorus, and then to the duodenum. Thus, fundal contraction is followed by antral contraction and then by sequential contraction of the pylorus and duodenum, with relaxation of the pyloric sphincter [142].

Diagnostic assessment

The terms diabetic gastroparesis and delay in gastric emptying are often used interchangeably, but caution should be exercised as delayed gastric emptying may also be due to hyperglycemia per se. The typical symptoms of gastroparesis are nausea, vomiting, anorexia, postprandial fullness, and early satiety, each affecting 10–20% of individuals with diabetes. However, abnormalities of gastric motor function correlate with symptoms only imperfectly, often have no clinical manifestations, and severe symptoms may remit spontaneously. Unstable blood glucose levels with

Table 40.6 Diabetic autonomic neuropathy of the gastrointestinal tract: clinical features, diagnostic work-up, and specific treatment.

Organ manifestations/clinical features	Diagnostic procedures	Treatment
All gastrointestinal manifestations	*Basic GI diagnostic work-up:*	
	History	
	Exclusion of structural and infectious diseases	
Dysphagia and reflux disease	*Extended diagnostic work-up:*	*Dysphagia:*
	Stage 1:	General measures
	Esophagogastroduodenoscopy	Prokinetic agents in individual cases
	Other imaging, as applicable	*Reflux:*
	Stage 2:	Proton pump inhibitors
	Esophagus manometry	
	24-h pH monitoring	
Diabetic gastroparesis (gastropathy)	Stage 1:	Gastroparesis
	Esophagogastroduodenoscopy	Dietary change: frequent, small, low-fiber meals with less fat
	Abdominal sonography	Adjust injection to meal interval
	Other imaging, as applicable	Prokinetic agents: metoclopramide, domperidone
	Laboratory tests	Erythromycin (off-label)
	Stage 2:	For severe refractory symptoms:
	Gastric emptying scintigraphy	Gastric electrical stimulation ("gastric pacemaker")
	[^{13}C]Octanoic acid breath test	Jejunal feeding tube
		Parenteral nutrition
Diabetic cholecystopathy	Laboratory tests	
	Abdominal sonography	
Diabetic diarrhea (enteropathy) and exocrine pancreatic insufficiency	Stage 1:	Diarrhea
	Endoscopy	Bulking agents
	Abdominal sonography	Loperamide
	Laboratory tests, including examination of stool for pathogenic organisms	Cholestyramine
		Clonidine
	Other imaging, as applicable	Octreotide
	Stage 2:	Bacterial overgrowth of the small intestine: broad-spectrum antibiotics (e.g. ciprofloxacine, metronidazole, and doxycycline one after the other, each for 10 days) with medical yeast (e.g. perenterol)
	Lactose, fructose, sorbitol hydrogen breath test	
	Glucose hydrogen breath test	
	Fecal elastase-1, as applicable	
	Lactulose hydrogen breath test, as applicable	Severe exocrine pancreatic insufficiency
	D-Xylose absorption test, as applicable	Pancreatic enzymes
Diabetic constipation (colonic hypomotility)	Stage 1:	Constipation:
	Digital rectal examination	Sufficient fluids, fiber, and physical activity
	Ileocolonoscopy	Gelling agents (pectins, psyllium preparations)
	Laboratory tests	Fiber-rich foods (e.g. wheat bran, linseed)
	Abdominal sonography, as applicable	Laxatives (e.g. sodium picosulfate, bisacodyl, macrogol, lactulose/lactitol))
	Other imaging, as applicable	
	Stage 2:	Depending on tolerance and efficacy
	(MRI) defecography	Biofeedback for rectal emptying disorder
	Anorectal manometry	Prucalopride (licensed only in women)
	Hinton test	
	Neurological examination	
Diabetic fecal incontinence	Stage 1:	Fecal incontinence:
	Digital rectal examination	Antidiarrheal medications
	Rectal endosonography	Pelvic floor gymnastics
	(MRI) defecography	Biofeedback
	Stage 2:	Sacral nerve stimulation in refractory cases
	Anorectal manometry	
	Neurological examination, as applicable

postprandial hypoglycemia may give rise to considerable problems in achieving satisfactory glycemic control. The actual incidence and prevalence of diabetic gastroparesis have not been adequately studied [142]. Since gastrointestinal symptoms are nonspecific and frequent both in people with and without diabetes, but may be absent in diabetic gastroparesis, possibly owing to a visceral afferent neuropathy, specific and sensitive diagnostic tests are required to confirm or exclude the diagnosis. Since the scintigraphic technique, which is generally accepted as the "gold standard" in the evaluation of disordered gastric emptying in people with diabetes is associated with exposure to radiation and requires expensive equipment, an alternative non-invasive and non-adversive approach is needed to allow for routine clinical application. A suitable candidate for this purpose appears to be the [^{13}C]octanoic acid breath test for emptying of solids, which has the advantage of avoiding radiation by using a stable isotope [143]. The [^{13}C]acetate breath test may be used to measure liquid emptying. Other techniques include ultrasonography, duplex sonography, electrogastrography, manometry, radiopaque markers, double sampling gastric aspiration technique, and magnetic resonance imaging. Endoscopy should be performed if other gastrointestinal diseases are suspected of causing the symptoms.

Management

General measures in the management of diabetic gastroparesis include first, multiple small feedings with nutritional modification by increasing the intake of liquid carbohydrate and decreasing the intake of fat and high-fiber-containing food, and second, optimization of insulin treatment by individual adaptation of the insulin dose, omission of the injection–meal interval (*cave*: insulin lispro) or postprandial insulin application if necessary.

The pharmacological treatment of symptomatic diabetic gastroparesis includes three prokinetic agents. At present, metoclopramide and domperidone are used as the first-line drugs, but the development of tachyphylaxia after long-term treatment is a problem. In December 2013, the European Medicines Agency (EMA) issued a warning that owing to the risk of neurological and other adverse reactions, metoclopramide should no longer be used in chronic conditions such as gastroparesis. In May 2014, the EMA issued a warning that owing to an increased risk of potentially serious cardiac adverse effects, domperidone should be used at the lowest effective dose for the shortest possible duration. The maximum treatment duration should not usually exceed 1 week. Domperidone has since then been licensed only for treating nausea and vomiting, and no longer for the relief of symptoms of fullness or epigastric bloating and discomfort. Erythromycin acts as a motilin agonist, but its use is limited by considerable side effects such as skin reactions, abdominal cramps, and diarrhea. Hence erythromycin (if necessary given 3 mg/kg i.v.) can be administered to people who did not respond to the aforementioned drugs. Whether motilin agonists (erythromycin analogs) may be added to these compounds in the future is currently being tested in multicenter trials. It has not been adequately assessed whether asymptomatic patients may also benefit from drug treatment by more stable glycemic control. In people who experience vomiting that is refractory to drug treatment, the implantation of a gastric pacemaker for high-frequency/low-energy gastric electrical stimulation may be considered [144]. In a few cases of intractable vomiting, satisfactory relief could be achieved by a 70% gastrectomy [145].

Diabetic diarrhea

Clinical features

Diabetic diarrhea is characterized by intermittent, brown, watery, and voluminous stools, and is occasionally accompanied by tenesmus. Diarrhea is reported by up to 20% of people with diabetes and may reflect rapid or slow transit, frequently complicated by bacterial overgrowth [146]. It may occur at any time of the day but is often thought to be nocturnal. However, some authors found it to be unusually nocturnal. Steatorrhea is also common and may occur in as many as 75% of people with diabetes with diarrhea. Typically, diabetic diarrhea occurs in middle-aged individuals with a long-standing and poorly controlled T1DM. It is more common in men than in women, with a ratio of 3:2. It is often episodic, separated by periods of normal bowel movements or constipation, and the episodes may last a few days to weeks. Unequivocal evidence for peripheral neuropathy is present in the majority of people and the visceral autonomic manifestations are common. Diabetic diarrhea seldom occurs in the absence of diabetic neuropathy. Multiple pathogenic mechanisms have been implicated, e.g. autonomic neuropathy, bacterial overgrowth, and pancreatic exocrine insufficiency. However, diabetic diarrhea does not have a uniform and unequivocal pathogenesis [147].

Medications are often a cause of chronic diarrhea, and the medication list should always be carefully scrutinized for those with diarrhea as a side effect. In individuals with diabetes, metformin is a common cause of diarrhea. Such individuals are also more likely to have associated diseases (e.g. celiac sprue and microscopic colitis) that present with diarrhea as the sole complaint. Ingested sugar-free foods that may contain sorbitol or other agents can cause diarrhea in persons with diabetes [148].

Management

Since the pathogenesis of diabetic diarrhea is not always clear, the treatment is symptomatic and often empirical. However, it has been suggested that treatment should be directed at the identified cause of diarrhea rather than sequential empirical trials. There have been no controlled studies that examined the effect of improved glycemic control on the frequency and severity of diabetic diarrhea. The use of broad-spectrum antibiotics to counteract the bacterial overgrowth, if present, should be the first therapeutic approach. Courses of 1–2 weeks in each month have shown a transient or persistent improvement in uncontrolled studies. The use of clonidine, an α_2-adrenergic agonist, has been shown to reduce the frequency and volume of episodes of diarrhea. The mechanism of action has been attributed to regulation of water

and salt metabolism mediated by stimulation of α_2-adrenergic receptors on enterocytes. For people in whom the pathogenesis of diarrhea is unclear, antidiarrheal agents such as loperamide may decrease the number of stools, particularly if the diarrhea is associated with rapid intestinal transit, but usually do not reduce the stool volume. However, retardation of motility may actually promote stasis and thereby potentially aggravate bacterial overgrowth. In general, diabetic diarrhea is frequently difficult to manage and, owing to its intermittent nature, it is difficult to determine the efficacy of a therapeutic attempt [147–149].

Colonic dysfunction

Clinical features

Constipation is one of the major gastrointestinal symptoms, affecting ~20% of persons with T2DM. After a 1000-calorie meal, people with diabetes and constipation have no increase in colonic spike activity, suggesting that the gastrocolonic response to a meal is abnormal. Dysfunction of colonic motility in people with diabetes may be primarily due to an abnormality in the autonomic neural control. The cholinergic nervous system appears to be disturbed. The underlying pathophysiological processes include loss of enteric neurons in the colon due to increased oxidative stress and apoptosis, which may play a causative role in the motility disturbances [150].

The extent of the diagnostic assessment in an individual with diabetes with constipation is not substantially different from that in a person without diabetes and depends on the symptom severity. Digital examination, testing of stools for occult blood, proctosigmoidoscopy, barium enema, or colonoscopy should be performed, particularly if there is weight loss or rectal bleeding. There are no pathognomonic radiographic findings on barium enema in people with diabetes. A dilated ahaustral colon, similar to that associated with laxative abuse, may occur in some cases. Megacolon or megasigmoid may be found occasionally. Significant symptoms may be present, however, in the absence of radiographic abnormalities. In other disorders associated with a hypomotile colonic state, such as scleroderma, severe barium impaction has occurred. This should be kept in mind when barium studies are performed on persons with diabetes with severe colonic hypomotility. Thorough cleansing maneuvers should be performed post-examination. The colonic segmental transit time can be examined using radiopaque markers to distinguish between diffuse colonic hypomotility and rectosigmoid dysfunction (outlet obstruction) [142].

Management

The first approach in treating the constipation should be an increase in dietary fiber to reduce the intestinal transit time. Some high-fiber foods may lead to increased gas production, hence the quantity of fiber in the diet should be increased gradually to avoid excessive flatulence and bloating. Supplementation with a hydrophilic mucilloid psyllium preparation is a practical method of increasing stool bulk. Lactulose has been proposed for use in chronic constipation. This non-absorbing carbohydrate is degraded by the colonic bacteria to low molecular weight fatty acids which act as osmotically active particles. The acidic pH and increased osmotic activity stimulate colonic propulsive activity. Periodic use of stool softeners, mineral oil, or enemas may be needed to prevent fecal impaction. Patients should be counseled against chronic laxative use, particularly with the anthraquinone group (senna, cascara, aloes), which may produce progressive toxic damage to the intrinsic nerve plexuses of the colon, thus aggravating an already existing autonomic neuropathy of the gastrointestinal tract.

A small group of individuals with advanced diabetic enteropathy may develop severe constipation or obstipation that is unresponsive to the above measures. These people may benefit from a trial of drugs that stimulate the colonic smooth muscle. Cholinergic agents such as bethanechol (cholinergic agonist) or pyridostigmine (cholinesterase inhibitor) can be tried. Those with recalcitrant constipation may be helped by prokinetic drugs such as metoclopramide. This clinical observation is consistent with the cholinergic-like stimulatory effect of these drugs on colonic smooth muscle [142].

Prucalopride, a 5-hydroxytryptamine receptor-4 agonist, has recently been licensed for the treatment of chronic constipation in women in whom laxatives fail to provide satisfactory relief. A meta-analysis with data from 936 women with chronic constipation reported greater improvements with prucalopride (2 mg/day) than placebo in overall symptom score, abdominal symptoms score, stool symptoms score, and rectal symptoms score after 12 weeks [151]. However, diabetes was an exclusion criterion in these studies. There is a relationship between increased colonic transit time and increased symptom severity in individuals with chronic constipation, and treatment with prucalopride accelerates colonic transit time [152]. Whether prucalopride is effective in chronic constipation in men and people with diabetes remains to be established.

Anorectal dysfunction

Diagnosis

Fecal incontinence may be associated with diabetic diarrhea or constitute an independent disorder of presumably multifactorial etiology. Although a reduction in rectal sensitivity has been reported, most people with diabetes and fecal incontinence are aware of the presence of stool in the rectum but are unable to prevent its passage. Anorectal function can be examined by anorectal manometry and tests of continence for solids and liquids. Some manometric studies have shown reduced internal sphincter tone but normal external sphincter pressures, but others found both to be abnormal. Continence for solids and liquids can be directly assessed by simulating the stress of stools with a solid sphere or with rectally infused saline [153].

Management

As fecal incontinence is usually associated with diarrhea, the most successful treatment strategy is to treat the diarrhea. Several studies evaluated biofeedback conditioning for fecal incontinence related to various medical disorders. A small number of individuals with diabetes were among those studied. Patients were taught to develop reflex transient contraction of the external sphincter in response to rectal distention. Ability to sense rectal distention was a major prerequisite for successful conditioning [153].

Autonomic neuropathy of the urogenital system

Urogenital complications are frequently found in individuals with diabetes. In most, neuropathy and/or angiopathy are the etiologies or most pronounced co-etiologies of micturition or sexual dysfunctions. Since the impairment of bladder storage and emptying and also erectile and ejaculatory dysfunction may have severe organic and psychosocial consequences, their existence (often not apparent to the patient) should be systematically screened in the routine diabetes clinic. Given hints of existence, comprehensive evaluation of the impaired organ system is mandatory. For treatment, a wide range of various approaches is available and can be individually offered following appropriate diagnosis [154] The clinical features, diagnostic work-up, and specific treatment of diabetic autonomic neuropathy involving the urogenital system are summarized in Table 40.7.

Urinary bladder dysfunction

Clinical features and diagnosis

Diabetic bladder dysfunction is mainly due to neurogenic detrusor muscle dysfunction. In the early stages of diabetic autonomic neuropathy, the motor function of the bladder is not impaired, but the sensation of bladder distention may be blunted by selectively reduced afferent autonomic nerve activity from the bladder. Many individuals with mild autonomic neuropathy report diminished urinary frequency, but other symptoms or signs are relatively rare. As the autonomic efferent fibers become damaged, urination is less frequent and the person is no longer able to void completely; dribbling and overflow incontinence are common complaints. Individuals may be aware of prolonged intervals between micturition and also experience a sensation of incomplete bladder voiding [154, 155].

Typically, residual urine volumes are greater than 150 mL, predisposing the person to recurrent urinary tract infections. Residual urine volume increases gradually with time and gross bladder retention with abdominal swelling and sometimes overflow incontinence may occur in severe cases. The bladder is frequently

Table 40.7 Diabetic autonomic neuropathy of the urogenital system: clinical features, diagnostic work-up, and specific treatment.

Organ manifestations/ clinical features	Diagnostic procedures	Treatment
Diabetic cystopathy (bladder emptying dysfunction)	*Basic diagnostic work-up* Micturition diary over 48 h *Extended diagnostic work-up* Questionnaire (e.g. International Prostate Symptom Score [IPSS]) Uroflowmetry Residual urine measurement Digital rectal examination for men Urodynamic testing, as applicable	Behavioral changes Electrical stimulation Biofeedback Anticholinergics α-Rreceptor blockers Antibiotic therapy, as applicable Bladder neck incision Self-catheterization Suprapubic cystostomy
Erectile dysfunction	*Basic diagnostic work-up* Stage 1: Sexual history, IIEF-5 Laboratory tests Total (free) testosterone, prolactin, FSH, LH Stage 2 (optional) Test with a PDE-5 inhibitor (sildenafil, vardenafil, tadalafil) *Extended diagnostic work-up* Stage 3 (only if surgical therapy is planned/indicated): Intracavernosal injection test Doppler/duplex sonography Cavernosometry/cavernosography Nocturnal tumescence measurement	Erectile dysfunction: Avoidance of medication side effects (caused by antihypertensives, tranquilizers, antidepressants) Stage 1: PDE-5 inhibitors (sildenafil, tadalafil, vardenafil) Stage 2: Erection aid system (vacuum pump) Corpus cavernosum auto-injection therapy Stage 3: Corpus cavernosum implant Hypogonadism Testosterone substitution

palpable at the time of presentation, but painful acute urinary retention is rare, as are hydroureter and hydronephrosis [154, 155].

Lower urinary tract symptoms (LUTS) are common age-related complaints that are often attributed to benign prostatic hyperplasia (BPH). LUTS and BPH increase rapidly with age, starting at about 50 years of age. Straining, intermittency, post-void dribbling, and weak stream may signify urethral obstruction from BPH. However, among men with diabetes, similar symptoms may also result from bladder dysfunction due to denervation and poor detrusor contractility. Other complex associations of LUTS and BPH among men with diabetes include symptoms of urgency, frequency, and nocturia that may occur from detrusor overactivity, resulting from BPH, and/or microvascular complications associated with diabetes, increasing hyperactivity of the detrusor. Because previous studies have failed to differentiate LUTS from BPH in men with diabetes, the effect of diabetes on the development or presence of LUTS and BPH remains controversial [154].

Diagnostic assessment should include ultrasound examination before and after emptying. Urodynamic evaluation should be performed to differentiate between people with diabetic cystopathy and those with other causes of bladder outflow obstruction. Cystometry usually shows the presence of residual urine and reduced sensation of bladder filling. The total bladder capacity may exceed 1 L. Voiding is usually at a slow rate (5 mL/s), intermittent, and facilitated by abdominal straining [154, 155].

Management

The principles of treatment are to compensate for the deficient bladder sensation and thereby to prevent the development of a high residual urine volume. Patients should be educated to void every third hour during daytime to compensate for the lack of first desire to void. Repetitive voiding by double- or triple-voiding techniques may replace a deficient detrusor contraction and enable the patient to discharge almost all of the bladder volume. The Credé maneuver (manual suprapubic pressure) may be recommended to those who find it difficult to maintain sufficient straining. This particularly occurs in women without sufficient pelvic support of the bladder. To compensate for the loss of the afferent part of the reflex arc triggering detrusor function, cholinergic agents such as bethanecol (10–20 mg orally three times daily) may be used. However, side effects such as sweating, salivation, tachycardia, and flushing limit daily use. Booster doses of bethanecol with 30–60 mg orally twice per week may be an alternative option. Prazosin, an α_1-adrenergic blocker, may be effective by reducing urethral resistance. Intermittent catheterization may offer an alternative for individuals who do not benefit from education and pharmacological treatment. This method needs to be applied with care to minimize the risk of urinary tract infection. Bladder neck resection or incision of the internal sphincter may be necessary in very severe cases. Such surgery leaves the external sphincter intact, maintaining urinary continence, but can cause premature ejaculation or, in women, cystourethrocele. Moreover, this irreversible step should be approached with caution, since the external sphincter may also be impaired as a result of autonomic neuropathy, and urinary incontinence following bladder neck incision has been reported [154, 155].

Erectile dysfunction

Epidemiology

The term erectile dysfunction describes the persistent or recurrent inability to achieve and maintain a penile erection of sufficient rigidity to permit satisfactory sexual activity for at least 3 months (See Chapter 49) [156]. Erectile dysfunction is more common with advancing age, and since the aged population will increase, its prevalence will continue to rise. Diabetes is the most frequent organic cause of erectile dysfunction, the onset of which starts about 15 years earlier in individuals with diabetes than in those without. Around 50% of men with diabetes report erectile dysfunction, which may be the earliest clinical feature of autonomic neuropathy. Risk factors and clinical correlates include duration of diabetes, glycemic control, the various components of the metabolic syndrome, each of the chronic diabetic complications, and smoking [154].

Pathophysiology

Cholinergic and non-cholinergic non-adrenergic neurotransmitters mediate erectile function by relaxing the smooth muscle of the corpus cavernosum. A principal neural mediator of erection is nitric oxide, which activates guanyl cyclase to form intracellular guanosine monophosphate, a potent second messenger for smooth muscle relaxation. The importance of this pathway is mirrored by the clinical effect of facilitated erection by a selective inhibitor of phosphodiesterase-5 (which breaks down cyclic guanosine monophosphate). *In vivo* studies of isolated corpus cavernosum tissue from men with diabetes have shown functional impairment in autonomic and endothelium-dependent relaxation of corpus cavernosum smooth muscle [154].

Diagnosis

Frequently, a careful history, physical examination, serum glucose or HbA_{1c}, lipid profile, and optional hormonal testing facilitate the diagnosis of erectile dysfunction and effective therapy. Patient history can differentiate erectile dysfunction from other male sexual dysfunctions, including ejaculatory disorders (premature ejaculation and other abnormalities), hypogonadism, disorders of orgasm, and Peyronie disease. Underlying risk factors associated with erectile dysfunction are common to cardiovascular disease in general, and should be identified during evaluation as they may represent the initial clinical sign of generalized endothelial disease (vascular insufficiency). Evaluation of family history, nicotine use, blood pressure, lipid profile, and glucose is required or should be documented if previously performed. Active management of identified cardiac risk factors should be instituted (e.g. smoking cessation, blood pressure treatment) [156].

An interview with the partner is advisable and will confirm the problem but may also reveal other causes of the difficulties, e.g. vaginal dryness. The relative importance of psychological and organic factors may be determined from the history. Drugs that may be associated with erectile dysfunction include tranquilizers (phenothiazines, benzodiazepines), antidepressants (tricyclics, SSRIs), and antihypertensives (β-blockers, vasodilators, central sympathomimetics, ganglion blockers, diuretics). In most men, sophisticated investigation is unnecessary [154].

Management

The initial management should able to advise the man to reduce possible risk factors and to optimize glycemic control. Even if the cause is organic, almost all men with ED will be affected psychologically. Sexual counseling is an important aspect of any treatment, and it is preferable also to involve the partner. Once reversible causes of erectile dysfunction have been ruled out, a trial of oral medication is recommended as first-line therapy, based on treatment efficacy, side-effect profile, and minimal invasiveness (Table 40.7). In a trade-off network meta-analysis of starting dosages of phosphodiesterase-5 (PDE-5) inhibitors, sildenafil 50 mg had the greatest efficacy but also had the highest rate of overall adverse events. Tadalafil 10 mg had intermediate efficacy but had the lowest overall rate of all adverse events. Vardenafil 10 mg had similar overall adverse events to sildenafil 50 mg but a markedly lower global efficacy [157]. However, the majority of men with diabetes will require the maximum dose of each compound. Specialized testing and referral are generally reserved for cases where oral first-line treatments fail or are not appropriate, or if greater insight into the etiology is desired by the patient/physician. Second-line therapies, although more invasive than oral agents, are generally well tolerated and effective. Surgery remains an important option for men refractory to medical management, offering effective and durable erectile dysfunction treatment outcomes [156].

Other sexual problems in men

Diminished or absent testicular pain has been described as an early sign of autonomic neuropathy. Retrograde ejaculation from the prostatic urethra into the bladder may occur occasionally and follows loss of sympathetic innervation of the internal sphincter which normally contracts during ejaculation. Complete loss of ejaculation probably indicates widespread pelvic sympathetic involvement and, like retrograde ejaculation, causes infertility, which may be treated by insemination.

Female sexual dysfunction

Female sexual dysfunction include persistent or recurrent disorders of sexual interest/desire, disorders of subjective and genital arousal, orgasm disorder, and pain and difficulty with attempted or completed intercourse (see Chapter 49). The scientific knowledge on sexual dysfunction in women with diabetes is rudimentary. There is evidence to suggest that in men with diabetes, sexual dysfunction is related to somatic and psychological factors, whereas in women with diabetes, psychological factors are more predominant [158]. The effect of diabetes on women's sexual function is complex; the most consistent finding is a correlation between sexual dysfunction and depression [159]. Sexual dysfunction was observed in 27% of women with T1DM. Female sexual dysfunction was not related to age, body mass index (BMI), HbA_{1c}, duration of diabetes, and diabetic complications. However, female sexual dysfunction was related to depression and the quality of the partner relationship [158]. According to a recent meta-analysis, frequency of female sexual dysfunction was higher in T1DM (OR [95% CI] 2.3 [1.2–4.2]), in T2DM (2.5 [1.6–4.0]), and in women with "any diabetes" (T1DM and T2DM) (2.0 [1.5–2.7]) than in women without diabetes for any duration of diabetes. Depression was significantly more frequent in women with diabetes than in those without diabetes. In meta-regression, only BMI was significantly associated with effect size. In weighted regression, the only significant association was found between age and female sexual function index score [160].

Problems affecting sexuality in women with diabetes include fatigue, changes in premenstrual blood glucose control, vaginitis, decreased sexual desire, decreased vaginal lubrication, and increased time to reach orgasm. Even minor episodes of depression, which is twice as frequent than in men, can result in a loss of libido. The extent to which these symptoms are related to autonomic neuropathy has also been examined in a few studies, the results of which are at variance [161]. The examination of a woman with diabetes with sexual dysfunction should include the duration of symptoms, psychological state, concomitant medications, presence of vaginitis, cystitis, and other infections, frequency of intercourse, blood pressure, BMI, retinal status, pelvic examination, presence of discharge, and glycemic control.

Key points

- Diabetes accounts for 75–90% of excess coronary artery disease (CAD) risk seen in people with diabetes and enhances the effects of other cardiovascular risk factors.
- A range of hemodynamic and metabolic factors contribute to macrovascular disease in diabetes.
- The link between glucose control and cardiovascular disease (CVD) is not as strong as that seen with microvascular complications of diabetes.
- There is clear *in vitro* and *in vivo* evidence that glucose exerts direct and indirect toxic effects on the vasculature.
- Glycemic memory describes the deferred long-term injurious effects of prior glycemic status; early glycemic control appears to be important to reduce vascular complications in subsequent decades.
- Specific insulin resistance pathways appear to contribute to atherogenesis in diabetes.
- The accumulation of advanced glycation end-products (AGEs) exerts proinflammatory and profibrotic effects on the vasculature via receptor-independent and receptor-dependent effects. The AGE receptor (RAGE) is pivotally involved in the pathogenesis of diabetes-accelerated atherosclerosis.
- The components of the classic renin–angiotensin system (RAS) and in particular more recently discovered components such as angiotensin-converting enzyme 2 appear to contribute to macrovascular disease in diabetes. Inhibitors of the RAS have consistently demonstrated reduced endothelial dysfunction and atherosclerosis in animal models via suppression of inflammation, fibrosis, and oxidative stress. There is also strong clinical evidence for vasculoprotection by RAS blockade.
- Other vasoactive components such as endothelin and urotensin II are also likely to contribute to macrovascular complications in diabetes and interact with the RAS. Furthermore, the role of novel tumor necrosis factor (TNF)-related ligands, such as TNF-related Apoptosis-inducing ligand and osteoprotegerin, and the complement system in atherosclerosis are currently under evaluation.
- Treatments that reduce oxidative stress and inhibit inflammation have been shown to be antiatherosclerotic in experimental studies with some evidence, albeit not uniform, also having been obtained in clinical studies.
- A multifactorial approach treating conventional cardiovascular risk factors in addition to diabetes-specific risk factors is currently viewed as the optimal strategy to reduce the burden of CVD in diabetes.

Epidemiology of diabetic macrovascular complications

Macrovascular complications develop in people with type 1 (T1DM) [1–3] and type 2 diabetes mellitus (T2DM) [4–6]. This is of a particular concern as the increasing prevalence of diabetes now also affects adolescents and younger adults, thus promoting the earlier development of long-term cardiovascular complications. Even after adjusting for concomitant risk factors such as hypertension and hyperlipidemia, there remains an excess risk for cardiovascular disease (CVD) in people with diabetes [7, 8]. Indeed, diabetes itself accounts for 75–90% of the excess coronary artery disease (CAD) risk and enhances the effects of other cardiovascular risk factors. Death from stroke and myocardial infarction (MI) are the leading causes of mortality in T1DM and T2DM [1, 9].

A range of hemodynamic and metabolic factors have been considered responsible for the development and progression of macrovascular disease in diabetes (Figure 41.1) [10]. In terms of hemodynamic factors, in particular the hormonal cascade known as the renin–angiotensin system (RAS) has been shown to have a pivotal role in diabetes-associated atherosclerosis; however, other

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

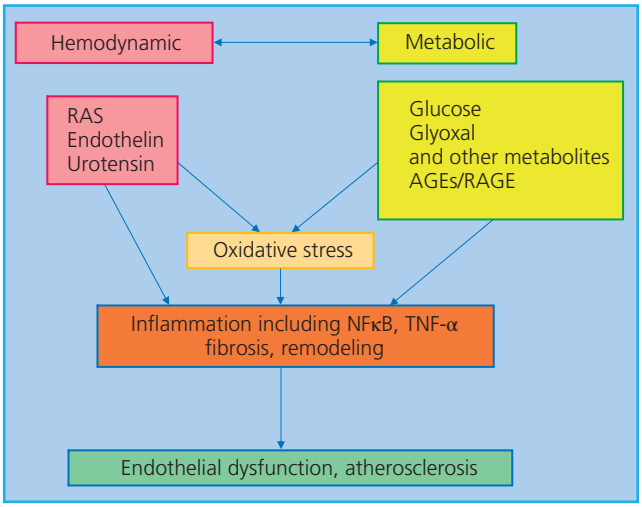

Figure 41.1 Hemodynamic and metabolic mediators contribute to the pathogenesis of diabetic vascular complications. Hemodynamic factors include the renin–angiotensin system (RAS) and other vasoactive factors. Metabolic factors include glucose and glucose metabolites such as the formation of advanced glycation end-products (AGEs). Both pathways interact with each other and lead to oxidative stress and inflammation, thus promoting endothelial dysfunction and atherosclerosis. NFκB, nuclear transcription factor κB; TNF-α, tumor necrosis factor α.

vasoactive hormone systems such as the endothelin (ET) [11] and urotensin systems [12, 13] have also been implicated in diabetic macrovascular disease. Furthermore, oxidative stress and a decrease in antioxidant defense have emerged as critical factors driving many atherogenic processes in diabetes [14], in addition to a host of immune–inflammatory responses involving factors such as tumor necrosis factor (TNF)-related, Apoptosis-inducing ligand (TRAIL) [15] and the complement system [16].

Pathogenesis of diabetic macrovascular disease

Chronic exposure of the vascular endothelium to hyperglycemia induces an inflammatory response involving the adhesion and transmigration of monocytes through the vascular wall into the sub-endothelial space [17]. Furthermore, accelerated generation and vascular deposition of AGEs in addition to interactions with RAGE in diabetes initiate oxidative reactions that promote the oxidation of low-density lipoprotein (LDL) (oxLDL) [18], which enhances the proinflammatory properties of the endothelium [19]. Monocytes differentiate into macrophages, which, via uptake of lipids, transform into foam cells and accumulate in the vascular wall. The early atherosclerotic process results in the formation of fatty streak lesions, which over time develop into more advanced lesions, characterized by infiltration with vascular smooth muscle cells (VSMCs), formation of a necrotic core, and further lipid accumulation [17]. In humans, these lesions can demonstrate features of instability and plaque rupture including intraplaque hemorrhages in addition to heightened thrombogenicity.

Role of hyperglycemia

A pivotal role for glycemic control and duration of diabetes exposure has been well established for microvascular complications in the UK Prospective Diabetes Study (UKPDS) study [6, 20], although the data are not as convincing for macrovascular disease. The importance of glycemic control for macrovascular injury was subsequently extensively investigated in a series of studies. It was suggested that HbA_{1c} acts as an independent and continuous risk factor for macrovascular disease [21–24]; however, this link is not as strong with respect to microvascular complications. For an increase in HbA_{1c} from 5.5% (37 mmol/mol) to 9.5% (80 mmol/mol), there is a 10-fold increase in microvascular disease endpoints, whereas the risk for macrovascular disease endpoints increases only twofold.

Clinical trials and hyperglycemia

Clinical trials such as the Action to Control Cardiovascular Risk in Diabetes trial (ACCORD) [25], Action in Diabetes and Vascular disease: PreterAx and DiamicroN-MR Controlled Evaluation (ADVANCE) trial [26], and the Veterans Affairs Diabetes Trial (VADT) [27], which explored tight glycemic control in people with T2DM with established CVD, investigated the association between tight glycemic control and cardiovascular endpoints. As observed in the initial reports of the Diabetes Control and Complications Trial (DCCT) in people with T1DM and in the UKPDS trial in people with T2DM, tight blood glucose control had little effect on macrovascular outcomes. This was further emphasized by subsequent studies including the ADVANCE [26] and ACCORD trials [25]. Both studies failed to demonstrate significant cardiovascular benefits, with the ACCORD study suggesting possibly deleterious cardiovascular outcomes in association with tight glucose control.

One possible explanation for the lack of a positive effect of tight glycemic control on cardiovascular outcomes may be the short duration of these trials (less than 5 years). Indeed, as best seen with respect to the longer follow-up of the Steno 2 study [28] and a long-term follow-up of the UKPDS [29], the benefits of prior intensified cardiovascular risk management including aggressive glucose control may not appear for up to 10 years after initiation of the studies. Thus, in view of the relative lack of an impact on CVD with intensive glucose control, other risk factor modification strategies need to be emphasized. The recent publication of the ADVANCE-ON trial did not show a benefit of the initially intensive glucose lowering treatment arm in terms of cardiovascular outcomes after 6 years of follow-up, whereas the initially treated blood pressure (BP) arm continued to show cardiovascular protection [30]. Several recent reports of newer glucose-lowering agents such as dipeptidyl peptidase 4 (DPP-4) inhibitors have failed to demonstrate superior protection with respect to macrovascular disease. These findings need to be considered in the context that these studies were aiming for equivalent glucose-lowering efficiency in both arms and therefore the findings do not disprove the potential of glucose lowering ultimately leading to less macrovascular disease [31, 32].

Direct and indirect glycotoxicity

Hyperglycemia is thought to have direct and indirect toxic effects on vascular cells. It has been suggested that increased glucose levels enter the polyol pathway at an increased flux rate leading to heightened formation of diacylglycerol. In addition, an increased flux of glucose into the hexosamine pathway may contribute to glucose-mediated vascular injury in diabetes. To investigate specifically hyperglycemia-mediated atherosclerosis, aldose reductase transgenic mice have been investigated [33]. These mice demonstrated increased glucose delivery via the polyol pathway and also showed early atherosclerosis, but did not develop advanced vascular lesions. It has been suggested that the formation of reactive dicarbonyls is a more reliable marker of glucose toxicity than the conventional measurements of fasting glucose or HbA_{1c} measurements [34], although this is as yet to be proven.

In vitro studies

Studies in cell culture experiments have obtained clear evidence that hyperglycemia induces a range of proatherogenic effects. Glucose directly activates monocytes–macrophages *in vitro,* initiating increased expression of cytokines such as interleukin 1β (IL-1β) and IL-6 [35]. Furthermore, this leads to protein kinase C (PKC) and nuclear factor κB (NFκB) activation resulting in increased production of reactive oxygen species (ROS). Auto-oxidation of glucose can also lead to the formation of ROS and can mediate oxLDL. Scavenger receptors on activated macrophages can mediate the uptake of modified lipids such as the proatherogenic oxidized LDL. The formation of advanced glycation end-products (AGEs) in the hyperglycemic milieu can lead to the formation of modified albumin, which inhibits scavenger receptor class B type 1-mediated efflux of cholesterol to high-density lipoprotein (HDL). Therefore, prolonged hyperglycemia can indirectly lead to a range of secondary changes, including changes in lipid profile, cellular lipid accumulation, and foam cell formation, in addition to AGE-mediated modification of proteins leading to altered cellular structure and function.

Animal models

The study of atherosclerosis in diabetes has long been hampered by the lack of an appropriate animal model. Our group and others have developed a murine model of diabetes-associated macrovascular disease, the ApoE knockout (KO) mouse rendered diabetic by multiple low doses of streptozotocin injections. This model is considered by the National Institutes of Health/Juvenile Diabetes Research Foundation (NIH/JDRF) co-sponsored Animal Models for Diabetes Complications Consortium (AMDCC) to be an appropriate model to study macrovascular disease in diabetes [36].

To address the separate roles of hyperglycemia and dyslipidemia in diabetes-associated atherosclerosis, mice deficient in the LDL receptor were bred with transgenic mice expressing a viral protein under control of the insulin promoter [37]. When infected with the virus, T cells mediate destruction of pancreatic β cells that express the viral protein, thus closely mimicking the autoimmune response in human T1DM. In these animals, atherosclerosis development was accelerated even on a normal diet, suggesting that hyperglycemia was driving atherosclerosis in these mice [37, 38]. When the animals were placed on a high-fat diet, a further acceleration of atherosclerosis occurred, suggesting that glucose and lipids may act through synergistic mechanisms to accelerate atherosclerosis. Furthermore, plaque disruption and intraplaque hemorrhages, features of plaque instability and potential plaque rupture, were observed in this model [37].

Metabolic memory

The concept of "glycemic memory" describes the deferred effects of prior glycemic status on the subsequent development of diabetic complications. Episodes of poor glycemic control during the earlier stages of diabetes can precipitate or accelerate the development of complications later in the course of diabetes even when glycemic control is subsequently improved. Two studies have provided evidence for such a metabolic imprint, the DCCT/EDIC trial in T1DM [1] and the UKPDS in T2DM [29]. Both studies have shown that poor glycemic control was associated with an increased subsequent burden of complications. Another study in people with T2DM, the VADT study, compared intensive with standard glucose control (6.9 vs. 8.4%, 52 vs. 68 mmol/mol), but did not demonstrate significant cardiovascular protection after the participants had been exposed to hyperglycemia for long periods (12–15 years) [27]. Therefore, it appears that early glycemic control is crucial for a long-term beneficial outcome on diabetic complications.

The concept of "metabolic memory" raises two important issues. First, hyperglycemia may expose people with diabetes to its harmful effects years before T2DM is diagnosed. Indeed, 25% of people show complications at the time of diagnosis of T2DM. Therefore, it has been postulated that early diagnosis and strict glycemic control may be pivotal to reduce the induction of this metabolic memory with subsequent development of long-term diabetic vascular complications. Second, glycemic oscillations including peaks and troughs, which are not reflected in the HbA_{1c} levels [39, 40], may have a key role in mediating growth factor and cytokine expression in addition to inducing chromatin remodeling [41].

There are many cellular and molecular processes that may contribute to the mechanisms underlying metabolic memory, with most of them relating to glycotoxicity. These pathways include the formation of AGEs, glycation of DNA, increased flux of glucose metabolism, leading to increased oxidative damage, overproduction of PKC-β and mitochondrial stress. It has been shown that transient hyperglycemia induces long-lasting activation of epigenetic changes in the promoter region of the NFκB subunit p65 in aortic endothelial cells both *in vitro* and *in vivo*. These hyperglycemia-induced epigenetic changes and increased p65 expression were prevented by reducing mitochondrial superoxide production or superoxide-induced generation of α-oxoaldehydes such as methylglyoxal (Figure 41.2) [41]. These studies suggest that transient hyperglycemia causes persistent atherogenic effects

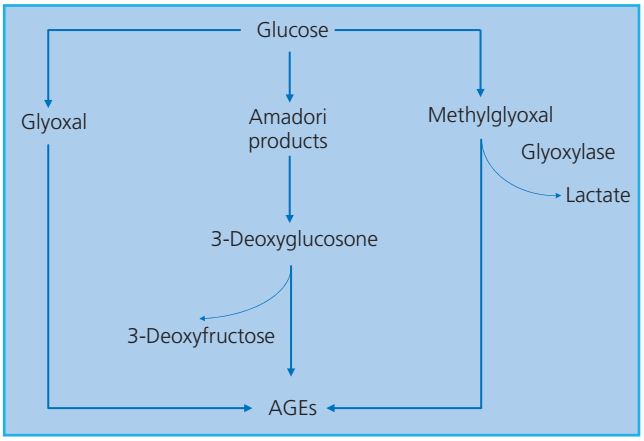

Figure 41.2 The formation of advanced glycation end-products (AGEs) can involve early glucose metabolites such as glyoxal and methylglyoxal, highly reactive dicarbonyls, and key precursors of AGEs.

during subsequent normoglycemia by inducing long-lasting changes in chromatin remodeling and highlight a critical role for ROS in epigenetic modulation of glucose-responsive pathways. Specifically, hyperglycemia results in recruitment of the mobilization of the histone methyl transferase Set7 to the nucleus with increased H3K4 monomethylation of the proximal promoter region of the NFκB subunit p65 gene, leading to increased expression of proatherogenic pathways including monocyte chemotactic protein 1 (MCP-1) and vascular cell adhesion molecule 1 (VCAM-1) [41]. Subsequent studies in mice, which were initially diabetic but returned spontaneously to normoglycemia, have also demonstrated persistent upregulation of proinflammatory genes such as p65 and MCP-1 as a result of prior hyperglycemia. Novel Set7 networks encompassing immune–inflammatory pathways [42] and also antioxidant molecules such as heme oxygenase 1 by H3K4m1-dependent but also H3K4m1-independent pathways have been implicated in the development of macrovascular disease in diabetes [43]. Recent studies by Paneni et al. validated Set7 as an epigenetic regulator of vascular cell inflammation in people with diabetes, which was associated with an increase in the oxidative stress marker 8-isoPGF2α [44]. Furthermore, more detailed epigenetic studies revealed that changes in histone modifications as a result of prior hyperglycemia also included changes in H3K9 methylation of the p65 promoter in addition to effects on various histone methyl transferases and interestingly also demethylases such as LSD-1 [45]. In-depth analysis of the elaborate epigenetic regulatory networks that are altered in diabetes and related metabolic syndromes has recently been reviewed [46].

Insulin resistance

Insulin resistance occurs in T2DM and in people with impaired glucose tolerance, and has been associated with increased cardiovascular risk [47–49]. There is now increasing evidence that insulin resistance promotes atherogenesis as an independent risk factor [50–52]. Furthermore, insulin resistance is often associated with a proatherogenic lipid profile that includes a high very low-density lipoprotein (VLDL) component, a low HDL and small dense LDL.

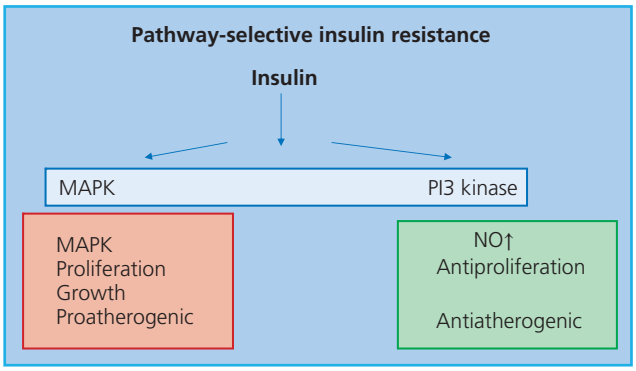

Figure 41.3 Pathway-selective insulin resistance leading to endothelial dysfunction and atherosclerosis. MAPK, mitogen-activated protein kinase; NO, nitric oxide; PI3 kinase, phosphatidylinositol 3 kinase.

In vitro studies have shown that insulin exerts both pro- and antiatherogenic effects [53, 54], which has led to the hypothesis of pathway-specific insulin resistance (Figure 41.3). It has been suggested that insulin resistance towards glucose transport also affects resistance to the antiproliferative effects of insulin, whereas the signaling pathways leading to cellular proliferation remain intact (Figure 41.3). Insulin signaling via phosphatidylinositol-3-kinase (PI3K) has been associated with antiproliferative and antithrombogenic effects with decreased adhesion molecule expression such as MCP-1, VCAM-1, and intercellular adhesion molecule 1 (ICAM-1). Furthermore, nitric oxide (NO) production is mediated via the PI3K signal transduction pathway and therefore is impaired in insulin resistance. NO has been shown to reduce oxLDL and proliferation of VSMCs. In contrast, effects on VSMC proliferation and migration are mediated via the Ras/Raf/MEKK/MAPK signal transduction pathway, which is further stimulated in the context of hyperinsulinemia, suggesting that pathway-specific insulin resistance contributes to the proatherogenic effects of insulin. More recently, it has been shown that IL-6 decreases insulin-stimulated NO production from endothelial cells via decreased activity of insulin signaling mediated by enhanced TNF-α production [55]. Paradoxically, IL-6 increases insulin-stimulated glucose uptake into skeletal muscle and adipose tissue via enhanced insulin signaling, yet IL-6 and insulin have not been linked to increased TNF-α expression in skeletal muscle [55].

Formation of AGE

AGE formation originates from early glycation products, the Schiff bases, which form the more stable Amadori products such as 1-amino-1-deoxyfructose derivatives. The Amadori products undergo further enzymatic modifications resulting in a number of reactive intermediates such as 3-deoxyglucosone and methylglyoxal (Figure 41.2). Methylglyoxal reacts with amino, sulfhydryl and guanidine functional groups in proteins, causing browning, denaturation, and redox-active diamine cross-linking

between lysine residues of the target amino acids. Methylglyoxal also generates hydroimidazolones, N^{ε}- (carboxyethyl)lysine, a homolog of carboxymethyllysine (CML) and methylglyoxal–lysine dimer [56, 57]. The AGE-based cross-links are resistant to enzymatic degradation and therefore very stable [58]. The rate of AGE formation is dependent on multiple factors, including the ambient concentrations of various sugars including glucose, the extent of oxidative stress, and the duration of exposure to these various stimuli [59, 60].

More recently, research has been focused not only on AGE modifications on cellular and short-lived extracellular proteins, lipids, and DNA, but also on the impact of key intermediates including the highly reactive dicarbonylmethylglyoxal [34, 61]. Methylglyoxal (MGO) is 20,000 times more reactive with proteins than glucose itself. The formation of MGO may correlate better with glucose fluctuations observed in diabetes and may explain why postprandial glucose concentrations are independent risk factors for CVD [62]. Impaired glucose metabolism and T2DM have been shown to correlate with higher plasma MGO levels. Furthermore, there is evidence that MGO-derived AGEs are associated with increased risk of CV events in people with T2DM [63].

The detoxifying enzyme glyoxalase-1 (GLO-1), which reduces MGO accumulation, has also been suggested to play a key role in diabetic vascular disease [63]. It is downregulated in diabetes and other states of inflammation, hypoxia, and aging. Genomic studies have shown GLO-1 as the molecular mechanism in the development of CVD [64, 65].

Direct effects of vascular AGE accumulation

There is evidence from experimental studies that AGEs directly influence endothelial function [66] in addition to enhancing the evolution of macrovascular disease [67, 68]. AGEs mediate their effects both directly and via receptor-mediated mechanisms. AGE accumulation in the vascular wall is associated with changes in the structural integrity of proteins, disturbance of their cellular function, and degradation of these proteins [35]. AGEs accumulate on many proteins, including collagen, albumin, and apolipoproteins. Furthermore, the cross-linking of AGEs with matrix molecules can disrupt matrix–matrix and matrix–cell interactions. It has been shown that AGE cross-linking to collagens decreases vascular elasticity and reduces vascular compliance, resulting in increased vascular stiffness [69, 70]. In addition, AGEs are also able to quench NO [66, 71] and generate ROS by stimulating nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activity [72].

AGE-binding proteins

The receptor-mediated effects of AGEs occur via binding to proteins such as RAGE [73], AGE-R1 (p60), AGE-R2 (p90), and AGE-R3 (galectin-3), the ezrin–radixin–moesin (ERM) family of proteins [74], macrophage scavenger receptor ScR-11, and CD-36 [75]. The exact roles of AGE-R1, -R2, and -R3 have not been fully elucidated. Finally, the interaction between AGEs and several macrophage scavenger receptors, such as CD36 [75], has been postulated also to promote atherosclerosis with studies using CD36 KO mice, supporting the view that CD36 promotes atherosclerosis [76].

Receptor for AGE (RAGE)

RAGE is a multiligand signal transduction receptor of the immunoglobulin superfamily of cell surface molecules that acts as a pattern recognition receptor [73]. In addition to binding ligands that actively participate in inflammation and immune responses, RAGE serves as an endothelial adhesion receptor for leukocyte integrins and promotes leukocyte recruitment and extravasation of infiltrating cells. Of direct relevance to diabetic macrovascular complications, RAGE is found on endothelial cells and monocytes–macrophages [68, 77, 78], and has been implicated in inflammatory lesions in many disorders [79].

Downstream effects of RAGE activation

Engagement of RAGE leads to activation of the proinflammatory transcription factor NFκB (Figure 41.4) [80]. AGE binding to RAGE activates various signaling pathways, including NADPH oxidase [72], MAPKs, $p21^{ras}$ [81], extracellular signal-regulated kinases (ERKs) [82], and PKC, causing activation and translocation of NFκB [80]. Furthermore, expression of RAGE

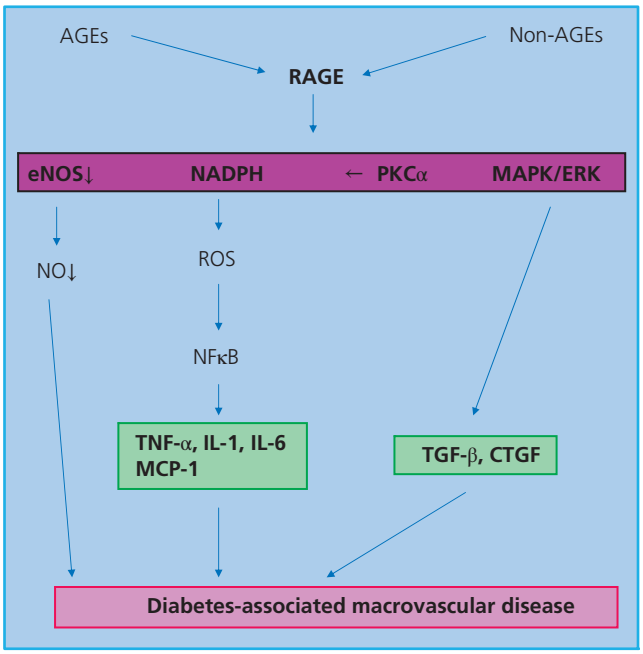

Figure 41.4 Activation of AGE receptor (RAGE) contributes to diabetes-associated macrovascular disease via increased production of reactive oxygen species (ROS), decrease in nitric oxide (NO) availability, activation of the nuclear transcription factor κB (NFκB), and tumor necrosis factor α (TNF-α), in addition to activation of profibrotic growth factors such as transforming growth factor β (TGF-β) and connective tissue growth factor (CTGF) associated with vascular remodeling. eNOS, endothelial nitric oxide synthase; ERK, extracellular signal-regulated kinase; MAPK, mitogen-activated protein kinase; MCP, monocyte chemotactic protein; NADPH, nicotinamide adenine dinucleotide phosphate; PKC, protein kinase C.

itself can be induced by NFκB [83]. RAGE expression within tissues is markedly enhanced in response to metabolic disturbances such as diabetes, dyslipidemia, uremia, and aging, possibly because of accumulation of AGEs in these conditions [77, 79]. In plaques from diabetic ApoE KO mice, upregulation of connective tissue growth factor (CTGF) has been demonstrated to be AGE dependent [67] and may be mediated via RAGE. Intracellular accumulation of AGEs may also promote phenotypic conversion of VSMCs into foam cells within atherosclerotic plaques [84].

Studies reducing vascular AGE accumulation

A variety of pharmacological interventions have been used to reduce the accumulation of AGEs via decreasing the total AGE load or via chemical modification of existing AGEs into inactive forms [85, 86]. Aminoguanidine is a potent inhibitor of the formation of AGEs, scavenges reactive dicarbonyl AGE precursors [85, 86], and decreases oxidative damage to mitochondrial proteins [87]. In experimental and clinical diabetes, aminoguanidine treatment has been shown to reduce microvascular [88] and more recently macrovascular complications in a model of accelerated atherosclerosis, the diabetic ApoE KO mouse [67].

Another potential agent that inhibits AGE accumulation is ALT-711 or alagebrium [89]. Based initially on a range of *in vitro* studies, this thiazolium compound and its original prototype, phenylthiazolium bromide [90], have been shown to cleave preformed AGEs, hence one of the postulated mechanisms of ALT-711 is as an AGE cross-link breaker [89].

The removal of established cross-links in rats with diabetes by ALT-711 has been shown to be associated with reversal of the diabetes-induced increase in large artery stiffness, increased collagen solubility, and reduced vascular and cardiac AGE accumulation [70, 91–93]. In addition, alagebrium prevents the progression of nephropathy [94, 95], possibly via direct inhibition of PKC-α phosphorylation [96], thus reducing renal expression of vascular endothelial growth factor (VEGF). Treatment with ALT-711 in diabetic ApoE KO mice was associated with a significant reduction in atherosclerosis [67]. This antiatherosclerotic effect was associated with reduced vascular AGE accumulation and RAGE expression. Alagebrium treatment was also associated with less inflammation and reduced expression of profibrotic growth factors, in particular CTGF [97, 98]. In the clinical setting, ALT-711 has been shown to reduce pulse pressure and improve vascular compliance in people with systolic hypertension [70].

Soluble RAGE

There are three major splice variants of RAGE [99]: first, the full-length RAGE receptor; second, the N-terminal variant that does not contain the AGE-binding domain; and third, a C-terminal splice variant, soluble RAGE (sRAGE), which does not contain the trans-membrane and effector domains. It remains controversial as to whether the effects of sRAGE are primarily as a decoy to ligands such as AGEs or whether sRAGE acts as a competitive antagonist to the full-length biologically active RAGE [99, 100].

Soluble RAGE and diabetes-associated atherosclerosis

sRAGE has been identified as having therapeutic value in a model of diabetes-associated atherosclerosis, the streptozotocin diabetic ApoE KO mouse [101, 102]. In the original study, Park et al. [102] reported that diabetic ApoE KO mice treated with sRAGE showed a dose-dependent suppression of atherosclerosis and reduced plaque complexity. These beneficial effects were independent of effects on glucose or lipid levels. Furthermore, AGE levels in these diabetic mice were suppressed in a dose-dependent manner by sRAGE to levels similar to those seen in non-diabetic mice. Furthermore, the effect of RAGE blockade with sRAGE was investigated in established atherosclerosis [101]. Administration of sRAGE decreased the expression of RAGE, in addition to reducing the number of infiltrating inflammatory cells and gene expression for transforming growth factor β (TGF-β), fibronectin, and type IV collagen in both the aorta and the kidney in association with reduced plaque area. Therefore, it was concluded by these investigators that RAGE activation contributes not only to lesion formation, but also to the progression of atherosclerosis.

sRAGE treatment has also been reported to be effective in reducing vascular complications in other models of atherosclerosis and diabetes. Atherosclerosis in the LDL receptor –/– mouse made diabetic by streptozotocin injection [103] was significantly attenuated by sRAGE treatment. ApoE KO mice bred onto a *db*/*db* background, a model of T2DM and deficient leptin receptor signaling, showed increased atherosclerosis that was significantly attenuated by daily sRAGE treatment [104].

To understand better the specific role of RAGE in the genesis of vascular lesions, mice selectively deficient in RAGE/ApoE ($RAGE^{-/-}$) have been created [105, 106]. These mice completely lack not only tissue bound full-length RAGE, but also sRAGE. As had been predicted by the pharmacological intervention studies directed towards the RAGE ligands and AGEs, RAGE KO mice bred onto an $ApoE^{-/-}$ background showed a marked reduction in plaque area in the presence and absence of diabetes [105, 106]. More recently, the effect of RAGE deletion on atherosclerosis development has been investigated in streptozotocin diabetic RAGE/ApoE KO mice and showed a significant reduction in atherosclerotic plaque area compared with diabetic ApoE KO mice expressing RAGE. These vascular changes seen in the streptozotocin diabetic double RAGE/ApoE KO mice were associated with reduced inflammation, less accumulation of RAGE ligands such as S100/CML, decreased infiltration by macrophages and T lymphocytes, and a reduction in expression of profibrotic and proinflammatory growth factors and cytokines [105].

These promising results with RAGE antagonism have encouraged the development of RAGE-neutralizing compounds for clinical use. The RAGE-modulating agent TTP488 is currently being considered in phase II clinical trials in people with Alzheimer disease, with some positive results [107]. Another compound, TTP4000, is in phase I clinical trials (www.clinicaltrials.gov and www.vtvtherapeutics.com); however, currently, the major focus of antagonizing RAGE does not appear to involve studies addressing CVD in the absence or presence of diabetes.

Interaction with the renin–angiotensin system

Because diabetic complications appear to be multifactorial in origin and involve interactions between hemodynamic pathways such as the RAS and metabolic pathways such as hyperglycemia and the formation of AGEs, there has been increasing investigation of the potential links between these various pathways (Figure 41.1) [108]. There is increasing evidence that AGE accumulation can induce an upregulation of certain components of the RAS, although these studies have been performed predominantly in the renal context [109]. Furthermore, angiotensin-converting enzyme (ACE) inhibition has been reported to confer its end-organ protective effect partly via a reduction in AGEs and an increase in sRAGE [110]. Therefore, the status of the RAS could represent a key modulator in AGE-induced diseases. More recently, other therapeutic interventions shown to be antiatherosclerotic have been reported to exert part of their vasculoprotective effect via inhibition of the AGE/RAGE pathway. These include angiotensin II receptor blockers (ARBs), peroxisome proliferator-activated receptor α (PPAR-α), and PPAR-γ agonists and statins [111–113].

Role of vasoactive hormones in diabetes-related atherosclerosis

Classic RAS

Renin was described more than 100 years ago by Tigerstedt and Bergman [114]. Nevertheless, our understanding of the RAS is still not complete and has grown increasingly complex over the last decade. The classic pathway is now very well characterized (Figure 41.5). The generation of angiotensin (AT) I and II is not restricted to the systemic circulation and also takes place in vascular and other tissues (Figure 41.5) [115].

Novel aspects of the RAS: ACE2

In 2000, a further enzyme associated with the generation of AT peptides was identified—ACE2, a carboxypeptidase with sequence similarity to ACE [116]. ACE2 does not generate AT II but increases the formation of AT-(1–7) (Figure 41.6). This heptapeptide causes vasodilation and has growth inhibitory effects [117]. Further research, including into specific inhibitors, is needed to elucidate the many functions of ACE2 inside and outside the RAS.

AT receptors

The effects of all AT peptides are mediated through specific cell surface receptors (Figures 41.5 and 41.6). The AT_1 receptor mediates most of the effects usually associated with AT II. The role of the AT_2 receptor subtype remains controversial, but it appears to antagonize certain effects of AT II mediated via the AT_1 receptor [118]. Its role in the macrovasculature remains controversial [119].

Role of the RAS in macrovascular disease

It is now recognized that local RAS activation has an important role in the pathogenesis of diabetes-induced endothelial dysfunction and atherosclerosis [120–122]. As a result, there is a strong rationale for blockade of the RAS to prevent cardiovascular events in individuals with diabetes. In addition, several clinical trials [123–128] have suggested that blockade of the RAS may protect against the development of T2DM in at-risk persons.

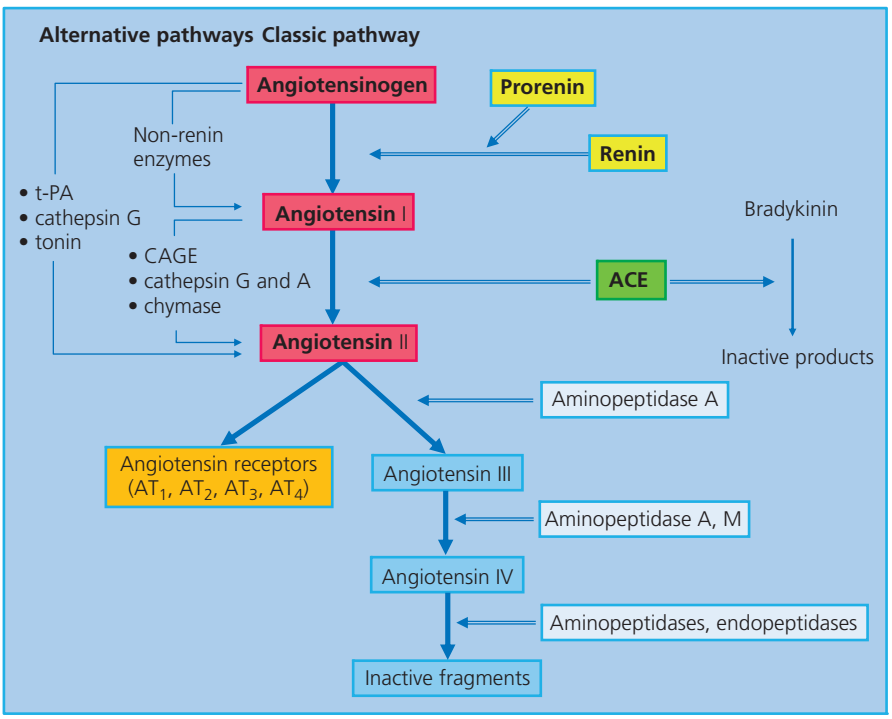

Figure 41.5 Overview of the enzymatic cascade of the renin–angiotensin system (RAS): classic and alternative pathways. In the classic pathway, renin cleaves the decapeptide angiotensin I from angiotensinogen. Angiotensin I is then converted to angiotensin II, which acts through several receptor subtypes, AT_1 and AT_2 receptors being the more relevant in the vasculature. CAGE, chymostatin-sensitive angiotensin II-generated enzyme; t-PA, tissue plasminogen activator.

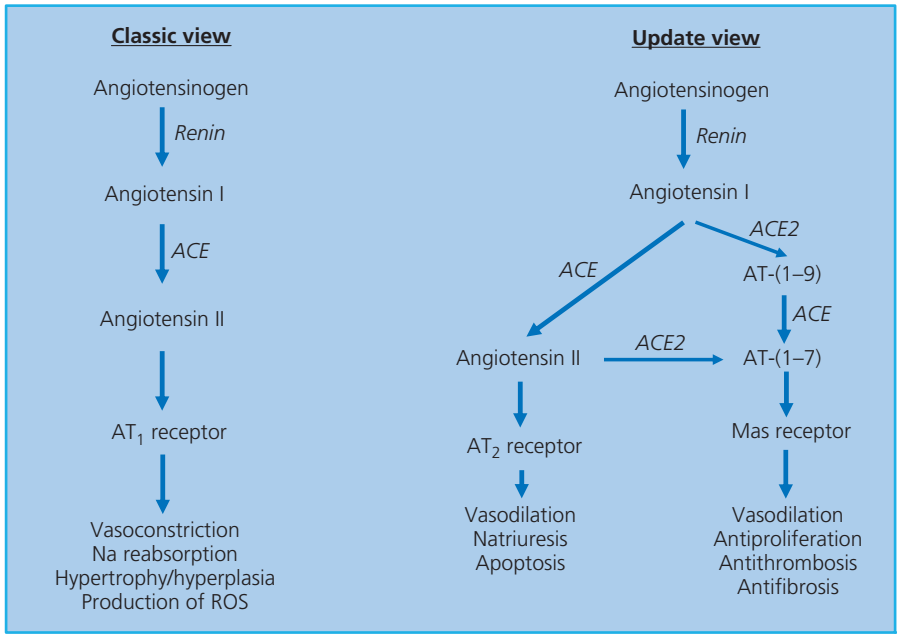

Figure 41.6 New aspects of the renin angiotensin system (RAS) components and its interactions. The classic RAS illustrates the main pathway for angiotensin II (AT II) generation from angiotensin I (AT I) via ACE, with effects being mediated via AT_1 receptor. The updated view illustrates the new components of the RAS in which ACE2 has a role to degrade AT I to AT-(1–9), and AT II to the vasodilator AT-(1–7), which acts through the Mas receptor.

RAS activation and endothelial dysfunction

Endothelial dysfunction has been considered as an imbalance between vasoconstrictors and vasodilators in the vascular tone [129] associated with a decrease in NO activity and increased AT II and ET activity [130]. Endothelial dysfunction is characterized by defective endothelium-dependent vasorelaxation in association with inflammatory cytokine-induced increased interactions with blood leukocytes, in which adhesion molecules such as VCAM-1 and chemoattractants such as MCP-1 are essential [131]. Endothelial dysfunction is strongly associated with atherosclerosis (Figure 41.7) [132, 133].

Crucial to the pathogenesis of diabetes-induced endothelial dysfunction in the early stages, in the absence of structural changes of the vessel wall, is the activation of the RAS. Although measurements of components of the RAS in plasma have, in general, suggested suppression of this system in diabetes, there is increasing evidence for activation of the local cardiovascular RAS in the diabetic context [134, 135]. It has been demonstrated that

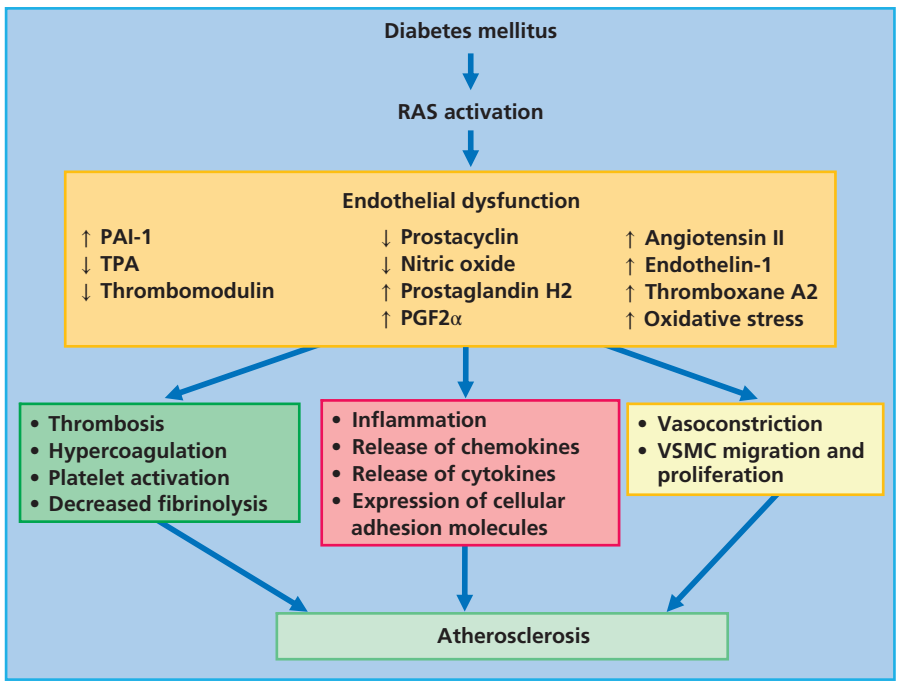

Figure 41.7 Effects of diabetes-induced renin–angiotensin system (RAS) activation on mechanisms associated with endothelial dysfunction and atherosclerosis. In diabetes, activation of RAS induces endothelial dysfunction that is characterized by vasoconstriction, inflammation, cellular growth, and thrombosis. By losing its protective properties, dysfunctional endothelium is a major promoter of atherogenesis and, consequently, cardiovascular events. PAI-1, plasminogen activator inhibitor-1; TPA, tissue plasminogen activator; VSMC, vascular smooth muscle cell.

there is an increase in ACE expression and activity, in AT II expression, and in AT_1 receptor expression in the aortic wall of diabetic ApoE KO mice, suggesting a key role for RAS activation in the pathogenesis of diabetes-associated endothelial dysfunction [120, 136].

RAS and regenerative endothelial cell repair

A role for the RAS has also been demonstrated in affecting the number of regenerative endothelial progenitor cells in individuals with diabetes. An increased concentration of circulating endothelial progenitor cells, which are believed to maintain the integrity of the vascular endothelium, has been associated with a favorable cardiovascular outcome in persons with CAD [137]. A study in individuals with T2DM [138] suggested that treatment with an ARB (olmesartan) increases the number of regenerative endothelial progenitor cells, which could contribute to the beneficial cardiovascular effects seen with AT_1 receptor blockade.

Role of AT-(1–7) and ACE2 in endothelial dysfunction

It has been hypothesized that disruption of the ACE–ACE2 balance may result in abnormal blood pressure, with increased ACE2 expression protecting against hypertension, and ACE2 deficiency causing hypertension (Figure 41.6) [139]. As reported above, it is well established that AT II produces endothelial dysfunction through different pathways, such as increasing oxidative stress and exerting proliferative and prothrombotic activities [140]. It has been observed that AT-(1–7), which is generated by the enzyme ACE2, promotes the release of NO and prostaglandins [141, 142] and potentiates bradykinin effects in different experimental models [141, 143]. In addition, AT-(1–7) inhibits growth of VSMCs [144], platelet aggregation and thrombosis [145], inflammation, fibrosis [146], and oxidative stress [147], which in turn might lead to restoration of endothelial function. It appears that AT-(1–7) can antagonize AT II effects, not only by the stimulation of other vasodilators but also through AT_1 receptor inhibition. In this regard, Kostenis et al. [148] reported that the Mas receptor, which is increasingly considered to be the major receptor conferring the biological effects of AT-(1–7), seems to act as a physiological antagonist of AT_1 receptor, thus counteracting many of the actions of AT II at the endothelial level.

RAS activation and atherosclerosis

Clinical and experimental evidence clearly indicates that activation of the RAS is central to almost all these proatherosclerotic pathways (Figure 41.7) [122, 149]. Diet et al. [121] observed increased ACE protein accumulation within the atherosclerotic plaque in human coronary arteries, suggesting that ACE may contribute to an increased production of local AT II, which may participate in the pathophysiology of artery disease. In addition, there is evidence that AT II and the AT_1 receptor are overexpressed in atherosclerotic plaques [120, 150, 151]. Indeed, blockade of the RAS with an ACE inhibitor or an AT_1 receptor antagonist prevents atherosclerosis by mechanisms involving inhibition of proinflammatory molecules such as VCAM-1 and MCP-1 and prosclerotic and proproliferative cytokines such as CTGF and platelet-derived growth factor. These observations confirm a key role for RAS activation in the development and progression of atherosclerosis.

Production of proinflammatory cytokines, such as IL-1β, TNF-α, and IL-6, have a major role in the pathogenesis of atherosclerosis [152]. IL-6, ACE, and AT_1 receptors have been detected in stable and unstable atherosclerotic plaques [151, 153]. AT II stimulates the redox-sensitive nuclear transcription factor, NFκB, which could serve as a unifying signaling system for inflammatory stimuli in atherogenesis through enhanced expression of adhesion molecules ICAM-1 and VCAM-1, E-selectin, MCP-1, and IL-8. Several clinical and experimental studies have demonstrated that both ACE inhibitors and AT_1 receptor blockers decrease the expression of several adhesion molecules, thus confirming that the chronic inflammatory response associated with atherosclerosis appears to be modulated by AT II at every level and can be targeted therapeutically by RAS inhibition [122, 135, 154].

Moreover, the sustained proinflammatory state seems to play an important part in the transformation of a stable atherosclerotic plaque into a vulnerable plaque prone to rupture. Plaque rupture has been connected with activation of matrix metalloproteinases in the fibrous cap of the atherosclerotic lesion [155], and there is evidence that AT II is implicated in matrix metalloproteinase activation, both through a direct action and through induction of proinflammatory cytokines such as IL-6.

ACE2 and diabetes accelerated atherosclerosis

Although studies on the expression and activity of ACE2 in atherosclerosis are limited, there is increasing evidence that such more recently identified components of the RAS may be involved in the development and progression of atherosclerosis. Zulli et al. [156] have shown very high expression of ACE2 in endothelial cells, macrophages, and α-smooth muscle cells within atherosclerotic plaques in a rabbit model of atherosclerosis. It is not clear whether this increase in ACE2 is in response to injury in an attempt to protect the vessel by increasing levels of AT-(1–7).

In the human context, there is evidence for a significant activation of the cardiac RAS after coronary artery occlusion, and it is well known that RAS blockade reduces remodeling and improves survival in humans after an MI. It has also been reported [157] that cardiac ACE2 expression and activity are also increased with experimental MI. Studies using ACE2 KO mice crossed with the atherosclerosis prone $ApoE^{-/-}$ mouse have shown that ACE2 KO mice develop a similar degree of atherosclerosis to diabetic $ApoE^{-/-}$ mice with a concomitant activation of inflammatory markers [158]. The induction of streptozocin diabetes in ACE2/ApoE KO mice was not associated with a further increase in plaque area, suggesting that the downregulation of ACE2 in diabetes plays a key role in the development of atherosclerosis [159]. All these observations suggest that an imbalance in the RAS plays a central role in the pathogenesis of atherosclerosis and that the preservation and augmentation of ACE2 expression and activity represents a potential therapeutic target for the prevention of CVD in diabetes.

RAS and oxidative stress

There is increasing evidence that the local production of ROS has a pivotal role in atherosclerosis, specifically in the diabetic milieu. Increased vascular superoxide production in aortas from diabetic atherosclerotic ApoE KO mice has been demonstrated [111]. These changes were mediated by increased NAD(P)H oxidase (Nox) activity in the aorta with increased expression of various Nox subunits including p47phox, gp91phox, and rac-1 [111]. Evidence of increased local vascular ROS generation in diabetes is further supported by the demonstration of increased nitrotyrosine staining in these diabetic plaques. Indeed, interventions that reduce vascular superoxide production such as PPAR-α and PPAR-γ agonists have been associated with reduced plaque formation, further emphasizing the link between vascular oxidative stress and atherosclerosis [111, 160]. Furthermore, the deletion of antioxidant enzymes such as glutathione peroxidase, specifically the Gpx1 isoform in the vascular wall, results in an increase in plaque area particularly in the diabetic context via increases in inflammatory mediators including adhesion molecules and chemokines [161]. More recently, it has been shown that treatment of GPx1-deficient mice with the Gpx1 analog ebselen reduced oxidative stress variables and atherosclerosis in diabetic GPx1/ApoE KO mice [162]. Furthermore, in the Gpx1/Apo E double KO mice, there was associated upregulation of RAGE, further linking vascular RAGE expression to increased oxidative stress and accelerated atherosclerosis in settings such as diabetes [161].

Therapeutic implications

RAS blockade and endothelial dysfunction

As a result of previous observations, RAS blockade has emerged as an obvious and attractive therapeutic target. Early evidence for a clinical beneficial effect of inhibition of this system on impaired endothelial function was derived from the Trial on Reversing Endothelial Dysfunction (TREND) [163], which showed that ACE inhibition improves endothelial function in people with CAD. Moreover, O'Driscoll et al. [164] observed that ACE inhibition with enalapril improved both basal and stimulated NO-dependent endothelial function in normotensive people with T2DM.

Data are also available for the role of ARBs in improving endothelial function such as the AT_1 receptor antagonist losartan [165, 166]. Furthermore, in people with T1DM, treatment with the ACE inhibitor ramipril or the ARB losartan for 3 weeks [167] improved endothelial dysfunction potentially mediated by increased bradykinin levels with ACE inhibition or increased levels of AT-(1–7) levels.

RAS inhibition and cardiovascular protection

There is accumulative evidence that pharmacological therapy that interrupts the RAS may afford special benefits in reducing CVD in people with diabetes [125, 168, 169]. In a post hoc subgroup analysis of the Captopril Prevention Project (CAPP) study, the participants with diabetes treated with captopril fared significantly better than those treated with conventional therapy (β-blockers and diuretics) in terms of primary endpoint and also for MI, all cardiac events, and total mortality [169]. These relative beneficial effects of ACE inhibitor therapy were particularly striking in those at highest risk, specifically those with the highest median fasting glucose or those with more elevated blood pressure. This is in contrast to the UKPDS [170], in which there were comparable CVD benefits for people with T2DM who were randomized to captopril or atenolol, perhaps reflecting a lower CVD risk in the newly diagnosed individuals with diabetes studied in the UKPDS.

In a substudy of the Hypertensive Old People in Edinburgh (HOPE) study, the MICRO-HOPE [171], which included 3577 individuals who had diabetes and one other CVD risk factor, there was a risk reduction of 25% for combined CVD events, 37% for CVD mortality, 22% for MI, and 33% for stroke. In the Fosinopril versus Amlodipine Cardiovascular Events Trial (FACET) study, the incidence of CVD events was less in participants with T2DM and hypertension treated with fosinopril than the amlodipine-treated group [172]. The European Trial on Reduction of Cardiac Events with Perindopril in Stable Coronary Artery Disease (EUROPA) [173] showed that ACE inhibition reduced cardiovascular mortality and morbidity in participants with established CAD without left ventricular dysfunction. The data from these trials were pooled with those of the Quinapril Ischemic Event Trial (QUIET) [174] study in a meta-analysis that included a total of 31,555 participants [175]. This analysis showed that, compared with placebo, ACE inhibitor therapy produced a significant 14% reduction in all-cause mortality and MI, a 23% reduction in stroke, and a 7% statistically significant reduction in revascularization procedures. The ADVANCE study [23] showed that the administration of the ACE inhibitor perindopril and the diuretic indapamide in high-risk people with T2DM induced a reduction in macrovascular outcome compared with placebo.

Reports of trials with ARBs indicate that these agents have CVD protection effects in individuals with T2DM similar to those observed with ACE inhibitors. In the Losartan Intervention For Endpoint reduction in hypertension (LIFE) study [125], treatment with losartan in people with T2DM and left ventricular hypertrophy (LVH) resulted in a significant reduction in death from CVD and in particular all-cause mortality. An analysis of the large Reduction of Endpoints in NIDDM with Angiotensin II Antagonist Losartan (RENAAL) study showed that treatment with losartan in participants with T2DM, nephropathy and LVH reduced the cardiovascular risk to levels similar to those observed in individuals without LVH [176]. The Ongoing Telmisartan Alone and in combination with Ramipril Global Endpoint Trial (ONTARGET) showed that the ARB telmisartan provides a benefit similar to that of a proven ACE inhibitor such as ramipril in high-risk people with CVD or those with diabetes who have end-organ damage. This is a population similar to that examined previously in the HOPE study [177]. Furthermore, in the ONTARGET study, the combination of ramipril with telmisartan, despite the further lowering of blood pressure, did not reduce the

risk of cardiovascular events compared with an ACE inhibitor alone, but was associated with additional adverse effects including hypotension and renal dysfunction. Hence an ACE inhibitor, or possibly an ARB, is an initial antihypertensive agent of choice in people with diabetes because these agents have been shown to have the capacity to prevent or retard the development of diabetic macrovascular complications, thus significantly reducing cardiovascular mortality and morbidity.

The endothelin system

Endothelin (ET) was first discovered in 1988 by Yanagisawa et al. [178] and is one of the most potent vasoconstrictors known. There are three distinct ET genes that encode different mature ET sequences, designated ET-1, ET-2, and ET-3. Big ET-1 is converted into mature 21 amino acid ET-1 by ET-converting enzyme. ET-1 is predominantly present in endothelial cells. In 1990, the ET_A and ET_B receptor subtypes [179] were cloned. ET_A receptors are found in VSMCs and mediate vasoconstriction and cell proliferation (Figure 41.8). ET_B receptors are found in endothelial cells (ET_{B1}), where they mediate vasodilation via the release of NO, and on smooth muscle cells, where they may elicit vessel contraction and cell proliferation (Figure 41.8).

Role of ET in diabetic macrovascular complications

Plasma concentrations of ET-1 are increased in people with T2DM complicated with atherosclerosis compared with those without diabetes with atherosclerosis and healthy individuals [180]. Kalogeropoulou et al. [181] demonstrated increased ET-1 levels in people with diabetes and carotid atherosclerosis. ET stimulates the production and release of inflammatory cytokines from monocytes [182] and enhances the uptake of LDL-cholesterol by these cells, promoting a phenotypic change into foam cells [183]. Cytokines released from monocytes–macrophages, in turn, stimulate ET-1 production, providing positive feedback for further cytokine production [184].

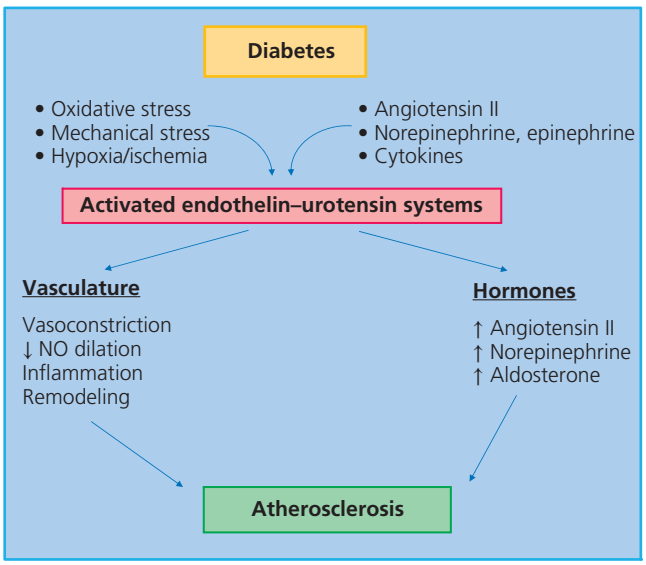

Figure 41.8 Proposed mechanisms of the endothelin and urotensin systems on atherosclerosis in diabetes. In diabetes, activation of the endothelin system induces vasoconstriction, vascular smooth muscle cell proliferation, wall thickening, inflammation, and tissue remodeling, thus leading to the development and progression of atherosclerosis.

In several animal models, both ET_A receptor-selective and non-selective ET_A/ET_B receptor blockade have been shown to inhibit the development of atherosclerotic lesions, suggesting that elevated vascular ET-1 tissue levels promote endothelial dysfunction and vascular structural alterations via the activation of ET_A receptors [183, 185]. Treatment with an ET_A receptor antagonist decreased the atherosclerotic lesion area in the aorta in ApoE KO mice [11]. Similar results have been reported with a non-selective ET_A/ET_B receptor blocker in rabbits. The role of the ET_B receptor in atherosclerosis remains controversial at this stage, although it has been shown to have antiatherosclerotic effects via stimulation of NO production [186].

Finally, some of the beneficial effects of ACE inhibitors in term of cardiovascular protection may be mediated at least in part by ET inhibition. Captopril inhibits the release of ET from cultured human endothelial cells and decreases 24-h urinary ET-1 excretion [187, 188]. Furthermore, ET_A receptor antagonism appears to be beneficial in the treatment of diabetic nephropathy, but there are currently no data to support a protective effect on macrovascular disease in people with diabetes. More recently, ET receptor antagonists have been trialed in T2DM nephropathy. A study using avosentan had to be terminated prematurely owing to off-target effects leading to fluid retention, heart failure, and CV mortality [189]. It is possible that the antidiuretic effect mediated by activation of the ET_B receptor is responsible for this effect. Newer and more ET_A receptor-selective endothelin blockers such as atrasentan have been evaluated and have demonstrated a reduction in the residual albuminuria in people with T2DM [190]. If these renoprotective effects will also translate into cardiovascular protection, as suggested in preclinical studies, it will need to be evaluated in long-term studies with predefined CV endpoints.

Urotensin II

Several reports have revealed the powerful vasocontractile effect of urotensin II (UT II) consistent with a potential importance of this peptide in cardiovascular physiology and diseases (Figure 41.8) [191]. A specific UT II receptor was identified in 1999 [192]. Elevated circulating concentrations of UT II have been detected in persons with various CVD states including heart failure, hypertension [193], carotid atherosclerosis, pre-eclampsia and eclampsia, renal dysfunction, and diabetes mellitus [194]. In addition, upregulation of the UT receptor system has been found in individuals with congestive heart failure and pulmonary hypertension [195].

Role of urotensin II in atherosclerosis

Expression of UT II is upregulated in endothelial, myointimal, and medial smooth muscle cells of atherosclerotic human coronary arteries. Bousette et al. [12] demonstrated that UT II expression is increased in both atherosclerotic carotid arteries and aortas. It has been shown that the plasma UT II level is correlated positively with carotid atherosclerosis in people with essential hypertension [196]. In ApoE KO mice, UT expression was significantly higher than in wild-type control mice [197]. Chronic infusion of UT II enhances atherosclerotic lesions in the aorta of ApoE KO mice by increasing ROS production and acyl-CoA–cholesterol acyl transferase 1 expression. UT II expression in endothelial cells and VSMCs is increased following balloon injury in rat carotid arteries [198]. Furthermore, treatment with a UT II receptor blocker was associated with a 60% reduction in intima lesion development.

UT II is linked to the activation of the redox-sensitive enzyme NADPH oxidase in the vascular wall and increased expression of inflammatory cytokines (Figure 41.8). In human peripheral blood mononuclear cells, inflammatory stimuli including IL-1β and TNF-α strongly enhance UT receptor mRNA and protein expression [199]. Of direct relevance to atherosclerosis, UT II has been shown, predominantly in *in vitro* studies, to enhance LDL-cholesterol and ROS production via NADPH oxidase and to promote monocyte recruitment.

Oxidative stress

Excessive production of ROS, in conjunction with dysfunctional antioxidant defense systems, shifts the redox state of the cellular environment in favor of oxidant species, a state termed "oxidative stress." Clinically, people with diabetes exhibit increased expression of various markers of oxidative stress [200, 201] and reduced antioxidant capacity [202, 203]. Despite a strong theoretical basis, clinical trials of antioxidant treatments for the lowering of cardiovascular disease burden have produced disappointing results [128, 204].

Role of reactive oxygen species in diabetes-accelerated atherosclerosis

Reactive ROS and its products can directly damage vascular endothelial cells leading to apoptosis [205], autophagy [206], and DNA damage [207,208]. Aberrant activation of redox-sensitive signaling molecules including protein kinases and transcription factors also plays a central part in diabetes-mediated vascular pathology [209]. Increased ROS production is associated with the induction of inflammatory gene expression, which occurs via upregulation of redox-sensitive inflammatory gene master regulator NFκB [210].

NADPH oxidase production of ROS

A number of enzymatic and non-enzymatic sources contribute to pathological increases in ROS generation in the diseased vasculature, including Nox, nitric oxide synthetase (NOS), myeloperoxidase (MPO) and xanthine oxidase (XO) [211]. However, the Nox enzymes are widely recognized as the major ROS producers in the vasculature [212] and also represent viable pharmacological targets for the treatment of diabetes-associated vascular disease [213].

The Nox isoforms Nox1, Nox2, Nox4, and Nox5 are differentially expressed in vascular cells, and play unique roles in physiology and disease [212, 214]. A number of groups, including our own, have demonstrated increased gene and protein expression of Nox1 and Nox4 in hyperglycemic conditions associated with increased atherosclerosis [67, 215–218]. Important roles for Nox1-derived superoxide have been described for AGE-mediated VSMC activation [219] and diabetes-associated endothelial dysfunction [220]. Recent evidence has identified a central role for Nox1 in accelerating atherosclerosis in the aorta of diabetic mice [218]. Controversy surrounds the role of Nox4 in vascular disease. Nox4 is constitutively expressed and produces predominantly hydrogen peroxide [214]. Its role in vascular disease appears to be dependent on the disease and experimental model under investigation. More recently, a vasculoprotective role for Nox4 has been demonstrated in a model of long-term diabetes-associated atherosclerosis [221]. Studies focusing on endothelial cell function following ischemia and angiotensin II stimulation have shown protective effects of Nox4 [222–224]. In contrast, Nox4-derived ROS have been shown to promote cardiac hypertrophy [225] and cardiovascular aging [226].

Nox5 is a calcium-dependent Nox isoform expressed in human endothelial and vascular smooth muscle cells [227] and also monocytes and macrophages [228]. The exact function of vascular Nox5 is not yet known, but it has been shown to affect endothelial nitric oxide synthase (eNOS) [229] and VSMC proliferation [230]. In macrophages, Nox5 expression and activity were induced by treatment with proinflammatory cytokine IFNγ [228], suggesting a link between Nox5 and inflammation. However, the lack of Nox5 in mice and rats has hindered investigations.

Inflammation and immune responses

There is an increasing body of evidence to support an altered immune response in diabetes-associated macrovascular disease [105, 231, 232]. In diabetes, elevated ROS upregulates the expression of proinflammatory genes that lead to foam cell formation [233]. Emerging links between Nox-derived ROS and innate-adaptive immune cell responses have provided insight into the potential immunomodulatory role of Nox in diabetes-associated atherosclerosis. Induction of Nox4 in human monocytes and macrophages has been shown to be required for oxLDL-stimulated ROS production and cytotoxicity [234]. Gray et al. also identified an important role for Nox1-derived ROS in monocyte adhesion and macrophage accumulation in the lesions of diabetic ApoE$^{-/-}$ mice [218]. More recently, we described an immunomodulatory role of Nox1- and Nox4-derived ROS in diabetes-associated atherosclerosis in the aortic sinus of ApoE$^{-/-}$ mice [235]. In humans, T cells isolated from atherosclerotic plaques have been shown to recognize and respond to oxLDL [236].

TNF-related apoptosis-inducing ligand and osteoprotegerin

TNF-related apoptosis inducing ligand (TRAIL) is a member of the TNF ligand family [237] and is expressed across all cell types of the vasculature, including macrophages of atherosclerotic plaques [238]. Both the membrane-bound and soluble forms of TRAIL rapidly induce apoptosis in multiple transformed cell lines and tumor cells, but not in normal cells [237, 239].

Osteoprotegerin (OPG) is a member of the TNF-receptor superfamily [240] that is produced by a variety of tissues, including the cardiovascular system. OPG has two known TNF family ligands: receptor activator of NFκB ligand (RANKL) [241] and TRAIL [242]. Increasing experimental evidence suggests that both TRAIL and OPG are involved in vascular pathophysiology.

The potential role of soluble recombinant (sr) TRAIL in the pathogenesis and/or treatment of diabetes-induced atherosclerosis has been investigated *in vivo* in streptozotocin diabetic ApoE KO mice [243]. Repeated intraperitoneal injections of srTRAIL significantly attenuated plaque development and contributed to the stabilization of atherosclerotic lesions by selectively decreasing the number of infiltrating macrophages and increasing the VSMCs within the atherosclerotic plaques [243]. Also, diabetic rats treated with srTRAIL had improved endothelial function and suppressed ROS generation [244]. Knockdown of Nox4 in VSMCs significantly reduced TRAIL-induced activity of the NFκB reporter gene and ICAM expression [245]. The potential clinical relevance of these results was corroborated by animal-based studies, which identified that TRAIL can be regulated by insulin levels and may be involved in regulating vascular tone [246], and two studies in people with acute coronary syndrome, revealing significantly lower srTRAIL serum levels in these individuals compared with those with stable angina or normal coronary arteries [247, 248]. Furthermore, individuals with untreated diabetes had lower concentrations of circulating TRAIL than healthy people in association with reduced flow-mediated endothelium-dependent arterial dilation (FMD). Diabetes treatment resulted in an increase in TRAIL concentrations and an improvement in FMD, but still lower than those without diabetes [249].

OPG-deficient mice demonstrated calcifications of the aorta and renal arteries [250], suggesting that OPG might have a role in protecting against vascular calcification. Interestingly, a study in elderly women found a significant correlation between elevated OPG serum levels and cardiovascular mortality [251]. The potential links between OPG and vascular disease in humans have been further supported by the detection of a single nucleotide polymorphism in the promoter region of the human gene for OPG related to vascular morphology and function [252]. Several independent studies have reported elevated serum and/or plasma OPG levels in people with diabetes, and in particular in people with diabetes and vascular complications [253–256]. Although some authors have proposed that the increase in OPG levels may represent a defense mechanism against other factors that promote vascular pathologies, other studies support a proatherosclerotic role for OPG in the vasculature [257].

Complement activation

The complement system consists of ~30 proteins that provide an important component of the innate immune system. The complement system is activated through three different pathways: the classic, the alternative and the mannose-binding lectin (MBL) complement pathway, respectively. These three pathways merge and stimulate the formation of a C3 convertase (Figure 41.9).

An increasing amount of evidence indicates that complement system activation may have a role in the development of diabetic macrovascular complications [16], in particular the MBL pathway as the initiating pathway of complement activation in people with diabetes [16]. Individuals with T1DM with nephropathy and CVD have significantly higher circulating levels of MBL than people with normoalbuminuria [258]. Furthermore, there is evidence that MBL levels may have prognostic relevance in people with diabetes. Several observations have suggested that MBL may be involved in the pathogenesis of microvascular and macrovascular complications in T1DM and that determination of MBL status might be useful in identifying individuals at increased risk of developing these complications [258, 259]. High levels of MBL early in the course of T1DM are significantly associated with later development of persistent microalbuminuria and macroalbuminuria [260]. In addition, in persons with T2DM, measurement of MBL has been shown to provide prognostic information on mortality and development of microalbuminuria [261]. The mechanism responsible for this potential activation of the complement system in individuals with diabetes is still

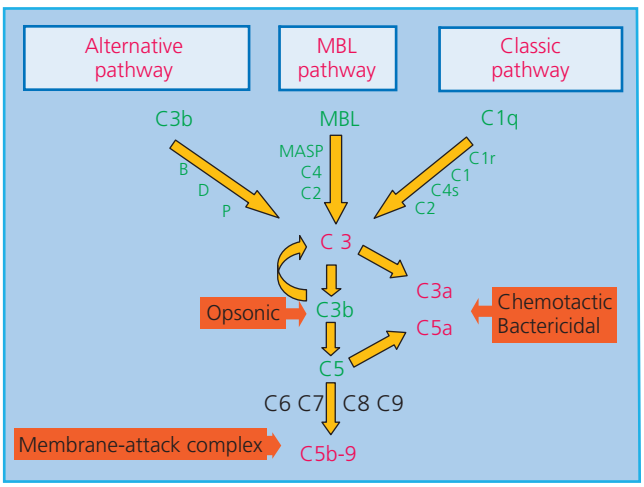

Figure 41.9 Schematic representation of the complement system. The complement cascade is activated by either of the three pathways: the classic, the mannose-binding lectin (MBL) pathway, or the alternative pathway. Activation leads to formation of the membrane-attack complex and also formation of opsonic, chemotactic, and bactericidal factors.

unknown. It has been hypothesized that hyperglycemia in people with diabetes may activate the complement system via mitochondrial ROS production or enhanced RAGE activation.

Clinical studies using pexelizumab, an inhibitor of C5, have recently demonstrated a significant reduction in mortality following acute MI in addition to reductions in the incidence of death or MI in people after coronary artery bypass graft surgery [262]. Further studies are needed to determine in particular if manipulation of the complement system may represent a promising target in the treatment and prevention of diabetes-associated macrovascular disease.

Interventions to reduce diabetes-associated macrovascular complications

A range of interventions have been proposed for reducing the macrovascular complications of diabetes, including lifestyle modification, weight reduction, dietary changes, and regular exercise.

Glucose control

Optimal glucose control is pivotal for the prevention and treatment of microvascular complications of diabetes; however, based on clinical trials [25, 26], the evidence for beneficial effects on macrovascular outcomes is less clear. Nevertheless, it has been suggested to aim for $HbA_{1c} < 7\%$ (53 mmol/mol), but to be more cautious in those with underlying and pre-existing CVD. Recently, a range of novel glucose-lowering interventions have entered the clinic arena, including DPP-4 inhibitors, GLP-1 receptor agonists, and SGLT-2 inhibitors. As yet, no clear superiority of these classes of drugs with respect to diabetes-associated macrovascular disease has been identified. Recent studies with newer classes of glucose-lowering drugs have demonstrated cardiovascular protection. For example, the SGLT-2 inhibitor Empagliflozin acts on sodium balance and has been shown to reduce the cardiovascular and total mortality in the EMPA-REG study [263]. Furthermore, there was an associated benefit on renal endpoints including end-stage renal failure, doubling of serum creatinine and albuminuria [264]. Recently, the LEADER study was completed using the GLP-1 receptor agonist Liraglutide, which also showed clear benefits on CV and renal disease [265]. These positive findings emphasize the importance of drug choice in individuals with type 2 diabetes.

Hypertension

Epidemiological studies have shown that the risk for cardiovascular events and mortality starts at blood pressure values as low as 115/75 mmHg for the general population and doubles for every increase of 20 mmHg in systolic and 10 mmHg in diastolic blood pressure (see Chapter 42). The question of what systolic or diastolic blood pressure level should be targeted has not been completely answered by currently available outcome trials. Based on studies such as the Hypertension Optimal Treatment (HOT) study [266], UKPDS [267], and the Appropriate Blood Pressure Control in type 2 Diabetes (ABCD) trial [268], a maximum systolic BP of 130–135 mmHg should be the goal for people with diabetes.

The more recently completed ADVANCE trial [26] evaluated the effect of a fixed dose of perindopril and indapamide on macrovascular and microvascular outcomes in participants with T2DM. The treatment group showed a mean reduction in systolic and diastolic BP of 5.6 and 2.2 mmHg, respectively, which was associated with an 18% reduction in cardiovascular deaths and a 14% reduction in coronary events in comparison with the control group. No lower limit for BP reduction appears to exist at which benefits related to cardiovascular outcomes are not observed, with a similar pattern reported subsequently for renal disease [269]. The later ACCORD trial tested the effects of lowering BP below 140/90 mmHg on cardiovascular outcomes. Specifically, it aimed to evaluate if a BP reduction to 120 mmHg systolic would further reduce the cardiovascular event rate. In the ADVANCE-ON trial, after 6 years of follow-up, benefits on CV outcomes were still present among those originally assigned to BP-lowering therapy but there was no evidence that glucose lowering had long-term benefits with respect to mortality of macrovascular events [30].

Choice of antihypertensive treatment

Experimental studies have clearly demonstrated a reduction in atherosclerosis with RAS inhibitors with a possible superiority of ACE inhibitors compared with ARBs in T2DM; however, in the human setting, there are no conclusive studies as yet to show clear superiority of one class of antihypertensive drugs over another. The majority of the beneficial effects on cardiovascular events appear to be related to the antihypertensive actions of these agents. The ONTARGET study was the first to evaluate the effect of combined RAS blockade in comparison with full-dose ramipril and telmisartan alone [270]. There was no superiority of the ACE inhibitor over the ARB in terms of cardiovascular events, and dual blockade did not confer greater cardiovascular protection and indeed was associated with more adverse events; however, only 30% of all participants in this study had diabetes, and no specific subgroup analysis has been reported so far. Therefore, this study cannot conclusively answer the question of the superiority of different blockers of the RAS and combination RAS–blockade on microvascular and macrovascular outcomes in diabetes.

Plasma aldosterone levels have been shown to correlate with the progression of atherosclerosis as assessed in the carotid plaque area [271]. Mineralocorticoid receptor antagonists have been evaluated with respect to CV outcomes. The RALES study initially showed a beneficial effect of the non-specific aldosterone antagonist spironolactone on mortality [272], but in the more recent EPHESUS trial [273] a 15% relative risk reduction in all-cause mortality and a 13% relative risk reduction in cardiovascular mortality/complications compared with participants on current standard therapy was demonstrated [274]. Although there is experimental evidence for eplerenone attenuating endothelial dysfunction [275] and early lesion size in experimental models of atherosclerosis [276], the evidence for a direct vasculoprotective effect of these newer agents awaits to be forthcoming, particularly in the context of diabetes.

Inhibitors of neutral endopeptidase (NEP) were associated with unwanted off-target effects, including angioedema [277, 278].

However, more recently the first-in-class combined angiotensin receptor blocker combined with a neprilysin inhibitor (ARNi) was evaluated for heart failure in the PARADIGM-HF trial [279]. Simultaneous inhibition of neprilysin enhanced the NEP system and blockade of the AT1 receptor with valsartan reduced cardiovascular death and heart failure by 20% and all-cause mortality by 16%. This new class of drugs is a potential new and effective treatment for heart failure but the effects in CVD and atherosclerosis need to be further elucidated.

Renal denervation

Initial encouraging results attenuating the overactivity of the sympathetic nervous system in hypertension using renal denervation (RDN) demonstrated substantial and sustained reductions in blood pressure in people with resistant hypertension [280, 281]. Furthermore, additional beneficial effects were observed, including reductions in serum glucose, insulin and C-peptide levels 3 months after denervation [282].

Surprisingly, a randomized clinical trial including a sham control arm (Symplicity HTN3) did not find superiority of the RDN arm compared with the sham control group [283]. Many reasons for the failure of this trial have been discussed, including ineffective denervation, inexperience of the operators, and suboptimal compliance with medication. Currently more than 100 randomized controlled trials are designed to confirm or reject further the initial findings in various chronic diseases, including CVD, heart failure, kidney disease, and diabetes [284].

Dyslipidemia

The lipid profile is usually altered in the diabetic milieu and further altered in the context of liver or renal disease. Dyslipidemia further accelerates atherosclerosis development and progression (see Chapter 43). At any given level of cholesterol, a person with diabetes has a 2–3-fold increased cardiovascular risk than a person without diabetes.

Current guidelines based on numerous studies particularly with statins (Heart Protective Study [HPS] [285], the Collaborative Atorvastatin Diabetes Study [CARDS] [286]) suggest reducing LDL levels below 2.5 mmol/L with some more recent evidence suggesting enhanced benefits if LDL is lowered to <2 mmol/L, triglycerides to <1 mmol/L, and HDL to >1 mmol/L according to pre-existing CVD and risk [287]. This area of research will significantly change with the recent advent of monoclonal antibodies against proprotein convertase subtilisin kexin 9 (PCSK9). These drugs are powerful agents that lower LDL levels by >60%. Furthermore, there have been early reports about beneficial effects on cardiovascular events [288, 289]. Whether there are antiatherosclerotic effects of these drugs beyond cholesterol lowering, as has been postulated for statins, and efficacy in diabetes needs to be shown in future trials.

Hypercoagulability

Diabetes is associated with prothrombotic changes and enhanced coagulability, thus increasing cardiovascular risk [290, 291]. Although not studied in detail, agents such as aspirin may be useful in people with diabetes, with increasing evidence that higher doses of these agents are often required in individuals with diabetes to confer cardiovascular benefits. Other drugs to consider in diabetes are clopidogrel and also agents such as abciximab [292], which has been reported to be particularly effective in people with diabetes.

Novel therapies

Several approaches have been used to intervene in diabetes-associated complications, including aldose reductase inhibitors and PKC isoform inhibitors, in particular PKCβ, but most of the evidence for a potential role for these agents has been obtained in the context of microvascular complications. Furthermore, inhibitors of glucose-induced ROS formation, such as benfotiamine, have been investigated in clinical trials with variable results. AGE inhibitors and RAGE antagonism have also been employed, mainly in the context of diabetic nephropathy. The cross-link breaker alagebrium has been shown to reduce arterial stiffness in people with hypertension and to improve left ventricular function. Direct antagonists of RAGE and human chimeric sRAGE are also currently being investigated in early clinical trials, but so far not with respect to macrovascular disease.

The role of PPAR-α and PPAR-γ agonists has also been investigated with modest or no effects on cardiovascular outcomes [293–295]. The dual PPAR-α/γ agonists such as muraglitazar do not appear to be likely to be introduced as a result of adverse side effects and the possibility of adverse cardiovascular events [296]. As outlined earlier, the landscape of novel therapies has changed with the advent of GLP-1 receptor agonists, DPP-4 inhibitors, and SGLT-2 inhibitors for diabetes control with positive effects on cardiovascular endpoints recently reported [263, 265].

Multifactorial approaches

The Steno 2 study, using a multifactorial approach addressing lipids, blood pressure, and hyperglycemia, demonstrated significant improvements on cardiovascular outcomes [28]. Thus, a synergistic multifactorial approach addressing glycemic control in the context of additional strategies to reduce concomitant cardiovascular risk factors remains the best approach to be currently considered. Furthermore, strategies directed towards a reduction in activation of vasoactive systems such as the RAS, the ET and UT systems, the AGE/RAGE axis, novel proteins such as TRAIL, and the complement system in addition to oxidative stress and inflammation may represent additional promising approaches to prevent and minimize macrovascular disease in diabetes.

42 Cardiovascular Risk Factors: Hypertension

Peter M. Nilsson
Lund University, Skåne University Hospital, Malmö, Sweden

Key points

- Hypertension in diabetes is a prevalent and treatable risk factor for cardiovascular complications and retinopathy.
- Evaluation by use of ambulatory blood pressure monitoring should be offered to all people with type 1 and type 2 diabetes.
- Most antihypertensive drugs can be used for treatment, but blockers of the renin–angiotensin system (RAS) may confer special clinical benefits for target organ protection.
- Drug combination therapy is needed for most people to achieve reasonable blood pressure control.
- Encouragement of home blood pressure measurements will make it possible to achieve better blood pressure control while also supporting the involvement and empowerment of the person with diabetes.
- The blood pressure goal for people with type 2 diabetes is <140/85 mmHg in the European Guidelines.

Introduction

Hypertension often accompanies both type 1 diabetes mellitus (T1DM) and type 2 diabetes (T2DM). The association between the two conditions has long been recognized. In 1923, the Swedish physician Eskil Kylin described a syndrome of diabetes, hypertension, and hyperuricemia [1], which are now regarded as aspects of the broader "metabolic syndrome" that has been linked to insulin resistance [2, 3]. The relationship between diabetes and hypertension is complex. Both are common and so are likely to be associated by chance, but in some instances they may have a common cause, even programmed in early life; moreover, hypertension can develop as a consequence of diabetic nephropathy, and some drugs used to treat hypertension can induce diabetes in susceptible individuals, at least at higher dosages.

Hypertension is important because, like diabetes, it is a major cardiovascular risk factor and one that synergizes with the deleterious effects of diabetes. It is also a risk factor for microvascular complications, namely nephropathy and retinopathy. The management of hypertension in diabetes has been widely debated, and there is still a need to agree on treatment targets and strategies. The current blood pressure goal for therapy is <140/80–90 mmHg in general, but lower in newly detected patients with shorter diabetes duration and fewer comorbidities. During the last two decades, several well-constructed trials have added considerably to the evidence base [4–8], demonstrating convincingly the benefits of lowering blood pressure, but also highlighting how difficult this can be to achieve in practice.

Size of the problem

Hypertension is widely defined according to the World Health Organization/International Society of Hypertension (WHO/ISH) criteria (Table 42.1). People with diabetes are still at risk of macrovascular and microvascular complications at blood pressure levels below these thresholds, and the treatment target range is therefore lower (in the range 130–140/80–90 mmHg).

Overall, hypertension (according to the WHO criteria) is up to twice as common in people with diabetes as in the general population [9]. In white Europeans, 10–30% of people with T1DM and 60–80% of those with newly diagnosed T2DM are hypertensive [10]. There are racial and ethnic differences in the prevalence of hypertension, which presumably are at least partly genetically determined. For example, hypertension (and macrovascular disease) is less frequent among the Pima Indians and Mexican Americans [11]. Impaired glucose tolerance (IGT) is also associated with hypertension (20–40% of cases), perhaps reflecting the common origins of these aspects of the metabolic syndrome [12].

There is evidence that the true prevalence of hypertension is increasing in the population with diabetes (especially T2DM) after allowing for the greater number of cases identified through improved screening and the lowering of thresholds for treatment of blood pressure [13]. The causes probably include the rising

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

Table 42.1 Criteria for hypertension and related tissue damage, defined by the World Health Organization (WHO) and the International Society for Hypertension, 1999 [40].

Category	Systolic (mmHg)	Diastolic (mmHg)
WHO criteria for the general population[a]		
Optimal	<120	<80
Normal	<130	<85
High normal	130–139	85–89
Grade 1 hypertension (mild)	140–159	90–99
Subgroup: borderline	140–149	90–94
Grade 2 hypertension (moderate)	160–179	100–109
Grade 3 hypertension (severe)	≥180	≥110
Isolated systolic hypertension	≥140	<90
Subgroup: borderline	140–149	<90
Hypertension-related tissue damage (WHO criteria)		
Grade I: none		
Grade II: subclinical damage (e.g. retinopathy, proteinuria)		
Grade III: clinical damage (e.g. heart failure, ischemia)		
Degree of proteinuria		
Microalbuminuria: 30–300 mg/24 h (20–200 mg/min)		
Macroalbuminuria: >300 mg/24 h (>300 mg/min)		

[a]Desirable blood pressure limits in people with diabetes are suggested in Figure 42.5.

Table 42.2 Associations between hypertension and diabetes.

Hypertension associated with T2DM, (insulin resistance or metabolic syndrome)
Hypertension associated with nephropathy in T1DM
Coincidental hypertension in people with diabetes
Essential hypertension
Isolated systolic hypertension
Renal scarring (e.g. from recurrent pyelonephritis)
Diabetogenic antihypertensive drugs
Potassium-losing diuretics (chlortalidone, high-dose thiazides)
β-Blockers (high dose)
Combined diuretics and beta-blockers
Drugs causing obesity, hypertension, and glucose intolerance
Glucocorticoids
Combined oral contraceptive pills
Antipsychotics
Endocrine disorders causing hypertension and glucose intolerance
Acromegaly
Cushing syndrome
Conn syndrome
Pheochromocytoma

prevalence of obesity and longer survival of older people with diabetes.

Causes of hypertension in diabetes

Associations between hypertension and diabetes are listed in Table 42.2. Essential hypertension and isolated systolic hypertension are both common in people without diabetes, especially in the elderly. It is estimated that essential hypertension accounts for about 10% of cases in people with diabetes. Other important causes are the hypertension that coexists with insulin resistance, obesity, and IGT in the metabolic syndrome, and hypertension secondary to diabetic nephropathy, as discussed in detail below.

Hypertension in the metabolic syndrome

This syndrome consists of insulin resistance, impaired fasting glycemia (including T2DM), a characteristic dyslipidemia—hypertriglyceridemia, low high-density lipoprotein (HDL) cholesterol, and somewhat raised low-density lipoprotein (LDL), with a clear excess of small, dense LDL particles—truncal obesity, procoagulant changes (raised plasminogen activator inhibitor 1 and fibrinogen levels) and hyperuricemia [2, 14, 15]. As these abnormalities are all risk factors for atherogenesis, the syndrome is completed by a marked tendency for early vascular aging, leading to macrovascular disease, especially coronary heart disease (CHD) and stroke (Figure 42.1). As discussed in Chapter 13, insulin resistance has been proposed by Reaven [2], DeFronzo and Ferrannini [14], and others [15] to be a fundamental cause of hypertension and cardiovascular disease (CVD) in addition to T2DM. Insulin resistance is partly genetically determined, while acquired factors such as obesity, physical inactivity, and perhaps malnutrition *in utero* and during early infancy may also contribute [16]. In support of the latter, family studies have revealed a correlation between the blood pressure of the mother and her offspring that appears to be non-hereditary in origin; early growth retardation is suggested to program abnormal development of the vasculature and also the tissues that regulate glucose homeostasis.

Insulin resistance is closely associated with high blood pressure in both humans and animals. Experimental induction of insulin resistance (e.g. feeding rats with fructose) is accompanied by a rise in blood pressure. More persuasively, an inverse relationship has been demonstrated in humans between blood pressure and insulin sensitivity [17] (Figure 42.2). Various mechanisms have been proposed to explain how insulin resistance and/or the accompanying hyperinsulinemia could increase blood pressure (Figure 42.3). First, there is some evidence that insulin is an endothelium-dependent vasodilator, releasing nitric oxide (NO) from the endothelium, which relaxes vascular smooth muscle [18, 19]; blunting of this effect, caused by insensitivity to the action of insulin on the endothelium and also on metabolically important tissues, could contribute to the increased peripheral resistance that is the hallmark of hypertension in obesity and T2DM. Impaired endothelium-mediated vasodilation is associated with insulin resistant states and may have a key role in the initiation and progression of atherosclerosis [20], further negatively influenced by smoking.

By contrast, insulin also has several actions that tend to raise blood pressure, and there is some evidence that these are accentuated in insulin resistant states, presumably because sensitivity

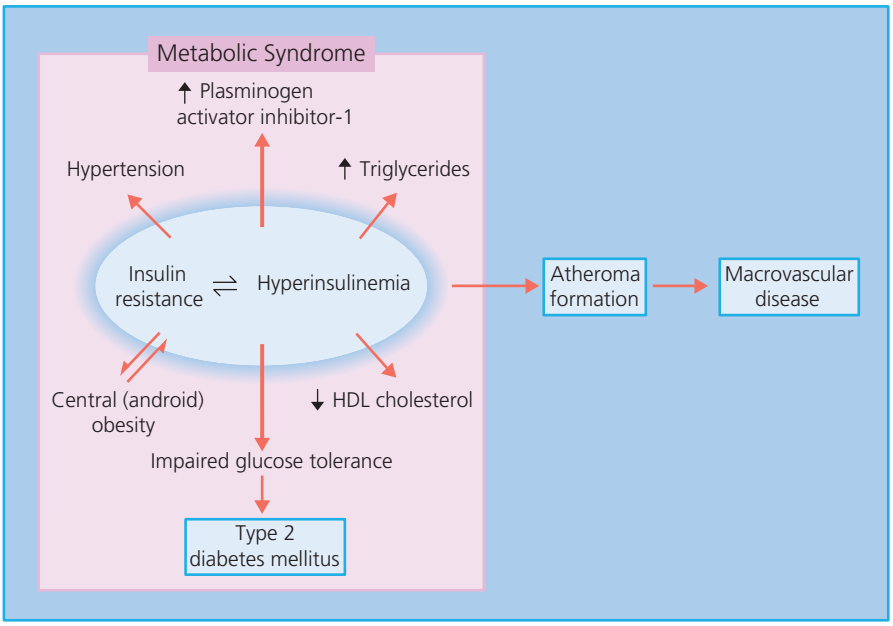

Figure 42.1 The metabolic syndrome. HDL, high-density lipoprotein.

to the effects of the raised insulin levels is preserved. Insulin acts on the distal renal tubule to retain Na^+ ions and water [20, 21], an effect that still operates in people with insulin resistance [22], and so could contribute to the rise in total body Na^+ content that occurs in obesity and T2DM [23]. Insulin also stimulates the cell membrane Na^+–K^+ ATPase, which would raise intracellular Na^+ concentrations in vascular smooth muscle and, by increasing systolic Ca^{2+} levels, would enhance contractility and increase peripheral resistance [22, 23]. Through its effects on the central nervous system (CNS), insulin may stimulate the sympathetic outflow. Theoretically, this could also increase blood pressure, although direct evidence in humans is lacking [22, 24]. Finally, insulin may stimulate the proliferation of vascular smooth muscle cells, which could lead to medial hypertrophy and increased peripheral resistance [22, 25].

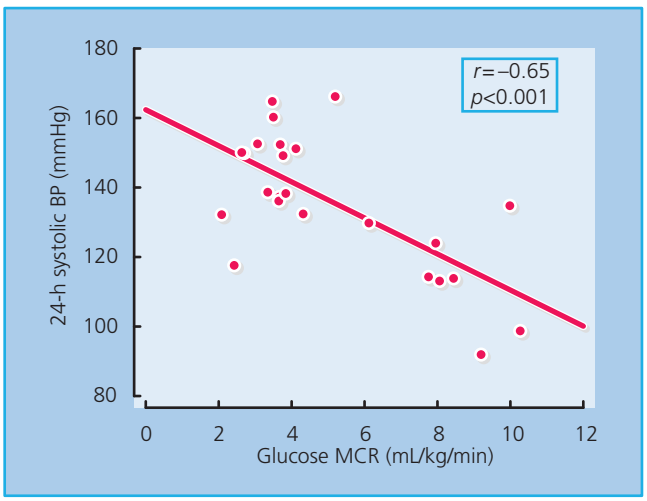

Figure 42.2 Hypertension is associated with insulin resistance. Insulin sensitivity, measured as the metabolic clearance rate (MCR) of glucose during an insulin clamp study, is inversely related to the mean 24-h systolic and ambulatory blood pressure (BP). Hypertension and diabetic nephropathy

This association is most obvious in young people with T1DM, in whom the presence of hypertension is strikingly related to renal damage and even minor degrees of proteinuria. Blood pressure begins to rise when the urinary albumin excretion (UAE) enters the microalbuminuric range (>30 mg/24 h) and is usually over the WHO threshold when UAE reaches the macroalbuminuric stage (>300 mg/24 h) [26]. The association may be partly genetically determined: people with diabetes and microalbuminuria commonly have parents with hypertension and may also inherit overactivity of the cell-membrane Na^+–H^+ pump (indicated by increased Na^+–Li^+ counter-transport in red blood cells), which would tend to raise intracellular Na^+ concentrations and thus increase vascular smooth muscle tone [27].

The basic mechanisms of hypertension include decreased Na^+ excretion with Na^+ and water retention. Peripheral resistance is increased, to which raised intracellular Na^+ will contribute. The role of the renin–angiotensin aldosterone system (RAS) is uncertain, as both increased and decreased activity has been reported [28, 29]. These discrepancies may be explained by differences in diet, treatment, metabolic control, and the type and duration of diabetes. Na^+ retention and hypertension would be predicted to suppress the RAS, whereas renin levels may be influenced by other complications of diabetes: renal tubular acidosis type 4 causes hyporeninemic hypoaldosteronism and neuropathy can also lower plasma renin, while renin may be raised in retinopathy and advanced nephropathy. Individuals with microalbuminuria who are insulin resistant appear to be particularly susceptible to hypertension [30].

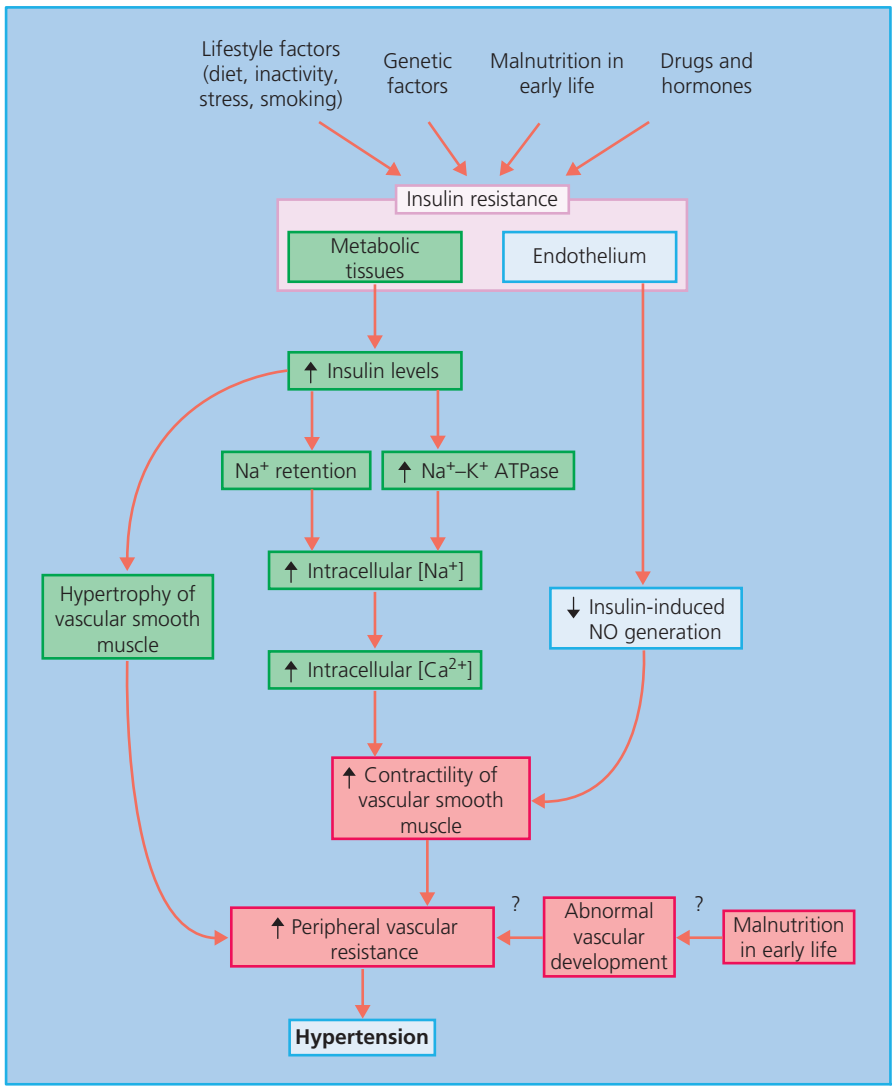

Figure 42.3 Possible mechanisms of hypertension in conditions of insulin resistance.

Impact of hypertension in diabetes

A large proportion of people with hypertension and diabetes show signs of cardiovascular aging and target-organ damage [10]. Hypertension, as an independent risk factor for atherogenesis, synergizes with the effects of diabetes and significantly increases the development and progression of CHD and cerebrovascular and peripheral vascular disease. Overall, the effects of hypertension on deaths from CHD are increased 2–5-fold in people with diabetes, with the greatest increase occurring at the lowest blood pressure levels (Figure 42.4).

The deleterious effects of hypertension on left ventricular function are also accentuated by the presence of diabetes. These include impaired left ventricular relaxation [31] and increased left ventricular mass [32], the latter being an independent predictor of premature death from CHD.

Hypertension also predisposes to the development of certain microvascular complications, particularly nephropathy and end-stage renal disease, for which the risk is increased 2–3-fold (see Chapter 39). Hypertension is also a risk factor for retinopathy, as has been confirmed by the beneficial effects of improved blood pressure control in people with T2DM, reported by the UK Prospective Diabetes Study (UKPDS) [4].

In recent years, interest in arterial stiffness (arteriosclerosis) has increased and it has been shown that arterial stiffness is a characteristic of people with the metabolic syndrome and T2DM [33]. It is believed that increased aortic pulse wave velocity (aPWV) is a marker of the arterial stiffness that is supposed to precede, but later also to interact with, atherosclerosis [34]. A threshold of aPWV >10 m/s [35] is a marker of increased arterial stiffness that can also independently predict cardiovascular risk and total mortality [36]. At early stages, the degree of hyperglycemia and dyslipidemia increases arterial stiffness also in people with normoglycemia or impaired glucose metabolism [37], resulting in early vascular aging (EVA) [38].

Vaccaro, paper presented at the 26th Annual Meeting of the European Diabetes Epidemiology Group, Lund, 1991.

Screening for hypertension in diabetes

As the two conditions are so commonly associated, people with diabetes must be regularly screened for hypertension and vice versa. People with hypertension, especially if obese or receiving treatment with potentially diabetogenic drugs, should be screened for diabetes at diagnosis and during follow-up. Should hyperglycemia be detected, potentially diabetogenic antihypertensive drugs should be reduced or changed to others or used in combinations that do not impair glucose tolerance; normoglycemia can then often be restored when lifestyle improvements are also supported.

All people with diabetes should have their blood pressure checked at diagnosis and at least annually thereafter. This is especially important in those with other cardiovascular risk factors, such as nephropathy (which is associated with a substantial increase in the cardiovascular mortality rate), obesity, dyslipidemia, smoking, or poor glycemic control, or with a positive family history of cardiovascular disease.

Measurement of blood pressure

Blood pressure should be measured with the patient in the supine or sitting position, with an accurate sphygmomanometer and a cuff of appropriate size (i.e. wider for obese people with an arm circumference of >32 cm). Systolic and diastolic blood pressure should be recorded, to the nearest 2 mmHg if using a manual sphygmomanometer, from phases I and V (i.e. appearance and final disappearance of the sounds of Korotkoff). Usual precautions should be taken to ensure reliability and avoid "white coat" stress effects, which can acutely raise blood pressure. Conditions should be quiet and relaxed, and at least two readings should be taken initially and then repeated at intervals over weeks or months to determine the person's typical values and any trend to change. Office blood pressure could be complemented by repeated home blood pressure recordings.

Blood pressure should also be checked with the patient in the upright position (1 min after standing), because there may be a significant postural fall (>20 mmHg systolic) in people with diabetic autonomic neuropathy, the elderly, or those treated with vasodilators or diuretics. Marked postural hypotension, which can coexist with supine hypertension, may indicate the need to change or reduce antihypertensive medication, especially if symptoms are provoked.

Ambulatory blood pressure monitoring over 24 h may be useful in some cases to exclude "white coat" effects, and in people with early nephropathy who have nearly normal blood pressure during the day, but who may be at risk of hypertensive tissue damage because they fail to show the physiological blood pressure dip during sleep. Masked hypertension is also a common phenomenon in about 20–30% of all individuals with T2DM [39].

Diagnosis of hypertension in diabetes

The criteria issued in 1999 by the WHO and ISH [40] define hypertension as an office blood pressure exceeding 140/90 mmHg (Korotkoff I–V) and borderline hypertension as being below these limits but above 130 mmHg systolic and/or 85 mmHg diastolic (Figure 42.5) [40]. Established hypertension is diagnosed when readings consistently exceed 140/90 mmHg over several weeks, or when the blood pressure is very high (diastolic blood pressure >110 mmHg), or when there are clinical signs of tissue organ damage from long-standing hypertension.

It is clear from numerous epidemiological studies that the WHO/ISH threshold is sometimes too high in people with diabetes because of their additional risk of both macrovascular and microvascular disease, and that there are definite benefits from treating people with microalbuminuria whose diastolic blood pressure is <90 mmHg [41]. Various other expert bodies have suggested alternative, generally lower target levels (Figure 42.5). A consensus would be to aim for a blood pressure in the range 130–140 mmHg systolic and below 80–85 mmHg diastolic, and to treat any one whose blood pressure is consistently above one or both of these thresholds, supported by modern guidelines [42–45].

Investigation of hypertension in diabetes

Initial investigation of the person with diabetes and hypertension aims to exclude rare causes of secondary hypertension (Table 42.2), to assess the extent of tissue organ damage caused by hypertension and diabetes (Table 42.1), and to identify other

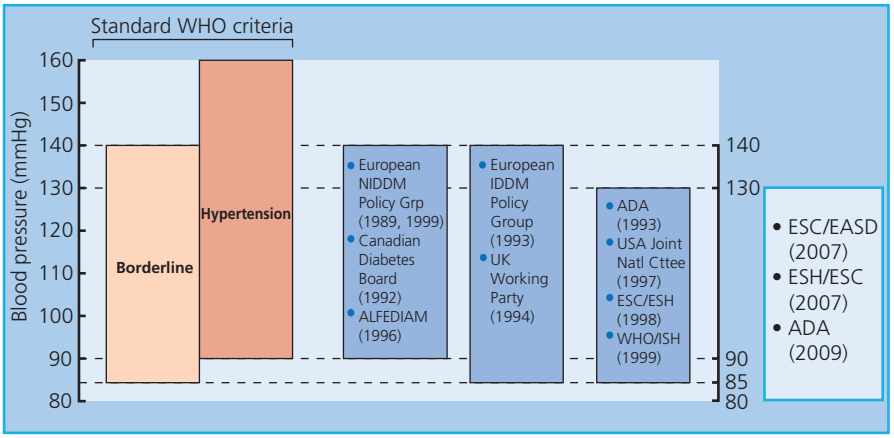

Figure 42.5 Previous blood pressure treatment targets suggested for people with diabetes, compared with the World Health Organization/International Society of Hypertension definition of hypertension and borderline hypertension [40]. potentially treatable risk factors for vascular disease. The major points in the medical history and examination are shown in Table 42.3.

- *Cardiac function.* A standard 12-lead electrocardiogram may show obvious ischemia, arrhythmia, or left ventricular hypertrophy; the last is more accurately demonstrated by echocardiography, which will also reveal left ventricular dysfunction and decreased ejection fraction. Exercise testing (or stress-echo) testing and 24-h Holter monitoring may also be appropriate.
- *Renal function.* A fresh urine sample should be tested for microalbuminuria (see Chapter 39) and another examined microscopically for red and white blood cells, casts, and other signs of renal disease. Microscopic hematuria can occasionally occur in people with T1DM (particularly children) in the apparent absence of significant renal dysfunction, but coexisting renal disease must always be excluded. Serum urea, creatinine, and electrolytes should be checked. If the serum creatinine concentration is raised, measurement of the glomerular filtration rate (GFR) should be considered, ideally using a specific clearance method such as using chromium–ethylenediaminetetraacetic acid complex (Cr-EDTA), iohexol, or cystatin C. Further specialist investigations needed include an isotope renogram and other tests for renal artery stenosis (Figure 42.6). This complication of renal arterial atherosclerosis may affect up to 20% of older people with T2DM and, if bilateral, can lead to severe and sometimes permanent renal impairment if angiotensin-converting enzyme (ACE) inhibitors are given.
- *Lipid profile.* Fasting serum lipid concentrations should be checked. If total cholesterol or triglyceride levels are found to be elevated after repeated measurements, further investigation of lipoprotein subclasses—very low-density lipoprotein (VLDL), LDL, HDL, and also the apo-B : apo-A1 lipoprotein ratio—is recommended. Treatment for hyperlipidemia should be considered if the total cholesterol is >4.0 mmol/L, the LDL cholesterol level is >2.5 mmol/L, or the LDL : HDL cholesterol ratio is >4 [43]. This is discussed in more detail in Chapters 43, 44, and 46.

Other forms of secondary hypertension may be indicated by clinical findings of endocrine or renal disease, significant hypokalemia (plasma potassium <3.5 mmol/L without previous

Table 42.3 Investigation of the person with diabetes and hypertension.

Investigations	
History	Is hypertension significant?
Cardiovascular symptoms	Does hypertension have an underlying cause?
Previous urinary disease	• Renal
Smoking and alcohol use	• Endocrine
Medication	• Drug-induced
Family history of hypertension or cardiovascular disease	Has hypertension caused tissue damage?
Examination	• Left ventricular hypertrophy
Blood pressure erect and supine	• Ischemic heart disease
Left ventricular hypertrophy	• Cardiac failure
Cardiac failure	• Peripheral vascular disease
Peripheral pulses (including renal bruits and radiofemoral delay)	• Renal impairment
Ankle–brachial index	• Fundal changes
Fundal changes of hypertension	Are other cardiovascular risk factors present?
Evidence of underlying endocrine or renal disease	• Smoking
Electrocardiography	• Hyperlipidemia
Left ventricular hypertrophy	• Poor glycemic control
Ischemic changes	• Positive family history of cardiovascular disease

diuretic treatment), failure of hypertension to respond to standard treatment, or a sudden decline in GFR after starting treatment with ACE inhibitors (suggestive of renal artery stenosis).

Management of hypertension in diabetes

Strict blood pressure control is the primary goal of treatment. In recent years, target treatment levels have declined progressively to the current recommendation of a mean office blood pressure in the range 130–140/80–85 mmHg for all people who can tolerate this without side effects such as orthostatic reactions or compromising arterial circulation in critical vascular beds. Recent observations indicate that there may be subgroups of susceptible individuals who will not tolerate a dramatic reduction below 130 mmHg systolic blood pressure, so caution should be exercised, especially when comorbidities are present.

Management begins with lifestyle modification, but few people respond to this alone, and most will require more than one antihypertensive drug to control blood pressure adequately [4, 5], a fact that new guidelines emphasize [42–45].

Non-pharmacological treatment

The treatment of hypertension in people with diabetes must be based on structured lifestyle intervention. This means weight reduction or weight stabilization in the obese, sodium restriction, diet modification, and regular physical exercise (moderate intensity, 40–60 min, 2–3 times weekly). Dietary intake of saturated fat has been associated with impaired insulin sensitivity and should therefore be reduced [46]. Alcohol should be restricted to 2–3 units/day in men and 2 units/day in women, but omitted altogether if hypertension proves difficult to control. It should be remembered that the Look-AHEAD study in the United States provided no evidence for benefits of weight loss per se as a strategy to lower cardiovascular risk in obese individuals with T2DM of long duration, even though metabolic and risk factor control may improve [47]. This is therefore a rationale to aim for control of risk factors in these persons in the first place, not weight loss itself, with drugs based on evidence and guidelines [42–45].

Smoking causes an acute increase in blood pressure and greater variability overall [48]. Smoking cessation is especially important, as smoking not only accelerates the progression of atherosclerosis and vascular aging, but also impairs insulin sensitivity [49] and worsens albuminuria [50]. Treatment with nicotine supplementation for 4–6 weeks (chewing gum or patches), bupropion, or varenicline may be useful.

When adopted in full lifestyle modification can be effective for blood pressure control itself, and is believed to benefit cardiovascular risk in general even if the evidence is scanty. The above measures can lower systolic and diastolic blood pressure by 11 and 8 mmHg, respectively [51]—as much as many antihypertensive drugs—and sometimes enough to lessen the need for drug therapy. Weight reduction in those with obesity can similarly reduce blood pressure, but not cardiovascular events, according to the Look-AHEAD Study, which is why more research is needed [47].

Antihypertensive drug therapy

Numerous drugs are available to lower blood pressure, but some are better suited than others to the particular needs of people with diabetes because of their favorable or neutral effects on glucose metabolism and other factors. Most people with diabetes (at least two-thirds) will require combinations of antihypertensive drugs to control blood pressure—an average of around three different drugs in two large studies [4, 5]. Accordingly, the clinician must be able to use a wide variety of antihypertensive drugs and to choose combinations that exploit pharmacological synergy. Combination therapy usually means that lower dosages of individual drugs can often be used, thus reducing the risk of their adverse effects.

Diuretics

Diuretics are often effective antihypertensive agents for people with diabetes, in whom the total body sodium load is increased and the extracellular fluid volume expanded [52]; however, diuretics that increase urinary potassium and magnesium losses can worsen hyperglycemia, as insulin secretion is impaired by potassium depletion, and insulin sensitivity in peripheral tissues may also be decreased [53]. The use of high-dose thiazide diuretics, equivalent to ≥5 mg/day bendroflumethiazide (bendrofluazide), is reported to increase the risk of people with hypertension developing diabetes by up to threefold; this does not seem to occur with low dosages (up to 2.5 mg/day bendroflumethiazide) [54]. Potassium depletion is particularly severe with high-dose chlortalidone (chlorthalidone), less so with furosemide (frusemide) and bendroflumethiazide, and apparently negligible with indapamide. This mechanism is irrelevant to those with C-peptide-negative T1DM who are totally dependent on exogenous insulin. Thiazides may also aggravate dyslipidemia [55], although

low dosages probably carry a small risk. Thiazides have also been associated with gout and erectile dysfunction and are generally avoided in middle-aged men with diabetes and hyperuricemia or erectile dysfunction; nevertheless, some evidence suggests that the risk of erectile failure may have been overstated. Diuretics may precipitate hyperosmolar hyperglycemia syndrome and should be avoided or used at the lowest effective dose in people with a history of this complication.

Diuretics have been shown to prevent CVD successfully in elderly people with T2DM and systolic hypertension [56], but one observational study suggested that the use of diuretics increased cardiovascular mortality in people with hypertension and T2DM who were still hyperglycemic in spite of treatment [57]. Overall, these drugs are effective and safe when used appropriately in people with diabetes.

Diuretics suitable for use in diabetic hypertension include furosemide, bendroflumethiazide (≤2.5 mg/day), hydrochlorothiazide, spironolactone, and indapamide. Low dosages should be used, sometimes in combination with potassium supplements or potassium-sparing drugs, such as amiloride. If ineffective, diuretics should be combined with another first-line drug (e.g. an ACE inhibitor or an angiotensin II receptor blocker [ARB]), rather than given at increased dosage. Spironolactone is best not combined with an ACE inhibitor, as this increases the risk of hyperkalemia. Furosemide is useful in people with renal impairment (serum creatinine >150 μmol/L) or edema.

Serum urea, creatinine, and potassium should be checked when starting diuretic therapy and every 6–12 months thereafter, as dangerous disturbances in plasma potassium levels can develop, especially in individuals with diabetes and renal impairment.

β-Adrenergic blocking agents

β-Blockers may significantly lower blood pressure levels in people with diabetes and hypertension, even though renin release (a major target for these drugs) is commonly reduced in diabetes because of Na^+ and fluid retention. These drugs are often ineffective in Afro-Caribbean people, who commonly have low renin hypertension. Other mechanisms of action that reduce blood pressure include reductions in heart rate and cardiac output via interaction with β_1- and β_2-receptors in the myocardium and in the vessel wall.

Like diuretics, β-receptor blockers may aggravate both hyperglycemia and dyslipidemia [58]. These effects depend on both the dosage and the degree of selectivity of the individual drug. The hyperglycemic effect is attributed to inhibition of β_2-adrenergic-mediated insulin release and decreased insulin action in peripheral tissues; the long-term risk for a person without diabetes developing the disease may be increased sixfold [59], and even more if given together with thiazides. Some studies suggest that the hazards of both hyperglycemia and hyperlipidemia have been exaggerated and may be both dose dependent and secondary to weight gain [60]. The metabolic side effects of β-blockers can be reduced by using low dosages combined with other agents, particularly dihydropyridine calcium-channel antagonists, or by intensifying non-pharmacological efforts to decrease weight and improve physical activity.

β-Blockers have other side effects relevant to diabetes. They may interfere with the counter-regulatory effects of catecholamines released during hypoglycemia, thereby blunting manifestations such as tachycardia and tremor and delaying recovery from hypoglycemia [61]. In clinical practice, however, this rarely presents a serious problem, especially when cardioselective β_1-blockers are used. β-Blockers may also aggravate erectile dysfunction, and are generally contraindicated in second- or third-degree atrioventricular (AV) heart block, severe peripheral vascular disease, asthma, and chronic airway obstruction. Some studies have shown that certain β-blockers such as metoprolol and carvedilol [62, 63] can be used favorably in cardiac failure in people with diabetes, as shown in the Metoprolol CR/XL Randomized Intervention Trial in Congestive Heart Failure (MERIT-HF) study, in which 25% of the participants had diabetes [62].

Atenolol is a commonly used drug, as it is cardioselective and water soluble, which reduces CNS side effects and renders its metabolism and dosage more predictable. It is mostly effective as a single daily dose, which probably encourages medication adherence. In the UKPDS, its effect was comparable to that of the ACE inhibitor captopril [64]; however, it should be kept in mind that the stroke-preventive effect of atenolol is 16% less than that of other antihypertensive drugs, based on data from meta-analyses. Metoprolol is an alternative, in moderate dosages. Both non-selective and selective β-blockers are effective in the secondary prevention of myocardial infarction (MI) after an initial event in people with diabetes [65]. Metoprolol or carvedilol may be indicated in those who also have heart failure [62, 63], and β-blockers in general are useful in individuals who also have angina or tachyarrhythmias.

Calcium-channel antagonists

These useful vasodilator agents do not generally worsen metabolic control when used at conventional dosages, although sporadic cases of hyperglycemia have been reported after starting a calcium-channel antagonist of the dihydropyridine class [66]. This may be caused by inhibition of insulin secretion (a calcium-dependent process) in susceptible persons, or a compensatory sympathetic nervous activation, which antagonizes both insulin secretion and action, following vasodilation.

Calcium-channel antagonists have a slight negative inotropic effect and are contraindicated in significant cardiac failure; they often cause mild ankle edema, but this is caused by relaxation of the peripheral precapillary sphincters and raised capillary pressure rather than by right ventricular failure. Because of their potent vasodilator properties, these drugs can cause postural hypotension and can aggravate that brought about by autonomic neuropathy. Non-dihydropyridine calcium-channel antagonists (e.g. verapamil) reduce proteinuria in diabetic nephropathy, but this effect is not seen with dihydropyridine derivatives such as nifedipine, amlodipine, felodipine, and isradipine [67].

Because of their other cardiac actions, these drugs are particularly indicated in people with hypertension who also have angina (e.g. sustained-release nifedipine and diltiazem) or supraventricular tachycardia (e.g. verapamil). Their vasodilator properties may also be beneficial in peripheral vascular disease. Calcium-channel antagonists are ideally combined with selective β_1-blockers, but the specific combination of verapamil and β-blockers (especially together with digoxin) must be avoided because of the risk of conduction block and asystole. Overall, calcium-channel antagonists appear less or similarly cardioprotective but better at preventing stroke than either β-blockers or thiazide diuretics [68, 69].

Amlodipine given once daily is an evidence-based and convenient preparation for general use, and felodipine, isradipine, and sustained-release nifedipine are suitable alternatives.

Angiotensin-converting enzyme inhibitors

ACE inhibitors may be used in diabetic hypertension, even in cases where the general RAS is not activated as the drugs may interfere with local angiotensin action in specific target tissues. When used alone, however, these agents have a limited hypotensive action in many Afro-Caribbean persons, who tend to have suppressed RAS activity.

ACE inhibitors have no adverse metabolic effects and may even improve insulin sensitivity [70]; hypoglycemia has rarely been reported [71]. These drugs are particularly beneficial in diabetic nephropathy by reducing albuminuria and possibly delaying progression of renal damage [72]. Their antiproteinuric effect may be caused specifically by relaxation of the efferent arterioles in the glomerulus, which are highly sensitive to vasoconstriction by angiotensin II, thus reducing the intraglomerular hypertension that is postulated to favor albumin filtration; however, the importance of this mechanism remains controversial [73]. ACE inhibitors are also indicated in cardiac failure, in combination with relatively low dosages of diuretics.

A dry cough is reported by 10–15% of people treated with ACE inhibitors, because these drugs also interfere with the breakdown of kinins in the bronchial epithelium. Changing to another ACE inhibitor or an ARB may avoid this problem. ACE inhibitors occasionally precipitate acute renal failure, particularly in the elderly and in individuals taking non-steroidal anti-inflammatory drugs (NSAIDs), or who have bilateral renal artery stenosis. Other side effects (rashes, neutropenia, taste disturbance) are unusual with the low dosages currently recommended, but become more prominent in renal failure. Because ACE inhibitors cause potassium retention, they should not generally be taken concurrently with potassium-sparing diuretics (spironolactone and amiloride) or potassium supplements. Serum creatinine and potassium levels should be monitored regularly, especially in individuals with renal failure or type 4 renal tubular acidosis, in whom hyperkalemia can rapidly reach dangerous levels.

Ramipril, enalapril, lisinopril, and perindopril, given once daily for hypertension, are all established ACE inhibitors that are suitable for use in people with diabetes. The first dose of an ACE inhibitor should be small and taken just before bedtime to minimize postural hypotension, which may be marked in people receiving diuretics or on a strict sodium-restricted diet. The same problem may arise in those with autonomic neuropathy. ACE inhibitors are now recommended in people with left ventricular dysfunction following MI (see Chapters 44 and 45). Ramipril has been shown to prevent cardiovascular morbidity and mortality in high-risk people with diabetes, with or without pre-existing ischemic heart disease [74].

Angiotensin II type 1 receptor blockers

This class includes losartan, irbesartan, valsartan, candesartan, and telmisartan, which act on the AT1 receptor to decrease blood pressure. They are metabolically neutral [75] and, unlike the ACE inhibitors, do not cause cough. They are effective antihypertensive drugs in people with diabetes [76] and have been shown to slow the progression of nephropathy in those with diabetes and varying degrees of albuminuria (in the RENAAL, IDNT, and PRIME-2 studies) [77–79]. Losartan has also been shown (in a subgroup of the LIFE study) to be better than atenolol in reducing both cardiovascular endpoints (by 25%) and total mortality (by 40%) in high-risk people with T2DM with hypertension and left ventricular hypertrophy [80]. Interestingly, the combination of an ACE inhibitor (lisinopril) with an AT1 antagonist (candesartan) was more effective than either agent alone in lowering blood pressure and UAE in people with T2DM [81]; however, in the ONTARGET study, no extra benefits were recorded for the combination of telmisartan and ramipril on cardiovascular endpoints compared with monotherapy [82]. The combination of an ACE inhibitor and an AT1 receptor blocker for treatment of hypertension is discouraged owing to the negative interaction and risk of adverse renal effects, as evident from the ONTARGET study [83].

Direct renin inhibitor

Another approach to block RAS is via direct renin inhibition. In the ALTITUDE study, this strategy was not successful when the renin inhibitor aliskiren was combined with either an ACE inhibitor or an AT1 receptor blocker versus placebo for cardiovascular and renal protection [84]. As a result, this combination is not recommended for people with T2DM, hypertension, and microalbuminuria in current guidelines [42–45].

α1-Adrenoceptor antagonists

α_1-Blockers can lower blood pressure effectively and also improve dyslipidemia and insulin sensitivity. Doxazosin is normally well tolerated, especially in combination therapy; side effects include nasal congestion and postural hypotension. Doxazosin has been reported to be inferior to the diuretic chlortalidone in the prevention of stroke and heart failure [85].

Treatment strategies

In general, lifestyle modification should be tried initially for ~3 months. If moderate hypertension (systolic blood pressure >160 mmHg or diastolic blood pressure >100 mmHg) or signs of

hypertensive tissue damage are present, then drug therapy should be started at the outset. Initially, monotherapy with one of the first-line drugs suggested above should be used, the choice being influenced by other factors such as coexistence of angina, heart failure, or nephropathy. All drug treatment should aim at being evidence based and cost-effective in the individual. A move to combination drug treatment is recommended for many people owing to the high prevalence of target organ damage when early blood pressure control is mandatory [42–45].

Hypertension in T1DM

ACE inhibitors are especially suitable if the person has albuminuria or more advanced stages of diabetic nephropathy. Diuretics, β_1-selective blockers, and calcium-channel antagonists are equally valid alternatives with regard to blood pressure reduction.

If renal function is moderately impaired (serum creatinine values >150 μmol/L), thiazide diuretics become less effective, and furosemide or other loop diuretics should be used instead; however, in established end stage renal disease (serum creatinine >500 μmol/L), furosemide may be toxic, and dialysis must be started. In some people, hypoglycemia attacks may be masked by the use of β-blockers.

Hypertension in T2DM

Blood pressure control is generally more important than the choice of individual drugs. First-line agents, according to evidence from clinical studies, are ACE inhibitors, ARBs, β-blockers, low-dose thiazide diuretics (in the elderly), furosemide, and calcium-channel antagonists [4–8, 42–45].

Ramipril has evidence-based support for its use in individuals with T2DM because of their high cardiovascular risk [74]. β-Blockers (in combination with low-dose aspirin) are indicated as secondary prevention for those who have had an MI, provided that no serious contraindications are present. Low doses of thiazide diuretics are useful in older people with diabetes, as this class of drugs has proven efficacy in preventing stroke and all-cause mortality in older people with hypertension [8].

α_1-Blockers may be used as part of combination therapy, especially in those with dyslipidemia (high triglycerides and low HDL-cholesterol levels) and prostatic hyperplasia. Indapamide is well tolerated and has no metabolic side effects. Spironolactone may also be of value, especially for elderly obese women with hypertension and hypervolemia with a low renin profile, even though evidence from large-scale randomized studies is so far lacking.

Combination therapy

Combination therapy is needed in most people with diabetes (especially those with T2DM) to achieve satisfactory blood pressure control [42–45]. It is often better to use low-dose combinations than to increase dosages of single agents, as side effects are commonly dose dependent. Potassium-sparing agents (spironolactone and amiloride) should not be combined with an ACE inhibitor, because of the increased risk for hyperkalemia.

Certain combinations of antihypertensive drugs have proved very safe and effective in low to moderate doses, e.g. ACE inhibitor plus diuretic, for example in the ADVANCE study [86]; calcium-channel antagonists plus ACE inhibitor, for example in the ACCOMPLISH study [87]; selective β_1-blocker plus calcium-channel antagonist; or β_1-blocker plus α_1-blocker. In many high-risk patients, a combination treatment could also be considered as initial therapy, especially when signs of target organ damage are present.

Special considerations in ethnic groups

Hypertension in diabetes represents a serious medical problem in many ethnic groups, such as African Americans [88]. In non-white European individuals, β-blockers and ACE inhibitors are often less effective at lowering blood pressure because the RAS is already underactive. Diuretics and calcium-channel antagonists are often drugs to be preferred, particularly in African Americans [89].

Outcome of treating hypertension in diabetes

It has long been recognized that effective treatment of hypertension can slow the progression of diabetic nephropathy, lowering UAE and decreasing the rate of fall of the GFR [90]. The assumptions that improved blood pressure control would improve cardiovascular and other prognoses in T2DM have been confirmed by the UKPDS [4]. In this study, tighter blood pressure control (averaging 144/82 mmHg) for over 8 years led to significant improvements in several outcomes, compared with less strict control that averaged 154/87 mmHg (Table 42.4). Interestingly, the most powerful effects were related to microvascular complications (retinopathy and nephropathy), although significant reductions were also seen in the risk of stroke (44%) and heart failure (56%). MI and peripheral vascular disease showed non-significant reductions (Table 42.4; Figures 42.7 and 42.8).

Table 42.4 Impact of stricter control of hypertension on diabetic complications, macrovascular disease, and diabetes-related deaths in T2DM.

Measure	Relative risk with tight control (mean, 95% confidence intervals)	*p*-Value
Diabetes-related deaths	0.76 (0.62–0.92)	0.19
All-cause mortality	0.82 (0.63–1.08)	0.17
Myocardial infarction	0.79 (0.59–1.07)	0.13
Stroke	0.56 (0.35–0.89)	0.013
Peripheral vascular disease	0.51 (0.19–1.37)	0.17
Microvascular disease	0.63 (0.44–0.89)	0.009

Source: Data from the UKPDS [4].

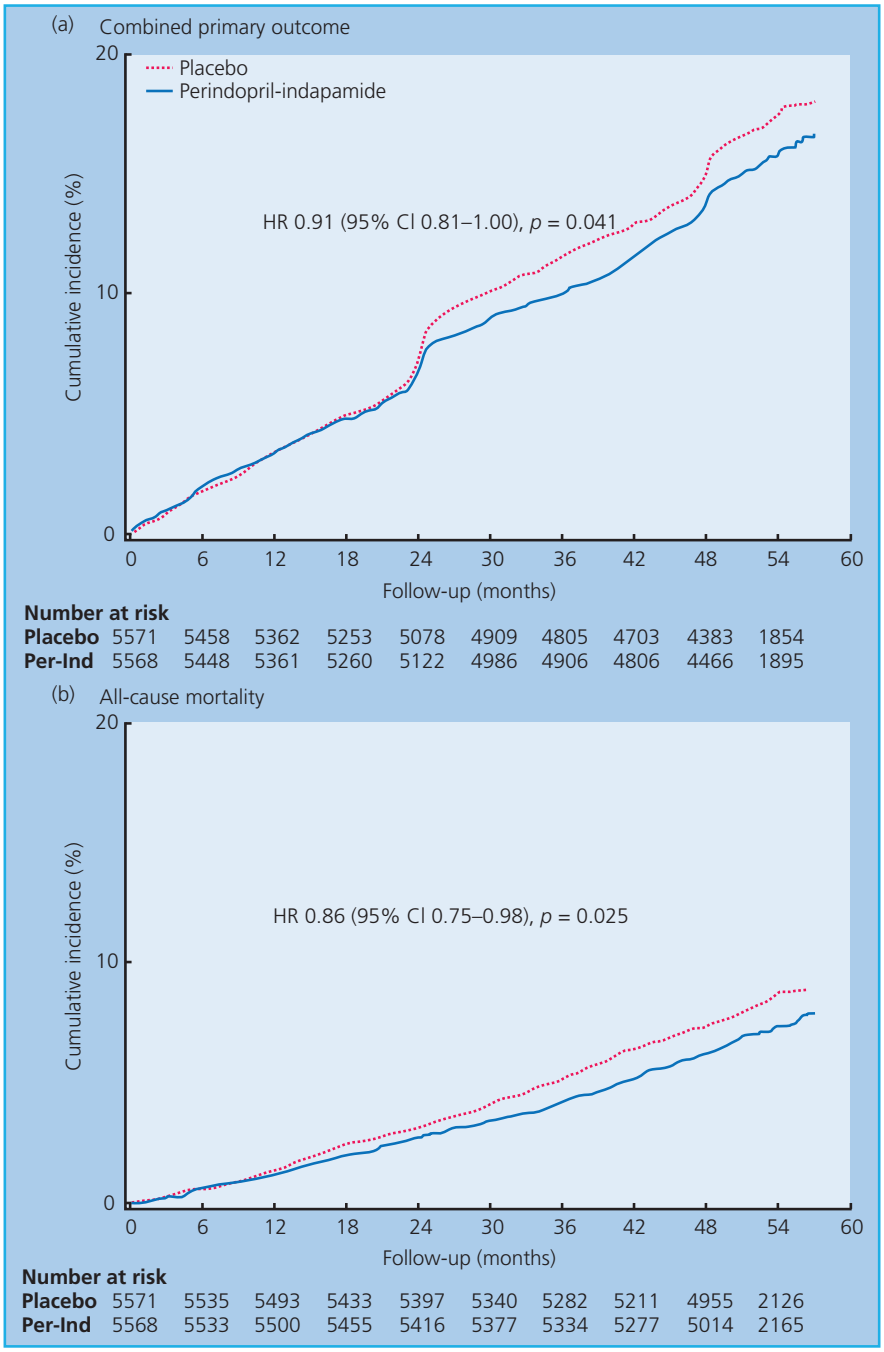

Figure 42.7 Kaplan–Meier curves for the primary outcome and all-cause mortality in the two study groups in the ADVANCE Trial [86]. The combined primary outcome were composites of major macrovascular and microvascular events. Major macrovascular events were cardiovascular death, non-fatal MI, or non-fatal stroke. Major microvascular events were new or worsening nephropathy or retinopathy.

Overall, therefore, tight blood pressure control has been proven to provide substantial benefits for people with hypertension and diabetes. Moreover, this treatment strategy seems to be cost-effective, at least according to the health economics analyses in the UKPDS [91]; however, it must be kept in mind that these benefits will not last if a continuous blood pressure reduction cannot be achieved long term, as shown by the 10-year follow-up of the UKPDS [92]. Antihypertensive treatment therefore has to be continued and not interrupted.

Conclusions

The diagnosis and treatment of hypertension are of great importance for the person with diabetes [42–45]. The treatment targets are demanding and require considerable effort from both people with diabetes and physicians, but the benefits are now undisputed.

New antihypertensive drugs are being introduced [93], but fewer now than previously. They have to prove themselves with

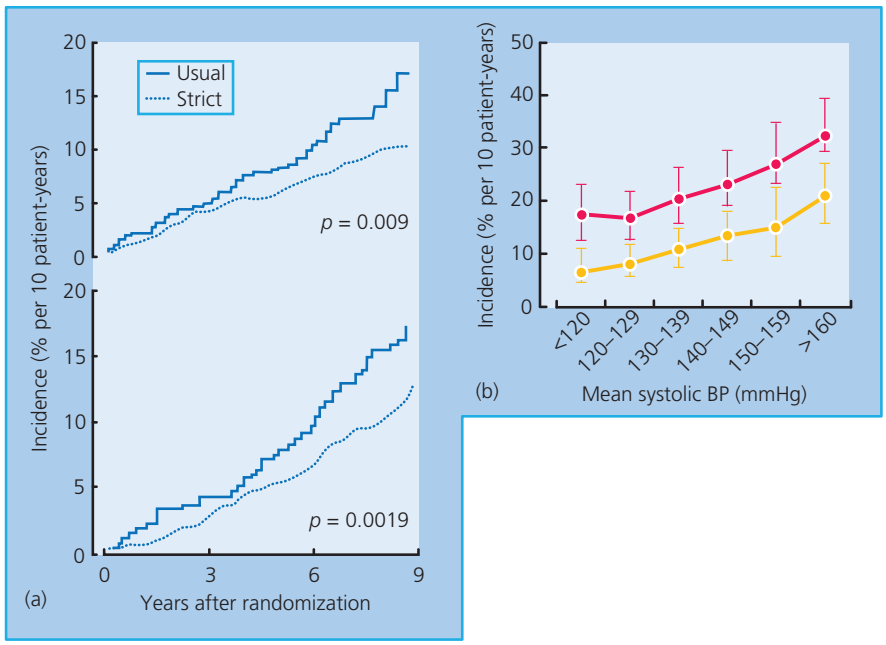

Figure 42.8 Treating hypertension improves the prognosis in T2DM. (a) Stricter blood pressure (BP) control (mean pressure 144/82 mmHg) significantly reduced the risks of both microvascular complications (top) and diabetes-related death (bottom), compared with less strict control (mean 154/82 mmHg). (b) Relationship between BP and rates of microvascular disease and MI. Lowering the BP progressively reduced the risk of microvascular complications, but there was no significant effect on MI. The red line represents MI and the yellow line represents microvascular complications. Source: UKPDS 1998 [4, 91]. Reproduced with permission from BMJ Publishing Group Ltd.

regard to both efficacy and tolerability. Even some antidiabetes drugs appear to lower blood pressure in addition to blood glucose [94, 95], but safety concerns are important.

In the future, the application of cardiovascular genomics may substantially change the approach to treating hypertension in diabetes [96], aiming at tailoring treatment according to the genotype of the individual.

In the recent ACCORD blood pressure study [97, 98], there was no significant difference in the primary composite outcome of cardiovascular events between participants randomized to achieve a systolic blood pressure goal below 120 mmHg versus below 140 mmHg, even though a reduction in stroke was noticed (secondary end-point) in the intensive arm. This means that the optimal blood pressure goal for people with hypertension and T2DM is still not fully established (Figure 42.9). According to the most recent meta-analysis, it was concluded that among people with T2DM, blood pressure lowering was associated with improved mortality and other clinical outcomes among those with baseline blood pressure of 140 mmHg and greater, but increased in those with baseline blood pressure below 140 mmHg. In younger people with shorter diabetes duration, fewer comorbidities, and higher estimated risk for stroke and renal events, the blood pressure goal could be at the lower range 130–140/80–90 mmHg [99].

Finally, it takes a multifactorial approach to address and to treat all major cardiovascular risk factors, not only blood pressure, to achieve lasting cardiovascular protection, as evidenced by the Steno 2 trial [100].

43 Diabetic Dyslipidemia and Risk of Cardiovascular Disease

Adie Viljoen,[1] Supriya Joshi,[1] and Anthony S. Wierzbicki[2]

[1] Lister Hospital, Stevenage, UK
[2] Guy's and St Thomas' Hospitals, London, UK

Key points

- The greatest long-term risk in diabetes is cardiovascular disease (CVD), with macrovascular disease being the cause of 80% of mortality.
- Epidemiological studies have established that glycemic control, nephropathy, and lipids are risk factors for CVD in type 1 diabetes mellitus (T1DM).
- Low-density lipoprotein cholesterol (LDL-C), high-density lipoprotein cholesterol (HDL-C), smoking, and hypertension are the principal risk factors in type 2 diabetes mellitus (T2DM).
- In T2DM, optimized glycemic control has modest effects in reducing CVD endpoints.
- Reduction of LDL-C with statins has consistently shown cardiovascular event reductions of 20% per 1 mmol/L LDL-C (or non-HDL-C) reduction.
- The dyslipidemia of T2DM is associated with elevated triglycerides, reduced HDL-C, and small, dense particles.
- Fibrates have shown a modest reduction in events in T2DM with monotherapy.
- Optimal control of all risk factors can reduce cardiovascular events and mortality in people with diabetes by 50%.

Introduction

An association between diabetes mellitus and heart disease was described more than a century ago. Two decades later, in 1906, it was hypothesized that this association was due to atherosclerosis. The importance of diabetes as a cardiovascular disease (CVD) risk factor became established following the Framingham Study, and was subsequently confirmed by other landmark studies [1, 2]. The magnitude of diabetes mellitus as a CVD risk factor is substantial, with the increase in cardiovascular risk being 2–4-fold. Many guidelines regard diabetes as a coronary heart disease (CHD) risk equivalent [3–5]. This concept is based originally on a Finnish cohort [6], which showed comparable risk of CVD outcomes such as myocardial infarction (MI) and CVD death, between those with type 2 diabetes mellitus (T2DM) for >10 years and people with established CVD. This was still apparent after adjusting for known risk factors such as age, sex, hypertension, total cholesterol, and smoking. The OASIS (Organization to Assess Strategies for Ischemic Syndromes) study showed that persons with diabetes with no previous CVD have the same long-term morbidity and mortality as those without diabetes with established CVD after hospitalization for unstable coronary artery disease [7]. However, there is wide variation in the rate of CVD in diabetes, which depends on the population studied, duration of diabetes, and existing risk factors [8, 9]. This equivalence has not been confirmed by a subsequent study and it also seems less valid in older people where those with existing CVD have a greater risk than individuals with diabetes but no CVD [9, 10] (Figure 43.1). Most of the literature that reports on CVD risk and diabetes considers only T2DM. However, people with type 1 diabetes mellitus (T1DM) are clearly at increased risk for CVD [11, 12]. In T1DM, the risk of premature CVD was increased with a cohort of 292 people with T1DM followed for 20–40 years; the cumulative mortality rate due to CHD was 35% by age 55 years [11]. A cohort study that examined 7479 individuals with T1DM registered in the UK General Practice research database showed that CVD occurred at a much younger age (10–15 years earlier) in persons with T1DM compared with the general population, the differences being greater in women [13, 14]. Hyperglycemia, hypertension, and microalbuminuria are the strongest risk factors associated with the development of CVD in T1DM, in addition to cigarette smoking, inflammation, and dyslipidemia. As T1DM mostly presents at an earlier age, it remains more difficult to assess and compare this, but rates of CVD are increased at all ages with prevalences being stated to be increased by 7.6-fold in women and 4.0-fold in men [13, 14]. Concomitant CVD risk factors also differ according to the type of diabetes [14]. The

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

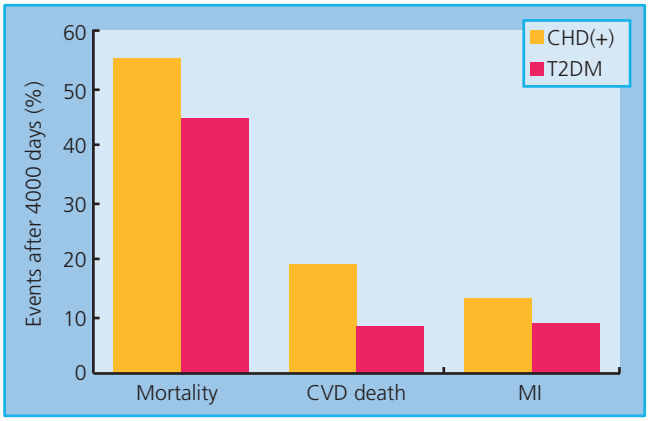

Figure 43.1 Cardiovascular risk in people with new-onset coronary heart disease ($n = 7414$) and those with new-onset diabetes ($n = 3477$) after 7 years' follow-up of the Tayside cohort study. Source: Data from Evans et al. 2002 [9].

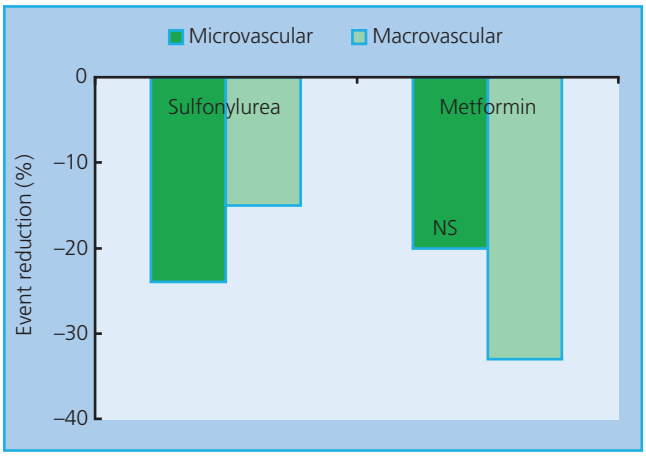

Figure 43.2 Results of the UK Prospective Diabetes Study (UKPDS) at 10 years' follow-up.

risk of CVD is notably increased in those developing diabetic nephropathy in T1DM. However, although the incidence of diabetic nephropathy has declined significantly, this has not been accompanied by a corresponding fall in CHD, indicating that other factors may be at play in the development of CHD in this population. Other markers of CVD risk in people with diabetes include diabetic retinopathy, autonomic neuropathy, erectile dysfunction, microalbuminuria, and proteinuria [15].

Most guidelines do not recommend formal CVD risk estimation in people with diabetes owing to the significant risk already present and term them to be a CVD-risk equivalent, i.e. a similar event risk to normoglycemic individuals with established CVD [16, 17]. This is an exaggeration for most persons with T2DM [9, 18]. Epidemiological or trial-based CVD risk calculators previously showed failures of calibration in individuals with diabetes. The Framingham algorithm underestimates risk in this group, while the UK Prospective Diabetes Study (UKPDS) overestimates CVD events [19, 20]. Recently, the UK QRISK2 calculator system has been updated with formally validated CVD risk tools based on 11,438 CVD events occurring in 48,889 persons with T2DM and 9724 persons with T1DM followed for 15 years [21]. QRISK2 is the only CVD risk calculation system available for T1DM. The NICE cardiovascular risk assessment guidelines (CG181) in the United Kingdom recommend the use of QRISK2 in T2DM but not T1DM, which they consider automatically high CVD risk after age 40 [22].

CVD risk factors in diabetes

Glucose

A risk continuum exists across a broad concentration range that incorporates individuals without diabetes, with the risk of CVD being the lowest when the fasting blood glucose is between 4 and 4.9 mmol/L [23–25]. Despite the well-established association between blood glucose and atherosclerosis, surprisingly few studies have been able to show an improvement in cardiovascular outcome by reduction in blood glucose. In T1DM, the Epidemiology of Diabetes Interventions and Complications (EDIC) [26] follow-up from the Diabetes Control and Complications Trial showed that glucose lowering was associated with a long-term benefit with regard to cardiovascular complications that became apparent only years after recruitment. In T2DM, 10-year follow-up data from the UKPDS with intensive glucose therapy showed long-term beneficial effects on macrovascular outcomes [27]. However, unlike the microvascular benefits, risk reductions for MI and death from any cause were observed only with extended post-trial follow-up (Figure 43.2). These results suggested that improved glucose control may result in a larger cardiovascular risk reduction in persons with T1DM than among those with T2DM, which is consistent with the results of one meta-analysis. Furthermore, neither the recent Action in Diabetes and Vascular Disease: Preterax and Diamicron Modified Release Controlled Evaluation (ADVANCE) [28] nor the Action to Control Cardiovascular Risk in Diabetes (ACCORD) [29] trials, each including in excess of 10,000 participants, could not show a significant beneficial effect on CVD outcome when targeting near-normal glucose levels in T2DM using an HbA_{1c} <48 mmol/mol (<6.5%) (Figure 43.3). More worrying was the finding in the ACCORD trial that near-normal glucose control was actually associated with a significantly increased risk of death from any cause and death from CVD [30].

Differential effects on CVD outcomes in recent meta-analyses have recently been reported with different members of the thiazolidinedione class of oral hypoglycemic drugs. The PROspective pioglitAzone Clinical Trial In macroVascular Events (PROACTIVE) study with pioglitazone in 5138 people with T2DM showed no effect on the primary composite CVD endpoint ($p = 0.10$) but did show a 16% reduction ($p = 0.03$) in the secondary CVD outcomes endpoint but an increase in heart failure admissions [31]. Analyses of the RECORD (Rosiglitazone Evaluated for Cardiac Outcomes and Regulation of Glycemia in Diabetes) trial

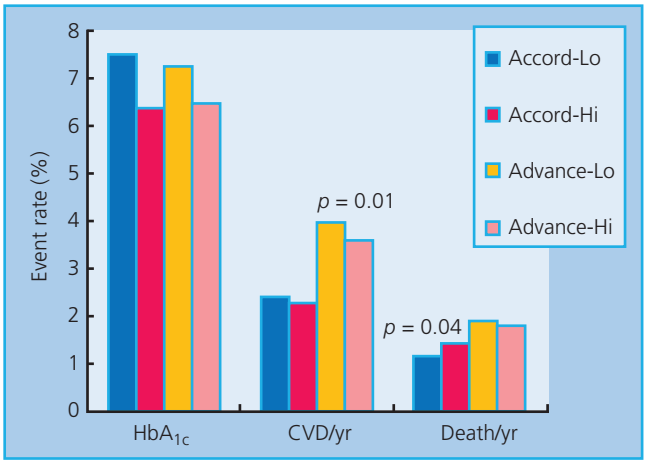

Figure 43.3 Effects of improved diabetes control to an HbA_{1c} <48 mmol/mol (<6.5%) in the ACCORD and ADVANCE studies. Hi refers to conventional treatment and lo refers to intensive glycemic control with lower achieved HbA_{1c}. Source: Data from ACCORD Group et al. 2008 [29]; ADVANCE Collaborative Group et al. 2008 [28].

in 4447 participants with T2DM eventually found no evidence for an increased CVD event rate with rosiglitazone [32]. The final conclusion has been that thiazolidinediones do not increase CVD events but do have adverse effects on heart failure admissions [33] and bone metabolism [34]. The controversy prompted by thiazolidinediones has led to all new hypoglycemic therapies having to be assessed in CVD outcomes trials to demonstrate no increase in CVD events. Recently, the EMPA-REG outcome study of the sodium-glucose-lithium transporter type 2 inhibitor empagliflozin in 7034 people with type 2 diabetes and established CVD showed a 14% reduction ($p<0.001$) in CVD events and a 32% reduction in overall mortality in the context of an overall 2 mmol/mol (0.35%) reduction in HbA_{1c} [35]. Multiple other outcomes trials are under way that should improve our understanding of the problem of glycemic control and CVD [36].

Dyslipidemia

As opposed to hyperglycemia, targeting dyslipidemia has proven much more effective in preventing the macrovascular complications of diabetes. However, for many years the benefits of intervention on lipoproteins as CVD factors in diabetes were uncertain. The principal reason was that people with diabetes were excluded from trials of lipid-lowering therapies. Hence virtually no data exist from early studies with bile acid sequestrants, fibrates, or nicotinic acid.

The reasons for excess CVD risk in diabetes are numerous and varied and in part relate to the lipid abnormalities seen in diabetes. Enhanced glycation of lipoproteins has direct effects on lipoprotein metabolism as these glycated lipoproteins are handled differently by lipoprotein receptors, particularly of the scavenger group, thus promoting atherogenesis [37]. Enhanced glycation also amplifies the effects of oxidative stress on lipoproteins, a feature of both T1DM and T2DM [38]. The term diabetic dyslipidemia refers to the lipid abnormalities typically seen in persons with T2DM and is synonymous with atherogenic dyslipidemia [39, 40]. It is characterized by elevated triglyceride-rich remnant lipoproteins (routinely measured as hypertriglyceridemia), small, dense LDL (sdLDL) particles, and low HDL cholesterol (HDL-C) concentrations. Guidelines have begun to recognize that errors in the calculation of LDL-C concentrations are significant especially in people with T2DM [41], fasting is often difficult for these individuals, and that even directly-measured LDL-C underestimates CVD risk in T2DM [42]. Hence they increasing favor the use of non-HDL-C (difference between total cholesterol and HDL-C) in people with diabetes as this has better predictive value and is less subject to error [16, 17, 22]. Several factors are likely to be responsible for diabetic dyslipidemia, including insulin effects on liver apolipoprotein (Apo) production, downregulation of lipoprotein lipase (LPL) as opposed to hepatic lipase, increased cholesteryl ester transfer protein (CETP) activity, and peripheral actions of insulin on adipose and muscle.

LDL cholesterol

LDL-C is identified as the primary target of lipid-lowering therapy. Analysis of the UKPDS showed that LDL-C was the strongest risk factor for CHD in this population and HDL-C was the second strongest [43]. Until relatively recently, the recruitment of people with diabetes to randomized controlled trials of lipid-lowering therapy was rare or they were specifically excluded. Only recently have studies been performed that recruited large groups of individuals with T2DM. There have still been no specifically designed randomized controlled CVD outcome studies of lipid-lowering drugs in T1DM.

Statins

The first study with statins to demonstrate their potential effectiveness was the Scandinavian Simvastatin Survival Study (4S) [44].The 4S included only 202 participants with T2DM out of 4444 yet simvastatin therapy was associated with a 55% reduction in major CHD (fatal and non-fatal CHD) ($p = 0.002$) compared with 32% in those without diabetes [45]. It was suggested that the absolute benefit of cholesterol lowering in people with diabetes may be greater than that in those without diabetes because of their higher absolute risk of CVD. This notion was later confirmed in several other studies that also recruited subgroups with T2DM [46].

A number of studies have subsequently been specifically designed to investigate the effects of statins in persons with T2DM. The Collaborative Atorvastatin Diabetes Study(CARDS) [47] randomized participants to atorvastatin 10 mg, which reduced LDL-C by 40%. It included persons with T2DM allied with one or more other CVD risk factors (e.g. uncontrolled hypertension and/or microalbuminuria) but without prior overt CVD. The study was terminated 2 years prematurely, showing unexpected early benefit of a 37% reduction in CVD events. However, the similarly designed Atorvastatin Study for Prevention of Coronary Heart Disease Endpoints in Non-Insulin-Dependent Diabetes Mellitus

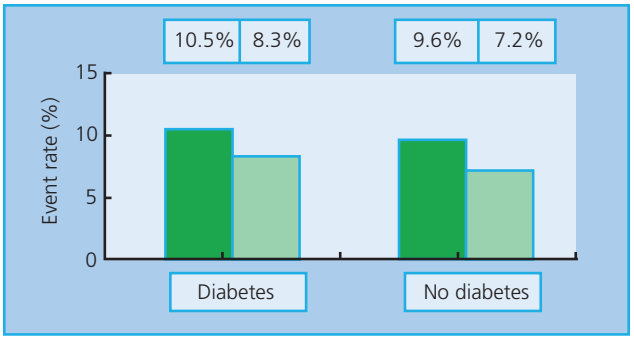

Figure 43.4 Comparison of the effects of reducing LDL-C with statins on CVD events in people with or without T2DM [51].

(ASPEN) study, also using atorvastatin 10 mg predominantly in people without CVD, showed only a non-significant 15% reduction in CVD events [48].

The Heart Protection Study (HPS) had a prespecified subgroup analysis for 5963 people with diabetes (29%) [49] and used simvastatin 40 mg. This reduced LDL-C by 33%, resulting in a 31% reduction in CVD endpoints. Further studies explored other populations with T2DM. However, treatment with atorvastatin 20 mg in people with T2DM and end-stage renal disease requiring dialysis (4D study) reduced LDL-C by 41% but showed a non-significant 8% reduction in CVD endpoints [50]. Hence the benefits of statin therapy seem to occur early in disease in diabetes. Overall, the accumulated evidence therefore supports the use of statin therapy to reduce CVD risk in individuals with diabetes. The Cholesterol Treatment Trialists' individual patient-based meta-analysis evaluated the efficacy of cholesterol-lowering therapy in 18,686 people with diabetes in 14 randomized trials of statins, including a small subgroup of 600 patients with T1DM. It reported a 9% proportional reduction in all-cause mortality and a 21% proportional reduction in major vascular events per 1 mmol/L reduction in LDL-C [51], similar to that in people without diabetes (Figure 43.4).

Other LDL-C-reducing drugs

There are only a few studies examining CVD outcome in people with diabetes for other drugs that reduce LDL-C. The effects of colesevelam on lipids and diabetes have been assessed in three randomized trials. All three trials showed that colesevelam reduced LDL-C by 12–16% and improved HbA_{1c} by 0.5%, sufficient for it to gain a US license as an oral antidiabetes agent [52].

Ezetimibe, which reduces gut cholesterol absorption through the Niemann-Pick-C-1-like protein-1 (NPC1L1) system, reduces LDL-C by 20–25% but has little effect on other lipid fractions. The IMProved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE-IT) study recruited 18,144 individuals with acute coronary syndromes of whom 27% had T2DM [53]. After initiation on baseline simvastatin 40 mg therapy, participants were randomized to ezetimibe or placebo. Further temporary up-titration to 80 mg simvastatin to achieve an LDL-C <2 mmol/L occurred in 27% of the statin-only group and 6% of the statin–ezetimibe group. Ezetimibe therapy reduced LDL-C by a net 0.41 mmol/L, resulting in a 6% reduction in CVD events after 7 years ($p = 0.02$) [53]. The overall absolute reduction in risk over 7 years was 2.0% (34.7 vs. 32.7%), but better results were seen in the T2DM subgroup, where the risk reduction was 5.5% (45.5 vs. 40%). Hence ezetimibe therapy is likely to be effective in persons with T2DM.

A number of studies have used ezetimibe in combination with statins. People with diabetes were excluded from the Simvastatin Ezetimibe Aortic Stenosis (SEAS) study [54]. The Simvastatin Heart and Renal Protection (SHARP) study examined primary prevention in 9270 people with chronic kidney disease (3023 on dialysis), of whom 23% had T2DM [55], randomized to a combination of simvastatin 20 mg and ezetimibe 10 mg or placebo. Combination therapy reduced LDL-C by 0.85 mmol/L, reducing CVD outcomes by 17% after a median follow-up of 4.9 years. Results were similar in the diabetes and non-diabetes subgroups.

Non-HDL-C and ApoB

Although the association of LDL-C with CVD risk is well known, measurement of LDL-C does not include all the atherogenic lipoproteins [56]. Non-HDL-C is calculated by subtracting HDL-C from total cholesterol. It does not require fasting samples as it is not dependent on the measurement of triglyceride levels. Non-HDL-C content and ApoB are indices of total atherogenic particle burden. They are better markers of CVD risk than LDL-C alone, especially in patients receiving statin therapy [57], although controversy exists about which is better [58]. The Emerging Risk Factors Collaboration (ERFC) analyzed data from 302,430 participants without CVD from 68 studies with 18,368 CVD outcomes over a median follow-up of 10.4 years and found that non-HDL-C was a better predictor of CVD risk than directly measured LDL-C [42]. However, in a subset of 37 studies containing 165,544 patients, adding ApoB to LDL-C added little to risk prediction [59].

LDL subfractions

The LDL class comprises a heterogeneous population of particles [60]. LDL is heterogeneous with respect to lipid composition, charge, density, and particle size and shape [61]. sdLDL particles may be more atherogenic than large particles as they are more readily oxidized and glycated [62]. Large numbers of studies, including the Quebec Cardiovascular study [63], have confirmed the association of sdLDL with CVD independent of LDL-C, triglyceride, and the total cholesterol : HDL-C ratio. Biochemical assays exist for sdLDL using either precipitation allied with spectrophotometric detection or nuclear magnetic resonance spectroscopic measurement of particle size and number [64]. However, no prospective studies have specifically examined whether altering particle size profiles results in benefits on CVD events although analysis of the VA-HIT study does suggest some role for this mechanism [65], although particle numbers (analogs of non-HDL-C, ApoB) are better. Even with effective LDL-C treatment,

the residual risk of further CVD remains high, emphasizing the potential importance of improving other lipid abnormalities commonly observed in these individuals [56, 66].

Triglycerides

Triglycerides (also referred to as triacylglycerols) are formed from a single molecule of glycerol combined with three fatty acids and represent a heterogeneous group of molecules that are measured collectively [67]. The two main sources of plasma triglycerides are exogenous (i.e. from dietary fat) carried in chylomicrons produced by the gut and endogenous sources carried in very low-density lipoprotein (VLDL) particles produced by the liver. These particles are hydrolyzed by LPL to release free fatty acids under the control of an activator, apolipoprotein C-2 (ApoC-2), or inhibited by the action of ApoC-3 [68]. The reason for the elevated triglycerides in diabetes is complex [69]. Defects in insulin action and hyperglycemia can lead to parallel changes in plasma lipoproteins in persons with diabetes, as is seen in acute-presenting poorly controlled T1DM. Alternatively, as often occurs in T2DM, obesity and insulin resistance lead to secondary lipid abnormalities [70, 71]. Hepatic VLDL particle and hence its ApoB core component production are increased in T2DM [56], secondary to increased free fatty acid flux to the liver as a consequence of increased adipose tissue lipolysis occurring a result of insulin resistance and/or insulin deficiency. Several meta-analyses have found, however, that triglycerides are an independent risk factor for CHD [72–74]. As high serum triglyceride levels are associated with abnormal lipoprotein metabolism, and co-segregate with other CVD factors including obesity, insulin resistance, diabetes, and low levels of HDL-C, it is difficult to establish them as an independent CVD risk factor, and studies can give conflicting results [42, 72]. Some causes of hypertriglyceridemia have no apparent effect on atherosclerotic vascular disease, making it difficult to prove that elevated triglycerides are a risk factor for it [75].

Statins and triglycerides

Statins form the mainstay of lipid management based their efficacy in lowering LDL-C. Statins upregulate LDL receptor (LDLR) expression. The LDLR can act as a receptor for ApoE at low affinity and for apolipoprotein B-100 (ApoB) at high affinity. Triglyceride-rich particles contain many molecules of ApoE but only one ApoB. Thus statins can reduce triglyceride levels through their effect on LDLR expression and its ApoE action in clearing triglyceride-rich particles. This effect on triglycerides can be quantified as being related to the efficacy of the statin in reducing LDL-C and to the baseline triglyceride level [76].

Fibrates

Fibrates act on the nuclear receptor peroxisome proliferator-activated receptor alpha (PPAR-α) to increase lipoprotein lipase activity and reduce ApoC-3 and may, in a drug-specific manner, also increase HDL-C or decrease fibrinogen [77]. They reduce non-HDL-C but either have no effect on LDL-C levels (gemfibrozil) or produce a slight reduction (fenofibrate). Clinical trials of these drugs have reported mixed results in general and most early trials recruited only a few individuals with diabetes [78, 79].

The Veterans Affairs High Density Lipoprotein Cholesterol Intervention Trial (VA-HIT) recruited 2531 men with established CVD with low HDL-C (0.95 mmol/L) and moderate LDL-C (2.90 mmol/L), of whom 25% had T2DM. Gemfibrozil treatment had no effect on LDL-C, decreased triglycerides by 31%, and increased HDL-C by 8%, leading to a 22% reduction in CVD events [80]. The effects of gemfibrozil correlated with changes in HDL-C in the trial but not triglycerides [81]. Gemfibrozil therapy was more effective in people with T2DM as they showed a 32% relative risk reduction versus 18% in the non-diabetes group [82]. However, the enthusiasm for fibrate use has been considerably damped by results of the Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) study [83]. This trial randomized 9795 people with T2DM, mostly without existing CVD, to fenofibrate (200 mg daily) or placebo. Fenofibrate produced a 12% LDL-C reduction, a 29% triglycerides reduction, and a 5% increase in HDL-C, resulting in a non-significant 11% reduction in the primary end-point of CHD events ($p = 0.16$). However, the similar 11% reduction in the secondary CVD events was significant ($p = 0.04$). The study was confounded by asymmetric statin drop-in with many more participants in the placebo arm being initiated on statin therapy during the trial (17%) than those in the fenofibrate arm (8%) [78]. Further analysis of the FIELD study showed benefits of fibrate therapy on microvascular endpoints, including reduced retinopathy complications and treatments, amelioration of diabetic proteinuria, and a reduction in amputation rates for peripheral arterial disease.

As statins are accepted first-line therapy for lipids in T2DM, the secondary role of fibrates is unclear. The ACCORD lipid study recruited 5518 participants with T2DM already treated with simvastatin 20 mg with moderate dyslipidemia. Fenofibrate therapy was associated with a 19% reduction (0.5 mmol/L) in LDL-C, a 26% reduction in triglycerides, and an 8% increase in HDL-C. These lipid changes were associated with an overall non-significant 8% reduction in CVD events. Subgroup analysis of the high triglyceride (>2.3 mmol/L), low HDL-C (<0.80 mmol/l) suggested a 29% reduction in CVD events with fibrate therapy. As in FIELD, fibrate therapy in ACCORD was associated with a reversible 13% rise in creatinine (with no increase in renal adverse outcomes and benefits on diabetic retinopathy). It is difficult to compare fibrate trials as they seem to give heterogeneous results depending on the compound used, with the greatest benefits with gemfibrozil. However, gemfibrozil interacts with statins to increase rates of myositis, so is not commonly used. Fibrates have not been shown to reduce all-cause or CVD mortality, but meta-analyses suggest that they do reduce non-fatal MI [84, 85] (Figure 43.5).

Omega-3 fatty acids

Omega-3 fatty acids reduce triglycerides in a dose–proportional manner [86] through actions at the GP120 receptor that links to both anti-inflammation and PPAR-γ pathways [87]. They have little effect on HDL-C and may increase LDL-C through a

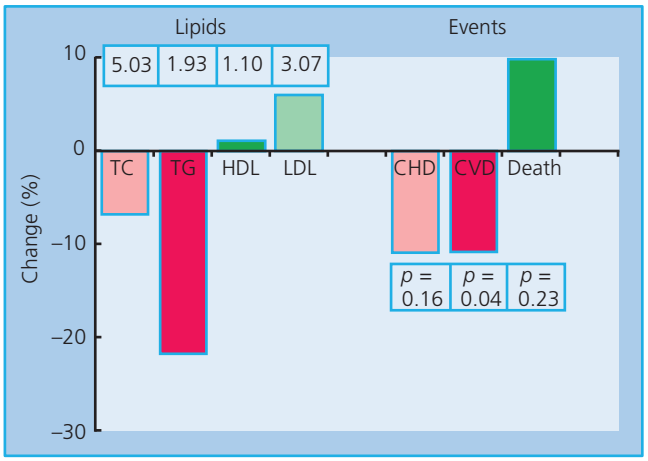

Figure 43.5 Reductions in mortality, CHD, and cardiovascular events with fibrate therapy [84, 85].

redistribution effect. Early dietary and intervention trials of low-dose omega-3 fatty acid acids suggested that they might have CVD benefits in some cases but the results could not be reproduced [88]. More recent clinical trials of omega-3 fatty acid therapy in 12,536 people with impaired glucose tolerance and T2DM failed to show any benefits for this intervention [89], and meta-analyses continue to find no evidence for their CVD benefit [88, 90].

Other triglyceride-reducing agents

Hypoglycemic agents may also have an effect on triglyceride concentrations due to the peripheral actions of insulin on adipose and muscle or via their action on LPL. In poorly controlled T1DM and even ketoacidosis, hypertriglyceridemia and reduced HDL-C are seen to occur and this is most often corrected with insulin therapy. In T2DM, metformin [91], sulfonylureas, acarbose, thiazolidinediones, dipeptidylpeptidase inhibitors [92], and glucagon-like peptide-1 (GLP-1) receptor agonists [93] all show modest reductions in triglycerides that correlate with glycemic control [94, 95]. However, pioglitazone and rosiglitazone have distinctly different effects on PPARs and lipid profiles [77, 96]. Pioglitazone is associated with a reduction in triglycerides, unlike rosiglitazone. Efforts have been made to unite the lipid- and glucose-lowering effects of PPARs in one molecule. Aleglitazar, a dual PPAR agonist (PPAR-α/γ), reduced HbA_{1c} (PPAR-γ), but also reduced triglycerides and LDL-C and increased HDL-C (PPAR-α). However, the AleCardio study in 7226 people with T2DM and acute coronary syndrome was stopped early as it failed to show any benefit of aleglitazar despite reductions in HbA_{1c} and benefits in lipid profiles [97]. None of the PPAR-α/γ class have shown an adequate safety or efficacy profile. Other new diabetes drugs are currently being assessed in CVD outcomes studies [98].

A number of other interventions exist that reduce triglycerides secondary to their action in reducing weight [99]. Orlistat has been shown to prevent progression to diabetes by 37% in the 3305 patients in the XENical in the Prevention of Diabetes in Obese Subjects (XENDOS) study [100]. Other weight-loss interventions, including sibutramine [101] and rimonabant [102], have shown adverse effects on CVD outcomes or on mental health and have been withdrawn. High-dose GLP-1 receptor agonists have recently been approved for weight reduction.

HDL-C

Analogous to LDL, the HDL class also comprises a heterogeneous population of particles [56, 103]. The inverse relationship between HDL-C levels and atherosclerotic CVD provides the epidemiological basis for the widely accepted hypothesis that HDL is atheroprotective, as it has several distinct but potentially overlapping atheroprotective functions. [104]. These include reverse cholesterol transport and reductions in oxidative stress and innate immune inflammation. More HDL-associated proteins are involved in immune/inflammatory functions than in lipid transport and metabolism, suggesting the fundamental role for HDL in innate immunity [105]. Reductions in HDL-C levels occur in T2DM secondary to insulin resistance and an increase in renal clearance of small dense HDL (sdHDL) particles as a consequence of overactivity of cholesterol ester transfer protein and hepatic lipase allied with inhibition of lipoprotein lipase activity and reduced LDLR uptake of triglyceride-rich lipoproteins [56]. In contrast, in T1DM HDL-C levels are normal or even increased [106]. However, HDL reverse cholesterol transport function is impaired in both T2DM [107] and T1DM [108]. The role of intervention in HDL-C levels to improve CVD outcomes is far from clear, although many drugs are under development for this indication [109].

HDL infusion studies

Some HDL therapies may reduce CVD without actually changing plasma HDL-C concentrations although they accelerate HDL particle and cholesterol turnover [110]. A pilot study of five infusions at weekly intervals of a hyperfunctional ApoA-I Milano produced significant regression of coronary atherosclerosis after 3 months in an intravascular ultrasound study in normoglycemic individuals [110]. However, infusion of similar quantities of exogenous native HDL particles failed to show any benefit [111].

Niacin

Niacin (nicotinic acid) raises HDL-C, reduces triglycerides and LDL-C, and has been referred to as the "broad-spectrum" lipid drug [112] through actions on adipose tissue receptors, inhibition of hepatic diacylglycerol acyl transferase, and HDL holoparticle receptors [113]. Niacin has been hampered by its side effects, particularly flushing and hyperglycemia. Niacin was the first lipid-lowering agent to show a significant reduction in CVD events but not mortality. The Coronary Drug Project (CDP) randomized 3908 men with previous MI to either 3 g niacin or placebo [114]. Niacin therapy reduced CVD events by 22% but there was no effect on mortality. However, in the 15-year post-trial follow-up, mortality was reduced by 11% in the niacin-treated group [115]. The CDP showed that niacin was equally effective in reducing CVD outcomes in participants with hyperglycemia

Table 43.1 Effects of different cardiovascular therapies on lipids and other cardiovascular risk factors and endpoint trial evidence of effects in prevention of diabetes and CVD.

	Component of the cardio-metabolic syndrome change (%)

CVD, cardiovascular disease; DM, diabetes mellitus; SBP, systolic blood pressure; TG, triglycerides.

(now classified as T2DM) as normoglycemia [116] but also that it increased new-onset T2DM by 16% [117]. Large outcome studies have now reported on the efficacy of niacin in the context of background statin therapy. The Atherothrombosis Intervention in Metabolic Syndrome with Low HDL/High Triglycerides: Impact on Global Health Outcomes (AIM-HIGH) trial recruited 3414 dyslipidemic high-risk individuals, including 34% with T2DM. The trial protocol allowed adjustment in-trial of LDL-C-lowering therapy including (unbalanced) addition of ezetimibe. Niacin treatment reduced LDL-C by 7% (0.14 mmol/L) and triglycerides by 20% and increased HDL-C by 16% with no effect on CVD outcomes, which led to the termination of the trial after 3 years [118]. The Heart Protection Study 2—Treatment of HDL to Reduce the Incidence of Vascular Events (HPS2-THRIVE) trial recruited 25,673 high-risk persons with prior CVD or diabetes (32%) with prior adjustment of LDL-C to <2 mmol/L with ezetimibe. Niacin–laropiprant reduced LDL-C by 16% (0.25 mmol/L) and increased HDL-C by 14% (0.16 mmol/L) but had no effect on CVD events [119]. Niacin therapy increased the risk of serious adverse events, including myositis, bleeding, infection, and increased rate of diabetes [119, 120]. Niacin–laropiprant has been withdrawn and guidelines discourage the use of niacin in diabetes.

CETP inhibition

CETP transfers cholesterol in exchange for triglyceride from HDL particles to VLDL particles. Individuals with CETP deficiency show very high plasma HDL-C and low plasma LDL-C and may have a reduced risk of CVD [56]. A number of therapies have been developed to inhibit CETP activity. The first CETP inhibitor, torcetrapib, increased HDL-C by 72% and decreased LDL-C by 25% in the Investigation of Lipid Level Management to Understand Its Impact in Atherosclerotic Events (ILLUMINATE) trial, which had recruited 15,067 participants at high risk of CVD [121]. This trial was terminated early owing to a 25% increase in CVD events and a 40% increase in CVD deaths in the torcetrapib arm, likely related to the hypertensive off-target effects of this particular molecule [121]. Another CETP inhibitor, dalcetrapib, had lesser effects on lipid profiles, increasing HDL-C by 30% and with no effect on LDL-C. The dal-OUTCOMES study, which recruited 15,871 individuals with acute coronary syndrome, showed no benefit of this drug and was terminated early on grounds of futility [122]. There was a slight reduction in triglyceride levels but no change in LDL-C levels. Two other CETP inhibitors, anacetrapib and evacetrapib, with HDL-C-increasing effects similar to that of torcetrapib but no blood pressure effects, remain in development [109].

Guidelines and lipids in diabetes

The major guidelines agree that diabetes is a major risk factor for CVD but differ in whether they classify diabetes as a CVD risk equivalent, thus mandating early lipid-lowering treatment. Most state or imply treatment from the age of 40 years [16] or after a 10-year history of diabetes if microvascular complications are present [17]. The UK NICE guidelines suggest the use of the QRISK2 calculator in T2DM with a 10% 10-year risk threshold similar to that for persons without diabetes [22].

All guidelines agree that LDL-C reduction is the first priority for reducing CVD risk in diabetes and that this should be done through high-intensity statin therapy [16, 17, 22]. The newest guidelines do not have LDL-C targets but recommend treatment with high-intensity statin (e.g. atorvastatin 20 mg or more) based on other underlying CVD risk factors [16, 22], while the European guidelines still suggest an LDL-C target of 2.0–2.5 mmol/L [17]. Guidelines do not recommend treatment to address triglycerides or HDL-C apart from statins based on current trial evidence, but comment that both hypertriglyceridemia and low HDL-C increase underlying CVD risk.

Future drug developments and drug targets

Drugs that target the exogenous and or the endogenous pathways of cholesterol metabolism may prove to be useful in the future [109]. These include additional therapeutics for LDL-C, for example, proprotein convertase subtilisin kexin type 9 (PCSK-9) inhibitors [123], thyroid mimetics (thyroid receptor β-agonists, e.g. eprotirome or derivatives), antisense oligonucleotides to ApoB (e.g. mipomersen), or microsomal transfer protein inhibitors (MTPIs) (e.g. lomiptapide); and triglycerides, for example, antisense oligonucleotides to ApoC-3, novel PPAR agonists, MTPIs, diacylglycerol acyl transferase-1 inhibitors, and HDL-C, for example, mimetic peptides; HDL delipidation strategies; or CETP inhibitors. Gene therapy using alipogene tiparvovec for lipoprotein lipase deficiency, a rare lipid disorder associated with T2DM caused by chronic pancreatitis, has now been licensed [124].

The most likely innovation in lipid management in diabetes is likely to be the introduction of the injectable anti-PCSK-9 antibody therapies. PCSK-9 is a recently discovered protein that regulates LDL receptor expression. Autosomal dominant activating mutations in PCSK-9 cause familial hypercholesterolemia (and thus increased CVD events) whereas inactivating mutations have been shown to be associated with 0.3–0.5 mmol/L reductions in plasma LDL-C and 70–80% lifetime reduced risks of CHD events [123]. Polymorphisms in PCSK-9 are associated with CVD risk in T2DM [125]. Antibodies to PCSK-9 reduce plasma LDL-C by 50–65% including in people with T2DM [126].

Given the importance of atherosclerosis as a cause of morbidity and mortality in diabetes, numerous therapeutic approaches are under development, but all will require systematic evaluation through endpoint clinical trials to validate their effects in animal models or on surrogate markers [127].

Conclusions

CVD is a very common complication of diabetes, with up to 80% of all people with diabetes dying from macrovascular complications. Lifestyle intervention is both effective and paramount to prevent and treat diabetes and its dyslipidemia. Statins have revolutionized preventive cardiovascular medicine and this has formed the foundation of therapeutic lipid intervention. The abnormalities in lipids and lipoproteins represent only one factor among several that are responsible for the increased risk in persons with diabetes (Table 43.1) and therefore multifactorial intervention is required. Trials suggest that multifactorial approaches to CVD risk in diabetes can reduce events and mortality by 50% [128, 129] (Figure 43.6).

Key points

- Ischemic heart disease (IHD) is the most common cause of death in people with diabetes.
- Glucose lowering is important for the prevention of microvascular disease in diabetes; its impact on IHD is less clear.
- Lowering low-density lipoprotein (LDL) cholesterol is highly effective in lowering cardiovascular event risk in persons with diabetes; the LDL cholesterol goal in persons with type 2 diabetes mellitus (T2DM) and also in those with type 1 diabetes mellitus (T1DM) who have end-organ damage is <70 mg/dL.
- Treating arterial hypertension also is important; currently a blood pressure <140/90 mmHg is recommended for people with diabetes, with <130/80 mmHg as an optional target especially for younger individuals.
- Aspirin is recommended in people with diabetes who already have established cardiovascular disease (CVD) or otherwise are at a >10% risk of atherosclerotic CVD over 10 years.
- Screening for coronary heart disease in asymptomatic individuals with diabetes is not generally recommended.

Epidemiology

Ischemic heart disease (IHD) is by far the leading cause of death in people with diabetes; about half of them will eventually die from IHD [1]. Understanding the pathophysiological links between diabetes and coronary heart disease and gaining a thorough knowledge of the therapeutic options to prevent IHD in persons with diabetes are therefore of the utmost importance.

The close link between diabetes and IHD has long been recognized. In a 1998 landmark study [2], Haffner et al. reported that individuals with diabetes who had not had a previous acute myocardial infarction (MI) were at the same risk of future IHD events as persons who had a prior MI but not diabetes. This observation, together with others, led to the concept of diabetes as a coronary heart disease risk equivalent [3].

This concept has been extremely important in establishing awareness of the very high-risk status of people with diabetes. Indeed, in current European prevention guidelines, the same aggressive approach to lipid lowering is recommended for persons with type 2 diabetes mellitus (T2DM) as is recommended for those with established cardiovascular disease (CVD) [4]. More recent research, however, including our own, revealed that the concept of diabetes as an IHD risk equivalent is an oversimplification [3, 5–7]. Not all people with diabetes are at the same risk of IHD. There are persons with diabetes, especially those with brief diabetes duration, who are at a much lower risk of future cardiovascular events than persons with established coronary heart disease, whereas other people with diabetes, in particular those with long diabetes duration and multiple other cardiovascular risk factors, are at a very much higher risk of cardiovascular events.

In this context, it is also important to consider that in persons with diabetes without a history of previous cardiovascular events, the prevalence of atherosclerotic disease is high [8]; subclinical atherosclerotic disease therefore may account for a large proportion of cardiovascular risk that has been falsely attributed to diabetes per se. When we characterized angiographically the coronary artery state both in people with and without T2DM, we found that those with diabetes who did not yet have significant coronary atherosclerosis were at a much lower risk of future cardiovascular events than those with established significant coronary artery disease (CAD) at angiography [5–7]. Importantly, cardiovascular risk in our investigation was extremely high in individuals with a combination of T2DM and significant coronary atherosclerosis at angiography.

[a] C.H.S. and K.V. contributed equally to this work.

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

This is a common result of all investigations addressing the individual and combined effects of diabetes and previous coronary IHD on future cardiovascular event risk: the cardiovascular prognosis of people with a combination of diabetes and CAD is extremely unfavorable [3]. An important difference between the moderate risk individual with diabetes who did not have significant CAD and the very high-risk patients with a combination of diabetes and CAD in our investigations and also in other was the longer diabetes duration of the latter. CAD typically appears to be present in individuals with long-standing diabetes and is responsible for a dismal cardiovascular prognosis in these subjects. This stresses the utmost importance of efficacious intervention to reduce the development of IHD in persons with diabetes to keep their cardiovascular risk moderate.

Not only diabetes is associated with an increased risk of IHD, but prediabetes is also closely linked to increased cardiovascular risk. Research at our institution showed that individuals with impaired glucose tolerance have a higher prevalence of coronary atherosclerosis at angiography [9] and that their risk of future cardiovascular events is significantly higher than that in persons with normal glucose tolerance [10]. Indeed, cardiovascular risk in people with impaired glucose tolerance is intermediate between those with normal glucose tolerance and those with T2DM [10].

From a clinical point of view, it is desirable to obtain objective risk estimations in persons with diabetes. For example, the recently published pooled cohort equations can also be used for estimating cardiovascular risk in persons with diabetes [11]. Using these equations, one could estimate a 20% 10-year risk of atherosclerotic CVD in a 58-year-old white man with a total cholesterol level of 190 mg/dL and high-density lipoprotein (HDL) cholesterol of 38 mg/dL, who receives treatment for high blood pressure and has a systolic blood pressure of 135 mmHg and no smoking history. This compares with a 4.8% 10-year risk in a similar man with optimal risk factors. Even more dramatically, the lifetime risk of atherosclerotic CVD in this person is 69%. These numbers demonstrate the paramount importance of cardiovascular risk modification in patients with diabetes.

An important consequence of IHD is congestive heart failure, hence heart failure is a very important problem in individuals with T2DM [12]. This issue is discussed in Chapter 45.

Pathophysiological perspective

It is not surprising that prediabetes is associated with IHD. Diabetes as a clinical entity is diagnosed when fasting plasma glucose is ≥126 mg/dL or when glucose by 2 h after a 75-g oral glucose load is ≥200 mg/dL [13]. However, metabolic abnormalities that are associated with atherosclerosis in general and with IHD in particular typically exist for years or decades before diabetes becomes manifest [14, 15]. In particular, in the sequence of events that eventually leads to the development of diabetes, insulin resistance is a very early feature. This in turn is the key pathophysiological mechanism behind the metabolic syndrome, a cluster of metabolic abnormalities including elevated glucose, dyslipidemia, visceral obesity, and elevated blood pressure, all of which are independently linked to the development of atherosclerotic disease [14, 15].

T2DM becomes manifest only when β-cell failure develops on the background of pre-existing insulin resistance, i.e. when the demand for insulin supply caused by insulin resistance can no longer be fulfilled [14]. The atherogenic environment of multiple cardiovascular risk factors associated with the metabolic syndrome then typically has existed for years or decades. From this, it is clear that cardiovascular prevention must not be started at the stage of established diabetes but should take place much earlier.

When glucose levels increase in the case of transition from the metabolic syndrome to T2DM, the cardiovascular risk becomes even greater. In addition to the atherogenic metabolic syndrome stigmata mentioned below, glucose, through oxidative stress, can cause additional harm to the endothelium [16]. Importantly, however, glucose even in the stage of established diabetes is not the only and not even the main driving force of IHD disease risk. This is an important difference in comparison with the paramount role of elevated glucose for diabetic microangiopathy. In contrast to diabetic macroangiopathy (i.e. atherosclerotic disease, of which IHD is the most important manifestation), diabetic microangiopathy is directly caused by elevated glucose and therefore is diabetes specific. The risk of macroangiography is strongly elevated in persons with diabetes, but of course atherosclerosis also occurs in individuals who do not have diabetes.

The above-mentioned pathophysiology applies to T2DM, which is particularly closely linked to CVD. Type 1 diabetes mellitus (T1DM) also is associated with an increased cardiovascular risk [17]. However, the time span between diabetes manifestation and the development of IHD is longer in T1DM than in T2DM. In addition to direct glucotoxicity, impairment of kidney function is an important mechanism linking T1DM to IHD risk. Indeed, once chronic kidney disease has developed, the cardiovascular risk strongly increases. In fact, we have found that albuminuria, a hallmark of diabetic nephropathy, is an MI risk equivalent [18].

How can cardiovascular risk be reduced in persons with diabetes?

Glucose lowering

Given that diabetes is diagnosed when glucose is elevated, at first sight lowering glucose would appear to be an attractive approach to reduce the increased cardiovascular risk in people with diabetes. Unfortunately, however, the results of numerous intervention trials addressing cardiovascular risk modification by lowering of glucose are disappointing.

The classical United Kingdom Perspective Diabetes Study (UKPDS) enrolled more than 4000 individuals with newly diagnosed T2DM [19]. Among other interventions, intensified glucose lowering was compared with conventional treatment;

participants were followed up over 10 years. Although the incidence of microvascular diabetes complications was significantly reduced with intensive glucose lowering, macrovascular events, in particular MI, stroke, and peripheral arterial disease, were not significantly reduced. There was a non-significant trend towards a lower MI incidence in people with intensive glucose control. One objection was that glucose lowering in the intervention arm might not have been aggressive enough in the UKPDS. However, three further trials, Action to Control Cardiovascular Risk in Diabetes (ACCORD), Action in Diabetes and Vascular Disease: Preterax and Diamicron Controlled Evaluation (ADVANCE), and the Veterans Affairs Diabetes Trial (VADT), also did not show a reduction in macrovascular diabetes events with more aggressive glucose lowering [20–22].

For example, in ADVANCE [21], more than 11,000 participants with T2DM were randomized to intensive glucose control, aiming at an HbA_{1c} of <6.5% versus standard glucose control according to country guidelines. During a follow-up period of 5 years, a combined macro- plus microvascular endpoint was significantly reduced by 14%; macrovascular events were not reduced at all.

Interestingly, however, when longer time periods were observed, a benefit of more intense glucose lowering appeared to emerge. For example, in the UKPDS trial, a 10-year post-trial follow-up revealed significant reductions in MI among individuals whose glucose was lowered more aggressively [23]. In ADVANCE, a long-term follow-up did not show a benefit with regard to major vascular events [24], whereas in the VADT [25], similarly to the UKPDS, a significant reduction in macrovascular events was observed with more aggressive treatment of glucose over 10 years.

In people with T1DM, the Diabetes Control and Complications (DCCT) trial failed to show a significant reduction in macrovascular events during the original study period [26], but a long-term follow-up suggested a significant reduction in macrovascular events over a long period of 17 years [27]; the pattern of a long-term benefit in the absence of a short-term benefit of glucose lowering with regard to cardiovascular event risk is therefore the same in T1DM as in T2DM.

Overall, glucose lowering appears to provide a long-term benefit with regard to IHD in persons with T2DM and T1DM. However, this must be treated with some caution because the analyses showing long-term benefit were not the primary study results but post hoc extension analyses of existing clinical trials.

Discomfortingly, in the ACCORD trial [20], mortality and cardiovascular event risk were higher in participants receiving more intense glucose lowering. This suggests that overly aggressive glucose lowering in people with diabetes in fact may do harm with respect to cardiovascular event risk. Indeed, more intensive glucose lowering is associated with more weight gain and, probably more important, with more hypoglycemia.

Hypoglycemia is associated with an increased risk of cardiovascular events [28]. Considering that hypoglycemia both prolongs the action potential and leads to myocyte calcium overload, this is not surprising: both diabetes itself and pre-existing CAD already lead to these electrophysiological abnormalities, which are then even more severely pronounced in the case of hypoglycemia. Prolongation of the action potential and myocyte calcium overload are the most important triggers of arrhythmia [29].

Because there currently is no clear evidence for the reduction of IHD events by aggressive glucose lowering, the American Diabetes Association (ADA) recommends an HbA_{1c} of <7.0% for the prevention of microvascular complications [13]. The above-mentioned results from long-term observations following clinical intervention trials for glucose lowering suggest that more aggressive glucose lowering may be favorable in the long term, especially for those individuals in whom lowering glucose values can be achieved without an increase in hypoglycemia. These are mainly relatively healthy individuals who do not have a long-standing history of diabetes and do not have severe comorbidities.

An important question is whether any particular antidiabetes drug has a benefit with regard to IHD in patients with T2DM. For insulin, the Outcome Reduction with Initial Glargine Intervention (ORIGIN) trial randomizing people to insulin glargine versus standard care did neither show a decrease or an increase in total cardiovascular events or IHD events with insulin glargine [30]. Metformin, in a small subset of 342 among a total of 1704 overweight individuals in the UKPDS, trial led to a 36% reduction in total mortality [31]. However, the small sample size makes it difficult to draw definite conclusions. In the STOP-Noninsulin-Dependent Diabetes Mellitus (STOP-NIDDM) trial, acarbose led to a reduced incidence of cardiovascular events among those with impaired glucose tolerance [32]; no corresponding data for people with diabetes are available.

Somewhat better evidence for cardiovascular risk reduction is available for pioglitazone. In the Prospective Pioglitazone Clinical Trial in Macrovascular Events (PROACTIVE), 5238 people with T2DM and macrovascular disease were randomized to either pioglitazone 45 mg daily or placebo [33], and followed up for 3 years. The primary endpoint of PROACTIVE was very broad, including, in addition to death, non-fatal MI, stroke, acute coronary syndrome, leg amputation, coronary revascularization, and revascularization of peripheral arteries. With regard to the primary endpoint, the risk reduction with pioglitazone was non-significant; however, when the clinically more relevant secondary endpoint, including death, non-fatal MI, and stroke, was considered, a significant 16% event reduction was observed with pioglitazone compared with placebo. This result was confirmed by a subsequent meta-analysis that showed a decreased risk of death, MI, and stroke with pioglitazone [34]. The Pioglitazone Effect on Regression of Intravascular Sonographic Coronary Obstruction Prospective Evaluation (PERISCOPE) trial [35] additionally showed a reduction in CAD progression as visualized by intravascular ultrasound with pioglitazone, and the Carotid Intima-Media Thickness in Atherosclerosis Using Pioglitazone (CHICAGO) trial [36] demonstrated a favorable impact of pioglitazone on the progression of the carotid intima media thickness compared with the sulfonylurea glimepiride.

A similar favorable cardioprotective effect was not observed for another peroxisome proliferator-activated receptor gamma (PPAR-γ) agonist, rosiglitazone. On the contrary, meta-analyses suggested that rosiglitazone even increased cardiovascular risk [37]. Based on the disappointing results for rosiglitazone, the US Food and Drug Administration (FDA) in 2008 demanded that for all new antidiabetes drugs an increase in cardiovascular risk must be excluded in cardiovascular safety trials [38].

Subsequently, several such cardiovascular safety trials were published. For example, the Cardiovascular Outcomes Study of Alogliptin in Patients with Type 2 Diabetes and Acute Coronary Syndrome (EXAMINE) trial [39] enrolled 5380 people with T2DM who had acute coronary syndrome between 15 and 90 days before randomization; individuals were randomized to alogliptin versus placebo and then followed up for a median of 18 months. A primary endpoint of cardiovascular death, MI, and ischemic stroke occurred with similar frequency in alogliptin-treated and placebo-treated individuals based on prespecified power calculations. From this it was concluded that alogliptin is safe with respect to IHD. Analogously, the Saxagliptin Assessment of Vascular Outcomes Recorded in Patients with Diabetes Mellitus (SAVOR-TIMI 53) trial [40] demonstrated safety of saxagliptin with regard to the incidence of cardiovascular endpoints, and the recent TECOS trial [41] demonstrated safety of sitagliptin with respect to cardiovascular events, in particular the incidence of IHD.

Most recently, the Empagliflozin Cardiovascular Outcome Event Trial in Type 2 Diabetes Mellitus Patients (EMPAREG-OUTCOME) [42] was published; this was a cardiovascular safety study for the sodium–glucose co-transporter-2 (SGLT-2) inhibitor empagliflozin. Here, 7020 participants with T2DM and established CVD who had a baseline HbA_{1c} between 7.0 and 9.0% were randomized to receive either empagliflozin (in dosages of 10 or 25 mg/day) or placebo; follow-up was 3.1 years and the primary endpoint was a total of cardiovascular death, MI, and stroke. The primary endpoint was significantly reduced by 14% in participants receiving empagliflozin versus those receiving placebo; the absolute risk reduction was 1.6%, corresponding to a number needed to treat of 63. Further, cardiovascular death was significantly reduced by 38% and all-cause death by 32%. Whereas hospitalizations for heart failure were strongly reduced by 35% with empagliflozin, the incidence of MI was not significantly affected; also, unstable angina and stroke events were not reduced. This may suggest that the main beneficial effect of empagliflozin was achieved by mechanisms other than the inhibition of atherosclerosis progression. Nevertheless, empagliflozin has a very interesting profile with regard to cardiovascular risk management: it not only lowers blood glucose but also blood pressure and leads to a moderate weight reduction [42].

Lipid management

Lipids play an essential role in the development of IHD, and therefore are a central target in preventive cardiology, in particular also in people with diabetes (see Chapter 43). Lipoprotein metabolism in T2DM typically is altered in a specific manner [43]: owing to insulin resistance, an increased amount of free fatty acids is set free from adipose tissue in persons with T2DM, which are used to synthesize triglycerides in the liver. These triglycerides are packed into very low-density (VLDL) particles, which consequently are secreted in the blood. Therefore, triglycerides are elevated in persons with T2DM. Lipases hydrolyze triglycerides from these VLDL particles, which through intermediate-density lipoprotein (IDL) particles finally turn into low-density lipoprotein (LDL) particles, which, mediated by LDL receptors, are taken up in the liver where cholesterol is degraded into bile acids and secreted into the bowel as such.

Elevated triglycerides have a profound impact on both LDL and HDL particles. Mediated by the enzyme cholesteryl ester transfer protein (CETP), triglyceride-rich lipoproteins are exchanged for cholesterol from LDL and HDL particles. LDL and HDL particles thus lose cholesterol and receive triglycerides in turn. These triglycerides are then removed by the action of hepatic lipase, rendering both LDL and HDL smaller and denser. Smaller HDL particles are more rapidly removed from the blood by the kidney, which explains the low HDL cholesterol of individuals with T2DM; small, dense LDL (sdLDL) particles are particularly atherogenic and explain why persons with diabetes already at moderate LDL cholesterol levels are at a high risk of cardiovascular events.

In summary, lipid metabolism in people with diabetes is characterized by hypertriglyceridemia, low HDL cholesterol and sdLDL particles. The level of LDL cholesterol per se typically is not very high in persons with T2DM; as we have shown, rather it is lower in these individuals than in those without diabetes [44]. Nevertheless, the most successful lipid approach to reduce cardiovascular risk, i.e. lowering LDL cholesterol, is also efficacious in people with diabetes. A large meta-analysis enrolling over 18,600 people with diabetes from 14 randomized trials of statins showed that per 1 mmol LDL cholesterol reduction, the MI risk could be reduced by 22% in persons with diabetes, which was not significantly different from the 19% event reduction achieved with the same amount of LDL reduction in individuals without diabetes [45].

The more LDL cholesterol is reduced, the more cardiovascular risk is reduced [46], and this important fact holds true for almost any population and in particular also for individuals with diabetes. Recently, the IMProved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE-IT) [47] showed that not only statins but also ezetimibe are effective in lowering both LDL cholesterol and the risk of atherosclerotic disease in persons with diabetes. In IMPROVE-IT, 18,144 people with acute coronary syndrome were randomized to receive either simvastatin alone or simvastatin plus ezetimibe; in the placebo arm, a mean LDL cholesterol of 70 mg/dL was achieved, whereas in participants allocated to ezetimibe treatment, the mean LDL cholesterol was 54 mg/dL. Compared with placebo, cardiovascular events were significantly reduced by 6% in those receiving ezetimibe during 7 years of follow-up; the amount of risk reduction was the same as would have been expected if the LDL reduction had been achieved with a statin.

Subgroup analysis suggested that in the IMPROVE-IT trial, people with diabetes benefited particularly from LDL cholesterol lowering with ezetimibe. Lowering of LDL cholesterol with a statin or with additional ezetimibe treatment thus has proven efficacy in reducing cardiovascular events in particular in those with diabetes.

Highly potent LDL cholesterol-lowering drugs, proprotein convertase subtilisin kexin type 9 (PCSK9) inhibitors, are now available that are effective in strongly lowering LDL beyond what can be achieved with potent statins [48]. Whether these drugs also reduce cardiovascular events in people with diabetes is under investigation in ongoing clinical outcome trials; preliminary data already suggest a dramatic cardiovascular risk reduction with these innovative drugs.

Given the clear impact of LDL cholesterol reduction on cardiovascular risk reduction in persons with diabetes, the European Society of Cardiology (ESC) recommends an LDL cholesterol level of <70 mg/dL for individuals with T2DM and also for those with T1DM who already have end organ damage, as it does for other populations at very high cardiovascular risk [4]. Importantly, the safety of lowering LDL cholesterol either with statins or with statins plus ezetimibe has been clearly shown in large populations [45, 47].

As mentioned above, the typical lipid abnormality in persons with diabetes is not elevated LDL cholesterol but rather a combination of high triglycerides, low HDL cholesterol and small LDL particle size. Indeed, this lipid triad is a stronger predictor of cardiovascular events than elevated LDL cholesterol in high-risk persons with diabetes [49, 50]. The most important drugs for lowering triglycerides or raising HDL cholesterol are fibrates and nicotinic acid.

Two large trials, Atherothrombosis Intervention in Metabolic Syndrome with Low HDL/High Triglycerides: Impact on Global Health Outcomes (AIM-HIGH) [51] and The Heart Protection Study 2—Treatment of HDL to Reduce the Incidence of Vascular Events (HPS2-THRIVE) [52] investigated the power of nicotinic acid to reduce cardiovascular events over and above background treatment with statins. Both trials were neutral with regard to the major cardiovascular event outcome; nicotinic acid did not lead to a further reduction of cardiovascular events in statin-treated participants. Also the ACCORD lipid arm [53], which tested fenofibrate versus placebo in statin-treated participants with T2DM who were treated with simvastatin, did not show a significant reduction in cardiovascular events. Only the subgroup of participants with both triglycerides ≥204 mg/dL and HDL cholesterol ≤34 mg/dL showed a better cardiovascular outcome with fenofibrate than with placebo. Similar subgroup results were also observed in other trials investigating the power of fibrates to reduce cardiovascular events, for example, in the Helsinki Heart Study, in the Veterans Affairs High-Density Lipoprotein Intervention Trial (VA-HIT), in the Bezafibrat Intervention Project, and in the Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) trial [54]. Therefore, in the subset of individuals with both high triglycerides and low HDL cholesterol, therapy with fibrates on top of statin therapy may reduce cardiovascular risk. Because of interaction and tolerability issues, fenofibrate should be used when a fibrate is combined with a statin.

Blood pressure management

The most recent Joint National Committee (JNC)-8 Guidelines recommend a general blood pressure target of ≤140/90 mmHg for the majority of individuals, in particular also for those with diabetes (see Chapter 42) [55]. Current ADA guidelines [13] recommend a blood pressure target of 130/80 mmHg as an optional target if this can be achieved with good tolerability, especially in younger individuals. Previously, a blood pressure target of <130/80 mmHg had been suggested for the majority of people with diabetes [56]. However, subsequent trial results became available that did not demonstrate a clear benefit of aggressive blood pressure lowering in persons with diabetes.

For example, in the blood pressure arm of the ACCORD trial, 4700 individuals with T2DM were randomized to a systolic blood pressure target <120 mmHg or standard therapy with a systolic BP target of <140 mmHg [57]. Mortality and IHD could not be reduced by more aggressive blood pressure lowering, but stroke events was reduced dramatically by 47%. More intense therapy, however, was associated with more arrhythmic events, hypokalemia, and hypotension, so this aggressive treatment target could not be generally recommended. Another study found that in persons with diabetes and established IHD, overly intense blood pressure lowering led to an increased mortality risk: in people with systolic blood pressure below 110 mmHg mortality was significantly increased compared with those with systolic BP between 125 and 130 mmHg [58]. Also in the VADT [59], a significant increase in cardiovascular event risk was observed when diastolic blood pressure was lowered to <70 mmHg. For persons with diabetes at high risk of cardiovascular events, in particular for those with established CAD, extremely low blood pressure targets therefore do not appear warranted.

Recently, the Systolic Blood Pressure Intervention Trial (SPRINT) was published, showing a significant reduction in cardiovascular events with aggressive blood pressure lowering to <120 versus <140 mmHg systolic blood pressure. However, persons with diabetes were excluded in SPRINT, so that definitive recommendations with regard to aggressive blood pressure lowering in diabetes will need further data [60].

Aspirin treatment

Whereas aspirin therapy in individuals with diabetes and established CAD is clearly indicated, the use of aspirin in the primary prevention of cardiovascular events is less clear, in persons both without and with diabetes. A potential reduction in cardiovascular event risk needs to be balanced against an increase in bleeding risk. Current ADA recommendations suggest aspirin use when the 10-year risk of atherosclerotic CVD is >10%, which usually is the case in men or women aged over 50 years who have at least one additional risk factor. No aspirin is recommended

when the 10-year cardiovascular risk of atherosclerotic cardiovascular disease is below 5%, which usually is the case in men or women below 50 years of age who do not have additional risk factors [13].

Screening for coronary heart disease in diabetes

An interesting issue is whether screening for CAD is useful in asymptomatic individuals with diabetes to guide treatment decisions. Current guidelines recommend against screening for CAD in persons with diabetes. Indeed, in this high-risk population, maximum risk factor control is indicated anyway, and randomized trials did not show a benefit regarding cardiovascular outcome with screening for CAD in individuals with diabetes [13].

45 Congestive Heart Failure

Anna Norhammar,[1] Isabelle Johansson,[1] Inga S. Thrainsdottir,[2] and Lars Rydén[1]

[1] Cardiology Unit, Department of Medicine K2, Karolinska Institutet, Karolinska University Hospital in Solna, Stockholm, Sweden
[2] Cardiology Unit, Landskapítalinn University Hospital, Reykjavík, Iceland

Key points

- There is a link between heart failure and not only diabetes but also impaired glucose tolerance.
- Glucose perturbations increase cardiovascular mortality in people with heart failure especially if due to ischemic heart disease.
- Evidence-based heart failure therapy has a proportionately similar efficacy in people with and without glucose perturbations.
- Certain glucose-lowering agents may be harmful (e.g. glitazones).
- Further studies are needed before glucose normalization can be recommended as a possibility for improving the prognosis.

Introduction

The concept that there may be a direct relation between diabetes and heart failure dates back to 1954 when the Danish Professor K. Lundbæk published an article on clinically important complications in people with diabetes underlining that heart disease was common; he was the first to suggest the presence of a diabetes specific cardiomyopathy [1]. Almost 20 years later, Rubler et al. [2] published supporting data, concluding that myocardial disease seemed to be a complication of diabetes in itself and was not caused merely by coronary artery disease (CAD). Shortly thereafter, the Framingham study presented epidemiological evidence for a strong relation between heart failure and diabetes. This study indicated that the relation between these conditions was not only due to traditional risk factors for CAD but also involved other mechanisms [3].

The prevalence of heart failure is increasing in Western societies owing to aging populations, but also because of increased survival in ischemic heart disease (IHD), especially myocardial infarction (MI) [4, 5]. There are many known causes of heart failure, including hypertension, CAD, valvular dysfunction, arrhythmias, anemia, renal failure, and thyroid dysfunction [4, 6–9]. Risk factors for and causes of the development of heart failure are presented in Figure 45.1. They include increasing age, hypertension, IHD (in particular previous MI), electrocardiographic signs of left ventricular hypertrophy, valvular dysfunction and cardiomegaly detected by chest X-ray, increased heart rate, and decreased pulmonary vital capacity. To these, diabetes is added as a strong risk factor. The Framingham study used several of these risk factors to construct a multivariate risk formula to identify high-risk candidates for heart failure [10]. Currently, however, IHD is the leading cause of heart failure in industrialized societies, with diabetes as a rapidly emerging risk factor [9]. Diabetes is one of the important risk factors in IHD [11, 12]. Considering the rapidly growing prevalence of diabetes [13], this means that the combination of diabetes and heart failure will be increasingly common in the future. Poor glucose control contributes to the development of heart failure, as reflected by the relation between an increase in glycated hemoglobin A_{1c} (HbA_{1c}) and the risk for developing heart failure [14, 15]. Based on data from the Swedish National Diabetes Registry, development of future heart failure was related to worse glucose control (>7%, 53 mmol/mol]) in persons with type 2 diabetes mellitus (T2DM) and with a 30% higher risk of heart failure for each 1% increase in HbA_{1c} in those with type 1 diabetes mellitus (T1DM) [14, 15]. Among individuals with heart failure, ~25% have previously known diabetes [16]. Interestingly, there are several reports describing that heart failure severity predicts the appearance of diabetes and increases the development of future glucose disturbances [17, 18]. Long-standing hyperglycemia may, even in the absence of other risk factors such as CAD, valvular heart disease, or hypertension, affect the myocardial tissue in individuals with diabetes, increasing the risk of myocardial dysfunction, and, as already indicated, there have been earlier reports on the existence of a specific diabetes cardiomyopathy [1]. This concept is still debated, however, because the frequent coexistence of diabetes,

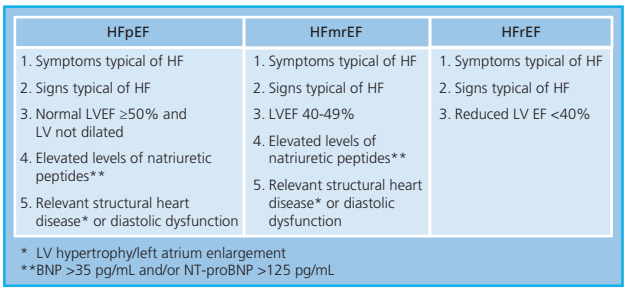
hypertension, and CAD, makes it difficult to decipher whether the myocardial dysfunction is triggered by the glucometabolic disorder itself, or rather is caused by synergistic action of these factors.

In summary, there is a strong link between the existence of heart failure and diabetes and both conditions are becoming increasingly common. The links between these disorders are complex and have not yet been fully explored.

Symptoms and diagnosis

The diagnosis and definition of heart failure

The diagnosis of heart failure is based on a combination of clinical symptoms and characteristic signs of myocardial dysfunction [4], as presented in Figure 45.2. In clinical practice, heart failure is commonly divided into two types based on left ventricular function usually investigated by echocardiography: heart failure with reduced ejection fraction (HF-REF) and with preserved ejection fraction (HF-PEF), also referred to as systolic and diastolic heart failure. The main differences are that in HF-REF systolic



HFpEF	HFmrEF	HFrEF
1. Symptoms typical of HF	1. Symptoms typical of HF	1. Symptoms typical of HF
2. Signs typical of HF	2. Signs typical of HF	2. Signs typical of HF

Figure 45.2 Types of heart failure according to European guidelines in 2016. HF, heart failure; HFpEF, heart failure with preserved ejection fraction; HFmrEF, heart failure with midrange ejection fraction; HFrEF, heart failure with reduced ejection fraction; LVEF, left ventricular ejection fraction. Based on Ponikowski et al. 2016 ESC Guidelines for the diagnosis and treatment of acute and chronic heart failure: The Task Force for the diagnosis and treatment of acute and chronic heart failure of the European Society of Cardiology (ESC). Developed with the special contribution of the Heart Failure Association (HFA) of the ESC. *Eur J Heart Fail* 2016 May 20. doi: 10.1002/ejhf.592. [Epub ahead of print]

Table 45.1 Classification of heart failure according to the New York Heart Association (NYHA).

NYHA Class I	No limitation of physical activities Patients without symptoms during ordinary activities
NYHA Class II	Slight to mild limitation of physical activity Patients comfortable at rest and mild exertion
NYHA Class III	Marked limitation of activity Patients comfortable only at rest
NYHA Class IV	Confined to complete rest in a bed or a chair

dysfunction is reduced, impairing the ejection of blood from the left ventricle. In HF-PEF, myocardial relaxation is compromised, which impairs ventricular filling. The diagnosis of HF-PEF is mainly performed by excluding causes other than cardiac for existing symptoms, making it a more difficult diagnosis than HF-REF. Echocardiography is the preferred and most commonly used method for documentation of left ventricular ejection fraction and function. Echocardiographic signs and criteria of diastolic dysfunction, which are influenced by age, heart rate, and body size, are developing and changing and it is important to appreciate that no single echocardiographic variable is sufficient. Judgment of diastolic function should include several variables from the echocardiogram, combining functional abnormalities, addressed by Doppler measurements (mitral inflow with E/A ratio, pulmonary vein velocity, and velocities on tissue Doppler imaging, E′), and structural abnormalities (e.g. left ventricular hypertrophy or dilation of the left atrium) [4, 19]. Further details can be found in published guidelines on heart failure [20, 21].

Plasma concentrations of natriuretic peptides and their precursors (N-terminal pro-brain-type natriuretic peptide [NT-proBNP]; BNP) are also helpful when diagnosing heart failure, particularly when the availability of echocardiography is limited. These peptides are secreted in increased amounts when the load of the atria or ventricles is increased. They are also useful in individuals with diabetes [4, 22]. Cut-off points differ for NT-proBNP and BNP. In individuals presenting with acute onset or worsening of symptoms, the optimal exclusion cut-off point is 300 ng/L for NT-proBNP and 100 ng/L for BNP [4].

The main clinical classification of the severity of heart failure is that presented by the New York Heart Association (Table 45.1). This classification is used for all people with heart failure irrespective of whether seen in a hospital or an outpatient setting and irrespective of etiology.

The diagnosis and definition of glucose abnormalities

Diabetes and its prestates are a group of metabolic disorders characterized by hyperglycemia due to defects in insulin secretion, insulin action, or both. Diabetes is associated with damage, dysfunction, and failure of various organs [23, 24]. The metabolic syndrome is an entity that has been defined in various ways [23], combining different cardiovascular risk factors including abnormalities in the glucose homeostasis. Further details on the classification and diagnosis of diabetes and other glucose abnormalities can be found in Chapter 2.

Epidemiology

Risk factors for heart failure and diabetes

The most important risk factors for cardiovascular disease (CVD) and MI are family history, smoking, abnormal blood lipids, hypertension, diabetes, obesity, and socioeconomic factors [11]. The morbidity is known to increase progressively with the number of existing risk factors [25]. Many of the risk factors for heart failure are by necessity similar to those of CVD, with IHD and hypertension as leading causes. Other common factors influencing the occurrence of heart failure are male gender, smoking, overweight, physical inactivity, valvular heart disease, and atrial fibrillation [4]. T1DM and T2DM and also poor glucose control observed as high fasting plasma glucose and elevated HbA_{1c} are also of considerable importance. In T1DM, glucose control and duration of diabetes are strong risk factors [14, 15, 26–31].

Risk factors for T2DM are family history, age, overweight or increased waist/hip ratio, and a sedentary life-style [32, 33], i.e. similar risk factors to those for heart failure and CAD. Particular risk factors for CAD in T2DM are lipid perturbations, including small, dense, easily oxidized low-density lipoprotein (LDL) particles, low high-density lipoprotein (HDL) cholesterol, and increased triglycerides. Moreover, poor glycemic control observed as high fasting plasma glucose and elevated HbA_{1c} also contribute [34]. Hypertension and signs of renal damage (proteinuria) are other important risk factors for cardiovascular complications and heart failure in persons with diabetes [35]. The Reykjavík Study showed a strong relation between fasting and post-load glucose levels and subsequent risk for hypertension, even after adjustment for age, body mass index, and weight gain, which is interesting since hypertension is one of the main risk factors for heart failure [28, 29]. Individuals with diabetes and heart failure have more IHD and hypertension and a higher HbA_{1c} than those without diabetes [16, 30]. In a registry report from Sweden, including 36,274 individuals hospitalized for heart failure during 2003–2011, 25% had diabetes and as many as 60% had a previous history of IHD [16]. In summary, there are many mutual risk factors for heart failure and glucose abnormalities.

Prevalence of heart failure and glucose abnormalities

Prevalence of heart failure

In the general population, the prevalence of heart failure varies in different studies, partly due to differences in the definition of this disease [4]. The demand that a diagnosis of heart failure should be supported by evidence of dysfunction on echocardiography may be difficult to fulfill in epidemiological studies. Modern echocardiographic techniques did not exist when several of the studies that still serve as important sources of information were conducted [36, 37]. The prevalence of heart failure has been estimated to be 0.6–6.2% in Swedish men with an increase with age [38]. This is similar to the overall prevalence of heart failure in both sexes in the Rotterdam population and in the Reykjavík Study [39, 40]. The prevalence of heart failure was 1–10% in a British outpatient population [20]. It increases considerably when considering elderly populations, as exemplified by the Italian Campania study, in which the prevalence was 9.5%, once again underlining the impact of age [17]. In summary, the prevalence of heart failure is about 1–2%, increasing to >10% at ages above 70 years [41].

Prevalence of diabetes

Diabetes is often an undiagnosed condition and the International Diabetes Federation (IDF) estimates that about 50% of all individuals with this disease are undiagnosed [42]. Diabetes prevalence depends highly on age, type of population investigated, and screening methods. When screening a Belgian outpatient population with one known cardiovascular risk factor, diabetes was detected in 11% and an additional 3% had impaired glucose tolerance (IGT) [43]. The prevalence of diabetes was 7.8% in Swedish men and 5.1% in women aged 35–79 years, with similar proportions reported from a Finnish middle-aged population [44, 45]. The prevalence of diabetes may be considerably higher in selected high-risk populations, especially those with CAD. In the GAMI study, as many as 25% of patients with MI had previously unknown diabetes when investigated with an oral glucose tolerance test (OGTT) 3 months thereafter, and 40% had IGT [46]. In the Euro Heart Survey Diabetes and the Heart, individuals admitted to hospital because of acute and stable CAD were investigated for the presence of diabetes and IGT. Only 29% of the 4961 participants had a normal glucose metabolism and 31% had known and 12% previously unknown diabetes; the remaining 28% had IGT [47]. Similar proportions were detected in populations with cerebral and peripheral vascular disease [48]. Thus the combination of CAD and glucose perturbations is very common and in many previous studies underestimated owing to lack of diagnostic accuracy in combination with a thorough investigation of the glucometabolic state.

There is increasing evidence that the prevalence of the combination of diabetes and heart failure is undiagnosed and common in the general population. In the Reykjavik population study, the prevalence of diabetes and heart failure was investigated with OGTT and X-ray examination, respectively. The prevalence of combined heart failure and diabetes was 0.5% in men and 0.4% in women, increasing with age [40]. Diabetes was found in 12% of those with heart failure compared with only 3% of those without heart failure. Hence there was a strong association between diabetes and heart failure.

Based on Framingham data, Rutter et al. [49] noted that the heart is prone to changes in the form of increased left ventricular mass and wall thickness with worsening glucose tolerance. Kannel et al. [3] and Gustafsson et al. [50] reported on the role of diabetes in heart failure from a general and a hospitalized population, respectively. Their findings indicated a strong association between heart failure and diabetes. Iribarren et al. [51], Bertoni et al. [52], and Nichols et al. [30], focusing on the role of heart failure in people with diabetes, noted that the prevalence of heart failure varied between 1.9 and 22.3%. Finally, Amato et al. found a strong association between diabetes and heart failure in a population of elderly people [17].

Information on the incidence, prevalence, and prediction of heart failure is summarized in Table 45.2.

Incidence of heart failure and glucose abnormalities

Incidence of heart failure

Results from the Framingham study indicate that the incidence of heart failure has declined during the last six decades [53]. These data are, however, not supported in other studies [54]. On the contrary, it seems that hospital admissions for heart failure are increasing, resulting in higher healthcare expenditure for people with this diagnosis [55]. Among British outpatients, the incidence of heart failure has been reported to be 4.4/1000 person-years in men and 3.9/1000 person-years in women, rising with age in both genders [56]. The incidence in Finland is similar

among men, 4.0/1000 person-years, but lower in women, 1.0/1000 person-years [57]. In the United States, the incidence of heart failure has remained stable over recent decades, with a level as high as >80 per 1000 individuals above 85 years of age [5, 58].

Incidence of diabetes

The age-standardized annual incidence of diabetes, reported to be 2.2 and 2.3/1000 person-years in Dutch men and women, respectively, is fairly uniform in several European countries [59]. When considering an elderly population, as in the Italian Campania study, the incidence was considerably higher, 6.1% per year. This is different from observations in The Netherlands, where the incidence decreased in the oldest age group [17, 59]. In a study of the local community Laxå in Sweden, the incidence of diabetes was found to have been stable for 30 years at 3.03 cases per 1000 inhabitants [60].

Considerably less is known about the incidence of the combination of diabetes and heart failure. In the Reykjavík population, the age- and gender-standardized incidence of abnormal glucose regulation was 12.6/1000/year, of diabetes 4.6/1000/year, and of heart failure 5.3/1000/year (Figure 45.3) [40]. In addition, there was a strong association between the incidence of glucose abnormalities and heart failure [61].

In the Framingham study, the incidence of heart failure among men and women with diabetes during 18 years of follow-up was two and five times higher, respectively, than among those free from diabetes. The excessive risk of heart failure remained high even after the exclusion of individuals with prior CAD [3].

Pathophysiology

Myocardial structural and biochemical alterations can be identified in the failing heart and many of them seems to be independent of the etiology of myocardial dysfunction. They include changes in myocardial energy production, altered expression of contractile proteins, a desynchronized excitation–contraction coupling, β-adrenergic receptor stimulation, myocyte depletion, and increased activity of a number of cytokines. Many of these aberrations are found in the diabetic heart. Bugger and Abel [62] presented an extensive review of possible pathways and mechanisms to diabetes cardiomyopathy, as summarized in (Figure 45.4). New imaging techniques, e.g. cardiac magnetic resonance imaging (MRI), suggests that there is more fibrotic tissue in the myocardium of people with diabetes and an increased extracellular volume [63], possibly a consequence of hyperglycemia and

the formation of advanced glycated proteins. In this section, some general features of the pathophysiology are presented, followed by a discussion of more diabetes-specific factors.

Heart failure

Heart failure is a clinical syndrome originally induced by myocardial damage but subsequently aggravated by the induction of unfavorable neurohormonal responses. Thus norepinephrine, angiotensin II, endothelin, and aldosterone are all linked to the vicious cycle of myocardial remodeling (Figure 45.5), which if left unopposed will cause successive deterioration of myocardial performance [64].

Metabolic conditions play a significant role in cardiac adaptation and remodeling. This leads to an increase of myosin heavy chain beta, altered troponin-T molecules, diminished storage of creatinine phosphatases, and decreased sarcoplasmatic ATPase activity, which may result in myocyte hypertrophy associated with impaired contractile function and less effective energy supply [65, 66].

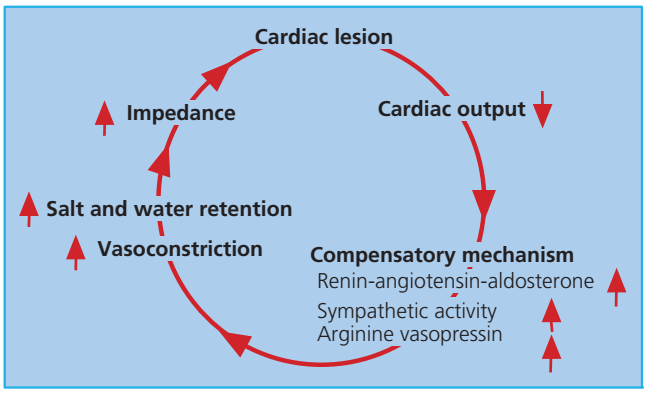

Figure 45.5 Neurohormonal activation caused by depressed myocardial function leads to a vicious circle further compromising the already compromised myocardial function [64].

The myocardium has a high energy turnover with adenosine triphosphate (ATP) as the important source of energy. The two pathways for energy supply are via the breakdown of free fatty acids (FFAs) and of carbohydrates (Figure 45.6). The lipolytic pathway transfers FFAs via β-oxidation to acetyl coenzyme A, which enters the citric acid or Krebs cycle. The carbohydrate pathway produces pyruvate via glycolysis, glycogenolysis, and lactate oxidation. Pyruvate is decarboxylated via pyruvate dehydrogenase to acetyl coenzyme A, which enters the Krebs cycle. The dominant pathway for myocardial energy production is β-oxidation of FFAs, but the myocardium is also dependent on glucose oxidation [67].

When the heart is subjected to ischemic stress or exposed to sustained enhancement of intraventricular pressure, it tends to change towards a more dominant glucose oxidation [67]. This may be counteracted by a reduction of the glucose transporter 4 (GLUT-4), which becomes reduced in heart failure, hampering glucose transport over the cell membrane. At the same time, the heart is subjected to increased FFA concentrations, released via stress influenced by an increased sympathetic tone [68]. It is assumed that prolonged intracellular accumulation of FFA and its metabolites may cause myocardial dysfunction [69].

In addition to these mechanisms, alterations in gene expression and inflammatory activity have been suggested to cause metabolic and mechanical disturbances in heart failure [70–73]. All nucleated cells, including the cardiomyocyte, can produce proinflammatory cytokines as a response to injury such as MI or myocarditis or when the heart fails. Both tumor necrosis factor α (TNF-α) and interleukin 6 (IL-6) levels increase in proportion to the severity and duration of heart failure [70, 71]. This cytokine release may trigger a cascade of events that lead to myocardial structural alterations, with further deterioration of the clinical expression of heart failure.

Heart failure and diabetes

Normally, myocardial energy production is based on β-oxidation of FFAs (70%) with a smaller contribution from glucose oxidation (30%) and lactate. FFAs are produced by lipolysis of endogenous cardiac or exogenous stores of triglycerides. Oxidation of FFAs is an effective supplier of energy in the form of ATP if oxygen supply is sufficient. In conditions with limited oxygen availability, glucose oxidation will provide more energy per mole of oxygen and support more work than FFAs [74]. In persons with diabetes, glucose utilization for energy production is substantially lower, about 10% (Figure 45.6). The shift to an even more pronounced β-oxidation of FFAs causes higher oxygen utilization than under normal circumstances [75]. The major restriction to glucose utilization in the diabetic heart is the slow rate of glucose transport across the sarcolemmal membrane in the myocardium [76, 77]. The impaired glucose oxidation in the diabetic heart can also result from a decreased rate of phosphorylation of glucose, which subsequently limits the entry of glucose into the cell. The depressed phosphorylation is triggered by the increased metabolism of FFAs [75]. Insulin deficiency enhances lipolysis, thereby increasing circulating FFAs [78].

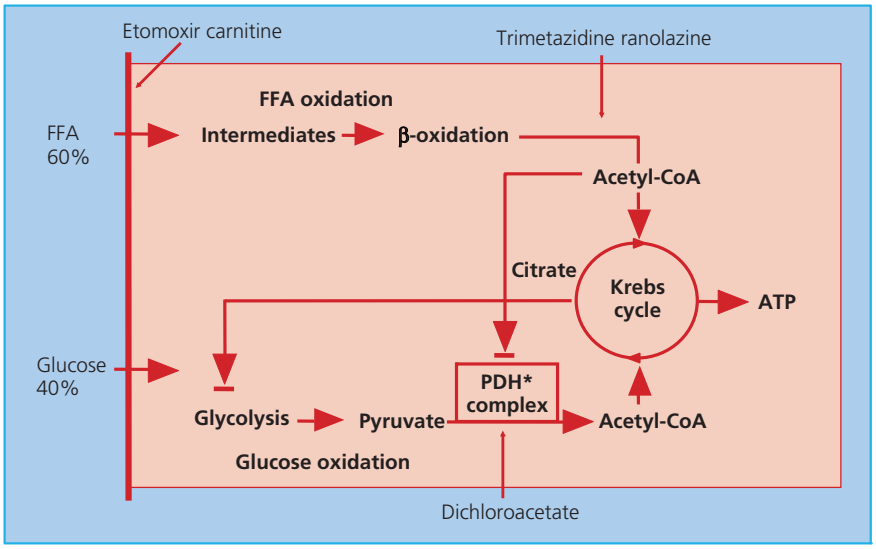

Figure 45.6 Schematic illustration of myocardial energy production of relevance for those with heart failure, with and without diabetes. The site of action for metabolic modulators are indicated. See text for further information [67]. CoA, coenzyme A; FFA, free fatty acid; PDH, pyruvate dehydrogenase.

Myocardial contractility may also be impaired by insulin resistance via reduced Ca^{2+} influx through L-type Ca^{2+} channels and by reverse-mode Na^{+}/Ca^{2+} exchange. Furthermore, chronic hyperinsulinemia is involved in impairment of the phosphatidylinositol 3-kinase (PI3K)/Akt pathway [79].

Individuals with diabetes are also known to have increased risk for other disturbances such as reduced myocardial blood flow and blunted hyperkinetic response to myocardial ischemia, resulting in diminished myocardial function [80–83]. Heart failure is an insulin-resistant state with an increased release of nonesterified fatty acids, which are taken up in muscular tissue and downregulate glucose uptake and utilization [84]. For more extensive information on recent postulated mechanisms for heart failure in diabetes, a review by Seferovic and Paulus [85] is highly recommended.

Another consequence of hyperglycemia is oxidative stress and activation of reactive oxygen species-driven pathways and of processes triggered by increased levels of diacylglycerol and protein kinase C (PKC) as depicted in Figure 45.7.

Prognosis

Heart failure in general

During the past 30 years, mortality from CAD has declined markedly among individuals free from diabetes. In those with diabetes, this decline has been substantially lower in men and not seen at all in women [86]. In the presence of heart failure, the prognosis becomes poor [87]. Survival after heart failure has improved, but the absolute mortality rate following the development of heart failure is still 50% within 5 years of diagnosis [88]. A 50-year follow-up of Framingham data indicated that heart failure survival has improved to some extent [53]. This observation is supported by a report based on the Swedish hospital discharge registry [89]. The mortality in an elderly population with heart failure recruited in Rotterdam was 47% during 6 years of follow-up, which is twice that of persons without heart failure [87]. In a comparable Italian study, the mortality rate was 21.3% after 3 years [17]. Hence heart failure is a malignant disease irrespective of the underlying reason for myocardial dysfunction.

Diabetes and heart failure

CVD is the most prevalent and vitally important complication of diabetes. In a very large population study in England of 1,921,260 individuals recruited during 1998–2012, heart failure and peripheral arterial disease were the most common initial manifestations of CVD in T2DM [12].

Diabetes increases the risk of death from CAD and, although mortality after MI has improved, the prognosis is still more severe in such individuals [90]. The prognosis for people with diabetes becomes even worse in the presence of heart failure [91–94]. In the first DIGAMI study, performed in people with diabetes and acute MI, heart failure was the most common reason for morbidity and mortality, accounting for 66% of the total mortality during the first year of follow-up [95]. In a recent nationwide registry study including 36,274 people hospitalized for heart failure during 2003–2011 and provided with modern heart failure therapies, survival was indeed significantly shorter in those with T2DM, who had a median survival period of 3.5 years compared with 4.6 years ($p < 0.0001$) (Figure 45.8). The presence of diabetes increased the risk of mortality by 60% (adjusted odds ratio 1.60; 95% confidence interval [CI]: 1.50–1.71) [16].

Treatment

General aspects

Evidence-based treatment of heart failure relies on a combination of angiotensin-converting enzyme (ACE) inhibitors and/or angiotensin receptor blockers (ARBs), β-blockers, diuretics, and aldosterone antagonists [4]. ACE inhibitors, ARBs, and β-blockers reduce mortality and improve symptoms in individuals with moderate to severe heart failure with and without diabetes [96–99]. Diuretics are mandatory for symptomatic treatment owing to fluid overload but should not be used in excess since they induce neurohormonal activation [100]. The addition of aldosterone antagonists is indicated in severe forms of heart failure and may then improve longevity [101]. However, although symptomatically improved, many patients are left with an unfavorable vital prognosis despite the best available pharmacological treatment. In 2014, the PARADIGM-HF study was presented, and showed significantly improved survival and a decreased need for hospitalizations for heart failure with the angiotensin–neprilysin inhibitor LCZ696 versus enalapril and standard treatment (hazard ratio 0.84; 95% CI: 0.76–0.93; $p < 0.001$). In the present context, it is of interest that the mortality benefit was particularly apparent in persons with diabetes [102, 103].

Metabolic modulations with compounds that influence the disturbed metabolic pathways in heart failure have been an area of research of particular importance in persons with diabetes. Attention has been paid to compounds that shift energy production from β-oxidation of FFAs towards the energetically more efficient glucose oxidation under conditions such as in myocardial ischemia and heart failure. Examples of such drugs are trimetazidine, ranolazine, etomoxir, and dichloroacetate [104, 105].

Not only pharmaceutical therapies are important in the treatment of heart failure. Modern heart failure treatment also includes physical activity programs. In severe heart failure with intraventricular conduction defects, cardiac resynchronization therapy (CRT) may be indicated.

Guidelines that deal specifically with diabetes and CVD including heart failure were not available until 2007, when the first European guidelines on the management of diabetes, prediabetes, and CVD were published; they were updated in 2013 [106]. As outlined in the latter, there have been few trials that specifically address the treatment of patients with a combination of glucose abnormalities and heart failure, and so there is a lack of firm evidence regarding the management of such patients. Current data are mostly based on analyses of subgroups of people with diabetes in large HF trials. This results in potential shortcomings related to a poor definition of diabetes and hidden diabetes, and actual glucose-lowering therapy, and also a risk for selection biases with an overrepresentation of less severe diabetes. With

these limitations in mind, available data favor a proportionately similar efficacy of pharmacological and device-oriented therapy in people with and without diabetes. Since the absolute prognosis is considerably worse in individuals with diabetes, the impact expressed as number needed to treat to avoid an event (e.g. hospitalization for heart failure or death) is considerably less in this group of individuals.

Pharmacological therapy of heart failure

Angiotensin-converting enzyme inhibition

ACE inhibitors are recommended in both asymptomatic myocardial dysfunction and overt heart failure. As shown in Table 45.3, they reduce mortality and improve symptoms in individuals with moderate to severe heart failure with and without diabetes [97, 99, 107–109]. Persons with diabetes represented fairly large subgroups in several trials. In SOLVD, the effect of enalapril on compromised left ventricular function was similar in participants with and without diabetes [110]. In ATLAS, comparing high- and a low-dose lisinopril treatment strategies, mortality reduction was at least as good in participants with diabetes as in those without [111]. The GISSI-3 and the SAVE trials reported beneficial effects on morbidity and mortality of ACE inhibitor treatment post-MI in people with diabetes [112–114].

Since hypoglycemic episodes may be provoked by ACE inhibitor therapy in individuals on glucose-lowering therapy, it is recommended that plasma glucose is monitored in the early phase of the introduction of an ACE inhibitor in those on glucose-lowering treatment [115, 116].

Angiotensin-receptor blockers

The use of angiotensin receptor blockers is an alternative to ACE inhibition and may be used, although not recommended in combination with ACE inhibition. They improve morbidity and mortality in people with heart failure with and without diabetes [117, 118].

Table 45.3 Effect of inhibition of the renin–angiotensin system in heart failure trials which included participants with diabetes.

Study [ref]	Participants (no.)	Diabetes (%)	Outcome
CONSENSUS [97]	253	18	31% reduction of 1-year mortality
SAVE [113]	2231	22	19% all-cause mortality risk reduction 21% risk reduction of cardiovascular morbidity
ATLAS [111]	3164	19	14% mortality risk reduction with high-dose ACE inhibitor treatment
GISSI 3 [114]	18131	15	30% reduction in mortality after 6 weeks

ACE, angiotensin-converting enzyme.

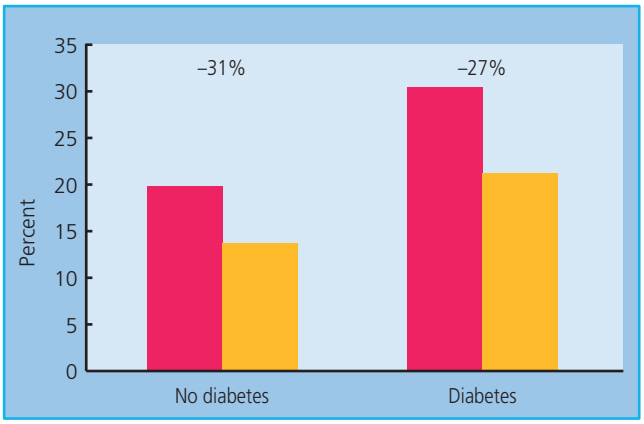

Figure 45.9 Impact of the β-blocker metoprolol on the combined endpoint mortality or hospitalization in individuals with heart failure with and without diabetes participating in the MERIT-HF trial [121]. Note that the relative risk reduction (given in % above the bars) is independent of diabetes state but that the absolute mortality even with metoprolol treatment is considerably higher in the diabetes subgroup [121]. Placebo, red bars; metoprolol, yellow bars.

β-Blockers

Beta blockade decreases myocardial FFA exposure and thereby such treatment has the capacity to favorably influence the metabolic pathway in persons with T2DM and heart failure [119, 120]. Subgroup analyses of participants with diabetes and moderate to severe heart failure in large trials revealed that β-blockers reduce mortality and improve symptoms, hence they are indicated as first-line treatment in such individuals [96, 98, 121–123]. An example of the impact of a β-blocker (metoprolol) added to treatment with ACE inhibitors and diuretics in people with heart failure with and without diabetes is given in Figure 45.9. The relative risk reduction following metoprolol treatment is similar in the two groups. The remaining event rate is still substantially higher in the diabetes cohort than among those without diabetes. Evidence indicates that the use of β-blockers in diabetes alters counter-regulatory responses to hypoglycemia with decreased tremor and palpitations but increased sweating. It seems that this is more common if a non-cardioselective β-blocker (e.g. propranolol) is used and less common with β_1-selective agents or carvedilol. However, the marked clinical benefits of β-blockers in people with diabetes and heart failure outweigh the risks of hypoglycemia [106].

Diuretics and mineralocorticoid receptor antagonists (MRAs)

Diuretics are mandatory for symptomatic relief owing to fluid overload. As already underlined, they should not be used in excess since they induce neurohormonal activation [100]. Loop diuretics are recommended rather than diuretics, which may further impair glucose metabolism. A low-dose MRA is indicated in those with persisting symptoms and a left ventricular ejection fraction ≤35%,

despite treatment with ACE inhibitors and a β-blocker and will reduce the risk of hospitalization and premature death. The mortality benefit with the use of either spironolactone or eplerenone is similar in people with and without diabetes [124–126]. Careful control of kidney function and potassium is essential, because of the increased risk of nephropathy in persons with diabetes.

Ivabradine

Ivabradine may be of use in persons with heart failure in sinus rhythm and a heart rate of ≥70 beats per minute. In the SHIFT trial, it reduced cardiovascular deaths and hospital admissions for worsening heart failure. The benefit was similar in a prespecified subgroup analysis of individuals with and without diabetes [127].

Statins

It has been debated whether statin treatment may impact morbidity and longevity in individuals with heart failure. Two clinical trials, CORONA and GISSI-HF, were both negative in this respect [128, 129]. Statin therapy therefore has no role in the management of heart failure per se. Since IHD with previous MI is frequent in persons with diabetes and heart failure [16], statins may still be indicated to lower LDL-cholesterol.

Cardiac resynchronization therapy

Cardiac resynchronization therapy will improve survival if added to optimal medical treatment in people with sinus rhythm if their left ventricular ejection fraction is low (≤30%), the QRS duration prolonged (≥150 ms) and the ECG shows left bundle branch morphology [130, 131]. There are no specific data on diabetes related to this treatment.

Glucose-lowering treatment

General aspects

In accordance with the pathophysiological aspects on heart failure in persons with diabetes, it has been postulated that meticulous metabolic control may have beneficial effects on progress and prognosis. Chapter 41 deals with some of these aspects. The European guidelines for the management of diabetes recommend an HbA_{1c} (DCCT standard) <7.0% or <53 mmol/mol [106] even in those with heart failure, although glucose control should be individualized. The scientific evidence for very tight glucose control is sparse although more solid for T1DM than T2DM [132]. The negative outcomes of some trials on aggressive glucose lowering have further underlined the uncertainty in this respect [133, 134]. These trials did not, however, consider specifically individuals with heart failure. Considering that both the 20-year follow-up of the first DIGAMI study and the 27-year follow-up of the DCCT study showed long-lasting effects of glucose control on mortality, glucose control should not be completely neglected [135, 136].

There are several already completed or ongoing trials addressing cardiovascular safety with new glucose-lowering agents, including GLP-1 receptor agonists or DPP-4 inhibitors. The increased hospitalization for heart failure observed with the DPP-4 inhibitor saxagliptin in the SAVOR-TIMI 53 trial [137] was not confirmed for sitagliptin in the TECOS trial [138], alogliptin in the EXAMINE trial [139], or the GLP-1 receptor agonist lixisenatide in the ELIXA trial [140]. Regarding cardiovascular benefits of glucose-lowering drugs, a paradigm shift was recently observed when the EMPA-REG OUTCOME study [141] showed a decrease in cardiovascular events, essentially driven by a 38% reduction in cardiovascular mortality and a 35% reduction in hospitalizations for heart failure, in people with T2DM with established CVD randomized to the sodium–glucose co-transporter 2 (SGLT-2) empagliflozin compared with placebo. The impact on heart failure hospitalizations and cardiovascular mortality was clear within the first few months on the drug. The exact mechanisms behind these beneficial effects have to be further elucidated in mechanistic studies. They cannot reasonably be explained by the modest glucose and blood pressure lowering or the weight-reducing effects of empagliflozin. A more plausible explanation, although still speculative, is that a decrease in volume load related to osmotic diuresis and increased sodium excretion, possibly in combination with reduced arterial stiffness, may have had a favorable impact on the development of heart failure, which is prognostically a very serious condition in individuals with IHD [16].

Choice of Glucose-lowering agents

Regarding specific-glucose lowering agents, there is some information available that is of importance for the choice of treatment in people with or at risk for heart failure. The insulin sensitizers thiazolidinediones can provoke or worsen heart failure because of their propensity to induce fluid retention because of sodium retention and plasma volume expansion. Several of these drugs have been withdrawn from the market and those that are still available should be used with great caution in persons with heart failure and are contraindicated in those in NYHA class III–IV [38, 142–144].

Metformin has long been regarded as contraindicated in persons with heart failure because of concerns regarding lactic acidosis, but recent reports have not confirmed this risk and the drug may be used, but not in people with severely compromised kidney function [145].

Insulin treatment in persons with diabetes and heart failure is under debate. The main effect of insulin is to decrease blood glucose, but it may also increase myocardial blood flow, decrease heart rate, and cause a modest increase in cardiac output [146, 147]. Beneficial effects on myocardial function have been reported, but it was also found that insulin may be associated with increased morbidity [148] and mortality [149, 150]. Further studies are needed to establish the specific role of insulin beyond its role as a glucose-lowering agent in persons with diabetes and heart failure.

In general, it can be summarized that there is little information of importance available for the choice of agents for glycemic control in individuals with diabetes and heart failure. Until such information is available, generally accepted management rules should apply [151].

HF-PEF

In general, no randomized clinical trial have shown beneficial treatment effects on prognosis and mortality in individuals with HF-PEF (4,6]. It is recommended that other risk factors are controlled, including hypertension, IHD, and rate control in atrial fibrillation. Impaired myocardial diastolic function and endothelial dysfunction are present in HF-PEF as early expressions of diabetes-related cardiovascular involvement causing decreased myocardial blood flow reserve. It has been suggested that hyperglycemia-related early myocardial and microcirculatory disturbances are dynamic and that they may be reversed by improved metabolic control [152]. One observational study [153] of individuals undergoing intensified glucose control in clinical routine gave support to the assumption that particularly insulin-based glycemic control may be useful. Unfortunately, these observations were not verified in a subsequent prospective study (DADD study), in which people with T2DM, free from previous cardiovascular events and signs of heart failure or CAD, with early signs of diastolic dysfunction were randomized to insulin- or oral-based glucose normalization [154]. It should be underlined that it still is too early to abandon the hypothesis of a favorable relation between glycemic control and myocardial diastolic dysfunction. It may be that the individuals in the DADD trial were too healthy to react to normalization of glucose control. Hence it would be of value to study new agents, such as incretins and SGLT-2 inhibitors, in future trials and to recruit persons at a more advanced disease stage than those selected for the DADD trial. The problem is then the obvious risk for biases caused by hypertensive and CAD and other complications to diabetes. Accordingly, such protocols must include detailed examinations of the participants with this in mind.

Metabolic modulators

Drugs, such as trimetazidine, etomoxir, and dichloroacetate, aimed at shifting myocardial metabolism from oxidation of FFAs towards glycolysis have been tested in people with myocardial dysfunction and diabetes. They act on different parts of the metabolic pathways, as indicated in Figure 45.6. The usefulness must be further explored in clinical trials of appropriate design until their therapeutic role can be considered established, despite some recent promising results [155–157].

Importance of revascularization

In persons with signs of coronary artery ischemia, in stable or unstable situations, revascularization of the coronary arteries with either percutaneous coronary intervention (PCI) or coronary artery bypass grafting (CABG) is recommended if prognosis can be improved and if symptoms are not relieved by medical treatment. The benefits should exceed the risks and should preferably be judged by a multidisciplinary decision-making heart team [158]. Several risk scores are available for judging such benefits and risks, for instance, the SYNTAX score. The most recent guidelines [106, 158] recommend that CABG is preferred in people with diabetes with multivessel coronary artery disease (three-vessel disease), mainly based on the results from the FREEDOM trial [159], but PCI with the use of drug-eluting stents can be considered if the SYNTAX score (based on the coronary angiography findings) is low (≤22). However, it must be borne in mind that it is not always possible to follow the guidelines in everyday practice. It is typical that people with diabetes have a more diffuse atherosclerosis of the coronary arteries and it is not always possible to perform CABG while PCI may be challenging owing to the configuration of the coronary artery stenosis (long and thin stenosis).

In a recent Swedish registry report, based on 36,274 patients hospitalized for heart failure, 60% of the people with diabetes had a reported history of IHD [16]. In those with already developed poor systolic left ventricular function, revascularization might be of use if there are signs of viable myocardium on non-invasive imaging [158]. Nuclear imaging techniques can be used for the detection of coronary ischemia and presence of viability, and MRI can be used for the detection of the transmural extent of myocardial scar tissue, but MRI is not better than nuclear imaging for detection of viability. The STICH trial, including individuals both with and without diabetes, addressed the prognostic importance of CABG in a randomized control trial of patients with left ventricular function ejection fraction <35% and with two- and three-vessel disease. In the intention-to-treat analyses, the STICH investigators reported improved cardiovascular and total mortality in the CABG group [160]. However, in the viability substudy of the STICH trial, there was no correlation of myocardial viability with benefits from CABG, and the recent European Society of Cardiology guidelines state that assessment of viability should not be the sole factor when deciding on the best strategy for people with severe left ventricular function and evident CAD [158].

Gender aspects

Diabetes attenuates the otherwise protective effect for CVD seen in women compared with men, resulting in a first MI at about the same age in women and men with diabetes [11, 161, 162]. The Framingham study was one of the first to report on the high prevalence of heart failure and poor prognosis in women with diabetes [3]. The reason for this equality in cardiovascular risk in men and women with diabetes is not completely understood [162], but women with diabetes more often have multivessel CAD compared with those without diabetes [163]. There is a lack of information on heart failure in women with diabetes, since often both women and those with diabetes were excluded in controlled trials. In registry reports, such as the meta-analysis MAGGIC [164, 165], it is often found that women with diabetes and heart failure are at a greater age and more often have preserved ejection fraction (HF-PEF) than men. Survival after a diagnosis of heart failure was as poor in women as in men with heart failure and much worse than in women without diabetes in several registry analyses addressing gender aspects [164, 165]. Future trials are needed to explore

further the mechanisms behind these findings, for instance, evaluating if CAD, diabetes-related complications affecting myocardial metabolism, and fibrosis are more common among these women.

46 Cerebrovascular Disease

Colum F. Amory[1] and Jesse Weinberger[2]

[1] Albany Medical College, Albany, NY, USA
[2] Mount Sinai School of Medicine, New York, NY, USA

Key points

- Diabetes is a strong and independent risk factor for ischemic cerebrovascular disease with a relative risk of ~2.
- Ischemic stroke in persons with diabetes has worse outcomes, including a higher rate of mortality, than in persons without diabetes.
- Although transient ischemic attacks (TIAs) appear to occur less frequently in individuals with diabetes, those who experience a TIA are more likely to go on to have a completed stroke in the immediate period following.
- Individuals with diabetes are predisposed to vascular events, including stroke, for a number of reasons, such as premature atherosclerosis, reduced response to nitric oxide, and a general state of hypercoagulability.
- Prevention of stroke in persons with diabetes is best accomplished through aggressive management of coexisting hypertension and hyperlipidemia, in addition to lifestyle modifications.
- Reduction of glyclated hemoglobin as a proxy for good glycemic control is likely associated with a reduction in macrovascular events.
- Aggressive management of hyperglycemia in the acute stroke period may improve outcomes.

Epidemiology of stroke in general

Cerebrovascular disease is a leading cause of morbidity and mortality. It is a highly prevalent disease, with ~795,000 strokes occurring each year in the United States. Of these, 610,000 are first-time events and 185,000 are recurrent [1]. It is the fourth leading cause of death in the USA, following heart disease, all forms of cancer, and chronic lower respiratory disease. Thus, a woman is nearly twice as likely to die from a stroke as she is from breast cancer, and 10% more likely than to die from lung cancer [2]. Furthermore, it is the number one reason listed for discharge diagnosis for patients discharged from hospitals to chronic care facilities. In total, the cost of stroke to the healthcare system in the USA was $36.5 billion in 2010 [1].

Statistics in other countries are similar to those seen in the USA. The Oxford Vascular Study, which compiled stroke statistics for every person in the county of Oxfordshire in the United Kingdom, demonstrated an overall incidence of 1.62 strokes per 1000 per year [3]. The WHO MONICA study looked at 21 populations in 11 countries (10 in Europe plus China), and found an incidence of 125–361 per 100,000 men, and 61–194 per 100,000 women [4].

Diabetes as a risk factor for stroke

There is strong evidence that diabetes mellitus, whether type 1 (T1DM) or type 2 (T2DM), is a strong risk factor for ischemic cerebrovascular disease (Table 46.1). Observational studies have demonstrated associations between the two diseases. A model created from data from the Framingham Heart Study showed that diabetes confers an increased relative risk (RR) of 1.4 in men and 1.72 in women [5]. The Honolulu Heart Study showed that diabetes increases the risk of thromboembolic stroke 2–3-fold over individuals without the disease in Japanese men living in Hawaii [6].

The effect of diabetes is stronger in ethnic minorities in the USA. The Greater Cincinnati and Northern Kentucky Stroke Study found that as a sole risk factor, diabetes increased the odds ratio (OR) for having an ischemic stroke by 2.1 in people of white European ancestry; however, in African Americans, that OR was increased by 2.7. These results held true across all age cohorts [7].

Similarly, the Northern Manhattan Study found that diabetes was a stronger risk factor for ischemic stroke among African Americans and Caribbean Hispanics than among white Europeans. In these ethnicities, diabetes increased stroke risk by

- Carotid artery disease

1.8 and 2.1, respectively, partly due to increased prevalence of the disease. The fraction of strokes that could be directly attributable to diabetes as a risk factor was 14% among African Americans and 10% among Caribbean Hispanics [8].

The Copenhagen City Heart Study found a difference in the effect of diabetes among men and women. Thus, while diabetes increased the RR of first stroke, incident stroke, and hospital admission for stroke among men by 1.5–2, among women the same RRs were increased by 2.0–6.5 [9].

In addition to its effects as a sole risk factor, diabetes also exacerbates the effects of other risk factors. Thus, in people with isolated systolic hypertension, diabetes confers additional risk of ischemic stroke or transient ischemic attack (TIA).

Stroke in people with diabetes

In epidemiological studies, ischemic stroke occurs at a younger age in individuals who have diabetes. They are also more likely to be African American. Among other risk factors, persons with diabetes who have ischemic stroke are more likely to have hypertension and hyperlipidemia, and to have experienced a myocardial infarction in the past [7].

Furthermore, diabetes increases the risk of death from stroke. In a prospective study in a Finnish cohort, men had an increased RR of 6 for mortality from ischemic stroke, whereas women had an RR of 8.2. These RRs were higher than those for systolic blood pressure, smoking, or total serum cholesterol. In this cohort, the fractions of stroke deaths directly attributable to diabetes were 16% in men and 33.3% in women [10].

In terms of stroke subtype, diabetes is most commonly associated with lacunar infarcts, that is, a small, deep infarct in the region of a single penetrating arterial branch. Conversely, the highest prevalence of diabetes is found in people with demonstrated microvascular disease. Similarly, lacunar disease is more likely to be associated with diabetes than hemorrhages in the same location [11–14] (Figure 46.1).

Diabetes is also associated with both extracranial and intracranial stenosis. In a study of 510 people referred for asymptomatic carotid bruits, only 200 had extracranial stenosis by Doppler examination. A total of 66 had asymptomatic intracranial stenosis, of whom 37 had concurrent extracranial stenosis. Nineteen of the people with intracranial stenosis had diabetes [15] (Figure 46.2). Interestingly, a recent analysis of the SPS3 study demonstrated that people with diabetes and lacunar strokes had higher rates of intracranial stenosis, although whether this causally related to the infarct is not clear [16].

TIA is less common in persons with diabetes than in those without. This may indicate that diabetics are more likely to present with completed infarct rather than reversible ischemia [17]. However, individuals with diabetes who do present with TIA are more likely to go on to full-blown ischemic stroke in the following 2 days as predicted by the ABCD2 score, representing the predictive factors of age >60 years, blood pressure >140/90 mmHg, clinical features of motor or speech involvement, duration >60 min, and diabetes [18].

Diabetes is a risk factor for coronary artery disease, and therefore for myocardial infarction (MI) and subsequent development of atrial fibrillation. In one large retrospective study of the relation between diabetes and atrial fibrillation or atrial flutter, diabetes was found after logistic regression to be a strong independent predictor for atrial arrhythmias in a review of over 850,000 charts over a 10-year period. The OR found for diabetes was 2.13, 95% confidence interval (CI) 2.10–2.16 [19]. In turn, atrial fibrillation has been repeatedly demonstrated to be a strong risk factor for cardioembolic stroke, with an estimated 75,000 strokes per year attributable to the arrhythmia [20].

Furthermore, diabetes increases the risk of cardiac embolization. The CHADS2 score is a validated method of stratifying risk of cardioembolic stroke in people with atrial fibrillation. It assigns one point each for the presence of congestive heart failure, hypertension, age >75 years, and diabetes, and two points for previous stroke or transient ischemic attack. Each point increase was associated with a 1.5-fold increased risk of stroke. Diabetes alone, then, would increase the risk of stroke in a person with atrial fibrillation from 1.9 to 2.8 [21]. Although the CHADS2 score is not perfect, and attempts have been made to improve its precision [22], it has the benefit of being very easy to use, thus guiding the non-stroke practitioner towards using anticoagulation in the appropriate section of the population.

From large observational studies, there does not appear to be an association between diabetes and hemorrhagic strokes. However, in the Hemorrhagic Stroke Project, a case–control study of young people with intracerebral hemorrhage, diabetes conferred an adjusted OR of 2.4. The risk factor with the most impact was, as predicted, hypertension, which outweighed the contribution from diabetes by more than twofold [23].

Prediabetes and other risk factors

Whereas it is well established that diabetes is a strong risk factor for ischemic stroke, forms of prediabetes are not so clearly indicated as risk factors. Selvin et al. looked at individuals with and without diabetes in the Atherosclerosis Risk In Communities (ARIC) trial and compared HbA_{1c} levels drawn at a specified visit, not necessarily related to time of incident stroke [24]. With increasing tertiles of glycation across the normal

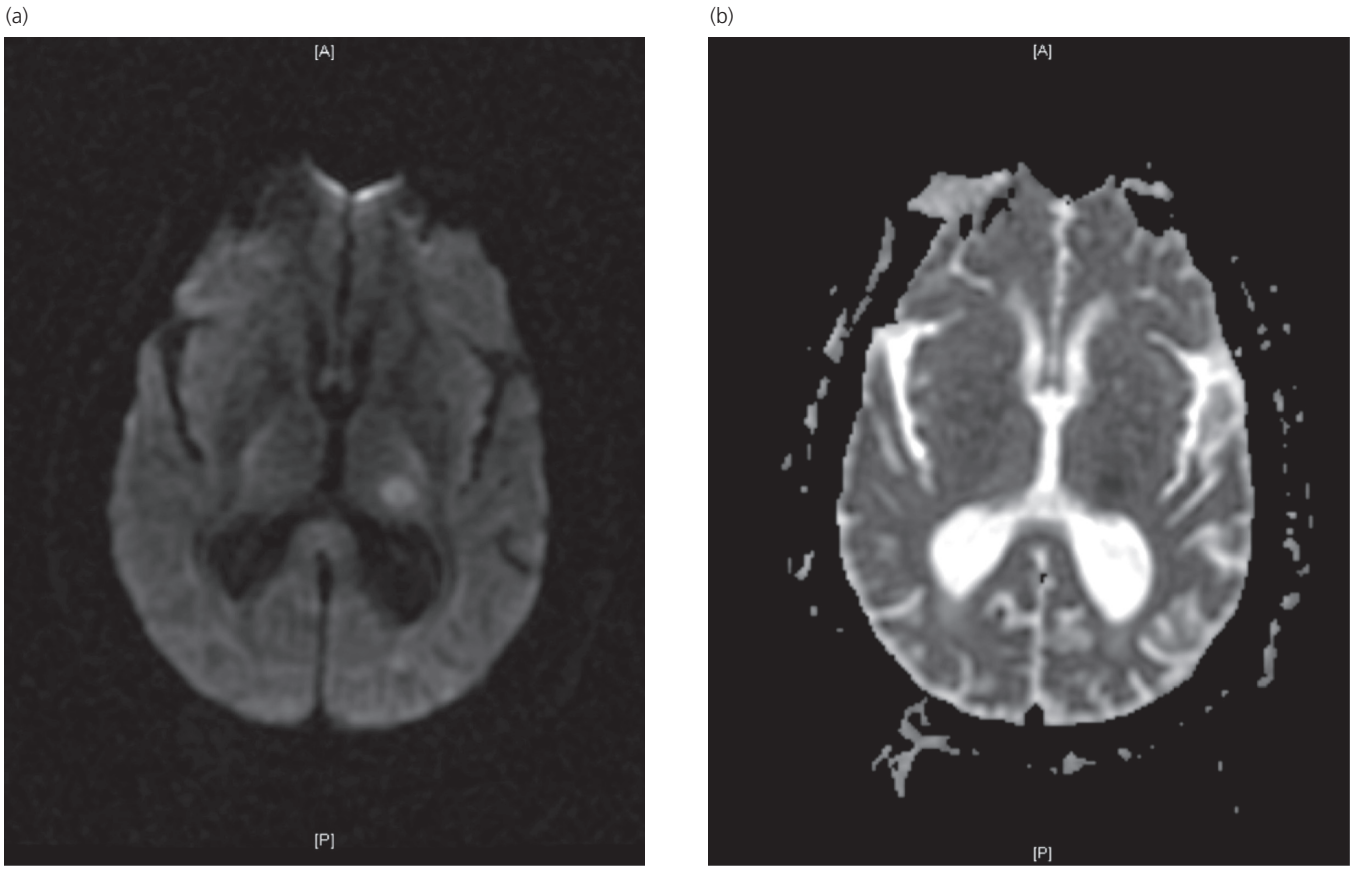

Figure 46.1 Lacunar infarct in the left posterior thalamus. (a) Diffusion-weighted imaging, showing hyperintensity in the area of restricted diffusion, corresponding to acute ischemia. (b) Apparent diffusion coefficient image corresponding to the slice seen in (a), demonstrating hypointensity in the same distribution, confirming the presence of acute ischemia.

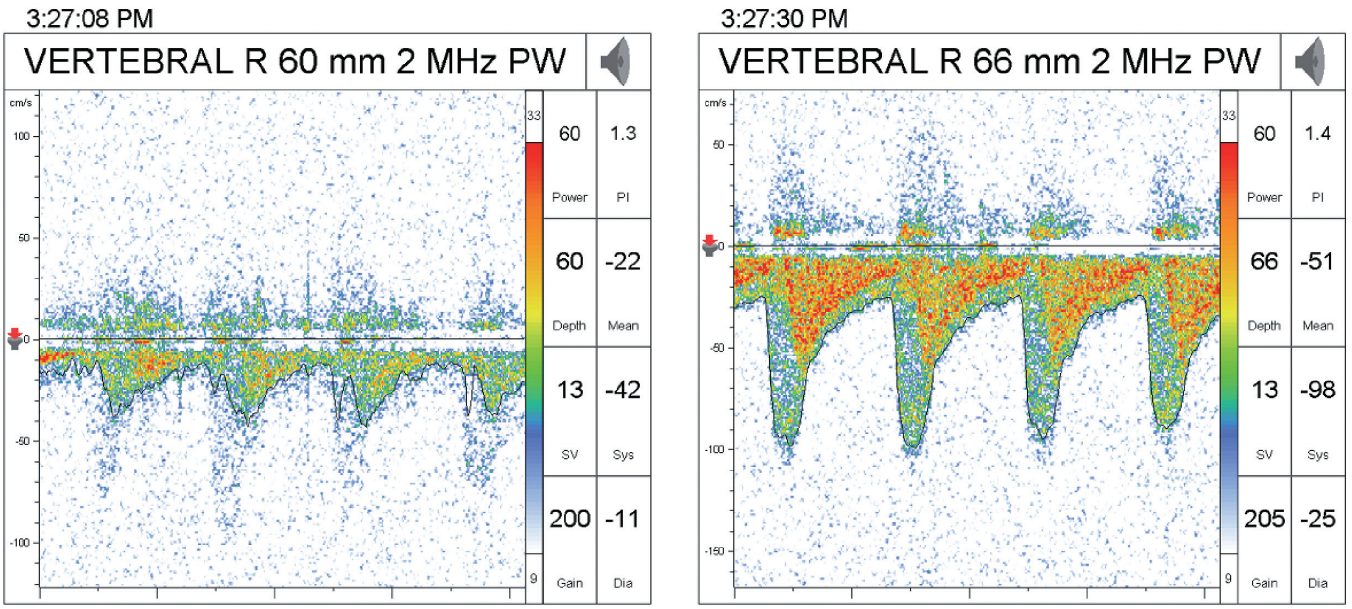

Figure 46.2 Intracranial vertebral artery stenosis as seen by transcranial Doppler ultrasound. The image on the left shows normal flow pre-stenosis and the image on the right shows increased velocity of flow post-stenosis.

distribution within each group, the risk of stroke increased in both cohorts, although it was only in those with diabetes that the difference achieved statistical significance.

In contrast, Myint et al. abstracted data from the European Prospective Investigation into Cancer (EPIC) on glycated hemoglobin levels in persons without known diabetes and correlated these data with stroke risk [25]. In this population, it was only after levels were higher than 7.0% that an increased risk of stroke was demonstrated, compared with those with HbA_{1c} <5.0% 31 mmol/mol. Given that these individuals most likely actually had undiagnosed diabetes, this finding may not implicate chronic hyperglycemia alone as the primary risk factor for stroke.

Insulin resistance, another forme fruste of diabetes, likewise has demonstrated conflicting evidence for association with stroke. The ARIC study investigated hyperinsulinemia in persons without diabetes and found a mild increase in risk of stroke of 1.19 with each increase of 50 pmol/L of fasting insulin. After adjustment for other risk factors such as age, systolic blood presire, and smoking, the increase in risk was not as well defined [26].

Obesity, a proxy for insulin resistance and prediabetes, has also been linked to stroke, through a number of epidemiological studies. For example, the Copenhagen City Heart Study found that body mass index (BMI) was independently associated with increased risk of stroke [27]. Similarly, the Nurses' Health Study found, as expected, an increasing risk of stroke with increasing BMI, with an RR of stroke of 2.37 (95% CI 1.60–3.50) seen in people with BMI >32 Kg/m^2 [28]. However, the ARIC study was unable to demonstrate any relationship between BMI and stroke, or between waist/hip ratio, a better measurement of abdominal obesity, and stroke [26]. In addition, when adjustment for cardiovascular risks is performed, the relative risk of BMI for stroke is once again attenuated.

Although these individual forms of prediabetes have not conclusively been shown to predispose people to stroke, the constellation of diseases together called the metabolic syndrome has been. The combination of hypertension, hyperlipidemia, insulin resistance, and abdominal obesity creates an environment that is highly susceptible to vascular damage and ischemic sequelae.

In a Finnish cohort, the metabolic syndrome in the absence of diabetes or cardiovascular disease (CVD) was associated with stroke with an RR of ~2, after adjustment for multiple other risk factors [29]. Similarly, a cohort from the ARIC study who likewise were free of diabetes, coronary heart disease (CHD), or stroke had an increased RR of 1.5–2 for ischemic stroke. In addition, on separating out each risk factor, there appeared to be a synergistic effect from the combination over the RRs inherent in each component [30].

Pathophysiology of ischemic stroke in diabetes

Diabetes predisposes individuals to vascular thrombo-occlusive events in a number of ways. There is accelerated atherosclerosis in both large- and medium-sized vessels. There is disordered endothelial response, and the blood is hypercoagulable [31].

Carotid intima-media thickness (IMT) is a useful proxy for early atherosclerosis, as it is easily measured by Doppler examination. Furthermore, IMT is associated with primary stroke, with an increased RR per standard deviation (0.163 mm) of 1.57 in individuals who had not had a previous stroke [32]. It also predicts recurrent stroke, with each 0.1 mm increase in IMT associated with an increased risk of 18% [33].

Diabetes is associated with increased IMT. The Insulin Resistance Atherosclerosis Study demonstrated an increase in common carotid IMT in people with long-standing diabetes, but not in those with newly diagnosed diabetes. Nor was there an association with internal carotid artery IMT [34].

Conversely, persons with diabetes with stroke have been found to have greater IMT. In A study of 438 Japanese people with T2DM, common carotid IMT was significantly higher in those who had stroke, even after adjustment for age, BMI, and smoking status [35]. Similarly, in a Czech cohort, IMT was increased in people with stroke and diabetes [36].

Atherosclerosis also affects the ability of endothelium to release nitric oxide (NO), a potent vasodilator. In diabetes, blood vessels have either reduced NO production or altered NO metabolism. In addition to its vasodilating effects, NO protects against platelet aggregation and enables the blood vessel to withstand ischemic conditions. With decreased NO activity, the vessel will tend more towards vasoconstriction, with predictably poor response to ischemia.

People who have suffered a stroke have decreased NO in circulating blood, along with increased peroxynitrite ($ONOO^-$), a reactive oxygen species. These results were particularly evident in larger strokes. Since the measurements were performed for acute stroke, these levels are likely to represent the outcome of ischemia rather than the cause. However, the correlation supports a role for decreased NO in the effects of stroke [37].

The cerebral vasculature has a diminished response to inhibition of NO synthase (NOS). In a small study of men with diabetes treated with a synthetic NOS inhibitor, N^G-monomethyl-L-arginine, the blood flow through the internal carotid artery was significantly lower than in men without diabetes treated likewise [38].

As further indirect evidence of the role of NO in stroke, 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins) have multiple beneficial effects beyond their most common one, that of lowering plasma cholesterol. Among these effects are increasing the expression of endothelial NOS and also decreasing the activity of Rho-kinase, a proconstrictor enzyme [39]. Statins have been demonstrated to lower the risk of recurrent stroke in several large studies [40–42]. Whether the beneficial effect of statins in stroke is due to their cholesterol-lowering effect, their ability to stabilize atherosclerotic plaques, their effects on vascular function, or more likely a combination of all of these, is very difficult to ascertain.

In addition to the above predisposing factors, the blood of a person with diabetes is hypercoagulable. Studies have demonstrated increased thrombin generation [43], increased prothrombin fragments, and increased thrombin–antithrombin III complexes [44]. Furthermore, the elevated prothrombotic levels were significantly associated with macroangiopathic complications.

Thrombus formation is further promoted by platelet hyperreactivity in the blood of individuals with diabetes. In persons with metabolic syndrome, platelets have been shown to have increased activity both through closure time as measured by the platelet function analyzer (PFA-100), increased fibrinogen binding after exposure to adenosine diphosphate, implying activation of the GPIIa/IIIb receptors, and by expression of activated ligands on the platelet surface [45]. In diabetes, platelets were hyperreactive as measured by light transmittance aggregometry and expression of surface ligands [46].

Hence, taken together, the person with diabetes has a vascular environment that is highly susceptible to thrombo-occlusive complications. With early atherosclerosis and disordered endothelial response, the person with diabetes is predisposed to thrombophilia. The blood, in its hypercoagulable state combined with platelets that are highly active in themselves, is far more likely to form clots.

Lacunar strokes are caused by damage to smaller parenchymal vessels. The most common cause is microatheroma, as demonstrated in pathological case series published by Fisher [47–49], the neurologist responsible for naming the lacunar syndromes. Lipohyalinosis and fibrinoid necrosis also cause microangiopathies, and both are most commonly found in the setting of chronic hypertension of severe acute blood pressure elevations, as seen in hypertensive encephalopathy [50, 51].

Primary prevention of stroke in persons with diabetes

Primary prevention of stroke is of paramount importance, as the disability from stroke and healthcare costs associated with the acute and chronic care of stroke are so extensive. The approach to prevention in the person with diabetes is of necessity multifactorial.

Medical therapy aimed at achieving normoglycemia is the foundation. The Diabetes Control and Complications Trial (DCCT) investigated intensive insulin regimens including subcutaneous insulin injections and external insulin pumps in T1DM. The goal for treatment was HbA_{1c} levels of <6.0% (42 mmol/mol). The comparison group had no such goals apart from prevention of hyperglycemia or hypoglycemia [52]. The intensive treatment group achieved a reduction of 57% in the combined endpoints of non-fatal MI or stroke, cardiac death, or revascularization procedure. The majority of this improvement was associated with the decrease in HbA1c [52].

Among oral antidiabetes agents, metformin has been shown to decrease diabetes-related endpoints including stroke by 32% and diabetes-related mortality including from stroke by 42% compared with conventional therapy. Furthermore, it was more effective in reducing these outcomes compared with other intensive therapies such as sulfonylureas (e.g. chlorpropamide or glibenclamide) or insulin. However, it should be noted that the HbA1c was similar among the groups, and so the benefits obtained were not explicable on the basis of improved glycemic control [53].

Rosiglitazone, a thiazolidinedione, on the other hand, has been linked with increased risk of MI and death from cardiovascular causes. Stroke was not assessed separately in the meta-analysis reporting these findings [54]. An interim report from an ongoing trial directly assessing the effect of rosiglitazone on cardiovascular outcomes has not upheld these findings [55]. Pioglitazone, another medication in the same class, was not associated with worse cardiovascular outcomes including stroke, and in fact reduced a secondary outcome of all-cause mortality, non-fatal MI and non-fatal stroke, by 16% [56].

The United Kingdom Prospective Diabetes Study (UKPDS) failed to show any reduction in macrovascular complications of T2DM despite a 0.9% reduction in HbA_{1c} in an intensive treatment group. Microvascular complications such as retinopathy and neuropathy were significantly reduced [57]. A 10-year follow-up study of the same cohort after attempts to maintain treatment differences had desisted showed that the original treatment cohort had persistent decrease in microvascular complications and also in MIs and deaths from any cause [58]. Hence glycemic control, at least in T2DM, has not been linked to a reduction in risk for stroke.

Given how susceptible persons with diabetes are to the effects of other vascular risk factors such as hypertension and hyperlipidemia, the therapeutic regimen must also address these states. In treating hypertension in persons with diabetes, the classes of medications with effects on the angiotensin–renin system appear to have the greatest benefit (see Chapter 42).

The HOPE trial examined people either with vascular disease (including coronary artery disease or stroke) or diabetes plus one other cardiovascular risk factor, such as hypertension, tobacco use, or elevated low-density lipoprotein cholesterol (LDL-C) levels. In this high-risk population, ramipril, an angiotensin converting-enzyme (ACE) inhibitor, decreased the risk of death from cardiovascular causes with an RR of 0.74, and reduced the risk of stroke with an RR of 0.68. As the mean reduction in blood pressure was only 3/2, the benefits were not attributable to the blood pressure-lowering effect of the medication. The effect was similar whether or not the participants had had a stroke prior to enrolment [59].

The LIFE trial examined people with diabetes, hypertension, and left ventricular hypertrophy. Participants were treated with either losartan, an angiotensin-2 receptor antagonist, or atenolol. Although, again, both medications achieved the same reduction in blood pressure, the primary endpoint of cardiovascular mortality, MI, or non-fatal stroke was reduced with an RR of 0.76. Notably in this trial, only 40% of participants achieved a systolic blood pressure of <140 mmHg, implying that further benefits would likely accrue with more intensive management [60].

A recent trial of intensive multifactorial medical management in individuals with diabetes with microalbuminuria showed a reduction in all-cause mortality, cardiovascular mortality, and cardiovascular events. The regimen was designed to achieve the following goals: HbA_{1c} levels of <6.5% (48 mmol/mol), fasting total serum cholesterol levels of <175 mg/dL, systolic blood pressure of <130 mmHg, and diastolic blood pressure of <80 mmHg. Stroke was not a prespecified endpoint in this study; however, there were six strokes in six participants in the intensive medical group, compared with 30 strokes in 18 participants in the control group [61].

Although antiplatelet treatment has been recommended for the primary prevention of coronary disease, the Antithrombotic Trialists' Collaboration meta-analysis failed to demonstrate a significant improvement in the primary prevention of ischemic stroke in persons with diabetes. Overall, nearly 5000 people were treated with aspirin, with only a 7% reduction in serious vascular events. The 95% CI was wide enough to include a possible 25% risk reduction, a value that is consistent with the prevention of secondary stroke in this population. It may be that in this population at high risk, the potential benefits of prophylactic aspirin outweigh the hemorrhagic complications [62].

Most of the early trials of antithrombotic medications were performed only on men. In the Women's Health Study, a study performed among female health professionals with no history of coronary or cerebrovascular disease, low-dose aspirin (100 mg every other day) was associated with a 17% risk reduction in stroke, a result of a 24% risk reduction in ischemic stroke and a non-significant increase in hemorrhagic stroke. These findings were especially pronounced in women older than 65 years of age at the time of enrolment, and also in the subgroup with diabetes [63].

Treatment of acute stroke in persons with diabetes

Treatment of acute stroke is limited by the vulnerability of the neuron to ischemic insult. With decreasing cerebral blood flow, the parenchyma becomes less likely to recover from even short durations of ischemia. With cerebral blood flow <20 mL per 100 g of tissue, neurological dysfunction begins to appear. However, it is not until the cerebral blood flow falls below 10 mL per 100 g of tissue that irreversible ischemia occurs, in a matter of minutes [64].

Thrombolysis has been demonstrated to be effective in the treatment of acute stroke provided that the medication is given within the first 3 h after symptom onset, as defined by the last time the individual was seen at their neurological functional baseline (Table 46.2). The NINDS trial of intravenous tissue plasminogen activator (t-PA) demonstrated a 30–50% increased likelihood of minimal or no disability 3 months after treatment. The thrombolysis was associated with a 6.4% chance of symptomatic intracranial hemorrhage, but the mortality data at 3 months were not statistically different between the treatment and the placebo groups [65].

Based on this trial, treatment with intravenous t-PA became standard of care in this early time period. Although more recent data from the ECASS-III trial [66] suggested that it is not only safe but also clinically effective to a lesser extent in a select group of patients to give intravenous t-PA in the window between 3 and 4.5 h after the onset of symptoms, this has not yet become standard practice. In addition, individuals with diabetes who had had a previous stroke by history or on imaging were excluded from the trial.

Table 46.2 Management of acute ischemic stroke.

- 0–3 h Intravenous tissue-plasminogen activator (t-PA)
- 0–6 h Intra-arterial t-PA
- 0–8 h Mechanical clot retrieval (MERCI device)
- Permissive hypertension for the first 3–5 days
- Aspiration precautions
- DVT prophylaxis

Intravenous t-PA is the only acute intervention approved by the US FDA. Both intra-arterial t-PA and mechanical clot retrieval remain experimental, although widely used. Intravenous t-PA should remain the standard of care when it is not contraindicated, with the other interventions to be used as auxiliary therapy

Thrombolysis in the person with diabetes with acute stroke is not as successful as in the general population. In a series of 27 individuals treated with intravenous t-PA, none of those with diabetes achieved recanalization of the occluded artery as measured by transcranial Doppler ultrasound [67]. The series was not large enough to demonstrate a significant difference. In another study examining which factors might predict major neurological improvement in people treated with intravenous t-PA, there was a trend towards people with diabetes being less likely to achieve that improvement [68].

Beyond intravenous thrombolysis, intra-arterial thrombolysis has been examined in patients up to 6 h after the onset of stroke symptoms. The PROACT II trial found that participants treated with intra-arterial urokinase had a 58% RR reduction to achieve minimal or no functional disability at 90 days after treatment. Mortality rates were comparable, and recanalization rates were greatly improved with the medication [69]. Current guidelines support the use of intra-arterial thrombolysis in the period between 3 and 6 h after the onset of symptoms. However, the medication has not been approved by the US Food and Drug Administration (FDA) for this indication [70].

In a case series of 100 people treated with intra-arterial thrombolysis with urokinase, diabetes was associated with poor functional outcome at 3 months. It was not associated with symptomatic intracranial hemorrhage [71]. However, since diabetes is independently associated with worse outcomes following acute ischemic stroke, it is not clear whether these data have any meaning for clinical practice.

Other interventional techniques include clot retrieval. Three devices have been tested: the MERCI device, a corkscrew type device; the PENUMBRA device, a direct clot aspirator; and the Solitaire stent retrieval system. The last device is the one most commonly used clinically today: compared with the MERCI

device, it had improved chances of restoring partial or complete restoration of blood flow with an OR of 4.87 [72]. However, a note of caution about interventional therapy has been raised with the publication of the IMS-III trial, which failed to show any benefit of endovascular therapy after treatment with intravenous t-PA, although there was no increased risk of these therapies either [73]. At the same time, these sorts of trials are very difficult to carry out, and analysis of IMS-III shows that a sizable proportion of participants randomized to receive endovascular therapy did not have any procedure attempted owing to lack of an appropriate target thrombus [74]. In support of the use of interventional therapy, the MR CLEAN trial enrolled 500 people in The Netherlands and randomized them to endovascular intervention plus usual care (which could include intravenous t-PA) versus usual care alone. The majority of interventional treatments used stent retrieval. The interventional group had an absolute risk reduction of achieving a good functional outcome of 13.5%, with a number needed to treat of 7.4 [75].

Hyperglycemia at the time of stroke treatment is associated with worsened outcomes. In a series of 73 people treated with intravenous t-PA, age, diabetes, admission glucose >140 mg/dL, and early reocclusion on transcranial Doppler ultrasound were significantly associated with worsened functional outcome as defined by a score of >3 on the modified Rankin scale. However, after logistic regression, only the hyperglycemia remained as an independent predictor of poor outcome. In particular, it was associated with larger infarct size, lesser degree of neurological improvement, and worse clinical outcome if recanalization was achieved [76].

Similarly, baseline hyperglycemia is associated with a greater likelihood of going on to symptomatic intracranial hemorrhage after intravenous thrombolysis. There appears to be a dose–response relationship between levels of serum glucose and likelihood of hemorrhage. This was especially true when levels were above 11.1 mmol/L (200 mg/dL), where 25% of patients suffered symptomatic intracranial hemorrhage. In a repeat analysis substituting the presence of diabetes for glucose levels, diabetes was associated with an OR of 3.61 for all hemorrhages, and 7.46 for symptomatic hemorrhage [77].

Furthermore, both those individuals who acutely worsened and those who showed lack of improvement at 24 h were more likely to have elevated blood glucose at baseline. Hyperacute worsening in patients treated with either intravenous or intra-arterial thrombolysis, or both, was not surprisingly associated with intracerebral hemorrhage and lack of recanalization. However, it was also associated with higher serum glucose. With every increase of 50 mg/dL of glucose, the OR for worsened outcome was 1.50 and the OR for mortality was 1.38. Even in those individuals who achieved recanalization, higher blood glucose predicted worse outcomes [78]. Similarly, serum glucose >144 mg/dL and also cortical involvement and time to treatment were independent predictors of lack of improvement at 24 h after treatment with intravenous thrombolysis. The OR for hyperglycemia was 2.89. Furthermore, lack of improvement at 24 h predicted poor functional outcome at 3 months [79].

Although these data are understandably disheartening, they should by no means be taken to imply that people with diabetes and acute stroke should not receive thrombolysis, or that these individuals do not benefit from the treatment. Furthermore, it is not clear whether the hyperglycemia seen in people with acute stroke and diabetes is secondary to the ischemic insult as a stress response or instead part of the chronic diabetic state and thus purely a complicating factor.

Interestingly, one study examined how persistent hyperglycemia differed from transient hyperglycemia in functional outcomes in addition to mortality. When hyperglycemia was present at baseline and when measured 24 h after admission, it was inversely associated with neurological improvement in the first 7 days, 30-day functional outcome, and 90-day negligible dependence. At the same time, persistent hyperglycemia was positively associated with increased mortality at 90 days and parenchymal hemorrhage. When hyperglycemia was absent at baseline but present at 24 h after admission, it was likewise inversely associated with 90-day negligible dependence and positively associated with death and parenchymal hemorrhage. In this study, baseline hyperglycemia alone (without persistence at 24 h) was not associated with poor outcomes. These data suggest that it may not be the stress response hyperglycemia that causes damage in the acute stroke setting [80].

However, intensive treatment of hyperglycemia may be associated with improved outcomes, as has been demonstrated for MIs [81]. A small pilot study found that hyperglycemic patients could be treated with insulin infusions safely, but the numbers were too small to compare functional outcomes at 1 month [82]. The use of insulin drips in another study to maintain glucose levels between 5.0 and 7.2 mmol/L (90–130 mg/dL) in people with acute ischemic stroke, started no later than 12 h after the onset of symptoms, was associated with a trend towards better functional outcomes and minimal or no neurological symptoms as measured by the NIH stroke scale. There were hypoglycemic episodes in the group treated with continuous infusion, but the majority of these were asymptomatic [83]. Clearly, further study is required on this subject.

Hyperglycemia as defined by serum glucose >400 mg/dL was a contraindication for inclusion in the NINDS trial for some of the reasons above, and also because extreme hyperglycemia can cause focal neurological deficits that mimic stroke [65]. Current guidelines recommend starting aggressive glycemic control if serum glucose is >200 mg/dL, while acknowledging that levels above 140–185 mg/dL may still be harmful [70]. Although it may be reasonable to attempt to bring down the glucose level and see if any focal symptoms improve or resolve, and then treat with thrombolysis if no improvement is seen, this approach has yet to be tested.

In terms of oral antidiabetes agents in the acute stroke setting, one study looked at the role of sulfonylureas taken pre-stroke and during the acute hospitalization. Sulfonylureas have an effect on $NC_{Ca\text{-}ATP}$ channels that are regulated by the SUR1 receptor, like pancreatic β cells, and which are open only during ischemic episodes, causing cell death. Theoretically, then,

treatment with sulfonylureas should be neuroprotective during ischemia. Although the numbers were small, and people with more severe strokes (NIH stroke scale >9) were excluded, people on the medication were more likely to have a decrease of 4 points on the NIH stroke scale or a score of 0, and were more likely to achieve an excellent functional recovery at discharge. The effect was particularly noticeable in non-lacunar strokes [84].

Further care for the person with acute stroke is best handled in a certified stroke unit, with multidisciplinary care from a team consisting of vascular neurologists, stroke-trained registered nurses, physical therapists, occupational therapists, and speech and swallow specialists. This care results in a reduction in mortality of ~25% [85].

Blood pressure control in acute ischemic stroke is a subject of ongoing debate. Current thinking still supports the concept of permissive hypertension in the peri-stroke period. Most vascular neurologists would allow the blood pressure to remain untreated until the systolic blood pressure rises above 220 mmHg or the diastolic blood pressure above 120 mmHg. The period when permissive hypertension should be allowed is also controversial. Typically, the blood pressure is left untreated for the first 3–5 days after stroke [70].

The majority of medical complications after stroke relate to the disability associated with neurological deficits. However, deep venous thrombosis (DVT) and aspiration pneumonitis are the two preventable complications. Prevention of DVT is accomplished through subcutaneous anticoagulation with either heparin or low molecular weight heparin with or without external compressive devices [70]. Initiation of treatment is typically immediately on admission, regardless of the size of infarct. One unblinded study studied heparin versus enoxaparin and found a reduction in thrombosis with the low molecular weight heparin [86].

Prevention of aspiration is more complicated. Protection of the airway is often compromised in the acute period after stroke. Frequent suctioning and positioning help to prevent aspiration. Swallow evaluations should be undertaken before oral nutrition is started in any one in whom dysphagia is suspected. Placement of nasogastric tubes (NGTs) is often required for nutrition, and frequently patients will require a percutaneous endoscopic gastrostomy (PEG) tube for long-term provision of nutrition. Hydration is necessary, either intravenously before enteral access is established, or via NGT or PEG tubes to prevent dehydration and electrolyte abnormalities. Antibiotics should be started in any patient suspected of infection, and fever should prompt an aggressive search for a source. Hyperthermia itself causes neurological deterioration, so antipyretics should be administered [70].

Secondary Prevention of Stroke in Diabetes

The management of the person with diabetes after stroke is similar to that for primary prevention as outlined above. The eighth report of the Joint National Committee on Prevention and Treatment of Hypertension recommends that persons with diabetes should be maintained at a blood pressure of <140/90 mmHg, and that it may take multiple antihypertensive medications to achieve this goal [87]. As suggested by the studies described above, ACE inhibitors and angiotensin receptor blockers provide greater protection against cardiovascular events including stroke.

Table 46.3 Prevention of ischemic stroke in the person with diabetes.

- Tight glycemic control
- Antihypertensives with ACE inhibitors or angiotensin receptor blockers
- Anticholesterol treatment, especially with HMG-CoA reductase inhibitors (statins)
- Lifestyle modifications (tobacco cessation, weight loss, etc.)
- Antiplatelet therapy (either aspirin, clopidogrel, or dipyridamole) *or*
- Anticoagulation in people with atrial fibrillation

Similarly, the American Heart Association and the American College of Cardiology have published guidelines on the management of cholesterol in individuals with diabetes [88]. All people who have clinical atherosclerotic cardiovascular disease, including stroke or TIA, should be offered treatment with a statin medication, at high intensity if there are no known safety concerns. In the situation where such an event has not occurred, people with diabetes and an LDL-C >70 mg/dL should also be treated with a statin. The guidelines suggest a goal of lowering the LDL-C by 50% when high-intensity statin treatment is used. Guidelines from the Endocrine Society likewise endorse aggressive lowering of LDL-C without specific goal thresholds for treatment [89].

Antiplatelet therapy should be started in all people who have had a non-cardioembolic ischemic stroke (Table 46.3). Although the Antithrombotic Trialists' Collaboration meta-analysis failed to show benefit in people with diabetes, post hoc analysis of data from the CAPRIE study found that such individuals treated with clopidogrel had a decreased rate of stroke, MI, or death of 15.6% compared with a 17.7% risk in those treated with aspirin [90]. Similarly, in a post hoc subgroup analysis of a study of cilostazol, people with diabetes had a decreased rate of recurrent stroke on the medication compared with placebo, with an RR reduction of 41.7%. This finding was especially evident in those with lacunar stroke [91]. These findings need to be verified with further trials. The use of a combination of dipyridamole and aspirin was demonstrated to be non-inferior to clopidogrel in the prevention of recurrent stroke in the PRoFESS trial. The prevalence of diabetes in this study was 28% in each group, and subgroup analysis within diabetes likewise did not demonstrate any difference between the two treatments [92].

In individuals who have had ischemic stroke secondary to extracranial carotid stenosis, carotid endarterectomy remains the preferred treatment of choice for carotid artery stenosis >70% (Figure 46.3). For degrees of stenosis between 50 and 70%, the benefits of surgery are much smaller, and decisions to treat will depend on the complication rate at local institutions [29]. However, the recent CREST trial suggests that carotid artery stenting is equivalent to surgical revascularization with respect to rates of

Figure 46.3 Computed tomography angiography with iodinated contrast of the neck. There is mild stenosis seen at the origin of the right internal carotid artery. There is critical stenosis ("string sign") at the origin of the left internal carotid artery, corresponding to severe atherosclerotic plaque.

periprocedural stroke, MI, or death, or rate of recurrent stroke. However, periprocedural stroke was more likely in the stenting group, whereas MI was more likely in the endarterectomy group. People younger than 70 years of age fared better when stented, whereas those over 70 years of age had better outcomes when they received endarterectomy. This dichotomization likely represents the risk of undergoing an endovascular procedure with an increasing atherosclerotic burden [93].

Persons with diabetes with atrial fibrillation, paroxysmal or otherwise, should be anticoagulated with warfarin to a goal of an International Normalized Ratio (INR) of 2.0–3.0. The risk reduction associated with treatment with anticoagulation is 68%, with an absolute risk reduction in the annual stroke rate from 4.5 to 1.4% [94]. This reduction in risk is so strong that one study estimated that a person would have to fall 295 times in one year for the risk of subdural hematoma secondary to trauma to outweigh the benefits gained from anticoagulation [95]. There is no reason to assume that this is any different for persons with diabetes.

Recently, several novel oral anticoagulants have been developed for the prevention of stroke in people with atrial fibrillation. Dabigatran [96], a direct thrombin inhibitor, and rivaroxaban [97] and apixaban [98], both direct Factor Xa inhibitors, have been demonstrated to be at least equivalent to warfarin in reducing the risk of recurrent ischemic stroke, with fewer hemorrhagic complications. These medications have a significant advantage over warfarin in convenience for both practitioner and patient, in that they do not require monitoring of levels, nor do they interact significantly with other medications, or require dietary adjustment. However, at present, there is no reliable method of reversing their anticoagulant effect in the setting of a hemorrhagic complication or need for emergency surgery. Prothrombin complex concentrate has normalized prothrombin times in animal models, and a dedicated reversal agent is being developed for the direct Factor Xa inhibitors (andexanet alfa) [99]. At present, we prefer the use of warfarin for prevention of stroke in people with atrial fibrillation unless they are unable to tolerate it or if their INR is too difficult to maintain in the therapeutic range.

Conclusions

Diabetes is a strong risk factor for ischemic stroke, and stroke in diabetes is both more severe in presentation and outcome and more recalcitrant to acute treatment. Although many etiologies of stroke are made more common by diabetes, the most common type of stroke found in persons with diabetes is lacunar microvascular infarction. Prevention of stroke in the person with diabetes is best served through aggressive management of concurrent hypertension and hyperlipidemia. Careful glycemic control also likely reduces the risk of stroke, but the risk reduction is not nearly as robust. Antiplatelet therapy also plays important role; a single antithrombotic agent is sufficient for the prevention of ischemic stroke. Hyperglycemia in the acute phase after ischemic stroke is associated with poor outcomes, and aggressive management likely improves functional recovery.

47 Peripheral Vascular Disease

Henrik H. Sillesen
Department of Vascular Surgery, Rigshospitalet, University of Copenhagen, Copenhagen, Denmark

Key points

- Peripheral arterial disease is very common, affecting up to 30% of all people with diabetes.
- Amputations are much more common in people with diabetes and occur 5–8 times more often than in those without the disease.
- Atherosclerosis is common in people with diabetes, and measurement of ankle blood pressure may identify both people with peripheral arterial disease at an early asymptomatic stage.
- People with diabetes have atherosclerotic lesions located more peripherally than people without diabetes and therefore are more commonly inoperable for technical reasons.
- People with diabetes have more complications in surgery, both locally (infections) and systemically (e.g. cardiac, pulmonary) than people without diabetes.
- Treatment of atherosclerosis in people with diabetes is basically the same as in those without diabetes.

Introduction

Peripheral vascular disease includes diseases to arteries and veins outside the thoracic region. Because of space limitations, this chapter mainly covers the three most common arterial diseases: peripheral arterial disease, carotid artery disease, and aortic aneurysmatic disease. Other, rarer, manifestations of atherosclerotic disease (e.g. renovascular hypertension, abdominal angina, and ischemia of the upper extremities) are mentioned briefly. Special considerations in individuals with diabetes are dealt with in relevant sections, e.g. infection in an ischemic foot in a person with diabetes is described in the section that includes critical limb ischemia.

Atherosclerosis is the main cause of peripheral arterial disease, and the overall pathogenesis is covered in Chapter 41. It is important to appreciate that the pathogenetic mechanisms of clinical atherosclerosis are dual: chronic obstructive and thrombotic. Whereas the chronic obstructive mechanism is the main cause of lower limb ischemia, including in persons with diabetes, it is often preceded by a thrombotic event; a person with mild claudication suddenly experiences significantly shortening of walking distance or sudden onset of rest pain. Alternatively, the seemingly healthy person suddenly develops claudication. Of course, a heart attack or stroke in a person with chronic obstructive disease and claudication is also a thrombotic event.

In general, individuals with diabetes more often develop symptoms of atherosclerotic complications, they do so at a younger age, they are more difficult to treat, and they have more complications with treatment (especially with invasive treatment).

Peripheral arterial disease

Peripheral arterial disease is a chronic condition that, like atherosclerosis in other vascular beds, develops over decades. The World Health Organization (WHO) definition includes exercise-related pain and/or ankle brachial index (ABI) <0.9. On average, symptoms from the lower limbs develop 5–10 years later than from the coronary circulation. Acute ischemia may develop because of:

1 thrombosis in a vessel with pre-existing atherosclerotic plaques and/or stenosis;
2 embolism (e.g. from mural thrombus in the heart);
3 an arterial lesion upstream; or
4 as a result of trauma.

Diabetes is a major contributor to peripheral arterial disease.

Peripheral arterial disease is traditionally divided into four stages (Fontaine):

1 asymptomatic (ABI <0.9);
2 functional pain (claudication);
3 rest pain; and
4 non-healing ulcers or gangrene.

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

Incidence

In population-based studies in Western Europe, the incidence of symptomatic peripheral arterial disease is 3–4% among 60–65-year-olds, increasing to 15–20% in persons aged 85–90 years [1–3]. Similar findings have been reported in the United States. Looking at asymptomatic cases where the ABI is <0.9, the incidence is much higher, in ~20% of all persons above 65 years of age, ranging from 10% in those 60–65 years of age to almost 50% in those aged 85–90 years [1–3]. Critical limb ischemia, defined as ABI <0.4 or rest pain and/or non-healing ulcers, occurs in 1% of persons aged 65 years or older.

Prevalence of peripheral arterial disease in people with diabetes

The prevalence of peripheral arterial disease in people with diabetes depends on the usual atherosclerosis risk factors and duration of diabetes. There have been only a few demographic studies of the general population. Using ABI <0.9 as the selection criterion, Lange et al. [4] found a prevalence of 26.3% in people with diabetes compared with 15.3% in people without diabetes on screening 6880 Germans above 65 years of age, of whom 1743 had diabetes. Similar findings have been reported by others: 20–30% of those with diabetes have peripheral arterial disease [5, 6]. Claudication is twice as common in those with diabetes as those who do not have diabetes.

Pathophysiology

It is outside the scope of this chapter to describe the pathophysiology of peripheral arterial disease in detail (see Chapter 41); however, in brief, the pathophysiology in people with diabetes is similar to that in people without diabetes. The abnormal metabolic state that accompanies diabetes directly contributes to the development of atherosclerosis. Proatherogenic changes include increases in vascular inflammation and alterations in multiple cell types. Both mechanisms of atherosclerotic complications are of importance in peripheral arterial disease (gradual narrowing resulting in stenosis and acute thrombosis in existing atherosclerotic lesions). Obviously, the long-term accumulation of lipids in the vessel wall is important and sudden local thrombosis can occur at any time, although in most cases this happens after symptoms (claudication) have developed.

To reach the stage of critical limb-threatening ischemia, advanced atherosclerosis has developed. Often, multiple segments of the arterial tree from the aorta to the foot are affected (stenotic and/or occluded). In people with diabetes, the atherosclerotic lesions are more peripherally located than in people without diabetes. Whereas the iliac and femoral arteries are most commonly stenotic and/or occluded in individuals without diabetes, in those with diabetes it is most often the crural or pedal arteries that are severely affected by atherosclerosis. In fact, in some cases of ischemic ulcers of the toe in a person with diabetes, foot pulses may be present due to very distal occlusive disease. This poses a challenge for revascularization because the results in general are better the more proximal the reconstruction is, and worse with distal disease and poor "run off" (vessels to receive the blood supply due to the revascularization procedure).

In order to develop ischemic non-healing ulcers, perfusion has to be very poor. The most reliable method for assessment of peripheral perfusion in those with diabetes is measurement of toe pressure. A toe pressure below 20–25 mmHg signals a poor chance of healing of a peripherally located ulcer. The special considerations related to the potentially dramatic course of infection in a diabetic foot are dealt with in Chapter 48.

Asymptomatic stage

The asymptomatic stage of peripheral arterial disease is especially interesting because it is associated with an approximately threefold increased mortality compared with matched controls [7, 8]. This excess mortality is caused by accompanying cardiovascular disease (CVD). Asymptomatic peripheral arterial disease can be identified by a very simple test: measurement of ankle blood pressure. This test takes only a few minutes and is expressed as the ABI, where the ankle pressure is divided by the highest of the two arm blood pressures. In this manner, variations in blood pressure between measurements do not influence the test result. Not only is an ABI <0.9 associated with increased mortality from cardiovascular causes, but also the level of ABI reduction is predictive: the lower the ABI, the worse is the prognosis [7].

Identifying an asymptomatic person with an ABI <0.9 is not a case for evaluation with respect to revascularization of the lower limbs, but a case for serious preventive cardiovascular medicine.

Claudication

Claudication is experienced by the individual as pain in lower limb muscles appearing after walking, most often in the calf, the thigh, and more rarely the buttocks. The walking distance eliciting the pain is very variable, beginning after 10–15 m in severe cases, whereas other may report pain only when walking fast uphill for more than 500 m. It is important for both the patient and the treating physician to understand that claudication, although it may be incapacitating for a few, and troublesome for many, signals severe vascular disease systemically, and that cardiovascular morbidity and mortality are high (elevated 3–4-fold compared with matched controls).

Rest pain

Rest pain typically begins at night when the individual is in the horizontal position. The positive effect of gravity on lower limb perfusion is then abolished. The person typically complains about pain in the toes or feet during the night, and most have experienced that standing or sitting up relieves the pain. Many people will sleep sitting in a chair.

In individuals with diabetes, symptomatology may differ because of coincidal peripheral neuropathy. Just as myocardial ischemia can be masked, symptoms from the lower extremity may be lacking even though peripheral ischemia exists. This is especially important when a person with diabetes presents with a small ulcer or wound on the lower limb, even if they think that there is a good explanation for developing the ulcer, such

as a relevant trauma. The lack of symptoms to signal peripheral ischemia combined with the risk of escalating infection in a diabetic foot has prompted many diabetologists to recommend routine assessment of peripheral circulation at regular intervals in all people with diabetes.

Non-healing ulcers

Non-healing ulcers often begin after minor trauma (e.g. hitting a toe against a chair or wearing shoes that are too small). In some cases the ulcers develop without any trauma and those will often progress to gangrene if not treated. Ischemic ulcers develop on toes or on the foot, typically at points where shoes are in firm contact. Hence they are usually easy to discriminate from venous ulcers, which are located at the level of the ankles or lower calf.

Rest pain, non-healing ulcers, and/or gangrene are often referred to as critical ischemia. The "diabetic foot" is dealt with in Chapter 48.

Diagnosis

Most often the history and objective findings will ensure the diagnosis, but measurement of ankle blood pressure (ABP) will quantify the ischemia and can be used to monitor changes in the disease (Figure 47.1). In some people with diabetes, the media of smaller arteries become calcified, making them incompressible. Thus, very high ankle pressures resulting in elevated ABI (>1.3) signal media sclerosis and should be recognized as a falsely elevated measurement. In fact, ABI >1.3 is associated with a marked increased mortality because media sclerosis is found in people with diabetes and those with renal failure.

Because small arteries are rarely affected by media sclerosis, measurement of toe pressure is an alternative for the assessment of peripheral arterial disease. The strain gauge technique is most commonly used (Figure 47.2), although alternative methods for measurement of toe pressure have been developed recently. Toe pressure is also useful for the prediction of healing of ulcers and amputation wounds.

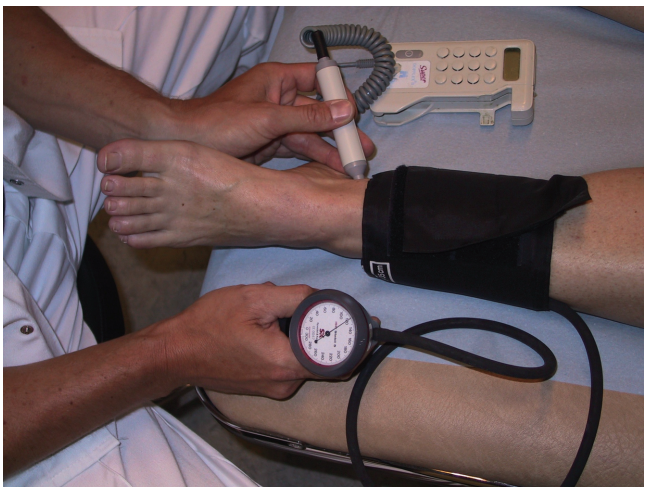

Figure 47.1 Measurement of ankle pressure using the Doppler technique.

Figure 47.2 Measurement of toe pressure using the strain gauge technique.

Prognosis

The risk of amputation is only 1–2% at 5 years. About 25% of people with claudication will experience a worsening of their symptoms from the lower legs; however, 75% will be unchanged or improve without revascularization [9]. In contrast, the "systemic" risk is huge; mortality at 5 years will be 15–25% and many more people will have non-fatal myocardial infarction (MI) or stroke.

The risk for a person with diabetes and peripheral arterial disease is much higher than that of a person with peripheral arterial disease. An individual with diabetes has an eight times greater risk of amputation at the level of the transmetatarsal bones or above than someone without diabetes [10]. In addition to the already severely increased mortality of peripheral arterial disease, people who additionally have diabetes have a further doubling of their risk of death [10–12].

Treatment

Treatment of people with symptoms from the lower limb therefore involves two aspects:

- treatment of symptoms from the lower limb; and
- prevention of cardiovascular complications.

The former includes lifestyle modification, medical therapy, and interventional therapy by either percutaneous transluminal angioplasty (PTA) or open surgery, whereas the latter includes lifestyle modification and preventive medical therapy.

It is beyond the scope of this chapter to detail all aspects of lifestyle modification and preventive medical therapy; however, it is extremely important for the reader to understand that individuals with peripheral arterial disease derive at least as much benefit from lifestyle modification and aggressive preventive medical therapy than any other group of people (see Chapter 42). Most of the lifestyle changes that are beneficial to the person with diabetes will also benefit the peripheral arterial disease, especially smoking cessation, regular exercise, weight loss, and dietary changes.

Medical prevention follows the same guidelines as for other clinical atherosclerotic manifestations such as ischemic heart disease and can be summarized as follows: aggressive statin treatment almost irrespective of cholesterol levels, antiplatelet therapy and blood pressure control. In this chapter, only details of lifestyle modification and medical therapy relevant to PTA and surgery are discussed.

Treatment of symptoms from the lower limb

Most people should be managed without invasive intervention with PTA (and/or surgery). Because the risk of cardiovascular complications (cardiac and cerebral) is much higher than the risk of amputation, the main focus should be on preventive measures in order to halt the atherosclerotic process. The conservative approach with respect to revascularization is especially important for people with diabetes because of the increased risk of surgical complications and poorer results of revascularization. One exception are those with critical limb ischemia. Early revascularization before widespread infection can be limb saving.

Exercise therapy has proven effective for improvement of walking distance, and regular exercise for 3 months can be expected to improve walking distance by 200–250% [13]. Because exercise also reduces cardiovascular morbidity and mortality, it cannot be stressed enough (for both the patient and the physician) that this is extremely important. Because the effect on walking distance is so good, and because it is important for survival, exercise therapy should always be tried before considering interventional treatment. There are only a few exceptions where interventional treatment may be considered early on:

- individuals with a very short walking distance, who are not able to carry out important daily responsibilities such as their work; and
- those at risk of amputation (rest pain and non-healing ulcers).

The dilemma of explaining to patients that the symptoms they are experiencing from the lower limb are signaling high cardiovascular risk rather than lower limb risk is challenging. First, there is (or has been) a general perception that atherosclerosis in the limb is less dangerous than in other locations. The author hopes that the introductory remarks in this chapter have changed this potential misperception for the reader. Medical therapy for claudication includes cilostazol and statins. Both drugs have been shown in placebo-controlled trials to improve walking distance by 30–50% and the latter furthermore reduces the cardiovascular risk. Other drugs have not proven useful in improving walking distance significantly [14].

Interventional treatment

Interventional treatment (endovascular or open surgery) for peripheral arterial disease is indicated when:

- exercise and other lifestyle modification have failed to improve symptoms to an acceptable state;
- claudication is incapacitating; or
- critical limb ischemia is present (rest pain, non-healing ulcers, and/or gangrene).

Again, for the person with diabetes, the indication for revascularization should be considered very carefully in those with only claudication. The choice between PTA and open surgical management depends on the location and extent of disease. In general, endovascular treatment can be expected to perform well in cases of shorter lesions, whereas open surgery is preferred in cases of extensive occlusive disease. Obviously, whenever comparable results can be obtained, PTA is preferred for the simple reason that it is less invasive and associated with fewer complications than open arterial reconstructions. In people with severe comorbidity that might complicate the outcome of open surgery, PTA would be preferred even though theoretically surgery would be the treatment of choice if only patency of the revascularization procedure was considered.

The arterial lesions that cause obstruction of blood supply to the lower limb are most often located in the distal abdominal aorta just proximal to the aorta–iliac bifurcation, in the iliac arteries, and in the common and superficial femoral arteries. The arteries in the calf, the anterior and posterior tibial and the peroneal arteries, are often involved in persons with diabetes with critical ischemia. In general, when individuals with diabetes present with symptoms, they have a more distal involvement with open arteries down to the level of the popliteal artery and then occlusive disease of the calf vessels and sometimes also the arteries in the foot. The results of revascularization for people with diabetes with toe or foot ulcers are worse than those for the general population partly because reconstructions yield better results with respect to patency when the lesions are more centrally located.

Percutaneus transluminal angioplasty

In principle, PTA can be performed anywhere between the heart and the feet. In general, the more centrally located the lesions being treated are, the better the results (especially with PTA). Also, the shorter the stenosis or occlusion, the better the results, and stenting improves patency in most cases. Endovascular-treated common iliac arteries, as an example, remain patent in 60–80% of cases after 5 years, and thereafter they may be redilated. Primary stenting has become the preferred treatment in most cases. Obviously, because serious complications are rare, the tendency to offer PTA for iliac artery obstruction is greater than for occlusive disease that is more peripherally located.

PTA of the superficial femoral artery (Figure 47.3) may relieve symptoms, but the results depend on the extent of disease. In principle, with increasing length of a lesion there is an increasing risk of early reocclusion. Stenting appears to improve patency, at least for longer lesions (Table 47.1) [15]. When the indication for PTA

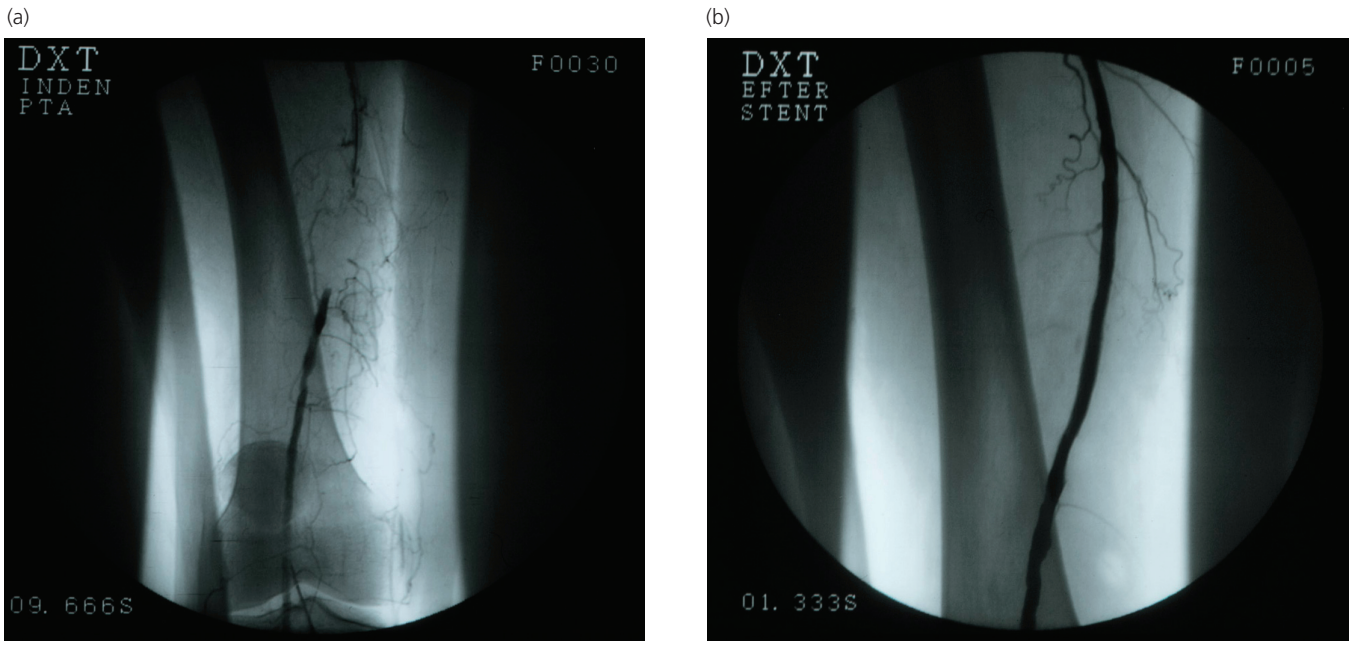

Figure 47.3 Short occlusion of the superficial femoral artery (a) treated with PTA and stenting (b).

is claudication, patency is better than if the indication is critical ischemia. This difference relates to the more extensive nature of the disease in the case of critical limb ischemia (poor run-off vessels). The 3-year patency is 48%, which may be improved to 64% if stenting is added. In cases of critical limb ischemia, the results at 3 years show a patency of 30% without stenting and 63% with stenting (Table 47.1) [15]. PTA of crural vessels is also feasible; however, the long-term results are not good. Data on limb salvage with PTA of crural vessels alone are still scarce despite these procedures having been developed extensively in the last 5 years. Adjunctive medical therapy to improve patency following PTA and stenting, with anticoagulation and/or antiplatelet therapy, has been tested in only a few trials. Antiplatelet drugs improve patency, and the combination of aspirin and clopidogrel may be beneficial [16].

Table 47.1 Pooled patency of vascular reconstructions (TASC[a] II).

	Patency (%)			
Reconstruction	**1 year**	**3 year**	**5 year**	**10 year**
Endovascular				
Iliac artery	86	82	71	
Fem-pop stenosis PTA	77	61	55

Open surgical revascularization

Open surgical revascularization still dominates as the treatment of choice in cases of critical limb ischemia, because of the extensive nature of the atherosclerotic lesions in these patients. For claudication, open surgical treatment is rarely performed, whereas for extensive disease of the distal aorta and iliac arteries, the aorto-bifemoral bypass remains the procedure with the best long-term outcome. In addition, femoral–femoral crossover bypass may be performed for unilateral iliac artery occlusion. Also, endarterectomy of the femoral artery, as described below, may be an option for treatment of claudication. Only one trial has compared open surgery with endovascular treatment of critical limb ischemia, the Bypass versus Angioplasty in Severe Ischaemia of the Leg (BASIL) trial [17]. The primary efficacy outcome measure was amputation-free survival, but because approximately two-thirds of the endpoints were deaths, only one-third of the endpoints really determined which procedure was best. Within 6 months postoperatively, there was no difference in the primary endpoint, but thereafter bypass patients seemed to do better [17].

In general, two surgical techniques are used: endarterectomy and bypass. Endarterectomy is performed by separating the intima from the media, and in this manner the atherosclerotic lesion can be removed. Endarterectomy can be used in cases with severe

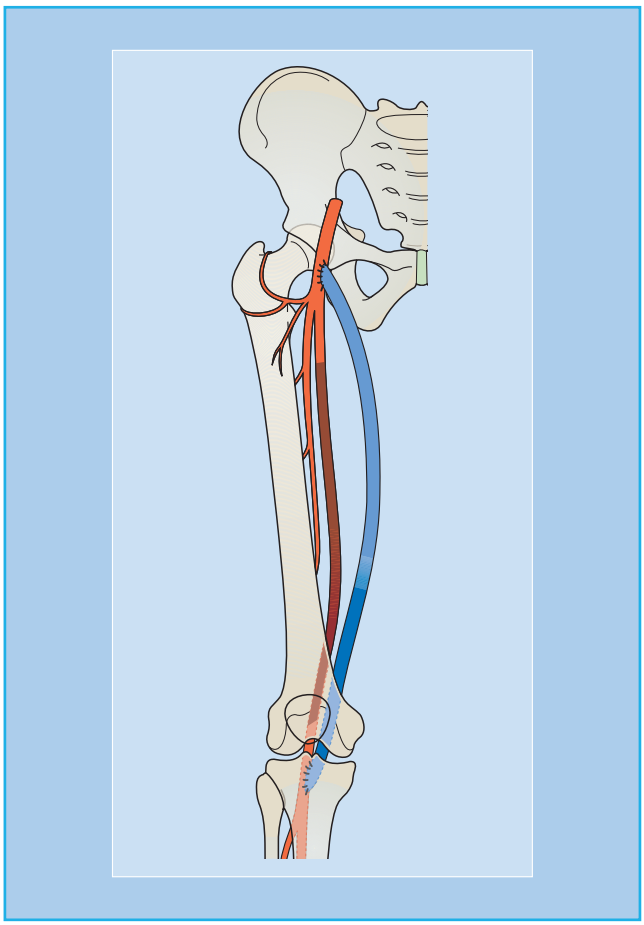

Figure 47.4 Long superficial femoral artery occlusion treated with femoro-popliteal bypass.

occlusive lesions of limited anatomic extension, in the external iliac or in the common femoral artery. The advantage of this technique is that it can often be performed without the use of artificial graft material and patency is excellent. Bypass is preferred when the obstructive and/or occlusive lesions are extensive (e.g. total superficial femoral artery occlusion or multiple serial lesions warranting a femoral–crural bypass) (Figure 47.4). Bypass surgery can be performed with artificial materials or with autologous veins. For bypass of aortic or iliac artery origin, artificial grafts are almost always used. This is because there is no easily removable vein with similar dimensions that can be used in these locations. Also, Dacron or polytetrafluoroethylene (PTFE) grafts perform very well in the aorto-iliac–femoral region. For peripheral bypasses, typically originating from the common femoral artery, autologous vein grafts are preferred for two reasons: they last longer (much better patency) (Table 47.1) and they carry less risk of infection. For longer bypasses, such as from the common femoral to the popliteal artery below the knee, a saphenous bypass is performed, leaving the vein *in situ*. This means that the vein is left in its original anatomical location; however, the proximal and distal ends are anatomized to the arterial system. The venous valves are cut with a knife mounted on a catheter and side branches are occluded. In this manner, the vein retains its nervous innervations and native vascularization.

Complications of endovascular treatment

Complications relate mainly to the site of puncture and the risk of peripheral embolization. "Systemic" cardiovascular complications are rare. Hematoma in the groin access point is common; however, it only rarely requires any action to be taken. Development of an iatrogenic pseudo-aneurysm is seen in 0.5–1% of cases and can easily be treated with ultrasound-guided compression or ultrasound-guided thrombin injection.

Complications of open surgical treatment

These can be divided into local and systemic categories. The former relate to the actual incisions and dissections including wound healing and infections. Whereas complications from accidental damage to other organs and/or structures are very rare, wound healing problems and infections are unfortunately fairly common. In particular, surgery on the lower limb involving the groin and peripheral incisions have wound complications in 10–20% of cases (e.g. hematoma, lymph oozing or necrosis of the wound) [18]. Infections are seen in 3–5% of cases, approximately one-third involving the vascular reconstruction. Infection of the vascular reconstruction is more frequent when using artificial graft material [18].

Systemic complications to open surgical revascularization relate to the surgical trauma and to the stress response. In vascular reconstructions involving the aorta and other central arteries, the cardiopulmonary complication rate is considerable. Implantation of an aorto-bifemoral bypass graft is associated with a 30-day mortality of 2–5% and a rate of "general" complications of 10–15% (e.g. pulmonary, cardiac, renal, prolonged stay in the intensive care unit and stroke) [18]. Systemic complications to peripheral revascularizations occur less frequently; however, they are considerable. When the indication is claudication, the morbidity with respect to general complications is low, 2–4%; however, in cases of critical ischemia and peripheral bypass surgery, the morbidity increases to 10% with a 30-day mortality of 3–5%. This difference in morbidity is a reflection of the more advanced level of generalized atherosclerotic disease in patients with critical ischemia. In people with diabetes, complications are more common especially with open surgery. A doubling of risk should be expected.

Results of endovascular and open surgical reconstructions

These are summarized in Table 47.1. In general, when treating more centrally located arterial obstruction, the long-term results are better. In addition, treating people with claudication results in better long-term outcome than operating on those with limb-threatening ischemia. This difference relates to the generally poorer condition of the peripheral circulation in cases of critical ischemia with better run-off vessels in the person with claudication.

In peripheral reconstructions, vein grafts perform better. It may seem unrewarding to treat people with critical limb ischemia with a peripheral bypass using an artificial graft when there is only a 50% chance of being patent at 1 year; however, if the alternative is amputation and/or very poor quality of life (i.e. severe rest pain), 1 year with a functioning graft may very well be worthwhile for both the patient and surgeon. Limb salvage as a result is almost always better than patency of the reconstruction because in many cases, once the ischemic limbs with tissue loss have healed, the "need" for amputation becomes less. This is because wound healing increases the needed blood supply, but once wounds are healed, resting blood flow needs are less. People with diabetes typically have poorer outcome of vascular reconstructions, with patency rates that are inferior to those in individuals without diabetes. People with diabetes have more complications to treatment; not only infections but also systemic complications are more common.

Acute lower limb ischemia

This condition is most often caused by thrombosis in existing atherosclerosis (i.e. a patient with previous symptoms of chronic peripheral arterial disease). Another common cause is thrombosis of a popliteal aneurysm. Embolism remains a common cause, although not as often as in the past because of better anticoagulant therapy for people with atrial fibrillation. About 80% of emboli are of cardiac origin; however, aneurysms of the aorta or peripheral aneurysms may give rise to peripheral emboli.

Other causes include trauma and iatrogenic lesions (e.g. from arteriography with puncture of the femoral artery). Aortic dissection may cause lower limb ischemia and also acute deep venous thrombosis (phlegmasia cerulea dolens). The incidence in Western Europe is 300–400 per million per year.

Pathophysiology

Thrombosis is caused by plaque rupture and subsequent thrombosis. Distal to the acute occlusion, arterial flow is slow and, when combined with a hypercoagulable condition, it may lead to further thrombosis. The degree of ischemia depends on the location and degree of collateral development. Therefore, thrombosis is often better tolerated than embolism because people with existing atherosclerosis most often have developed collaterals.

Emboli will typically occlude an artery at a bifurcation; in the lower limbs, at the aortic bifurcation (saddle embolus), iliac artery, and femoral artery bifurcation. About 60% of cardiac emboli will end in the lower limbs, 15% in the arms, and the rest in the brain and other organs. Microemboli, typically from aneurysms, affect small peripheral arteries, and are therefore the cause of "blue toe" syndrome.

Symptoms

Acute ischemia is characterized by pallor, pain, pulselessness, paresthesia, and paresis (the "5 Ps"). Symptoms may begin dramatically and in some cases the late signs of ischemia, paresthesia, and paresis occur within a few hours. More often, symptoms begin with pain and paresthesia and later sensory and muscular paresis. Acute ischemia is traditionally divided into three classes: viable, threatened, and irreversible (Table 47.2).

Diagnosis

Diagnosis is often easy, with typical clinical signs. ABI will be low, if measurable at all. Imaging with either duplex ultrasound, magnetic resonance angiography (MRA), computed tomography angiography (CTA), or digital subtraction angiography (DSA) is possible, but may delay treatment. In cases of thrombosis, it is most often desirable to perform arteriography with subsequent thrombolysis in order to visualize the underlying pathology causing the thrombosis.

Prognosis

If revascularization is possible before irreversible ischemia has occurred, the limb can be salvaged and normal function regained. Comorbidity is high in cases of acute ischemia; when acute revascularization is needed, the procedure-related mortality is 10–20% because of release of toxic substances from ischemic tissue combined with existing cardiac disease.

Treatment

Thrombosis in existing atherosclerotic lesions may be treated by endovascular or open surgery. The former is preferred if

Table 47.2 Separation of threatened from viable extremities.

		Findings		Doppler signals	
Category	**Description/prognosis**	**Sensory loss**	**Muscle weakness**	**Arterial**	**Venous**
Viable	Not immediately threatened	None	None	Audible	Audible
Threatened:					
a. Marginal	Salvageable if promptly treated	Minimal (toes) or none	None	(Often) inaudible	Audible
b. Immediate	Salvageable with immediate revascularization	More than toes, associated with rest pain	Mild, moderate	(Usually) inaudible	Audible
Irreversible	Major tissue loss or permanent nerve damage inevitable	Profound, anesthetic	Profound, paralysis (rigor)	Inaudible	Inaudible

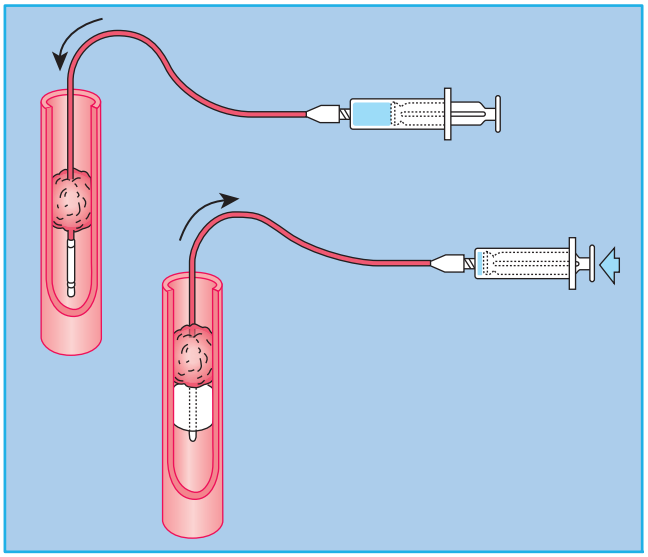

Figure 47.5 Embolectomy performed with a balloon catheter.

revascularization is not imminent. By catheter-directed intra-arterial thrombolysis, the underlying atherosclerotic lesions will be exposed and may in some cases be treated by PTA and/or stenting. In other cases, bypass surgery may be needed. Inoperable cases may be converted into operable cases by thrombolysis because distal thrombosis most often makes surgery (and PTA) useless when there are no run-off vessels. Another advantage of thrombolysis is that emergency surgery is converted into a less urgent intervention. Emboli can be treated by embolectomy by inserting a balloon catheter, in either the femoral or popliteal artery, and retracting the emboli after inflating the balloon (Figure 47.5). Some cases of embolism may also be treated by thrombolysis.

Prevention

Arterial emboli have a high recurrence rate and the underlying case should be treated, if possible, with corrective treatment for atrial fibrillation and resection or exclusion of aneurysms. If the source of embolism cannot be eliminated, anticoagulation must be considered.

Atherosclerosis of renal and mesenteric arteries

Renal artery obstruction

Renal artery obstruction can cause severe hypertension and renal failure but interventional treatment may improve both conditions. Today, open surgical management is only rarely performed because endovascular management is much less invasive and is feasible in the majority of cases. Open surgery, thromboendarterectomy or bypass, is performed when renal artery disease is combined with other pathology such as aortic occlusion or abdominal aortic aneurysms.

However, recently, the CORAL study showed that renal artery revascularization (stenting) of atherosclerotic lesions in order to treat renovascular hypertension is not better than optimal medical therapy [19]. This was surprising and has reduced the use of this intervention, and so it is now mainly used to (and indicated for) treat renal artery stenosis due to fibro-muscular dysplasia. There may be rare cases where revascularization is performed in order to improve renal function; however, this is done on an empirical background.

Mesenteric artery occlusive disease

Mesenteric artery occlusive disease may cause abdominal angina. Just like atherosclerotic lesions in other locations, many cases are asymptomatic and probably do not need intervention with regard to the obstructive disease, but lifestyle changes and medical preventive treatment are indicated. Patients with classic symptoms—postprandial pain occurring 10–20 min after a meal in addition to weight loss—often benefit from revascularization. However, many patients have less obvious symptoms, and the mere occurrence of a lesion on one of the three main vessels supplying blood to the gastrointestinal tract (celiac trunk, superior and inferior mesenteric artery) does not warrant interventional treatment. In general, a single lesion in one of the three arteries mentioned above is seldom thought to cause ischemia. Diagnosis is possible by ultrasound of the suprarenal vessels in most cases, otherwise CTA, MRA, or DSA may be needed. Interventional treatment today is mainly balloon angioplasty and stenting. Long occlusions of the superior mesenteric artery and/or occlusive mesenteric disease combined with other pathology of the aorta may be treated by open surgery (e.g. aorto-mesenteric bypass or transposition).

Ischemia of the arm

Atherosclerosis and ischemia of the arm are much less common than in the lower limb. The most common location for development of atherosclerosis in the arteries supplying the upper extremity is in the brachiocephalic trunk and subclavian arteries central for the origin of the vertebral arteries. Rarely, occlusive lesions are located more peripherally in the subclavian or axillary arteries. Takayasu vasculitis may also cause upper extremity ischemia.

Typical symptoms of chronic arm ischemia

These include "claudication," i.e. pain when using the arm. In typical cases, pain is encountered when performing tasks with the arms elevated, such as hanging laundry, or other physical use of the arm. Critical ischemia with rest pain or gangrene is rare but may occur. Diagnosis is easy, with lack of pulses at palpation. Measurement of bilateral blood pressure and ultrasound may locate and quantitate the stenotic lesion. If blood pressure cannot be measured by auscultation, a Doppler device may be used as for measurement of ankle blood pressure. Additionally, or in case of severe ischemia, finger pressure measurement by the strain gauge technique may be used. Upper arm angiography by CTA, MRA, or DSA may be supplemental.

The prognosis is often good because development of critical ischemia and the necessity for amputation are rare. Patients with finger gangrene should be investigated for vasculitis.

Treatment of upper extremity atherosclerosis is similar to that of atherosclerosis in other vascular distributions: risk factor reduction by lifestyle changes and preventive medications for all, and revascularization in some. In fact, only rarely is interventional treatment indicated, but in cases of incapacitating functional pain and/or critical ischemia, revascularization should be considered. Endovascular treatment dominates because of its less invasive nature for lesions near the origin of the brachiocephalic trunk and subclavian arteries. For lesions that cannot be treated by endovascular techniques, such as long lesions or lesions that cannot be crossed by a guide wire, bypass surgery is indicated (carotid–subclavian bypass). Peripheral bypass of the upper extremity (e.g. at the level of the brachial artery) is rare and patency is poor.

Acute arm ischemia

This is most often caused by embolization, but alternatively can be caused by thrombosis in an existing stenosis such as of the subclavian artery. Whereas the former may be treated easily by embolectomy via a small incision in the cubital fossa, the latter may be more complex to treat, perhaps requiring intra-arterial thrombolysis before vascular reconstruction. Embolism is most often of cardiac origin, from either atrial fibrillation, mural thrombus in the heart, or valve disease. Vascular causes include a subclavian aneurysm or stenosis. Microemboli may occur peripherally and present as gangrene of one or more fingers. Extravascular causes include a cervical rib. Obviously, eradication of the embolic source is crucial, if possible. Treatment of the peripheral ischemia may include thrombolysis, but in most cases collaterals develop and amputation does not become necessary.

Aortic aneurysmal disease (abdominal aortic aneurysm)

This section focuses on abdominal aortic aneurysms because thoracic aortic aneurysms are not considered part of peripheral vascular disease. The main difference between individuals with and without diabetes with respect to treatment of aneurysms is that those with diabetes are more prone to complications after surgery; however, because of the nature of preventive surgery for aneurysms, this only rarely causes changes in management once the risk of surgery has been weighed against non-surgical treatment.

Aneurysm of the aorta is a common condition in the elderly, especially in the infrarenal aorta. An artery by definition becomes aneurysmal when the diameter locally increases by more than 50% compared with the "normal" diameter proximal or distal to this site. In cases of the infrarenal aorta, an aneurysm is present when the diameter exceeds 30 mm.

The prevalence of abdominal aortic aneurysm is ~5% in men over 70 years of age; however, only a minority of them will have a size that mandates surgery (diameter >5–6 cm). In individuals with other atherosclerotic manifestations, such as peripheral arterial disease or carotid disease, the incidence of abdominal aortic aneurysms is 2–3 times greater. There is a 2 : 1 ratio of aortic aneurysms occurring in men : women. Finally, the tendency to develop abdominal aortic aneurysms is partly inherited, as the risk for a man with a father or brother with aortic aneurysm is ~20%. People with diabetes seem to have a slightly lower incidence of abdominal aortic aneurysm, ~80% of those without diabetes [20].

Pathophysiology

Arteries enlarge with age, and the diameter of the infrarenal aorta is normally below 20 mm in a 70-year-old man. If the wall weakens locally, an aneurysm develops. A true aneurysm develops when all three layers in the arterial wall are involved and dilate as in the case of the typical infrarenal aortic aneurysm. False aneurysms or pseudoaneurysms develop after iatrogenic trauma, such as PTA or other transfemoral procedures, and at arterial anastomotic sites. Finally, dissection occurs when a rupture of the intima allows blood to enter between the layers of the artery wall.

Aortic aneurysms may rupture, almost certainly leading to death. It is estimated that 80–90% of patients with ruptured aneurysms die before they get to hospital. Ruptured aneurysms causes an estimated 2–3% of all deaths among men, whereas the proportion for women is 1%.

In most abdominal aortic aneurysms, there is an atherosclerotic degeneration of the vessel wall that dilates; however, it is unclear why atherosclerosis in some people results in occlusive disease and in others in aneurysm development. Accelerated breakdown of elastin has a role in aneurysm development. The simultaneous presence of both occlusive and aneurysmal disease is common in many patients. Inflammatory aneurysms are present in 5–10% of aortic aneurysms where the aortic wall is thickened as part of perianeurysmal or retroperitoneal fibrosis.

Symptoms from abdominal aortic aneurysms

Symptoms are rare and most are asymptomatic. Diagnosis is often made coincidentally, such as when a patient complains of slight upper gastric pain and has an ultrasound of the gallbladder, which discloses the aortic aneurysm. Also, typically, a patient may complain of back pain and have a lumbar X-ray. Whether the patient's pain is really related to the abdominal aortic aneurysm, to gallstones, or to the back is often difficult to ascertain.

Some patients will sense a pulsation in the abdomen, while large aneurysms may cause discomfort or compress surrounding organs, mainly the gastrointestinal tract. The main risk is rupture, which, when intraperitoneal, most often leads to immediate death. If rupture is into the retroperitoneal space, a hematoma may be contained and the patient may survive for hours. Rupture and development of a hematoma lead to pain in the abdomen and/or back. Chronic rupture is rare because almost all cases will be fatal within hours.

Aneurysms may cause peripheral embolization, resulting in a cyanotic or gangrenous toe as the first symptom.

Diagnosis

Diagnosis is easy as ultrasound is very accurate in making the diagnosis and estimating the diameter of the aneurysm (Figure 47.6). In the few cases where ultrasound is inconclusive, a primary computed tomography (CT) scan may be necessary. Otherwise, CT or MR scanning is only performed when the size of the

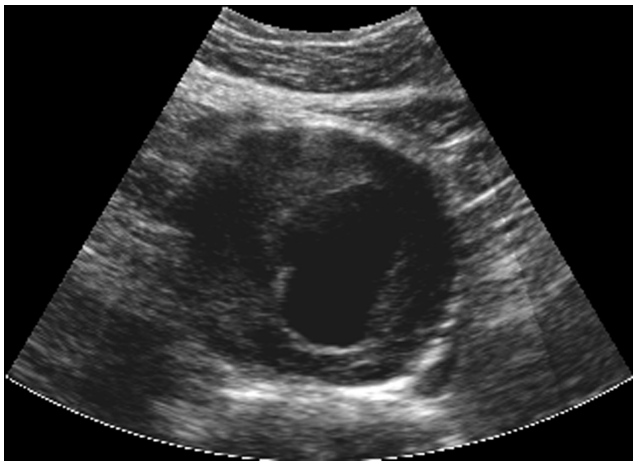

Figure 47.6 Ultrasound image of abdominal aortic aneurysm. Note the presence of a large thrombus inside the aneurysm sac.

aneurysm dictates to an extent that intervention should be considered. Arteriography is rarely performed for abdominal aortic aneurysm; however, in cases of both abdominal aortic aneurysm and symptoms of peripheral arterial disease, an arteriogram may be warranted for planning of the revascularization procedure. A patient with acute abdominal pain in preshock should always be suspected of ruptured abdominal aortic aneurysm.

Prognosis

The risk of rupture is related to the size of the aneurysm. When the diameter exceeds 6 cm, the annual risk of rupture is 10–20%, whereas the risk of rupture in the case of an aortic aneurysm with a diameter of 3–4 cm is <1%. Aneurysms tend to expand; small aneurysms dilate by 1–2 mm/year whereas larger aneurysms may expand 2–3 times faster. Smoking and hypertension seem to increase the rate of growth. Rupture is associated with 90% mortality but the survival for those who reach hospital and have immediate surgery is ~50–60%. Concomitant coronary disease is responsible for a 50–100% increased mortality of patients with aneurysms even when aneurysm mortality is disregarded.

Treatment

Treatment of abdominal aortic aneurysms involves, in addition to surgery for some, the same preventive treatment as is given to other people with atherosclerotic manifestations: lifestyle changes and medical therapy with platelet inhibitors, statins, and blood pressure control.

Treatment of a ruptured aortic aneurysm is always interventional (open surgical or endovascular) unless the patient's overall condition is considered too poor to attempt rescue. In some cases, a fatal aortic aneurysm may be a dignified death, for example, in an elderly person with both end-stage renal failure and heart failure. Symptomatic non-ruptured aneurysms should be treated acutely or subacutely because of the risk of imminent rupture.

Treatment of large asymptomatic abdominal aortic aneurysm reduces mortality [21], and those with an asymptomatic aneurysm should be offered elective interventional treatment if the risk of rupture exceeds the risk of the procedure and if the patient is fit for the procedure and expected to have some good-quality years remaining. Because any procedure for treatment of aortic aneurysm either carries a considerable perioperative risk or involves a very long postoperative period with potential reinterventions, the decision to offer interventional treatment is not always easy, and almost always a decision is made in consultation with the patient and their family.

The choice between treatment modalities is made keeping these facts in mind: open surgery is a well-proven procedure with known risks and long-term results, including an overall 3–5% perioperative mortality, but limited aneurysm morbidity after the procedure. Endovascular aneurysm repair (EVAR) has been shown to have lower perioperative morbidity: 1.5% for EVAR compared with 4.5% for open surgery [22–24]. Because the long-term results of EVAR are unknown (5–10 years), continuous surveillance with annual CT or ultrasound scans is necessary. Until fairly recently, the number of reinterventions because of either migration or failure of the implanted device, both leading to endo-leak (blood re-entering the excluded aneurysm sac, which is thereby again at risk of rupture) were considerable; however, more recent data show improvement and it is 10–15% at 3 years [24].

As an example of choice of treatment modality, a 65-year-old man with a 6-cm aneurysm and no other known comorbidity should be offered treatment, preferentially open surgery, because his perioperative risk will be low (2–3%), whereas the annual risk of rupture is ~10%. At the other end of the spectrum is the 80-year-old man with previous coronary artery bypass graft surgery and with a similar-sized aneurysm of 6 cm. His risk with open surgery includes >10% 30-day mortality in addition to a considerable risk of other complications. Endovascular treatment could be a good alternative for this man if he is expected to live at least 3–5 years.

EVAR has been considered to be a treatment alternative for patients unfit for open surgery. The EVAR-2 trial tested this hypothesis and participants found to be unfit for open repair were randomized to either conservative management or EVAR. Survival was not improved by EVAR and it was poor in both groups: ~50% of participants in both groups were dead at 3 years and only one-quarter of deaths were aneurysm related [25]. Hence being found unfit for surgery in this study indicated a poor prognosis in general that EVAR did not affect.

Open surgical treatment with resection of the aneurysm and replacement of the diseased part of aorta with an artificial graft has been performed for around 50 years (Figure 47.7). Complications of open surgical repair relate to the considerable surgical trauma of this major procedure. Approximately 10–20% of patients will develop general complications such as cardiac, pulmonary, and renal complications in addition to prolonged stay in the intensive care unit and stroke.

Endovascular treatment of aortic aneurysms involves inserting a collapsed prosthesis via the femoral artery, placing it below the renal arteries, and deploying and fixing it (stenting) under X-ray guidance. The technique mostly used today involves inserting

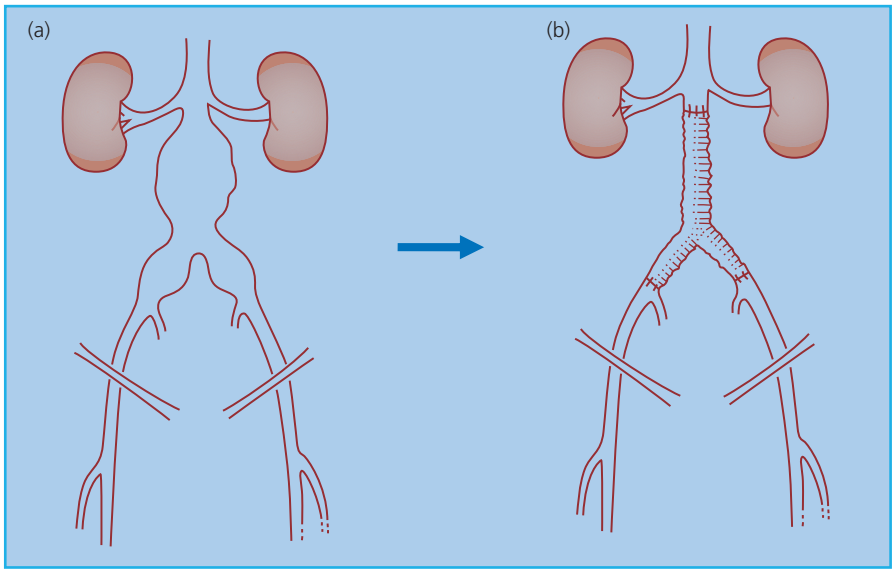

Figure 47.7 Abdominal aortic aneurysm treated by resection and implantation of an aorto-bi-iliac bypass graft.

a bifurcated graft from one femoral artery and then placing the other limb via the contralateral femoral artery (Figure 47.8). There are few complications to EVAR in the perioperative period, but a considerable number of patients will need reinterventions, which in most cases can be performed by endovascular techniques. These include placement of another proximal stent because of endo-leak and embolization of inferior mesenteric or internal iliac arteries.

Screening

The value of population-based screening for abdominal aortic aneurysms is now well documented. A meta-analysis of four randomized controlled trials found aneurysm-related mortality to be reduced by 43% in people being offered screening [26]. Today, it is recommended in many countries that men older than 65 years and previous smokers undergo ultrasound screening. Family members who are direct descendants and siblings of those with aortic aneurysms should also undergo screening.

Peripheral aneurysms

Aneurysms may develop at other locations, popliteal and femoral arteries being the second and third most common locations. More than 50% of patients with peripheral aneurysms also have an aortic aneurysm. Symptoms are different in the sense that rupture is less common; however, symptoms derived from compression (popliteal vein thrombosis, pain, and other symptoms of

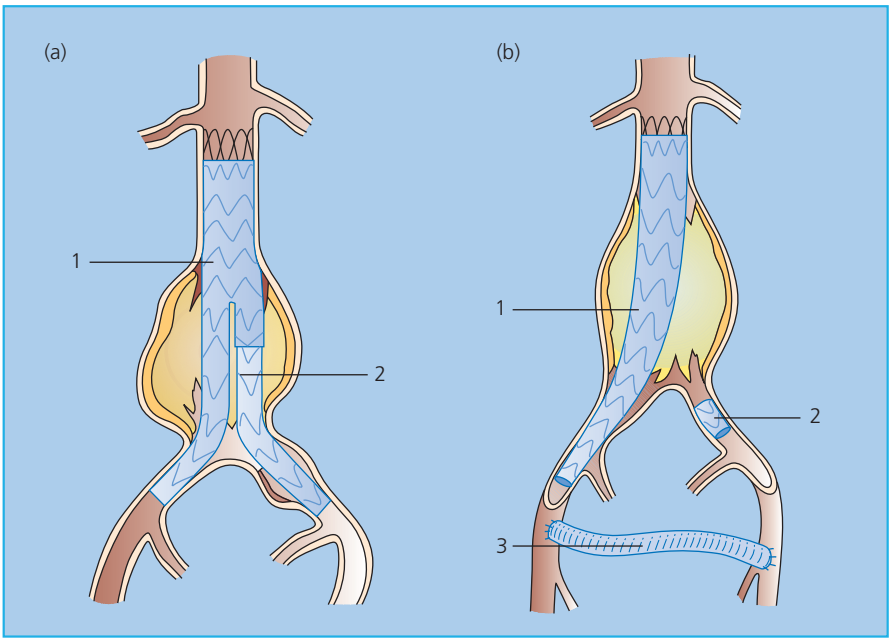

Figure 47.8 Abdominal aortic aneurysm treated by endovascular repair. (a) First the bifurcated graft is inserted via the right femoral artery and fixed by stenting at the proximal and distal end of the graft. The left limb (2) is inserted via the left femoral artery and connected to the main graft. (b) Insertion of an aorto-uni-iliac endograft (1) combined with a femoro-femoral bypass graft (3) is used when one of the iliac arteries (2) cannot be passed.

nerve compression), peripheral embolization, or thrombosis of the aneurysm most often bring the patient to medical attention.

Treatment is the same as for aortic aneurysms: general prevention against atherosclerotic disease and intervention in symptomatic cases. Popliteal aneurysms are generally treated surgically by exclusion and bypass or by resection and replacement by a short graft. Femoral aneurysms are treated by resection and placement of a graft. Endovascular management is possible; however, graft thrombosis and failure of stent graft material have so far made indications unclear. Large asymptomatic peripheral aneurysms should probably be treated by either open or endovascular surgery; however, no documentation is currently available that such treatment is beneficial.

Aneurysms of visceral or renal arteries may occur but are rare. Treatment is interventional when they are large. Endovascular management is under development; however, its indications are unsettled.

Carotid artery disease

This section focuses on stroke and carotid disease because cerebrovascular disease in general is dealt with in Chapter 46. The relationship to atherosclerosis for many people with stroke is well documented, although stroke, unlike other ischemic conditions, has other common pathogenetic mechanisms.

It is very important to discriminate between symptomatic disease and asymptomatic cases. People with recent cerebrovascular symptoms and an ipsilateral stenosis are comparable to those with a recent acute coronary event: the risk for a new thromboembolic event is very high and diagnostic workup and treatment should be started immediately. The pathogenetic mechanism is similar to that of an acute coronary event with plaque rupture and subsequent thrombosis; however, in the case of the carotid, embolization into a cerebral artery is much more common than thrombotic occlusion of the carotid artery itself. Perhaps the larger diameter of the carotid artery explains this difference.

The prevalence of carotid stenosis is high. Among people with acute cerebrovascular symptoms, an ipsilateral stenosis of >50% diameter reduction is found in 15–20% of cases. In people with other clinical atherosclerotic manifestations, a carotid stenosis is found in 20–30%.

Pathophysiology and symptoms

See Chapter 46, dealing with cerebrovascular disease.

Prognosis

The risk of stroke is increased in the presence of carotid stenosis. For asymptomatic people with a carotid stenosis exceeding 60% diameter reduction, the annual risk of ipsilateral stroke is ~1% with optimal medical prevention (antiatherosclerotic treatment). When carotid stenosis is related to recent ipsilateral cerebral ischemic symptoms (symptomatic stenosis), the risk is much higher, especially just after the first event. The 30-day risk of stroke in people with previous cerebrovascular symptoms is as high as 10% when an ipsilateral carotid stenosis is present. Thereafter, the risk gradually declines and after 1 year it is ~2–3% annually, similar to asymptomatic carotid stenosis. The 3-year risk of ipsilateral stroke is 15–30% in symptomatic patients with a stenosis >70% diameter reduction.

Figure 47.9 B-mode ultrasound image of carotid stenosis. The top part is echolucent, indicating a high content of lipid/necrotic core; the bottom part is echogenic, indicating a fibrous plaque.

Diagnosis

Diagnosis of carotid disease should be carried out by duplex ultrasound scanning (Figure 47.9). The accuracy of the method is well documented both for identification and quantification of degree of stenosis. Many surgeons will perform carotid endarterectomy based only on ultrasound examination.

Treatment

Treatment of people with carotid stenosis is like that of any other condition related to atherosclerosis: treatment of the atherosclerotic disease itself and treatment of local manifestations. Risk factor reduction, including changes in lifestyle, is exactly the same as for patients with other clinical manifestations of atherosclerosis, although there may be regional variation in the choice of antiplatelet agents. Aggressive lipid lowering reduces both the risk of recurrent stroke and the risk of coronary events especially in this patient group [27–29].

It is important to realize that any invasive treatment for carotid stenosis is performed to prevent future "local" events (stroke). Hence the risk of the intervention itself should be weighed against the absolute risk of an event. Furthermore, the most common complication of surgery and stenting is ipsilateral stroke, the event

that the procedure is supposed to prevent. Most important, the overall risk to the patient (including that of other conditions) should be weighed against the absolute risk reduction derived from the procedure.

Symptomatic carotid stenosis

Symptomatic patients with carotid stenosis benefit from endarterectomy when the stenosis is >50–70% diameter reduction and neurological symptoms are within 6 months of surgery [30, 31]. The North American Symptomatic Carotid Endarterectomy Trial (NASCET) and European Carotid Surgery Trialist's Collaborative Group (ECST) trials [30, 31] randomized simultaneously, but independently, symptomatic individuals with carotid stenosis to best medical treatment or best medical treatment plus endarterectomy. Both trials showed significant benefit (50% relative risk reduction) in those with stenosis >70% diameter reduction, whereas in the group with 50–69% stenosis there was only a marginal effect, and in participants with stenoses <50% there was no benefit.

Subsequent reanalysis of the pooled data from these two trials, however, showed that the time interval between onset of neurological symptoms and surgery was the most important predictive factor of benefit for the patient [32]. In general, the earlier an operation is executed, the greater is the benefit. The overall absolute risk reduction of ~15% conveyed by endarterectomy could be doubled when patients received surgery within 2 weeks of symptoms. With the knowledge gained during the last 10–15 years concerning the vulnerable plaque and plaque rupture, this finding does not come as a great surprise; however, when these trials were designed, this pathogenetic mechanism of acute ischemia was unknown.

Sex, age, and degree of stenosis are also factors that influence the benefit of surgery [32]. Male sex, older age, and greater severity of stenosis all increase the risk of future stroke in people with stenosis without any increased risk of the surgical procedure, hence the overall benefit is greater.

Asymptomatic carotid stenosis

Asymptomatic carotid stenosis is more controversial, although two major trials have shown a small but statistically significant benefit of surgery. First, the Asymptomatic Carotid Atherosclerosis Study (ACAS) trial showed a 50% relative risk reduction of ipsilateral stroke, but the absolute risk reduction was marginal, only 1% per year [33]. Later, the Asymptomatic Carotid Surgery Trial (ACST) reproduced these findings [34]. Taking into consideration that the average annual mortality during the trials was 3–4%, in addition to other ischemic events that were unaffected by the procedure, it may be questioned whether the cost–benefit is reasonable both for the patient and for society. The medical treatment offered during these trials was much poorer than that recommended today; hence the outcomes of these trials may not be reflective of the risk in these patients today. If or when better criteria for selection of patients at higher risk become available, selective surgery for high-risk cases of asymptomatic carotid stenosis may yield greater or even much greater benefit.

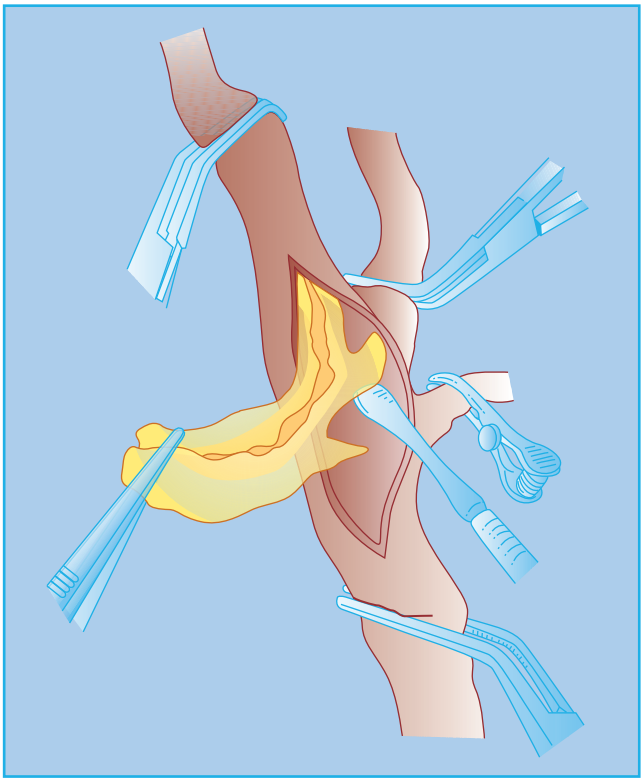

Figure 47.10 Carotid endarterectomy where the intima–media complex is dissected free of the adventitia and removed.

Technical considerations

Technically, carotid endarterectomy may be performed in two ways: classic endarterectomy (Figure 47.10) or eversion endarterectomy. In the latter, the internal carotid artery is divided from the bifurcation, and endarterectomy is performed by everting the vessel wall, thereby removing the carotid lesion. After the stenosis has been removed, the bifurcation is reconstructed by reanastomosing the internal carotid to the bifurcation.

Carotid endarterectomy may be performed under general or local anesthesia. Classically, general anesthesia has been preferred; however, this has carried the challenge of monitoring cerebral circulation during clamping of the carotid artery. A variety of methods have been used, including electroencephalography, stump pressure, distal internal carotid artery pressure, evoked potentials, near-infrared spectroscopy, transcranial Doppler ultrasound, and more. None of these methods has proven ideal, and so some surgeons use a shunt on a selective basis, whenever their method for monitoring indicates risk of cerebral ischemia during clamping, whereas others use a shunt routinely. By contrast, performing endarterectomy under local anesthesia gives the surgeon the opportunity to communicate with the patient during clamping. Having the patient awake and responsive during surgery may represent the best monitoring of cerebral function during clamping. Also, local anesthesia may carry less cardiac and pulmonary risk. Smaller trials and a meta-analysis indicated superiority of local anesthesia [35]; however, the later General Anesthesia versus

Local Anesthesia for carotid surgery (GALA) trial reported its results after randomizing 3529 participants to either universal or local anesthesia for carotid endarterectomy, and there was no difference in the risk of perioperative stroke or death [36].

Carotid stenting

This has not yet been proven in randomized clinical trials to prevent ipsilateral ischemic events. Seven randomized controlled trials comparing stenting with endarterectomy have been published; however, so far they have focused only on comparison of perioperative complications. The two most recent trials, the EVA-3S and the SPACE trials, failed to show an advantage of the less invasive carotid stenting method with respect to perioperative events [37, 38]. In fact, the EVA-3S trial was stopped early because of excess complications in the stenting group [37]. A Cochrane meta-analysis, including all seven randomized controlled trials, favored surgery with respect to the primary outcome of perioperative death and ipsilateral stroke [39]. Most recently, the CREST trial showed equivalence of stenting and endarterectomy, but in a trial with a combined endpoint of death, stroke, and MI. The latter included MI as detected by the increase in enzymes in patients without any other symptoms. So focusing on the risk of death and stroke, stenting was associated with more complications [40]. Nevertheless, it is important to acknowledge that technology does develop rapidly and some of the trials may have used devices and/or technologies that are already outdated. Similarly, there may be differences in trial design, and criticism has been made specifically regarding the training of the investigators in some studies. Interestingly, stenting appears to be associated with higher complication rates when performed early after onset of neurological symptoms and in the elderly—the two strongest indications. Finally, one should keep in mind that stenting should be evaluated in long-term studies, and compared not only with endarterectomy, but also with medical therapy, which has improved dramatically the last 10–20 years.

It may be questioned whether the evidence for carotid endarterectomy is outdated. Three of the four major trials proving endarterectomy to be of value for symptomatic and asymptomatic surgery were performed when the only fairly constant preventive medication given was aspirin. The last trial randomized 8–10 years ago, and only 30% of the participants were taking statins. It was stated in the design of these trials that hypertension and hypercholesterolemia were treated when present; however, in that era, the treatment goals for both hypertension and hypercholesterolemia were much more lax than they are now. Also, new drugs have been introduced and their benefit documented since these trials randomized patients (e.g. statins, newer antiplatelet agents, dual antiplatelet therapy, and newer antihypertensive drugs). It may be speculated that if these drugs were used systematically, the risk in people with carotid stenosis would be much less, not least in those with vulnerable plaques. Therefore, new trials are needed to test how today's medical therapy compares with intervention and if the best medical therapy remains inferior to surgery or stenting. New trials are *not* unethical—it is unethical not to undertake new trials.

Carotid revascularization prior to coronary artery bypass surgery has been practiced in some institutions whereas others have not found it useful. The potential advantage is avoiding cerebral ischemia during the relative hypotension "on pump"; however, the complications of carotid revascularization have outweighed the gains, as evaluated by recent reviews.

9 Other Complications of Diabetes

48 Foot Problems in People with Diabetes

Andrew J.M. Boulton
Department of Medicine, University of Manchester and Manchester Royal Infirmary, Manchester, UK and Miller School of Medicine, University of Miami, Miami, FL, USA

Key points

- Diabetic foot problems remain the most common cause of hospital admissions amongst persons with diabetes in Western countries.
- Up to 50% of older individuals with type 2 diabetes have risk factors for foot problems.
- Up to 85% of lower limb amputations are preceded by foot ulcers.
- All persons with diabetes should be screened for risk of foot problems on an annual basis: those with risk factors require regular podiatry, patient education, and instruction in foot self-care.
- Most foot ulcers should heal if pressure is removed from the ulcer site, the arterial circulation is sufficient, and infection is managed and treated aggressively.
- Any individual with a warm unilateral swollen foot without ulceration should be presumed to have an acute Charcot neuroarthropathy until proven otherwise.

Introduction

"Superior doctors prevent the disease. Mediocre doctors treat the disease before evident. Inferior doctors treat the full-blown disease."

[Huang Dee, China, 2600 BC]

This Chinese proverb suggests that inferior doctors treat the full-blown disease and, until recent years, this was sadly the case with diabetic foot disease. Realizing the global importance of diabetic foot disease, the International Diabetes Federation (IDF) focused on the diabetic foot throughout the year 2005, during which there was a worldwide campaign to "put feet first" and highlight the all too common problem of amputation among people with diabetes throughout the world. To coincide with World Diabetes Day in 2005, *The Lancet* launched an issue dedicated almost exclusively to the diabetic foot—this was the first time that any major non-specialist journal had focused on this worldwide problem; however, major challenges remain in getting across important messages relating to the diabetic foot:

1 Foot ulceration is common, affecting up to 25% of people with diabetes during their lifetime [1].

2 Over 85% of lower limb amputations are preceded by foot ulcers, and diabetes remains the most common cause of non-traumatic amputation in Western countries [2].

3 Prevention is the first step towards solving diabetic foot problems. Although it was estimated in 2005 that a leg is lost to diabetes somewhere in the world every 30 s and more recently every 20 s, a more important fact is that up to 85% of all amputations in diabetes should be preventable [2, 3].

4 Reductions in amputations will only be achieved if healthcare professionals from all specialties realize that, as Brand once stated, "pain is God's greatest gift to mankind": it is the loss of pain that permits people with neuropathy to develop ulcers and continue walking on them despite the presence of often overwhelming infection [4]. Moreover, the International Working Group on the Diabetic Foot (IWGDF) has now developed a risk score aimed at assessing the risk of a person with an infected foot ulcer subsequently requiring an amputation [3].

5 Strategies aimed at preventing foot ulcers are cost-effective and can even be cost-saving if increased education and effort are focused on those with recognized risk factors for the development of foot problems [5].

6 Diabetes is now the most common cause of Charcot neuroarthropathy in high-income countries, another condition that should generally be preventable [6].

Much progress in our understanding of the pathogenesis and management of the diabetic foot has been made over the last few decades. This has been matched by an increasing number

of publications in peer-reviewed journals. Taken as a percentage of all PubMed-listed articles on diabetes, those on the diabetic foot increased from 0.7% in the period 1980–1988 to more than 2.7% in 1998–2004 [4]. Prior to 1980, little progress had been made in the previous 100 years despite the fact that the association between gangrene and diabetes was recognized in the mid-19th century [7]. For the first 100 years following these descriptions, diabetic foot problems were considered to be predominantly vascular and complicated by infection. It was not until during the Second World War, for example, that McKeown performed the first ray excision on a person with diabetes and osteomyelitis but good blood supply; this was performed under the encouragement of Lawrence, who had diabetes himself and was co-founder of the British Diabetic Association, now Diabetes UK [8].

In the last three decades, many major national and international societies were formed, including diabetic foot study groups and the IWGDF was established in 1991. New editions of two leading international textbooks on the diabetic foot have been published in the last decade [9, 10], and a number of collaborative research groups are now tackling many of the outstanding problems regarding the pathogenesis and management of diabetic foot disease.

In this chapter, the global term "diabetic foot" will be used to refer to a variety of pathological conditions that might affect the feet of people with diabetes. First, the epidemiology and economic impact of diabetic foot disease are discussed, followed by the contributory factors that result in diabetic foot ulceration. The potential for prevention of these late sequelae of neuropathy and vascular disease are discussed, followed by a section on the management of foot ulcers. The chapter closes with a brief description of the pathogenesis and management of Charcot neuroarthropathy, an end-stage complication of diabetic neuropathy. Throughout, cross-referencing will be provided to other chapters that also cover aspects of diabetic foot disease, particularly those on diabetic neuropathy (see Chapter 40), peripheral vascular disease (see Chapter 47), bone and rheumatic disorders in diabetes (see Chapter 53), and infection (see Chapter 55).

Epidemiology and economic aspects of diabetic foot disease

As foot ulceration and amputation are closely inter-related in diabetes [2], they will be considered together in this section. A selection of epidemiological data for foot ulceration and amputation, originating from studies from a number of different countries [11–19], is provided in Table 48.1. Globally, diabetic foot complications remain major medical, social, and economic problems that are seen in all types of diabetes and in every country [20]; however, the reported frequencies of amputation and ulceration vary considerably as a consequence of different diagnostic criteria used and also regional differences [21]. Diabetes remains a major cause of non-traumatic amputation across the world, with rates being as much as 15 times higher than in people without diabetes.

Although many of the studies referred to and listed in Table 48.1 were well conducted, methodological issues remain, which make it difficult to perform direct comparisons between studies and/or countries. First, definitions as to what constitutes a foot ulcer vary, and second, surveys invariably include only people with previously diagnosed diabetes, whereas in type 2 diabetes, foot problems may be the presenting feature. In one study in the UK, for example, 15% of people undergoing amputation were first diagnosed with diabetes on that hospital admission [22]. Third, reported foot ulcers are not always confirmed by direct examination by the investigators involved in the study. Finally, as can be seen from the table, in those studies that assessed the percentage of the population that had risk factors for foot ulceration, 40–70% of people fell into that category. Such observations clearly indicate the need for all diabetes services to have a regular screening program to identify such high-risk individuals.

Health economics of diabetic foot disease

In addition to causing substantial morbidity and even mortality, foot lesions in individuals with diabetes additionally have substantial economic consequences.

Diabetic foot ulceration and amputations were estimated to cost United States healthcare payers $10.9 billion in 2001 [23, 24]. Corresponding estimates from England based upon national datasets and economic modeling suggested that the total annual costs of diabetes-related foot complications in 2010–2011 was £580 million, or 0.6% of the National Health Service expenditure [25]; however, similar problems to those noted with epidemiology exist when comparing data on the costs of diabetic foot lesions, related not only to methodology but also to whether direct and indirect costs were included. Moreover, few studies have estimated costs of the long-term follow-up of people with foot ulcers or amputations [2].

Data from the USA suggest that in 2007 $18.9 billion was spent on the care of diabetic foot ulcers and $11.7 billion on lower extremity amputations [26]. Having estimated the total cost of diabetic foot disease to be $30.6 billion in 2007, the authors went on to estimate the potential savings based upon realistic reductions in ulceration and amputation to be as high as $21.8 billion. Such strong economic arguments may help to drive improvements in preventive foot care that could potentially lead to significant savings for healthcare systems. A recent and worrying study from Arizona, USA, demonstrates the false economics of attempting to reduce costs in diabetic foot screening. In their attempt to reduce costs, the legislature removed payment to podiatrists for screening and treating Medicaid patients: although this resulted in an annual saving of $351,000, the increased hospitalizations in this population for diabetic foot disease cost $16.7 million per year [27]!

Etiopathogenesis of diabetic foot lesions

"Coming events cast their shadow before."

[Thomas Campbell]

If we are to be successful in reducing the high incidence of foot ulcers and ultimately amputation, a thorough understanding of the pathways that result in the development of an ulcer is increasingly important. The above words of the Scottish poet Thomas Campbell can usefully be applied to the breakdown of the diabetic foot. Ulceration does not occur spontaneously: rather, it is the combination of causative factors that result in the development of a lesion. There are many warning signs or "shadows" that can identify those at risk before the occurrence of an ulcer. It is not an inevitable consequence of having diabetes that ulcers occur: ulcers invariably result from an interaction between specific pathologies in the lower limb and environmental hazards. The breakdown of the diabetic foot traditionally has been considered to result from an interaction of peripheral vascular disease, peripheral neuropathy, and some form of trauma. Other causes are also briefly described.

Peripheral vascular disease

Although described in detail in Chapter 47, brief mention of the role of peripheral vascular disease in the genesis of foot ulcers must be made here. Peripheral vascular disease tends to occur at a younger age in people with diabetes and is more likely to involve distal vessels. Reports confirm that peripheral vascular disease is a major contributory factor in the pathogenesis of foot ulceration and subsequent major amputations [28, 29]. In the pathogenesis of ulceration, peripheral vascular disease itself in isolation rarely causes ulceration: as will be discussed for neuropathy, it is the combination of risk factors with minor trauma that inevitably leads to ulceration (Figure 48.1). Thus, minor injury and subsequent infection increase the demand for blood supply beyond the circulatory capacity and ischemic ulceration and the risk of amputation ensue. In recent years, neuroischemic ulcers in which the combination of neuropathy and PVD exists in the same person, together with some form of trauma, are becoming increasingly common in diabetic foot clinics.

Diabetic neuropathy

As discussed in Chapter 40, the diabetic neuropathies represent the most common form of the long-term complications of diabetes, affect different parts of the nervous system and may present with diverse clinical manifestations [30]. Most common amongst the neuropathies are chronic sensorimotor distal symmetrical polyneuropathy and the autonomic neuropathies. It is the common sensorimotor neuropathy together with peripheral autonomic sympathetic neuropathy that together have an important role in the pathogenesis of ulceration.

Sensorimotor neuropathy

As noted in Chapter 40, this type of neuropathy is very common and it has been estimated that up to 50% of older persons with type 2 diabetes have evidence of sensory loss on clinical examination and therefore must be considered at risk of insensitive foot injury [30]. This type of neuropathy commonly results in a sensory loss, confirmed on examination by a deficit in the stocking distribution to all sensory modalities; evidence of motor dysfunction in the form of small muscle wasting is also often present. While some individuals may give a history (past or present) of typical neuropathic symptoms such as burning pain, stabbing pain, and paresthesia with nocturnal exacerbation, others may develop sensory loss with no history of any symptoms. Other individuals may have the "painful-painless" leg with spontaneous discomfort secondary to neuropathic symptoms but who on examination have both small- and large-fiber sensory deficits; such people are at great risk of painless injury to their feet.

From the above, it should be clear that a spectrum of symptomatic severity may be present, with some individuals experiencing severe pain and, at the other end of the spectrum, those who have no spontaneous symptoms, but both groups may have significant sensory loss. The most challenging individuals are those who develop sensory loss with no symptoms because it is often difficult to convince them that they are at risk of foot ulceration as they feel

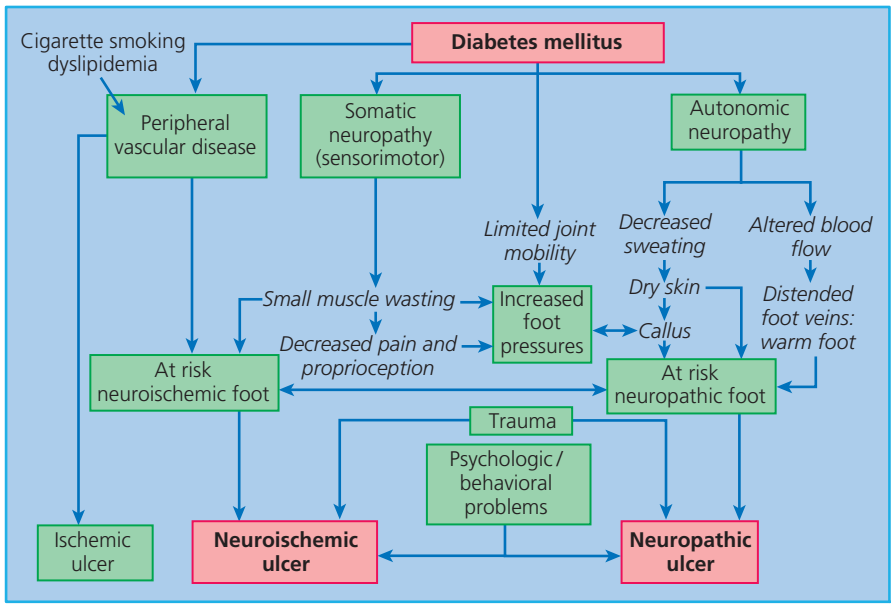

Figure 48.1 Pathways to foot ulceration in diabetes. Source: Boulton et al. 2006 [9]. Reproduced with permission of John Wiley & Sons.

no discomfort, and motivation to perform regular foot self-care is difficult. The important message is that neuropathic symptoms correlate poorly with sensory loss, and their absence must *never* be equated with lack of foot ulcer risk. Thus, assessment of foot ulcer risk must *always* include a careful foot examination after removal of shoes and socks, whatever the neuropathic history [30].

The person with sensory loss

A reduction in neuropathic foot problems will only be achieved if we remember that those with insensitive feet have lost their warning signal—pain—that ordinarily brings patients to their doctors. Hence the care of a someone with sensory loss is a new challenge for which we have no training. It is difficult for us to understand, for example, that an intelligent person would buy and wear a pair of shoes three sizes too small and come to the clinic with extensive shoe-induced ulceration. The explanation is simple: with reduced sensation, a very tight fit stimulates the remaining pressure nerve endings and is thus interpreted as a normal fit—hence the common complaint when we provide patients with custom-designed shoes that "these shoes are too loose." We can learn much about the management of such patients from the treatment of people with leprosy [31]. Although the cause of sensory loss is very different from that in diabetes, the end result is the same, hence work in leprosy has been very relevant to our understanding of the pathogenesis of diabetic foot lesions. It was Brand (1914–2003), who worked as a surgeon and a missionary in South India, who described pain as "God's greatest gift to mankind" [32]. He emphasized the power of clinical observation to his students and one remark of his that was very relevant to diabetic foot ulceration was that any person with a plantar ulcer who walks into the clinic without a limp must have neuropathy. Brand also taught us that if we are to succeed, we must realize that with loss of pain there is also diminished motivation in the healing of, and prevention of, injury.

Peripheral sympathetic autonomic neuropathy

Sympathetic autonomic dysfunction of the lower limbs leads to reduced sweating and results in both dry skin that is prone to crack and fissure and to increased blood flow (in the absence of large-vessel obstructive peripheral vascular disease) with arteriovenous shunting leading to the warm foot. The complex interactions of the neuropathies and other contributory factors in the causation of foot ulcers are summarized in Figure 48.1.

Other risk factors

Of all the other risk factors for ulceration (Table 48.2), one of the most important is a past history of similar problems. In many series this has been associated with an annual risk of reulceration of up to 50%.

Table 48.2 Factors increasing risk of diabetic foot ulceration. More common contributory factors are shown in bold.

Peripheral neuropathy
• **Somatic**
• **Autonomic**
Peripheral vascular disease
Past history of foot ulcers
Other long-term complication
• **End-stage renal disease**
• Visual loss
Plantar callus
Foot deformity
Edema
Ethnic background
Poor social background

Other long-term complications

Persons with other late complications, particularly nephropathy, have been reported to have an increased foot ulcer risk. Those most at risk are people with end-stage renal disease who are on dialysis [33, 34]. It must also be remembered that those with renal transplants and more recently combined pancreas–renal transplants are usually at high risk of ulceration even if normoglycemic as a result of the pancreas transplant.

Plantar callus

Callus forms under weight-bearing areas as a consequence of dry skin (autonomic dysfunction), insensitivity, and repetitive moderate stress from high foot pressure. It acts as a foreign body and causes ulceration [35]. The presence of callus in an insensate foot should alert the physician that this individual is at high risk of ulceration, and callus should be removed by the podiatrist or other trained healthcare professional.

Elevated foot pressures

Numerous studies have confirmed the contributory role that abnormal plantar pressures play in the pathogenesis of foot ulcers [4, 36].

Foot deformity

A combination of motor neuropathy, cheiroarthropathy, and altered gait patterns is thought to result in the "high-risk" neuropathic foot with clawing of the toes, prominent metatarsal heads, high arch, and small-muscle wasting (Figure 48.2).

Ethnicity and sex

Men have a 1.6-fold increase in ulcers [13]. With respect to ethnic origin, data from cross-sectional studies in Europe suggest that foot ulceration is more common in white Europeans than other racial groups; for example, the North-West Diabetes Foot Care Study in the United Kingdom showed that the age-adjusted prevalence of diabetic foot ulcers (past or present) for Europeans, South Asians, and African Caribbeans was 5.5, 1.8, and 2.7, respectively [37]. Reasons for these ethnic differences certainly warrant further investigation. In contrast, in the southern USA, ulceration was much more common in Latino Americans and Native Americans than in white people of Northern European ancestry [38]; however, more recent data confirmed this increased risk in Latinos, despite the foot pressures being actually lower in this group [39].

Figure 48.2 The high-risk neuropathic diabetic foot demonstrating high arch, prominent metatarsal heads, clawing of toes, and callus under first metatarsal head.

Pathway to ulceration

It is the combination of two or more risk factors that ultimately results in diabetic foot ulceration (Figure 48.1). Reiber et al. [40] took the Rothman model for causation and applied it to amputation and foot ulceration in diabetes. This model is based on the concept that a component cause (e.g. neuropathy) is not sufficient in itself to lead to ulceration, but when the component causes act together, they result in a sufficient cause that will inevitably result in ulceration. Applying this model to foot ulceration, a small number of causal pathways were identified; the most common triad of component causes, present in nearly two out of three incident foot ulcer cases, was neuropathy, deformity, and trauma. Edema and ischemia were also common component causes. Other simple examples of two-component causeways to ulceration are loss of sensation and mechanical trauma such as standing on a nail, wearing shoes that are too small; or neuropathy and thermal trauma (e.g. walking on hot surfaces or burning the feet in the bath); finally, neuropathy and chemical trauma may result in ulceration from the inappropriate use of, for example, chemical "corn cures." Similarly, this model can be applied to neuroischemic ulcers where the three-component causes comprising ischemia, trauma, and neuropathy are often seen [41].

Prevention of diabetic foot ulcers

Screening

It has been estimated that most foot ulcers are potentially preventable, and the first step in prevention is the identification of the "at-risk" population. Many countries have now adopted the principle of the "annual review" for persons with diabetes, whereby every person is screened at least annually for evidence of diabetic complications. Such a review can be carried out either in the primary care center or in a hospital clinic.

A taskforce of the American Diabetes Association addressed the question of what should be included for the annual review in the "comprehensive diabetic foot examination (CDFE)" [42]. The taskforce addressed and concisely summarized the recent literature in this area and recommended, where possible using evidence-based medicine, what should be included in the CDFE for adults with diabetes. Whereas a brief history was regarded as important, a careful examination of the foot, including assessing its neurological and vascular status, was regarded as essential. There is a strong evidence base to support the use of simple

Table 48.3 Key components of the diabetic foot examination.

Inspection
Evidence of past/present ulcers?

clinical tests as predictors of risk of foot ulcers [13, 42]. A summary of the key components of the CDFE is provided in Table 48.3. Whereas each potential simple neurological clinical test has advantages and disadvantages, it was felt that the 10-g monofilament had much evidence to support its use, hence the recommendation that assessment of neuropathy should comprise the use of a 10-g monofilament plus one other test. In addition to the simple tests listed in Table 48.3, a possible test for neuropathy was assessment of the vibration perception threshold. Although this is a semiquantitative test of sensation, it was included as many centers in both Europe and North America have such equipment. As can be seen from Table 48.3, this is not regarded as essential, but strong evidence does support the use of vibration perception threshold as an excellent predictor of foot ulceration [43, 44]. More recently, a "3-minute foot examination" has been proposed, mainly for use in primary care; this comprises 1 min each for history, physical examination, and what to teach [45].

With respect to the vasculature, the ankle brachial index was recommended, although it was realized that many centers in primary care may not be able to perform this in day-to-day clinical practice.

Intervention for high-risk individuals

Any abnormality found in the above screening test would put the person into a group at higher risk of foot ulceration. Potential interventions are discussed under a number of headings, the most important of which is education.

Education

Previous studies have suggested that persons with foot ulcer risk lack knowledge and skills and consequently are unable to provide appropriate foot self-care [46]. People need to be informed of the risk of having insensate feet and the need for regular self-inspection, foot hygiene, and chiropody/podiatry treatment as required, and they must be told what action to take in the event of an injury or the discovery of a foot ulcer. Studies summarized by Vileikyte et al. [47, 48] suggest that people with diabetes often have distorted beliefs about neuropathy, thinking that this is a circulatory problem and link neuropathy directly to amputation. Thus, an education program that focuses on reducing foot ulcers will be doomed to failure if patients do not believe that foot ulcers precede amputations. It is clear that much work is required in this area if appropriate education is to succeed in reducing foot ulcers and subsequently amputations. The potential for education and self-care at various points on the pathway to neuropathic ulceration is shown in Figure 48.3.

There have been a small number of reports that assessed educational interventions, but they were mostly small, single-center studies. In the most recently published study, even though the foot care education program was followed by improved foot care behavior, there was no evidence that such targeted education was associated with a reduced incidence of recurrent foot ulcers [49]. It has been suggested that people with diabetes find the concept of neuropathy difficult to understand: they are reassured because they have no discomfort or pain in their feet. It may be that using visual aids (which can also be used for the diagnosis of the at risk foot) may help people with diabetes to understand that there is something different about their feet compared with their partner's, for example. This might include the use of the administered indicator plaster (Neuropad): when applied to the foot this changes color from blue to pink if there is normal sweating [50]. The absence of sweating, such as in a high-risk foot, results in no color change, enabling patients to see that there is something different about their feet. A similar visual aid is the PressureStat (Podotrack) (Figure 48.4) [51]. This is a simple, inexpensive semiquantitative footprint mat that is able to identify high plantar pressures. The higher the pressure, the darker is the color of the footprint. Similarly, this can be used as an educational aid and might help the person with diabetes realize that specific areas under their feet are at particular risk of ulceration.

In summary, foot care education is believed to be crucial in the prevention of ulceration, although there is little support for this from randomized controlled trials. Further studies in this area are therefore urgently required.

Podiatry/chiropody

Although not available in every country, regular nail and skin care from a podiatrist/chiropodist is essential in the high-risk neuropathic foot. Attempted self-care has been reported in several cases to cause ulceration, and similarly self-care of calluses should be discouraged. Chiropodists and podiatrists should be attached to

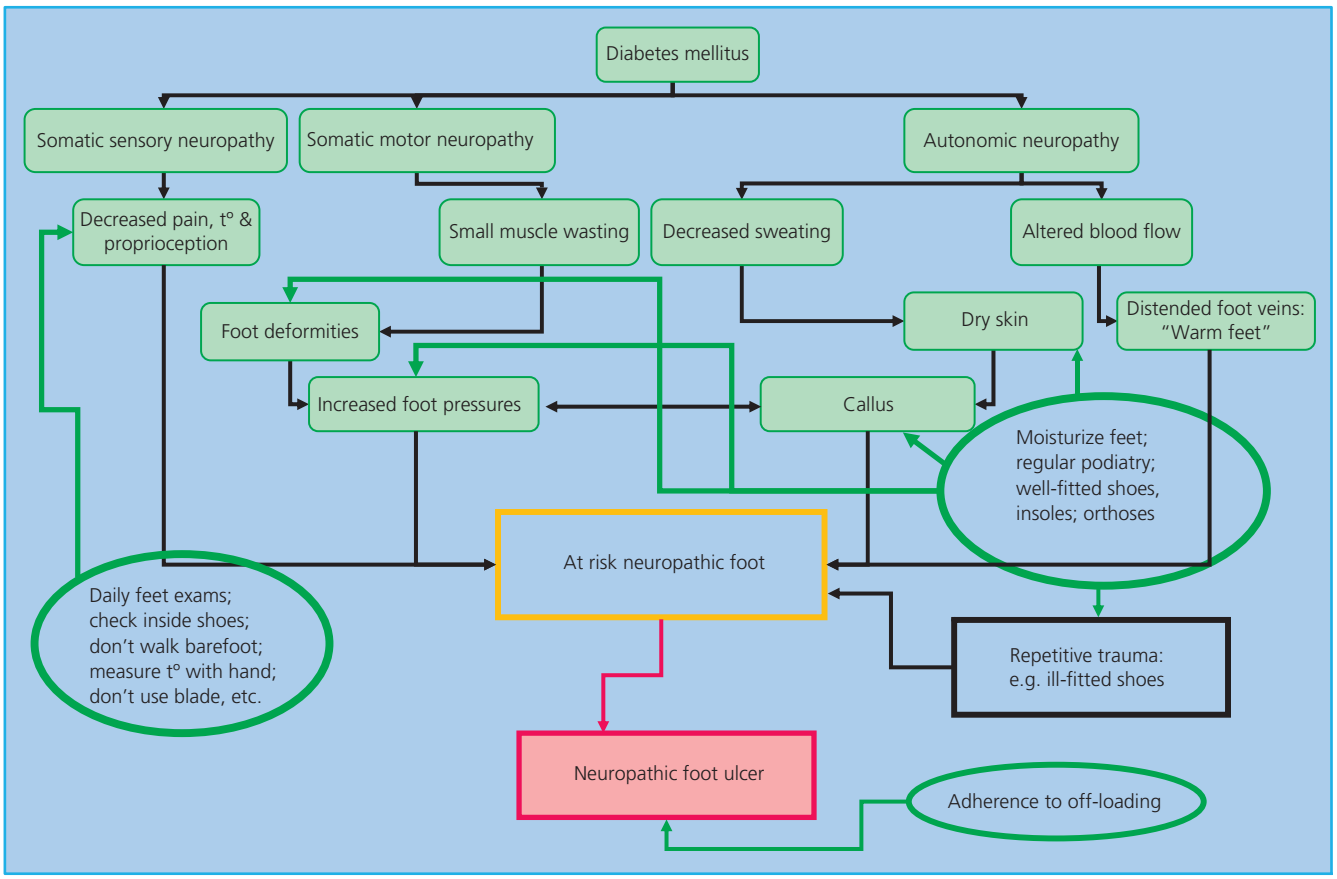

Figure 48.3 The potential for education and self-care in prevention of neuropathic foot ulcers. t°, temperature. Source: Courtesy of L. Vileikyte MD, PhD.

the foot care team if available and can also educate the person with diabetes while treating the feet.

Footwear/othoses/hosiery

Inappropriate footwear is a common cause of foot ulceration in insensitive feet, whereas good footwear can reduce ulcer occurrence [46]. This statement is supported by randomized controlled trials [52]. There is evidence from the literature also to support the use of specialist hosiery that might reduce foot pressures and give all-round protection to high-risk neuropathic feet [53, 54].

Self-monitoring of skin temperature

It has been known for some time that prior to skin breakdown and ulceration, the involved area of the foot tends to warm up as a consequence of local inflammation. In an appropriately designed, randomized controlled trial, Lavery et al. [55] randomized people with a history of neuropathic foot ulceration to one of three groups, the main intervention being self-monitoring of skin temperature of both feet; those who received this skin temperature thermometer were advised to rest or contact their foot clinic should there be a maintained difference in temperature between the two feet. This study clearly showed that those who monitored their skin temperatures and followed the advice had a markedly reduced incidence of recurrent ulceration (8% vs. 30%). Hence infrared temperature home monitoring might help to identify the "preulcerative" foot and permit intervention prior to actual skin breakdown. Another study provided further support for this notion [56].

Injected liquid silicone

Injected liquid silicone under high-pressure areas of the diabetic foot has been used for some years in the USA and is supported by a randomized controlled trial [57] that confirmed that people receiving active agent had reduced foot pressures and increased subcutaneous tissue under the high-pressure areas of the forefoot. This therapy is now available in certain European countries, and a follow-up study [58] confirmed that the effect of this "injectable orthosis" lasts for up to 2 years, although booster injections may be required from time to time.

Foot ulcers: diagnosis and management

Foot ulcer classification

Despite increasing efforts in the early identification and preventive foot care education of high-risk patients, foot ulcers continue to be a major issue in diabetes management and may indeed be

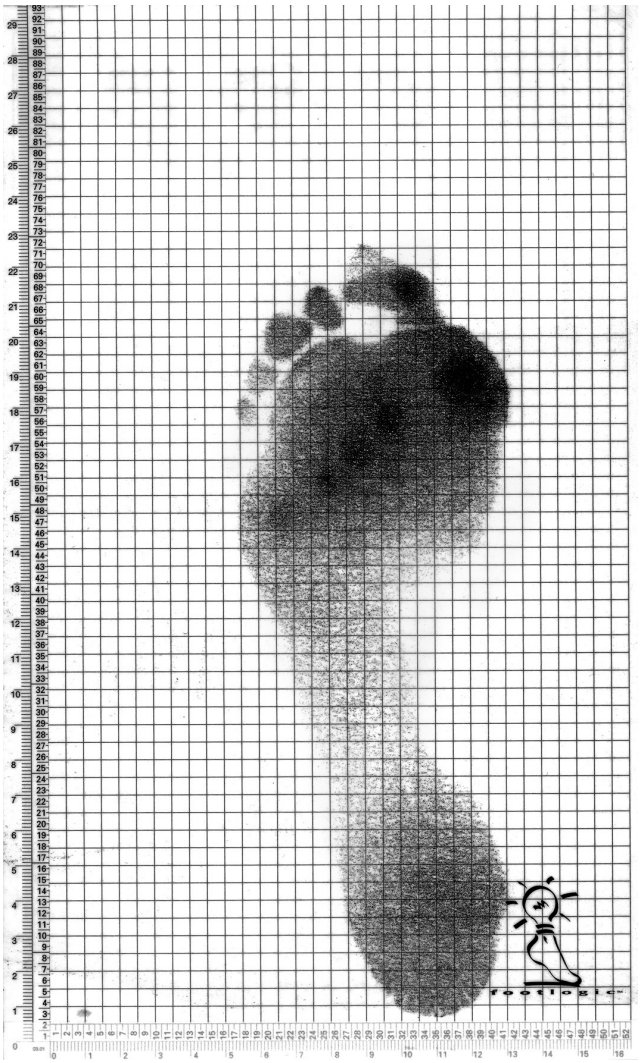

Figure 48.4 A black-and-white pressure distribution of one footstep using PressureStat: the darkest areas represent highest pressures, in this case under metatarsal heads 1 and 3 and the hallux.

the presenting feature of type 2 diabetes. The principles of management depend on a careful assessment of the causative factors, the presence or absence of infection, the degree of neuropathy, and/or ischemia in the foot. Before discussing the management of specific types of ulcers, it is important to consider how to classify foot lesions. Numerous classification systems for diabetic foot ulcers have been proposed [59] but only a few are described here.

Table 48.4 Meggitt–Wagner classification.

Grade	Description
0	No ulcer, but high-risk foot (deformity, callus, etc.)
1	Superficial ulcer
2	Deep ulcer, may involve tendons but not bone
3	Deep ulcer with bone involvement, osteomyelitis
4	Localized gangrene (e.g. toes)
5	Gangrene of whole foot

Source: Modified from Oyibo et al. 2001 [61].

The most widely used foot ulcer classification system worldwide at the time of writing is the Meggitt–Wagner grading, as shown in Table 48.4. Despite its wide use, this system lacks specificity and it does not refer to the neuropathic, ischemic or infective status of the ulcers.

The newer University of Texas (UT) wound classification system is currently widely used (Table 48.5) [60]. This is based on the Meggitt–Wagner system but with the addition of grades of ulcers and stages, each grade for the presence or absence of infection and ischemia. In a comparative study of these two systems, the UT system was shown to be a useful predictor of outcome, although the Meggitt–Wagner system was still confirmed to be useful [61]. A high-risk foot with preulcerative lesions (Wagner grade I, UT 1A) is shown in Figure 48.5. The two more recently described classification systems, S(AD) SAD system [size (area, depth), sepsis, arteriopathy, and denervation] and the PEDIS (perfusion, extent, depth, infection, sensation) systems appear to have some advantages over the earlier systems, but are not in widespread use [59]. Hence the UT system will be used to describe ulcer classification here. The most recently described WiFi system (Would ischemia, Foot infection) appears to have some advantages over the previously described systems, and has been shown to correlate with major amputation risk and time to wound healing [62].

Wound healing in the diabetic foot

Wound healing is a tissue response to injury and passes through the phases of inflammation, chemotaxis, cellular proliferation, extracellular matrix deposition, and finally wound remodeling and scarring. Diabetes may influence foot wound healing in a

Table 48.5 University of Texas ulcer classification system.

	Grade			
Stage	**0**	**1**	**2**	**3**
A	High-risk foot: no ulcer	Superficial ulcer	Deep ulcer to tendon/capsule	Wound penetrating bone/joint
B	+ Infection	+ Infection	+ Infection	+ Infection
C	+ Ischemia	+ Ischemia	+ Ischemia	+ Ischemia
D	+ Infection and ischemia	+ Infection and ischemia	+ Infection and ischemia	+ Infection and ischemia

Figure 48.5 Wagner grade I ulcer, UT 1A foot ulcer, showing a rim of callus and a punched-out neuropathic ulcer in the metatarsal head region with no evidence of infection.

number of different ways, including an impairment of the peripheral circulation, altered leukocyte function, disturbed balance of cytokines and proteases, and even chronic hyperglycemia itself [4, 63]. Thus, foot ulcers in people with diabetes are recalcitrant to healing because of many cellular and molecular aberrations. Compared with normal acute wound healing, chronic foot ulcers are often stalled in the chronic inflammatory phase with impaired granulation tissue formation. Key questions are therefore, is there a fundamental impairment of wound healing in diabetes and, if so, what are the molecular/cellular impairments, and are they specific to chronic wounds? A number of studies have reported abnormalities in cytokines and growth factors in tissue from chronic diabetic foot ulcers [64–66]. Most recently, it has been suggested that levels of matrix metalloproteinases (MMPs) are important in predicting the likelihood of wound healing, and a high level of MMP-1 seems essential to wound healing [66].

Another contributory factor to impaired wound healing in diabetes appears to be repetitive pressure on the wound. The pivotal role of offloading is therefore considered in the next section.

Offloading

A normal individual with a foot wound will limp: it has been known for some time that neuropathic plantar foot wounds will heal satisfactorily when offloaded in a total contact cast (TCC) [4]. The principle of TCC management is that pressure is mitigated but, in addition, the device is irremovable, thus enforcing adherence with therapy. A number of randomized controlled trials have compared the TCC with other removable offloading devices in plantar diabetic foot ulcers, and invariably healing is most rapid in those randomized to TCC treatment [4, 67]. As it is known that removable cast walkers (RCWs) redistribute pressure in a similar manner to the TCC, however, the question remained of why the TCC usually demonstrated superiority in terms of speed of wound closure. The most likely explanation, namely non-adherence, was confirmed in a study of 20 people with plantar neuropathic diabetic foot ulcers who were provided with RCWs and their total activity was recorded both from the waist and from an activity monitor hidden in the RCW. It transpired that participants only wore the RCW for 28% of all footsteps [68]. Subsequent to this observation, it was proposed that an RCW might be rendered irremovable by wrapping it with one or two bands of plaster of Paris, therefore addressing most of the disadvantages of the TCC but preserving irremovability. A subsequent randomized controlled trial of this modified, irremovable RCW versus the TCC showed that healing times were identical [69].

The impact of appropriate offloading on the histopathological features of neuropathic diabetic foot ulcers was reported by Piaggesi et al. [70]. They confirmed that appropriate offloading resulted in the foot wound appearing more like an acute wound with reparative patterns, angiogenesis, and fibroblast proliferation and the presence of granulation tissue. In contrast, biopsies from wounds that had not previously been offloaded confirmed the presence of hyperkeratosis, fibrosis, and chronic inflammation. These observations certainly suggest that appropriate offloading is associated with changes in the histology of neuropathic foot ulcers, including the reduction of inflammatory and reactive components and the acceleration of wound healing.

Another major consideration is the importance of emotional distress (e.g. depression and anxiety) in wound healing in people with diabetes [71]. This factor may have direct and indirect effects on wound healing. The direct effects include altered catecholamine and steroid secretion in addition to an imbalance of cytokines, which might directly impair wound healing. Indirectly, those who are depressed, for example, are less likely to adhere to treatment advice such as wearing an RCW at all times when walking. These important observations have previously been neglected by clinicians, and if any person with a plantar foot ulcer treated by an RCW shows no sign of healing, consideration should be given to the extent of adherence and the possibility of rendering the RCW irremovable as noted above.

As might be deduced from the above discussion, offloading is an essential component of the management of predominantly neuropathic plantar foot ulcers. This would include most UT 1A and 2A ulcers. Casts may also be used in the presence of localized infection in neuropathic foot ulcers (Figure 48.6). There is also evidence to support the use of offloading devices in the management

Figure 48.6 Radiograph from a person with a deep neuropathic ulcer under the right fifth metatarsal head. Gas in the tissues is not uncommon in radiographs of neuropathic foot ulcers as patients lacking pain sensation are able to walk despite the ulcer, "pumping" gas into the tissue. In this example, however, the gas makes it difficult to assess whether osteomyelitis is present.

of neuroischemic ulcers, but only if they are not clinically infected (UT 1C, 2C) [72].

For those treated with irremovable cast walkers, it is recommended that the cast be removed initially on a weekly basis for wound assessment, débridement, and cleansing. Healing can generally be a achieved in a period of 6–12 weeks in a cast; it is strongly recommended that after the plantar wound has healed, the cast be worn for a further 4 weeks to permit the scar tissue to firm up. Thereafter, the patient may be gradually transferred to appropriate footwear, which may need extra depth or, in the case of severe deformity, custom moulding.

Dressings

The danger of dressings and bandages is that some healthcare professionals may draw from them a false sense of security, believing that by dressing an ulcer they are curing it. Nothing could be further from the truth for a neuropathic ulcer. The three most important factors in the healing of a diabetic foot ulcer are freedom from pressure, freedom from infection, and good vascularity. The purpose of dressings is to protect the wound from local trauma, minimize the risk of infection, and optimize the wound environment, which should be moist in most cases. The evidence base to support the choice of any particular dressing is woefully inadequate, with few trials generally hampered by small numbers, inappropriate comparators, and poor study design [73, 74]. There is little evidence that any specific dressing will have a major impact on the rate of wound healing; indeed, a well-designed randomized trial comparing three commonly using dressings demonstrated no differences (except in cost) between them [75].

Management of infection

One of the first steps in the management of a foot ulcer is to determine whether infection is present or not: remember that all foot ulcers are colonized with potentially pathogenic organisms and it is generally accepted by the IWGDF that the diagnosis of infection in the diabetic foot ulcer remains a clinical one [76]. The presence of signs such as purulent discharge, erythema, local warmth, and swelling suggests infection requiring appropriate treatment. As recently emphasized by Abbas et al., it must be remembered that antibiotics are used to treat infection in the diabetic foot, they are not wound-healing agents [77].

Clinically non-infected ulcers

When ulcers are not infected and predominantly neuropathic (UT 1A, 2A), the use of antibiotics may be withheld, as Chantelau et al. [78] showed that with appropriate wound management, patients do equally well with or without systemic antibiotics in a randomized controlled trial. Nevertheless, frequent review, débridement, and callus removal together with offloading are essential parts of management of neuropathic foot ulcers and, should signs of infection develop, antibiotics may be needed. For those ulcers with an ischemic component that do not have gross signs of infection (UT 1C, 2C), antibiotics should probably be given in most cases as the combination of infection and ischemia in the diabetic foot is a common cause of ultimate lower extremity amputation.

Clinically infected ulcers

Non-limb-threatening infected ulcers (UT 1B, 1D, 2B, 2D) can generally be treated on an outpatient basis, and oral broad-spectrum antibiotics should be used initially until results of sensitivities are obtained. As reviewed by Lipsky's group, two sets of international guidelines have been published in recent years [76, 79, 80]. One important aspect of these recent guidelines has been the development of criteria by which to classify the severity of a diabetic foot infection. Generally, mild infections are relatively superficial and limited, moderate infections involve deeper tissues, and severe infections are accompanied by

systematic signs or symptoms of infection or metabolic disturbances [76]. Any ulcer with clinical evidence of infection should have tissue taken and sent for culture and sensitivity in the microbiology department. Although superficial swabs are commonly taken, deep (preferably tissue) specimens are preferable in terms of accuracy of diagnosis [76]. Most infective ulcers are polymicrobial, often with a mixture of anaerobes and aerobes. Unfortunately, a systematic review of antimicrobial treatments for diabetic foot ulcers revealed that few appropriately designed randomized controlled studies have been conducted, and it was difficult to give specific guidelines as to antibiotic regimens for specific infective organisms [81]; however, if there is any suspicion of osteomyelitis (signs such as a sausage-shaped toe or the ability to probe to bone may suggest this diagnosis), a radiograph of the infected foot should be taken and possibly further investigations initiated (see below and Chapter 55). The antibiotic prescription for a clinically infected non-limb-threatening foot ulcer without evidence of osteomyelitis should be guided by sensitivities after these are available from tissue specimens; when sensitivities are known, targeted appropriate narrow-spectrum agents should be prescribed. Suitable broad-spectrum antibiotics to start as soon as the clinical diagnosis of infection is made while waiting for a sensitivity result from the microbiology department would include drugs such as clindamycin or the amoxicillin–clavulanate combination [76].

Limb-threatening infection

People with limb-threatening infection usually have systemic symptoms and signs and require hospitalization with parenteral antibiotics. Deep wound and blood cultures should be taken and the circulation assessed with non-invasive studies initially, and metabolic control is usually achieved by intravenous insulin infusion. Early surgical débridement is often indicated in such cases, and initial antibiotic regimens should be broad-spectrum until sensitivities are determined from cultures. Examples of initial antibiotic regimens include clindamycin and ciprofloxacin, or flucloxacillin, ampicillin, and metronidazole. One problem with interpreting sensitivities is the question of whether the organism isolated is simply a colonizing bacterium or is a true infecting organism. One technique, the polymerase chain reaction (PCR) assay, has been shown to be effective at identifying many virulent organisms [76]. A study in France [82] showed the potential advantages of using this technique in the rapid distinction between colonizing and virulent infecting organisms.

An increasing problem in diabetic foot clinics is antibiotic-resistant pathogens such as methacillin-resistant *Staphylococcus aureus* (MRSA). In most cases, MRSA is isolated as an opportunistic colonizing organism following treatment with often inappropriate long-duration broad-spectrum antibiotics. If MRSA is felt to be an infecting organism, there are useful new agents such as linezolid [68], which can be given parenterally or orally, and are effective against such organisms. There is a suggestion that larval therapy [83] might be useful in eradicating MRSA that is contaminating diabetic foot wounds.

Figure 48.7 This radiograph displays two main abnormalities: (a) changes of osteomyelitis and septic arthritis involving the first metatarso-phalangeal joint, with destruction of the distal first metatarsal and proximal area of the proximal phalanx of the great toe; and (b) chronic changes of Charcot neuroarthropathy in the first cuneiform/metatarsal area.

Osteomyelitis

The diagnosis of osteomyelitis is a controversial topic, and several diagnostic tests have been recommended. Amongst these, "probing to bone" has been shown to have a relatively high predictive value whereas plain radiographs are insensitive early in the natural history of osteomyelitis. In most clinical cases, however, the diagnosis is ultimately made by a plain X-ray of the foot (Figure 48.7). Magnetic resonance imaging (MRI) is playing an increasing role in the diagnosis as it has high sensitivity [84]. The combination of an ulcer area >2 × 2 cm, a positive probe to bone test, an elevated sedimentation rate, and an abnormal radiograph are most helpful in diagnosing the presence of osteomyelitis in the diabetic foot, whereas a negative MRI scan makes a diagnosis much less likely [85]. A combination of clinical and laboratory findings together can significantly improve diagnostic accuracy for osteomyelitis in the diabetic foot: the specific combination of ulcer depth with serum inflammatory markers appears to be particularly sensitive [86]. Contrary to traditional teaching, it is increasingly recognized that some cases of localized osteomyelitis can be managed by long-term (10–12 weeks) antibiotic therapy, and this has recently been confirmed in a randomized controlled trial [87]; however, localized bony resection after appropriate antibiotic therapy remains a common approach. Those cases with osteomyelitis confined to one bone without involvement of a joint

are most likely to respond to antibiotic therapy, particularly in the absence of peripheral vascular disease. It must be pointed out that data to inform treatment choices in osteomyelitis of the diabetic foot for randomized controlled trials are limited and further research is urgently needed [88].

Adjunctive therapies

A number of newer approaches to promote more rapid healing in diabetic foot lesions have been described over the last two decades. Some of those are mentioned below but many have also been reviewed by the IWGDF [89].

Growth factors

A number of growth factors and other agents designed to modify abnormalities of the biochemistry of the wound bed or surrounding tissues have been described, but there is still no consensus on their place in day-to-day clinical practice [89]. One example is platelet-derived growth factor (PDGF), which is available for clinical use in a number of countries. Although there is some support for their use for randomized clinical studies [90], their expense, together with the fact that most neuropathic ulcers can be healed with appropriate offloading, have limited their use. Unfortunately, PDGF together with other topically applied agents such as epidermal growth factor do not have sufficient robust data to support their day-to-day use in routine clinical practice.

Hyperbaric oxygen

Hyperbaric oxygen has been widely promoted for the management of non-healing diabetic foot ulcers, particularly in the USA, for some years. Many of the reported studies have been poorly designed or anecdotal and have given rise to serious concerns about the widespread use of this treatment [91]; however, there have been well-designed randomized controlled trials to assess the efficacy of hyperbaric oxygen in ischemic diabetic foot wounds [92]. Whereas a recent systematic review that considered hyperbaric oxygen accepted that there was some evidence to support its use, it is clear that more data are required from larger controlled trials not only to confirm efficacy but also to clarify which wounds might best benefit from this expensive treatment [89, 93]. These data might be forthcoming in 2017, when the largest ever controlled trial of hyperbaric oxygen in diabetic foot wounds from multiple Dutch centers should be reported [94].

Negative pressure wound therapy

In recent decades, negative pressure wound therapy using vacuum-assisted closure has emerged as a commonly employed option in the treatment of complex wounds of the diabetic foot [95]. Earlier work suggested that the application of negative pressure optimizes blood flow, decreases local tissue edema, and removes excessive fluid and proinflammatory exudates from the wound bed. Subsequently, controlled trial evidence emerged for the use of negative pressure wound therapy in both local postoperative wounds in the diabetic foot [96] and, more recently, in the management of complex but non-surgical diabetic foot ulcers [97]. It is clear that this treatment helps promote the formation of granulation tissue, but its cost will limit its use to those complex diabetic foot wounds not responding to standard therapies. However, a more recent Cochrane review concluded that, because of the risk of bias in recent studies, further well-designed trials are required to help identify who might benefit from this therapy [98].

Bioengineered skin substitutes

Similarly to other treatments in this group of adjunctive therapies, although there is some evidence to support the use of bioengineered skin substitutes in non-infected neuropathic ulcers, its use is somewhat restricted by cost [89]. A systematic review on this topic concluded that the trials assessed were of questionable quality and until high-quality studies were performed, recommendations for the use of these skin substitutes could not be made [99].

Charcot neuroarthropathy

Charcot neuroarthropathy is a non-infective arthropathy that occurs in a well-perfused insensate foot. Although the exact mechanism underlying the development of Charcot neuroarthropathy remains unclear, progress has been made in our understanding of the etiopathogenesis of this disorder in the last two decades. It is clear that the classic neurotraumatic and neurotrophic theories for the pathogenesis of acute Charcot neuroarthropathy in diabetes do not address certain key features of the disease [100]. If the former theory were correct, Charcot neuroarthropathy would be much more common and should be symmetrical; in fact, acute Charcot neuroarthropathy is relatively rare among people with neuropathy and is usually asymmetric, although there is an increased risk of developing Charcot neuroarthropathy in the contralateral foot some years later.

Charcot neuroarthropathy occurs in a well-perfused insensate foot. Typically, patients present with a warm, swollen foot and, contrary to reports in some of the earlier texts, may be accompanied by pain or at least discomfort in the affected limb. The affected person tends to be slightly younger than is usual for individuals presenting with a diabetic foot ulcer and typically presents with a warm, swollen foot that may or may not be painful. Although a history of trauma may be present, the trauma is rarely of sufficient severity to account for the abnormalities observed on clinical examination (Figure 48.7). Although Charcot neuroarthropathy is characterized by increased local bone resorption, the exact cellular mechanisms that contribute to this condition remain unresolved. Fairly recently, receptor activator of nuclear factor κB ligand (RANKL) was identified as an essential mediator of osteoclast formation and activation. It has been hypothesized that the RANKL/osteoprotegerin (OPG) pathway may play an important part in the development of acute Charcot neuroarthropathy [100]. It has subsequently been confirmed that peripheral blood monocytes isolated from people with Charcot neuroarthropathy and cultured in the presence of macrophage colony-stimulating factor led to increased osteoclast formation compared with healthy and diabetic controlled monocytes [101].

These observations suggested that RANKL-mediated osteoclastic resorption occurs in acute Charcot neuroarthropathy. Hence the RANKL-dependent pathway is important in the pathogenesis of acute Charcot neuroarthropathy, suggesting that in the future, inhibition of RANKL might be useful in management. Other inflammatory markers, including tumor necrosis factor alpha and interleukin-6, have also been shown to be elevated in the acute phase of Charcot neuroarthropathy, showing significant reduction on resolution, suggesting that these could be used as potential markers of Charcot neuroarthropathy activity [102].

As discussed in Chapter 53, the treatment of the foot in CN depends upon the stage in which the disease is diagnosed. In the acute phase, that offloading of the affected foot by use of a plaster cast is the most effective method of reducing disease activity and local inflammation. Use of the cast should continue until the swelling and hyperemia have resolved and the skin temperature differential is 1 °C or less, at which time custom-moulded shoes with appropriate insoles are indicated [103]. The role of medical treatments has still to be clarified and none is currently recommended.

The management of advanced Charcot neuroarthropathy with bone deformity requiring reconstructive surgery is beyond the scope of this chapter and the reader is referred to recent reviews, e.g. [104].

Conclusions

There can be no doubt that despite our efforts in early identification, prevention, and aggressive treatment of diabetic foot problems, the incidence of diabetic foot disease is likely to increase in the next few decades with the global explosion of the prevalence in type 2 diabetes. It is also clear that diabetic foot disease carries not only a significant morbidity, but even mortality: Armstrong et al. [105] pointed out that the outlook for those with diabetic foot disease is worse than many malignant diseases. There is increasing recognition of the multifactorial nature of complications that led Young et al. [106] to review the survival of their patients with diabetic foot lesions over the previous 13 years. They reported that survival has improved and this has been accompanied by the adoption of an aggressive cardiovascular risk management policy that should be encouraged in all people with diabetic foot disease. The ultimate prognosis for the limb with a diabetic foot lesion depends upon the presence or absence of an ischemic component: it has been shown that people with higher Wagner or UT gradings and severity are more likely to end up with minor or even major amputation. Thus, neuropathic foot lesions generally carry a good prognosis, whereas those with a significant ischemic component are more likely to require the input of the vascular surgeon (see Chapter 47).

The team approach

It should be clear that the spectrum of diabetic foot problems requires the involvement of individuals from many specialties. The diabetic foot cannot be regarded as the sole responsibility of the diabetologist, and a number of reports over the last two decades or more have promoted the benefits of a multidisciplinary approach to diabetic foot care [107]. This started in the early 1990s, when the concept of the "annual review" was adopted by most national diabetes societies. This requires that all people with diabetes be screened on an annual basis for evidence of long-term complications [108]. There is increasing evidence from a number of long-term studies that the adoption of this approach not only in hospital but also in community care has been associated with a reduced incidence of foot problems [109–111]. The improved management of diabetic foot care in the district of Leverkusen, Germany, ultimately resulted in a 37% reduction in non-traumatic amputations in people with diabetes; however, this took more than 10 years after the establishment of specialist foot care [109]. Two studies from the UK [110, 111] have reported reductions of up to 60% in diabetic amputations and both of these followed either the introduction of multidisciplinary team work in the community or the improved organization of general diabetes care. Finally, a sustained reduction in major amputations over the previous 20 years was reported in a study in Sweden, suggesting that a substantial decrease in diabetes-related amputations can not only be achieved, but also maintained over a long period of time [112].

The team approach, involving diabetologists working together with surgeons (orthopedic and vascular), specialist nurses, podiatrists, orthotists, and often many other healthcare professionals is therefore strongly recommended in the management of complex lesions of the diabetic foot. It should be remembered, however, that it is the patient at risk of, or with foot ulceration, who must be regarded as the most important member of this team. Without the patient's willing participation, there is little that other team members can achieve to improve the overall outlook for the diabetic foot in the 21st century.

49 Sexual Function in Men and Women with Diabetes

David Price
Morriston Hospital, Swansea, UK

Key points

- The prevalence of erectile dysfunction in men with diabetes increases with age and is about 35–50% overall.
- Penile erection occurs as a result of engorgement of the erectile tissue following vascular smooth muscle relaxation in the corpus cavernosum mediated by nitric oxide (NO), which is derived from both parasympathetic nerve terminals and the vascular endothelium.
- Erectile dysfunction in diabetes is largely due to failure of NO-mediated smooth-muscle relaxation secondary to endothelial dysfunction and autonomic neuropathy.
- Erectile dysfunction is an early indicator of endothelial dysfunction and a marker of increased cardiovascular risk.
- Sildenafil and other phosphodiesterase 5 (PDE5) inhibitors act by inhibiting the breakdown of cyclic guanosine monophosphate (cGMP), the second messenger in the NO pathway, and hence enhance erections under conditions of sexual stimulation.
- PDE5 inhibitors are safe and effective and can be used to treat erectile dysfunction in a diabetes clinic or general practice.
- Other options for treating erectile dysfunction in diabetes are intracavernosal injection therapy, transurethral alprostadil, vacuum therapy, and surgical insertion of penile prostheses.
- In women with diabetes, sexual dysfunction is less common, but there is an increased risk of vaginal dryness and arousal disorder.
- Contraceptive advice is essential in diabetes, as unplanned pregnancies carry an increased risk of morbidity and fetal abnormalities. Most forms of contraception are safe and effective in women with diabetes, but the oral contraceptive pill is recommended, as it is reliable and well tolerated.
- Hormone replacement therapy should be considered on a short-term basis in all women with an appropriate indication, particularly if they have diabetes. It has no adverse effects on glycemic control or lipid profiles.

Male erectile dysfunction

Erectile dysfunction is one of the commonest clinically apparent complications in men with diabetes. It can cause distress and unhappiness but is usually treatable. It may also be a marker of cardiovascular risk, and so it is a condition of which all diabetes professionals should be aware and understand.

Physiology of erectile function

Tumescence is a vascular process under the control of the autonomic nervous system. The erectile tissue of the corpus cavernosum behaves as a sponge, and erection occurs when it becomes engorged with blood. As shown in Figure 49.1, dilatation of the arterioles and vasculature of the corpus cavernosum leads to compression of the outflow venules against the rigid tunica albuginea [1, 2]. Hence smooth-muscle relaxation is the key phenomenon in this process, as it leads to increased arterial inflow and reduced venous outflow [3, 4]. The process is under the control of parasympathetic fibers, which were previously known as non-adrenergic, non-cholinergic neurones, as the neurotransmitter was unknown; however, it is now clear that nitric oxide (NO) is the agent largely responsible for smooth-muscle relaxation in the corpus cavernosum. It is both produced in the parasympathetic nerve terminals and is generated by NO synthase in the vascular endothelium. Within the smooth-muscle cell of the corpus cavernosum, NO stimulates guanylate cyclase, leading to increased production of the second messenger, cyclic guanosine monophosphate (cGMP), which induces the activation of protein kinase G. This inhibits calcium release, which leads to smooth-muscle relaxation [4–6] (Figure 49.2).

There is some evidence that neuronally derived NO is important in initiation, whereas NO from the endothelium is responsible for maintenance of erection [7].

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

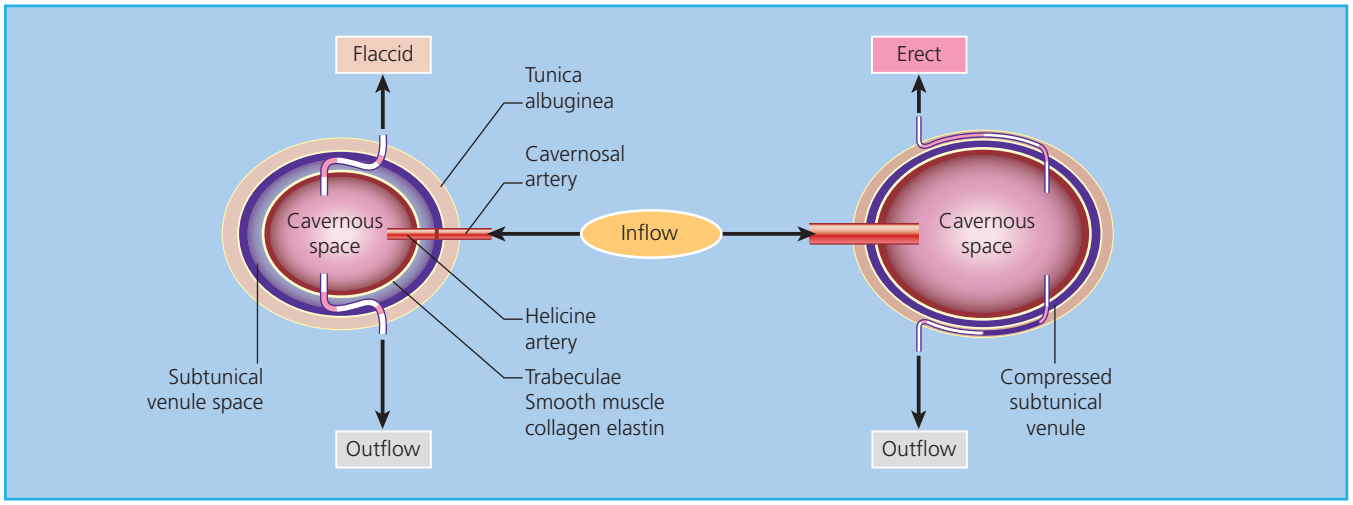

Figure 49.1 Diagrammatic representation of the corpus cavernosum. During tumescence, dilation of the helicine and cavernosal arteries produces expansion of the cavernosal space and compression of the outflow venules against the rigid tunica albuginea.

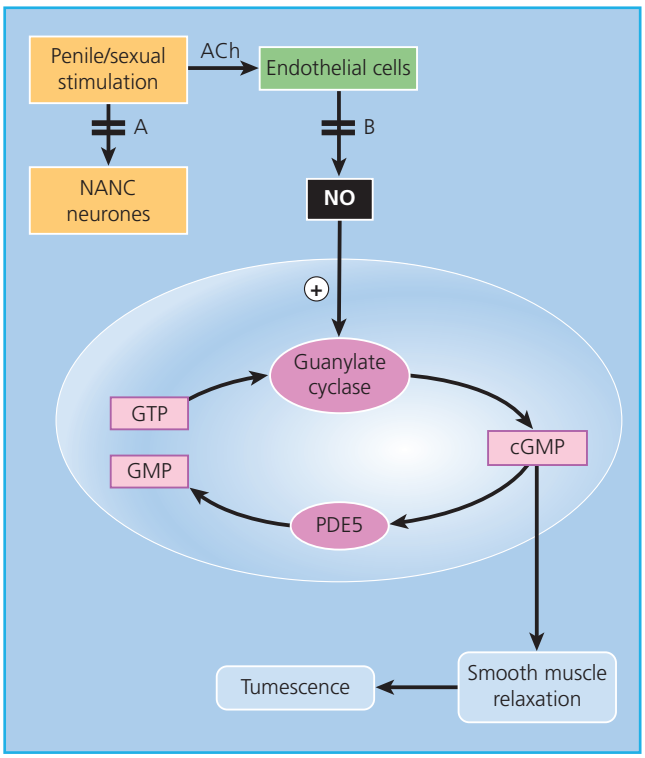

Figure 49.2 Pathophysiology of erectile function in diabetes. Diagrammatic representation of the pathways leading to the relaxation of a corpus cavernosal smooth muscle cell. In diabetes there are defects in nitric oxide mediated smooth muscle relaxation due to neuropathy of the NANC fibers (A) and endothelial dysfunction (B). Ach, acetylcholine; NANC, non-adrenergic, non-cholinergic neurones; NO, nitric oxide; PDE5, phospodiesterase type 5.

Pathophysiology of erectile dysfunction in diabetes

In men with diabetes, there is good evidence that erectile dysfunction is due to failure of NO-induced smooth muscle relaxation due to both autonomic neuropathy and endothelial dysfunction [8]. Many men with diabetes report that in the early stages they do not have a problem initially achieving an erection but that they cannot maintain it. This suggests that in these individuals failure of endothelium-derived NO occurs before significant autonomic neuropathy.

More recently, other potential abnormalities have been described that may contribute to the development of erectile dysfunction in diabetes. Endothelium-derived hyperpolarizing factor (EDHF) plays a role in endothelium-dependent relaxation of human penile arteries [9], and EDHF-mediated endothelium-dependent relaxation is significantly impaired in penile resistance arteries in men with diabetes [10]. Impaired EDHF responses might therefore contribute to the endothelial dysfunction of diabetic erectile tissue.

A further body of evidence suggests that increased oxygen free-radical levels in diabetes may reduce the vasodilator effect of NO. In particular, the formation of products of non-enzymatic glycation to produce advanced glycation end-products (AGEs) generates reactive oxygen species, which impairs NO bioactivity [11, 12]. In animal models, inhibition of AGE formation improves endothelium-dependent relaxation and restores erectile function in diabetic rats [13, 14].

Other pathophysiological changes known to occur in diabetes have been postulated to contribute to erectile dysfunction. Non-enzymatic glycation of proteins has been reported to impair endothelium-dependent relaxation of the aorta in rats [15, 16]. Other factors, not limited to diabetes, may also contribute to the development of erectile dysfunction in men with diabetes.

Structural changes associated with large-vessel disease are commonly associated with erectile dysfunction in diabetes. However, this is usually associated with functional changes of widespread endothelial dysfunction in diabetes and it is difficult to separate the relative importance of the two factors.

Testosterone has a central role in the physiology of erectile function and also in the regulation of male sexual behavior and attitudes. Hypogonadism is a well-established, and treatable, cause of erectile dysfunction. In experimental studies, androgen deficiency leads to a reduction in smooth muscle and structural abnormalities in the erectile tissue [17, 18]. In recent years, there has been a great deal of interest in a potential association between reduced levels of testosterone and type 2 diabetes mellitus (T2DM) and the metabolic syndrome. However, it is controversial whether there is a causal link between diabetes and hypogonadism, and this will be discussed later in this chapter.

Box 49.1 Medications associated with erectile dysfunction.

Antihypertensives
Thiazide diuretics
Beta-blockers
Calcium channel blockers
ACE inhibitors
Central sympatholytics (methyldopa, clonidine)
Aldosterone receptor antagonists

Antidepressants
Tricyclics
Monoamine oxidase inhibitors
(NB: Selective serotonin reuptake inhibitors can cause ejaculatory problems)

Antipsychotics
Phenothiazines
Haloperidol

Hormones
Luteinizing hormone-releasing hormone (goserilin, buserilin)
Estrogens (stilbestrol)
Antiandrogens (cyproterone)

Miscellaneous
5α-Reductase inhibitors (finasteride)
Statins (simvastatin, atorvastatin, pravastatin)
Cimetidine
Digoxin
Metoclopramide

Drugs of abuse
Alcohol
Tobacco
Marijuana
Amphetamines
Anabolic steroids
Barbiturates
Opiates

Other factors contributing to erectile dysfunction in diabetes

In addition to endothelial dysfunction and autonomic neuropathy, erectile dysfunction is associated with other conditions common in diabetes, such as hypertension and large-vessel disease [19]. Furthermore, men with diabetes are more likely to be taking medications that can impair erectile function. A list of these is given in Box 49.1. Antihypertensive agents are commonly reported to be associated with erectile dysfunction, although much of the evidence is anecdotal; β-blockers, aldosterone receptor blockers, and thiazide diuretics are the most commonly reported culprits [20]; the α-blockers perhaps have the least risk [21]. Finally, it should be remembered that there are many other potential causes of erectile dysfunction unrelated to diabetes, from which men with diabetes are not immune. The conditions associated with erectile dysfunction are listed in Box 49.2.

Box 49.2 Conditions associated with erectile dysfunction.

Psychological disorders
Anxiety about sexual performance
Psychological trauma or abuse
Misconceptions
Sexual problems in the partner
Depression
Psychoses

Vascular disorders
Peripheral vascular disease

Hypertension
Venous leak
Pelvic trauma

Neurological disorders
Stroke
Multiple sclerosis
Spinal and pelvic trauma
Peripheral neuropathies

Endocrine and metabolic disorders
Diabetes
Hypogonadism
Hyperprolactinemia
Hypopituitarism
Thyroid dysfunction
Hyperlipidemia
Renal disease
Liver disease

Miscellaneous
Surgery and trauma
Smoking
Drug and alcohol abuse
Structural abnormalities of the penis

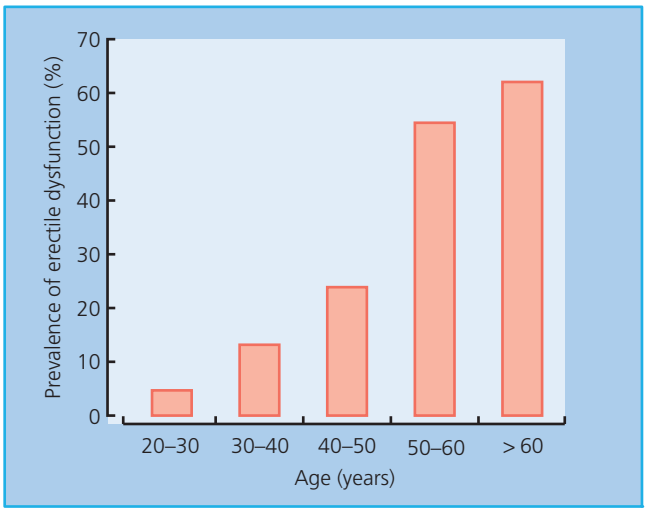

Figure 49.3 Prevalence of erectile dysfunction by age of men attending a hospital diabetes men clinic [22].

Clinical aspects of erectile dysfunction in diabetes

Erectile dysfunction becomes commoner with age. In a population-based study in Massachusetts, United States, the prevalence of complete erectile failure was reported to be 5% in men in their 40s and 15% in those over 70 years of age [19]. The prevalence in men with diabetes is significantly higher and also increases with age. In a survey of men attending a hospital diabetes clinic in the United Kingdom, the prevalence of erectile dysfunction increased from 13% among 30-year-olds to 61% among men aged over 60 years [22] (Figure 49.3). Overall, the prevalence was 38%. The prevalence of erectile dysfunction in diabetes in a general practice population was reported to be even higher, at 55% [19]. These data suggest that erectile dysfunction is the commonest clinically apparent complication of diabetes in men.

Conversely, diabetes is a common finding in men presenting with erectile dysfunction. Approximately 20% of men seen in erectile dysfunction clinics have been reported to have diabetes, of whom ~5% were previously undiagnosed [23, 24].

The presence of other medical conditions increases the risk of erectile dysfunction. A population-based survey of 600 men in Brazil, Italy, Japan, and Malaysia in 2000 examined the prevalence of erectile dysfunction and its relationship to other diseases and lifestyles. The prevalence of erectile dysfunction among men with diabetes rose from 25% at age 40–44 to 70% at age 65–70 years [25]. Cardiovascular disease increased the risk of erectile dysfunction. The prevalence was 31.7% in men with diabetes only, 40% in men with diabetes and heart disease, and 46.5% in those with diabetes and hypertension. Men with diabetes who smoked and reported below-average levels of physical activity had a fourfold increase in the prevalence of erectile dysfunction.

Erectile dysfunction as a risk factor for cardiovascular disease

There is convincing evidence of an association of between erectile dysfunction and both cardiovascular disease [26, 27] and mortality [28]. This may be because they share common risk factors. Increased waist measurement and reduced physical activity, both important risk factors for ischemic heart disease, considerably increase the risk of erectile dysfunction [29–31].

Recent studies have suggested that the association between erectile dysfunction and cardiovascular disease may be due to more than shared risk factors and may arise because they are both manifestations of endothelial dysfunction. There is considerable evidence that endothelial dysfunction has a key role in the pathogenesis and progression of atherosclerosis [32]. It is clear that the endothelium has important and complex endocrine and paracrine functions, and one of its most important products is NO (previously known as endothelium-derived relaxing factor). NO derived from both nerve terminals and the vascular endothelium has a central role in the physiology of erection. Therefore, there are theoretical grounds to believe that erectile dysfunction might be an early marker of endothelial dysfunction and hence an important risk factor for cardiovascular disease, and there is good evidence that this is the case in animal studies [33] and humans [34, 35].

Hence the association between erectile dysfunction and increased cardiovascular risk may be a case of shared "common soil," in particular endothelial dysfunction and microvascular disease. In practical terms, this means that cardiovascular risk should be assessed in any man with erectile dysfunction whether he has diabetes or not. A man with T2DM and erectile dysfunction has approximately double the risk of developing coronary heart disease compared with a similar man without erectile dysfunction [36].

Smoking and alcohol consumption

Smoking greatly increases the risk of developing erectile dysfunction. A follow-up of the Massachusetts Male Aging Study reported that cigarette smoking almost doubled the risk of developing erectile dysfunction after about 7 years [19]. A similar finding was reported by the large Health Professionals' Follow-up Study [31]. Smoking appears to exert its effects via the NO signal transduction pathway [37].

In contrast to tobacco, it is well established that moderate alcohol consumption is associated with a reduced risk of a cardiovascular event. It is interesting, that drinking alcohol in moderation also appears to reduce the risk of developing erectile dysfunction [38].

Quality of life issues

That erectile dysfunction can significantly worsen a man's quality of life is not in doubt and there is reasonable evidence to show treating erectile dysfunction improves quality of life. A large study of men with T2DM reported that erectile problems were associated with a dramatic increase in depressive symptoms [39]. In another series in general practice, 45% of men with diabetes stated that they thought about their erectile dysfunction all or most of the time, 23% felt that it severely affected their quality of life, and 10% felt that it severely affected their relationship with their partner [40]. A systematic review of randomized trials of erectile

Box 49.3 Key features in the history of erectile dysfunction in diabetes.

Onset usually gradual and progressive
Earliest feature often inability to sustain erection long enough for satisfactory intercourse
Erectile failure may be intermittent initially
Sudden onset often stated to indicate a psychogenic cause but little evidence to support this
Preservation of spontaneous and early morning erections does not necessarily indicate a psychogenic cause
Loss of libido consistent with hypogonadism but not a reliable symptom
Men with erectile dysfunction often understate their sex drive for a variety of reasons

dysfunction treatment reported improvements in self-esteem, confidence, and depression scores after treatment [41].

Assessment and investigation of erectile dysfunction in diabetes

Clinical assessment

In most cases, a man with erectile dysfunction will have taken a long time to pluck up the courage to discuss his problem with a doctor and he may be anxious. Almost invariably, however, once the subject has been broached, men with erectile dysfunction and their partners do not usually have any difficulty discussing the problem. A description of the nature of the ED should be obtained, not least to ensure that the man is complaining of erectile dysfunction and not another related problem, such as premature ejaculation. The key features in the history of erectile dysfunction are listed in Box 49.3. Ideally, the man's partner should be present, but most men attend the consultation alone. Talking to the partner without the man present can reveal interesting and useful insights into the problem.

General physical examination may give clues as to the etiology of erectile dysfunction and the choice of treatment. The key features of the physical examination are listed in Box 49.4.

Investigation of erectile dysfunction in diabetes

The suggested investigations of erectile dysfunction in diabetes are listed in Box 49.5. It is unhelpful to try to determine whether

Box 49.4 Key physical signs on examination.

Any features of hypogonadism
Manual dexterity—may preclude physical treatment
Protuberant abdomen
External genitalia:
  Presence of phimosis
  Testicular volume

Box 49.5 Investigation of erectile dysfunction in diabetes.

Serum testosterone if libido reduced or hypogonadism suspected (ideally taken at 9 a.m.)
Serum prolactin and luteinizing hormone if serum testosterone subnormal
Assessment of cardiovascular status if clinically indicated:
ECG
Serum lipids
Glycated hemoglobin, electrolytes, if clinically indicated

or not erectile dysfunction is psychogenic in origin, particularly when managing a man with diabetes and erectile dysfunction. Few investigations are needed, but it is worth excluding other treatable causes of erectile dysfunction; in practical terms, hypogonadism is the only treatable one. The relationship between diabetes and hypogonadism is a matter of much debate (see below), but gonadal function should be assessed in all men with diabetes and erectile dysfunction. Some men presenting with erectile dysfunction will not have attended any form of clinic for many years, and so the consultation provides an opportunity to address other health issues. For the reasons given above, consideration should be given to assessing the man's cardiovascular status. The consultation also provides an opportunity to address the management of the man's diabetes.

General advice

Most men with diabetes and their partners seeking treatment for erectile dysfunction are middle-aged, have been married for many years, and require only simple, common-sense advice. Specialist psychosexual counseling is not needed for most couples; several series have reported that diabetologists can offer an effective service for the treatment of erectile dysfunction without the support of psychosexual counselors [42–45]. It is important that the cause of the erectile dysfunction is explained, as many men will blame themselves. They should be advised that if they wish to resume sexual relations they will require long-term treatment, as spontaneous return of erectile function in diabetes occurs only rarely [46].

Treating erectile dysfunction in an attempt to save a failing relationship is rarely successful and may make the situation worse. The assistance of a suitably qualified psychosexual counselor should be considered in this situation. Referral to a counselor should also be considered if there is any suggestion of severe anxiety, loss of attraction between partners, or marked performance anxiety. Any other medical problems should be addressed. Improving poor metabolic control may help general well-being, but poor control should not be used as a reason to refuse or delay treatment. Men who smoke should be advised to stop for reasons of general health, although there is no good evidence that stopping smoking will improve erectile function in a man with diabetes.

Many men with diabetes will be taking medication known to cause erectile dysfunction. Experience has shown that changing

Table 49.1 Characteristics of available PDE5 inhibitors.

Agent	Dosage (mg)	Onset of action (min)	Half-life (h)	Duration (h)
Sildenafil	25, 50, or 100 prn	30–60	3–5	<12
Vardenafil	5, 10, or 20 prn	30–60	4–5	<10
Tadalafil	10 or 20 prn 5 daily	60–120	17.5	<36
Avanafil	50, 100, or 200 prn		3	<6

the treatment in an attempt to improve sexual function rarely works and may cause delays and frustration for the man. It is therefore not advisable unless there is a strong temporal relationship between starting treatment and the onset of erectile dysfunction.

Treatment options

The advent of effective oral therapies has transformed the management of erectile dysfunction. These should be offered as first-line therapy to men with diabetes and erectile dysfunction, and the other treatment options should be reserved for those in whom oral therapy is contraindicated or ineffective.

Oral agents

Phosphodiesterase 5 inhibitors

Phosphodiesterase type 5 (PDE5) is an enzyme found in smooth muscle, platelets, and the corpus cavernosum. During tumescence, there is an increase in the intracellular concentration of NO, which produces smooth-muscle relaxation via the second messenger cGMP. This is broken down in turn by PDE5. Hence PDE5 inhibitors can enhance erections under conditions of sexual stimulation.

Sildenafil was the first PDE5 inhibitor and early small trials showed it to be a highly effective treatment for erectile dysfunction in men with and without diabetes [47, 48]. The first large study was published in 1998. A total of 532 men with erectile dysfunction of mixed etiology were studied. In the group given sildenafil, 69% of all attempts at intercourse were successful, compared with 22% in those given placebo [49]. Other studies in men with erectile dysfunction of mixed etiology have shown success rates between 65 and 77% [50, 51]. Studies of sildenafil in other patient groups have reported success rates of ~70% in hypertension [52], 76% in spinal cord injury [53], 63% in spina bifida [54], and 40% following radical prostatectomy [55].

In men with diabetes, the success rates for sildenafil have been reported to be between 56 and 59% [48, 56]. A study in elderly men reported success rates of 69% overall and 50% in men with diabetes [57]. Most of these studies of sildenafil have been short term. A trial examining the long-term efficacy of sildenafil in men with erectile dysfunction due to a variety of causes reported that only 52% continued to use it after 2 years [58]. This figure may seem surprisingly low, but it is certainly considerably higher than for any other type of erectile dysfunction treatment.

Other PDE5 inhibitors

There are currently four PDE5 inhibitors licensed for the treatment of ED: sildenafil (Viagra), tadalafil (Cialis), vardenafil (Levitra), and avanafil (Stendra). Their key characteristics are listed in Table 49.1 and adverse effects from the key trials of PDE5 inhibitors in men with diabetes are given in Table 49.2 [59–65]. All four PDE5 inhibitors have similar efficacy and safety profiles. Their side-effect profiles differ slightly, but the most notable difference is the longer half-life of tadalafil. Thus a single dose of tadalafil offers the potential to restore erectile function to normal for 2 days and thereby remove the need for medication to be taken each time prior to sexual activity. The choice between this form of treatment and on-demand dosing is largely a matter of patient choice. Patient preference studies of agents with differing dosing instructions are difficult to perform in a blinded fashion. Several have been reported and

Table 49.2 Adverse effects of PDE5 inhibitors (%). The prevalence quoted for each adverse effect is for the top dose used in each study.

Effect	Sildenafil [56–58, 61]	Tadalafil [59, 60, 62]	Vardenafil [64, 65]	Avanafil [63]
Headache	8.1–9.3	8.0–21	5–11	11.5
Flushing	7.4–8.1	3.0–9.0	5.4–10	4
Back pain	2.5	4.6–9.0	0	1
Dyspepsia	2.7–3.0	4.1–17	2.3	3
Nasal congestion	2.7–4.1	2.0–5	10	3
Dizziness	2.5	1.6		
Diarrhea	2.5	0.8		
Abnormal vision	1.4	0		1
Muscle cramps	4.1	3–7		0

have generally shown a preference for tadalafil over sildenafil [62, 66–70].

Adverse effects

The commonest adverse effects related to PDE5 inhibitors are headache, dyspepsia, and flushing. Headache and flushing might be expected, as the inhibitors are vasodilators. The dyspepsia is usually mild and may be due to relaxation of the cardiac sphincter of the stomach. Abnormal vision is experienced by about 6% of men taking sildenafil; this may be because the drug has some activity against PDE6, which is a retinal enzyme. Back pain and muscle cramps are particularly an adverse effect of tadalafil. In all the studies, the discontinuation rate due to adverse effects was low.

The cardiovascular safety of PDE5 inhibitors

The launch of sildenafil, the first PDE5 inhibitor, was soon followed by case reports of cardiovascular events and deaths associated with its use. However, there is now good evidence that PDE5 inhibitors are not associated with increased cardiovascular risk [71–74]. Restoring sexual function, however, is not completely without risk. Sexual activity, like any form of physical activity, can precipitate cardiovascular events in those at risk. A large case–control study reported the risk of a cardiovascular event in the 2 h after intercourse was increased by 2.5-fold in healthy men and by 3-fold if there was a history of previous myocardial infarction [75]. Although the absolute risk remains very small, the issue of cardiovascular safety must be addressed in all men before treating erectile dysfunction. Jackson et al. suggested a classification scheme for assessing cardiovascular risk in men undergoing treatment for erectile dysfunction; those with the highest risk should be referred for specialist cardiac evaluation whereas the lowest risk group could be managed in primary care [71].

Drug interactions with PDE5 inhibitors

PDE5 inhibitors can be used safely in men taking a wide range of other drugs, but there are several potential important interactions. They are contraindicated in the presence of any nitrate therapy (including nicorandil) as the combination can cause profound hypotension. A man taking nitrates seeking treatment for erectile dysfunction can be offered alternatives to PDE5 inhibitors or the nitrates can be stopped or changed to an alternative therapy. Nitrates are a symptomatic treatment with no prognostic implications and so this is possible in most cases, but it should be done in consultation with a cardiologist in all but the most straightforward cases.

Nitrate therapy should not be given within 24 h of taking sildenafil, avanafil, or vardenafil and at least 48 h of taking tadalafil. If angina develops during or after sexual activity following the use of a PDE5 inhibitor, the man should be advised to discontinue any sexual activity and to stand up, as this reduces the work of the heart by reducing venous return.

PDE5 inhibitors should be used with caution in men who take α-blockers because the combination may lead to symptomatic hypotension in some men. Patients should be stable on α-blocker therapy before initiating a PDE5 inhibitor, which should be initiated at the lowest dose [72].

How to use PDE5 inhibitors

These agents should be taken orally about 1 hour before sexual activity. This period can be shortened if the drug is taken on an empty stomach. After the 1-h period, there is a "window of opportunity" when sexual activity can take place. For sildenafil, avanafil, and vardenafil, this is at least 4 h but may be over 8 h [72]. For tadalafil, the window of opportunity may last 48 h. Men with diabetes usually require the maximum recommended dose. The men should be warned that the drug only works in conjunction with sexual stimulation.

Tadalafil can be prescribed as a daily 5-mg dose rather than on an as-required basis. Many men find this more acceptable as it obviates the need to "plan for sex." It is effective when taken in this way [76] and may be slightly more effective than as-required tadalafil [77], but it is more expensive.

Management of non-responsiveness of PDE5 inhibitors

It is difficult to predict whether a man will respond to a PDE5 inhibitor. Failure to respond is more likely in men with long-standing and severe erectile dysfunction [35, 41]. However, no single factor precludes a successful outcome, and in practical terms it is worth trying a PDE5 inhibitor in all men with erectile dysfunction unless there is a contraindication. It is important that men are advised on how to take their medication properly. It has been suggested that intercourse success rates reached a plateau after eight attempts, so men should try at least eight times with a PDE5 inhibitor at the maximum recommended dose before being considered a non-responder [78].

Even with the maximum dose taken correctly, a large proportion of men with diabetes will not respond to PDE5 inhibitors. Treating any underlying hypogonadism may improve the outcome in this situation, but most men should be offered an alternative treatment.

Hypogonadism

The relationship between diabetes, the metabolic syndrome, and hypogonadism has been the subject of considerable interest in recent years. The overweight middle-aged man with T2DM, sexual dysfunction, fatigue, and borderline low serum testosterone is a common clinical problem. The term "late-onset male hypogonadism" has been coined to describe this condition. Pharmaceutical companies have been quick to promote research in this area as they look to widen the market for testosterone products. It is clear that reduced serum testosterone is more common in men with the metabolic syndrome and T2DM [79, 80]. Conversely, hypogonadism is associated with a near doubling of the risk of diabetes [81]. However, a causal relationship between the two has not been established and there are many confounding factors. The US Endocrine Society Clinical Practice Guidelines offer clear advice on the management of hypogonadism. It should only be treated if there are symptoms associated with hypogonadism (such as

Figure 49.4 Alprostadil self-injection pen device.

erectile dysfunction) and unequivocal biochemical evidence of hypogonadism [82]. There is certainly insufficient evidence to support treating hypogonadism to improve glucose tolerance or cardiovascular risk.

However, a serum testosterone should always be measured in men with diabetes and erectile dysfunction, particularly in those who do not respond to PDE5 inhibitors. Hypogonadism due to confirmed pituitary or testicular disease may be an uncommon finding in this situation but it usually responds well to treatment with testosterone. In the more common group of men with "late-onset male hypogonadism," there is some evidence that testosterone replacement can improve erectile dysfunction as a sole treatment [83] and enhance the response to PDE5 inhibitors [84, 85].

Other oral therapies

Various oral agents have been tried as treatments for erectile dysfunction in the past, including apomorphine, trazodone, yohimbine, and phentolamine. The data on all of them are limited and none has stood the test of time. They have been supplanted by the PDE5 inhibitors and probably have little role in the management of erectile dysfunction in diabetes.

Intracavernosal injection therapy

The technique of intracavernosal self-injection using phentolamine was first described in 1983 by Brindley [86], although the French urologist Virag [87] reported the use of papaverine slightly earlier. Although papaverine was more effective than phentolamine, it was an unlicensed treatment and was superseded by alprostadil (prostaglandin E), which was licensed for the treatment of ED in 1996.

Alprostadil is supplied in a self-injection pen device, which is easy to use, and supplied with excellent instructions (Figure 49.4). In spite of this, most studies show that self-injection therapy has a disappointingly high long-term discontinuation rate [88–90]. Self-injection treatment carries a small risk of priapism (a sustained unwanted erection). Although an infrequent complication, priapism is important, as it must be treated within 6 h by aspirating blood from the corpus cavernosum. Men undertaking self-injection must be warned of this potential problem and given instructions on what to do should it occur (Box 49.6).

Box 49.6 Instructions to medical staff for treating prolonged erections due to prostaglandin E_1.

Do not delay treatment beyond 6 h

Using an aseptic technique, aspirate 20–25 mL of blood from the corpus cavernosum (19- or 21-gauge butterfly needle)

Repeat the above on the opposite side of the penis if detumescence does not occur

If still unsuccessful, inject 0.5–1.0 mL of a 300 mg/mL solution of phenylephrine every 5–10 min (maximum dosage 5 mL) into the corpus cavernosum. If necessary, this may be followed by further aspiration of blood through the same needle. Extreme caution is necessary in men taking monoamine oxidase inhibitors, as a hypertensive crisis may result. Use carefully in those with coronary heart disease, uncontrolled hypertension, or cerebral ischemia. Monitor pulse rate and blood pressure throughout

If the above are unsuccessful, refer for urgent surgical treatment, such as a shunt procedure

Transurethral alprostadil (MUSE)

Many men find injection therapy unacceptable because it requires injecting the penis, and transurethral administration of the vasoactive agent appears largely to overcome this problem. The principle is simple: a slender applicator is inserted into the urethra to deposit a pellet containing alprostadil in polyethylene glycol. This gradually dissolves, allowing the prostaglandin to diffuse into the corpus cavernosum. In a placebo-controlled study of 1511 men with erectile dysfunction of mixed etiology, 65% were able to have intercourse using this system [91]. The results in the 240 men with diabetes in the study were similar [92]. Penile pain was reported in 10.8% and hypotension in 3.3% of the men receiving alprostadil. Priapism and penile fibrosis were not reported. As with most non-oral erectile dysfunction treatments, the long-term usage has been disappointing [93].

Topical alprostadil cream

Alprostadil is also available as a cream (Vitaros), which is applied around the urethral meatus. It contains dodecyl 2-*N*,*N*-dimethylaminopropionate, a novel penetration enhancer to allow the prostaglandin reach the erectile tissue. Published data are limited but it seems to be well tolerated and as effective as transurethral alprostadil [94].

Vacuum therapy

Vacuum devices became widely available in the 1970s. They consist of a translucent tube, which is placed over the penis, and an attached vacuum pump (Figure 49.5). The air is pumped out of

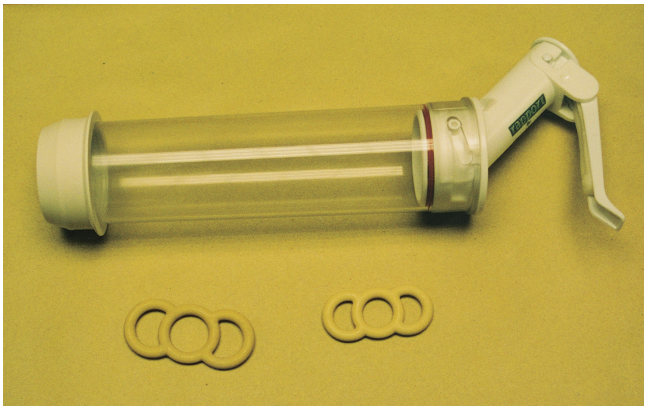

Figure 49.5 Typical vacuum device with constriction rings.

the tube, and the negative pressure draws blood into the erectile tissue, producing tumescence. A constriction band (which has previously been placed over the base of the tube) is then slipped off to remain firmly around the base of the penis so as to maintain the erection, and the tube is removed. The devices require some practice and dexterity, but most couples are able to use them satisfactorily. Trials of vacuum therapy have reported success rates of ~70% in men both with and without diabetes, suggesting that it is an effective treatment, provided that couples are prepared to use them [95–98].

Vacuum devices are safe and effective treatments, and inexpensive to use after an initial outlay (in the UK) of ~£100–250. The side effects are discomfort from the constriction band, failure to ejaculate, and a cold penis (reported by the female partner). Many couples find the use of vacuum devices unacceptable, and since the introduction of newer treatments their use has declined. They still have a role, however, in men who do not respond or who cannot use other treatments. Vacuum devices have the advantage over other erectile dysfunction treatments that they do not need repeat prescriptions and visits to a pharmacist for continued use.

Surgery

In spite of recent advances in the management of erectile dysfunction, some men will not be able to use the available treatment options. There will therefore always be a limited role for surgery.

The surgical options available are as follows:

1 The insertion of penile prostheses.

2 Corrective surgery for associated Peyronie disease or post-injection corporal fibrosis.

3 Venous and arterial surgery.

Discussion of vascular and corrective surgery of the penis is best left to a specialist urology textbook, but a general practitioner or diabetes physician needs to know which men might benefit from referral for insertion of a penile prosthesis. This form of surgery is best reserved for those in whom conventional treatments have failed and who are keen to resume full sexual activity.

Counseling of the man, and whenever possible his partner, is extremely important, particularly about the choice of prosthesis. The man's or couple's wishes are very important factors in device selection, as is the cost of the prosthesis.

The men must be warned regarding postoperative pain or discomfort and the potential for the need for reoperation. The men will need to restrict physical activity and refrain from intercourse for 4–6 weeks after the operation. They should be warned about the possible complications of infection, erosion, and prosthesis failure, and that these problems usually require device removal. It is also very important that the man and his partner are aware that the erection produced by a prosthesis is different from a normal erection, depending very much on the type of prosthesis chosen. It is useful to show examples of the prostheses and to describe how they are inserted and the mechanism of action.

There is uncertainty as to whether men with diabetes are at higher risk of infection than those without diabetes after insertion of a penile prosthesis, but there is a consensus that, should infection occur, it is more serious [99]. Good preoperative control of diabetes is important to minimize the risk. Most published series of well-selected groups of men who have undergone penile prosthesis insertion have reported acceptable results, with good levels of patient satisfaction [100].

Organization of the management of erectile dysfunction

Traditionally, erectile dysfunction has been managed in a dedicated clinic, often run by a urologist. The advent of effective oral therapies has made the management much simpler, so that erectile dysfunction in diabetes can usually be managed by any diabetologist or general practitioner. A physician considering treating erectile dysfunction will have to decide whether to run a separate clinic or to see the men in a routine diabetes clinic. Such a decision will depend on local resources and circumstances, but it is certainly possible to manage erectile dysfunction in a diabetes clinic. If this is to be done, it is advisable to have patient information literature on erectile dysfunction available. A great deal of useful patient information is produced by pharmaceutical companies and national diabetes organizations such as Diabetes UK both in printed form and online. It is often wise to let the man read this and to consider the matter, with treatment being started at a subsequent visit.

Managing erectile dysfunction in primary care

There are considerable advantages in the treatment of erectile dysfunction in primary care. A general practitioner is more likely to know and understand a man's particular circumstances. The men may be less intimidated in seeking help from their family practitioner than from a hospital specialist or sexual therapist. Little specialized equipment is required, and so there is no reason why interested general practitioners should not effectively treat the majority of men presenting with erectile dysfunction.

As with many disorders encountered in primary care, the general practitioner may choose to manage the problem in a standard consultation with the man. Others may choose to refer their patients to a fellow partner or colleague with a particular interest in erectile dysfunction or to their practice nurse, who may

have received appropriate training in the assessment of men with erectile dysfunction.

When a man presents with erectile dysfunction, there is an opportunity to consider other health issues and screen for underlying causes. Erectile dysfunction is often associated with conditions that benefit from early detection such as diabetes, hypertension, and hyperlipidemia. It is therefore important to consider general health issues and to address lifestyle factors.

The specialist erectile dysfunction service

Although most men with erectile dysfunction will be managed in primary care, there is still a role for a specialist service. It is likely that these clinics will mainly treat men who have failed to respond to oral therapies and that they will maintain expertise in the use of other treatments, such as intracavernosal injection therapy and vacuum devices, referring the men when necessary to urological surgeons for penile prosthesis insertion. Many specialist clinics are run very effectively by specialist nurses.

Conclusions on male sexual dysfunction

NO-mediated relaxation of the smooth muscle of the corpus cavernosum is the key phenomenon leading to penile erection. In diabetes, there is impairment of NO production by autonomic nerve terminals (due to autonomic neuropathy) and by endothelial cells (due to endothelial cell dysfunction). Sildenafil and other PDE5 inhibitors work by inhibiting the breakdown of cGMP, the second messenger in the NO pathway, and hence enhance erections under conditions of sexual stimulation. These agents are safe and effective treatments and can be used to treat erectile dysfunction in a diabetes clinic or in general practice.

Female sexual dysfunction

It is the universal experience of diabetes professionals that women with diabetes rarely complain of sexual problems There may be good reasons for this. In physiological terms, the female equivalent of male erectile dysfunction is reduced vasocongestion of the vulva and vagina, leading to impaired arousal and reduced vaginal lubrication. Failure to achieve an erection makes sexual intercourse impossible, but reduced vaginal lubrication is easily overcome with simple treatments such as lubricating creams and may not even be considered to be abnormal by a postmenopausal woman. Although sexual problems may not often be volunteered by women with diabetes, there is good evidence that they are more common in diabetes. Studying and managing female sexual problems is complicated by the changing and overlapping definitions of female sexual dysfunction. An in-depth review of this subject is beyond the scope of this book. For practicing diabetes professionals, the categories used by the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) provide a simple and workable classification for dealing with female sexual dysfunction [101, 102]. This has reduced the number of disorders to three:

1 *Female sexual interest/arousal disorder*. A lack of sexual interest or failure to become aroused.
2 *Female orgasmic disorder*. Difficulty achieving orgasm.
3 *Genito-pelvic pain/penetration disorder*. Dyspareunia or vaginismus.

All of the reviews of female sexual dysfunction in diabetes agree that there is great variation between published studies [103–105]. It is clear, however, that female sexual dysfunction is more common in both type 1 diabetes mellitus (T1DM) and T2DM than in women without diabetes. There is a general consensus that failure of arousal is significantly more common, occurring in 14–45% of women with diabetes [103, 106]. In contrast, studies have reported conflicting results on the prevalence of orgasmic disorder [107, 108] and genito-pelvic pain in diabetes [109, 110]. It would be reasonable to summarize the results of all the studies by saying that sexual dysfunction is more common in women with diabetes and is mainly characterized by failure of arousal but orgasmic problems and dyspareunia may also occur.

The studies of sexual function in women with diabetes have reported with much greater consistency that there is poor or no correlation between sexual dysfunction and risk factors associated with diabetes, including duration of diabetes, age, body mass index, complications of diabetes, glycemic control, and menopausal status [104, 105]. In contrast, female sexual dysfunction in diabetes is closely related to psychosocial factors. Enzlin et al. reported that in women with T1DM, sexual dysfunction was related to the presence of depression and the quality of the relationship [107]. In a follow-up study of the Diabetes Control and Complications Trial (DCCT) (type 1) cohort, multivariate analysis showed that only depression and marital status predicted female sexual dysfunction [111]. A study in women with T2DM reported the same findings, that only depression and marital status predicted sexual dysfunction [112].

Anecdotally, women with severe autonomic neuropathy can have an excellent sex life, unlike men, and so it is likely that there are differences between men and women in the way in which the autonomic nervous system controls genital responses [113]. Clearly, sexual dysfunction in women with diabetes, unlike men, cannot be viewed as mainly the end result of endothelial dysfunction and autonomic neuropathy and managed as such. It is a very different disease entity in which factors such as depression and relationship status have a central role.

Management of female sexual dysfunction

Many women attending a diabetes clinic will be over 50 years of age and some will have problems associated with the menopause, including vaginal dryness and dyspareunia. It can be difficult to distinguish the effects of the menopause from those of diabetes, but in practical terms the treatment is the same. Topical estrogen or simple lubricant gels are usually effective. Managing loss of libido in women with diabetes is more complex and beyond the scope of this book. It is much more likely to be due to psychosocial and relationship, rather than somatic, problems. Similarly, anorgasmia is complex and best left to a specialist, although it is worth

remembering that selective serotonin reuptake inhibitor antidepressants are a common cause.

The mechanism of action of PDE5 inhibitors suggests that they might improve arousal and vaginal lubrication. However, trials of PDE5 inhibitors for this purpose in women with and without diabetes have shown conflicting results. Measures of genital vasocongestion and clitoral blood flow have been reported to improve, but the impact on self-reported measures of sexual satisfaction has been disappointing [114, 115]. PDE5 inhibitors probably have little role in the management of sexual dysfunction in women with diabetes.

Genitourinary infections in women with diabetes

Vaginal candidiasis is a common finding in women with diabetes, particularly if the blood glucose control is poor, probably because yeasts thrive in a glucose-rich environment. Severe infection can be very irritating and painful and can interfere with sexual intercourse. Infections usually respond to conventional antifungal creams and pessaries; resistant cases usually respond to a single oral dose of fluconazole. To reduce the chances of reinfection, attempts should be made to improve diabetic control. The male partner may also need treatment for candidiasis for the same reason.

Other genital infections also occur in women with diabetes, but probably no more frequently than in the general population. These cases should be referred to the appropriate genitourinary service.

Conclusions on female sexual dysfunction

When asked, women with diabetes admit to an increased prevalence of sexual dysfunction, vaginal dryness, and impaired arousal in particular, but these are not common problems in the day-to-day management of diabetes. Psychosocial factors are much more important than any degree of female sexual dysfunction that occurs as a result of diabetes. Arousal problems and vaginal dryness can be treated in the usual way with simple lubricants or topical estrogens. Other associated problems, such as vaginal candidiasis, should also be addressed. If there are relationship problems, referral to a counselor should be considered.

Contraception

Contraception and family planning are especially important in women with diabetes. Poor glycemic control during the first trimester of pregnancy is associated with an increased risk of fetal morbidity and mortality [116–118]. It is therefore essential that women with diabetes are advised to plan their pregnancies and achieve strict control of their diabetes prior to conception (see Chapter 61).

Contraindications to pregnancy

As medical and obstetric care has improved, the list of contraindications to pregnancy in women with diabetes has shrunk (see Chapter 61). If pregnancy is contraindicated, sterilization should be considered.

Method of contraception

Few diabetes organizations make any recommendation on the preferred method of contraception to be used in individuals with diabetes. The American Diabetes Association's recent Standards of Medical Care in Diabetes recommend that effective contraception is particularly important in women with diabetes, but the options and recommendations are largely the same as those for women without diabetes [119]. This is true, of course, but certain factors, in particular impact on risk factors and carbohydrate tolerance should be taken into consideration before choosing any particular method.

Hormonal contraception

The oral contraceptive pill (OCP) remains one of the popular methods of contraception in women with diabetes in high-income countries [120]. It is easy to understand why: it is simple to use and, most importantly, very reliable. If properly used, it has the lowest failure rate for any contraceptive method, apart from sterilization [121]. There have always been concerns, however, about the safety of hormonal contraception in women with diabetes.

Hormonal contraception, carbohydrate tolerance, micro- and macrovascular risk

There is no evidence that hormonal contraceptive affect carbohydrate tolerance or metabolic control in women with diabetes. A Cochrane review of studies examining the impact of steroidal contraception in women without diabetes reported there was minimal impact on carbohydrate metabolism and no major differences between different types of hormonal contraceptives [122]. In women with T1DM and T2DM, a more recent Cochrane review reported that there was no evidence that either combined or progestin-only contraceptives had a significantly different effect than non-hormonal contraception on metabolic control, lipid metabolism, or complications [123]. A small impact of hormonal contraception on metabolic control cannot be ruled out, but in practical terms we should not let any slight risk deter us from using it in women with diabetes.

We cannot yet be completely reassured, however, about the cardiovascular safety of hormonal contraception. Most reported studies were flawed or small. A large definitive study examining the effects on cardiovascular morbidity and mortality in women with diabetes is needed. When considering prescribing hormonal contraception to a woman with diabetes, the same factors should be considered as in a woman without diabetes. Smoking, hypertension, age, and vascular disease should be taken into account and the risks weighed for the individual woman. The World Health Organization's published criteria for contraceptive use provide useful practical advice on the choice of contraception in women with diabetes [124].

In practical terms, once the risks have been assessed, any combined or progestin-only contraceptive can be used in women with

T1DM or T2DM and patient preference should be taken into account. Any woman taking hormonal contraception should be reviewed regularly for assessment of blood pressure and serum lipids.

Combined hormonal contraceptive preparations carry an increased risk of venous thromboembolism. The risk is probably greatest (50–80% increase) with the "third-generation" progestins desogestrel and gestodene compared with preparations containing levonorgestrel [125]. The risk remains very small, however, and these are still safe preparations. There is as yet no evidence that progestin-only contraceptives are associated with an increased risk of thrombosis.

The intrauterine contraceptive device (IUD)

The IUD is a safe and effective form of contraception in women with diabetes. Early concerns about the risk of pelvic inflammatory disease in diabetes were largely unfounded; studies have suggested no increased risk of pelvic inflammatory disease in women with T1DM [126] or T2DM [127]. Similarly, early suggestions of an increased failure rate for IUDs in women with diabetes have not been borne out [126].

Barrier methods

Since the advent of acquired immune deficiency syndrome (AIDS), the condom has been widely advocated to reduce the risk of transmission of sexually transmitted diseases. It has a higher failure rate than OCPs and IUDs and for this reason is not recommended if pregnancy is contraindicated. For high-risk individuals, many genitourinary clinics recommend a combination of the OCP and condom to minimize the risk of pregnancy and sexually transmitted diseases—a technique known as "double-Dutch."

Emergency contraception

Three methods of emergency contraception are licensed in the UK and are available in many other countries: progestogen-only and combined estrogen–progesterone pills, and the copper IUD. The hormonal preparations can be taken up to 72 h after unprotected intercourse, but are most effective if taken within 24 h [128]. Nausea was reported in 23% and vomiting in ~6% of the women who used the progesterone-only regimen. Women with T1DM should be warned of these potential side effects. Little work on the use of these agents in women with diabetes has been published, but they may have a role in the prevention of unplanned pregnancies occurring at a time of poor metabolic control.

Summary

All women with diabetes of reproductive age should receive good contraceptive advice, as unplanned pregnancies occurring while glycemic control is poor carry an increased risk of morbidity and fetal abnormalities. Most forms of contraception are safe and effective in women with diabetes. The oral contraceptive pill has an important role, as it is very reliable and well tolerated.

Hormone replacement therapy

Few areas of medicine have gone through as many changes in perception in modern times as hormone replacement therapy (HRT). It was used as a treatment for osteoporosis and menopausal symptoms but had become regarded as a potential treatment to reduce cardiovascular risk, largely based on observational studies. In 2001, a survey of general practitioners and hospital doctors in the UK suggested that the majority would advise HRT for women with diabetes as prophylaxis for cardiovascular disease [129]. Attitudes changed almost overnight, however, following the publication of the Women's Health Initiative trial in 2002 [130]. This was a large, randomized study of combined estrogen and progesterone HRT that was stopped early because of increased adverse outcomes including cardiovascular disease, stroke, thromboembolism, and breast cancer. Further evidence has accumulated and now HRT is viewed largely as a short-term treatment for menopausal symptoms that does not increase cardiovascular risk but is not without risk. Many women with diabetes are postmenopausal, and so diabetes professionals need to be aware of the potential risks and benefits.

HRT and glucose tolerance

There is evidence that HRT does not worsen glucose tolerance in women with or without diabetes and may produce a slight amelioration. In women without diabetes, estradiol and low-dose conjugated estrogens are associated with an improvement and no effect on insulin sensitivity, whereas higher doses of conjugated estrogens and alkylated estrogens may cause deterioration of glucose tolerance [131–133].

In postmenopausal women with diabetes, estradiol has been reported to improve the fasting blood glucose concentration and glycated hemoglobin [134]. A larger observational study of over 15,000 women with T2DM also reported that HRT was associated with an improvement in HbA_{1c} [135]. Any potential benefit to glucose tolerance is limited to oral HRT preparations; transdermal estradiol does not appear to have any effect on glucose tolerance [136].

HRT and lipids

Like glucose tolerance, the effect of HRT on lipid profiles appears to be at worst neutral and it may be slightly beneficial. In women without diabetes, estrogens reduce total and low-density lipoprotein (LDL) cholesterol and increase high-density lipoprotein (HDL) cholesterol and triglyceride levels [137, 138]. Transdermal estrogen preparations have a beneficial effect on plasma lipids, reducing LDL cholesterol and triglycerides and increasing HDL cholesterol [139].

The effect of HRT on lipid profiles in women with diabetes has been reported in several studies. In a small, randomized crossover study of overweight women with T2DM, conjugated estrogen therapy reduced central obesity, HbA_{1c}, and total cholesterol,

and improved physical functioning [140]. In another small, randomized crossover study, conjugated estrogens reduced total and LDL cholesterol and increased HDL cholesterol in both women with and without diabetes. The addition of medroxyprogesterone acetate abolished the increase in HDL in both groups. There was no apparent effect on fasting glucose or insulin levels [141]. In the largest study, 61 postmenopausal women received combined HRT in a randomized crossover design. HRT reduced total and LDL cholesterol, but there was no change in serum HDL or triglyceride levels [142].

HRT and blood pressure

HRT can be prescribed to hypertensive postmenopausal women under careful supervision. One of the few studies of HRT and blood pressure in diabetes suggested that it can be prescribed without any adverse effect on ambulatory blood pressure measurements in hypertensive and normotensive women [143].

HRT and ischemic heart disease

Early case–control studies suggested that HRT reduces the risk of ischemic heart disease in postmenopausal women by 30–50% [144, 145]. Subsequent clinical trials, however, reported very different results, which shows the limitations of case–control studies [130, 137]. A reasonable summary of subsequent studies would be that there is certainly no evidence that HRT reduces cardiovascular risk but it probably does not increase it [146, 147]. It is, however, associated with an increase in thromboembolic disease. No large studies on the effect of HRT on the risk of ischemic heart disease in women with diabetes have been reported. Therefore, when managing a postmenopausal woman with diabetes, guidance for the general population should probably be followed. Recently published guidance from the National Institute for Health and Care Excellence (NICE) provide useful practical advice [148]. In brief, HRT should be considered as a short-term treatment for menopausal symptoms. Cardiovascular risk factors are not a contraindication provided that they are adequately managed. Transdermal preparations should be considered if there is a history of thromboembolic disease.

HRT and osteoporosis

There is evidence to suggest that women with T1DM have reduced bone mineral density at the time of diagnosis [149]. Although women with T2DM might be expected to be protected from osteoporosis because of their increased tendency to obesity, they would appear to be at increased risk of hip fracture (Chapter 53). A very large prospective cohort study of postmenopausal women in Iowa reported that women with diabetes had a 1.7-fold higher risk of hip fracture than women without diabetes [150]. Hence the benefits of HRT in reducing the risk of osteoporotic fractures would appear to be at least as great in women with diabetes as in those without diabetes, and HRT should be considered in all postmenopausal women with diabetes with osteoporosis.

Summary

HRT is can be used as a short-term treatment for the symptoms of the menopause. It has no adverse effects on glycemic control or lipid profiles and may improve both. It does not appear to increase cardiovascular risk. It should be considered in all women with diabetes with an appropriate indication.

50 Gastrointestinal Manifestations of Diabetes

Adil E. Bharucha and Michael Camilleri

Clinical Enteric Neuroscience Translational and Epidemiological Research (CENTER), Division of Gastroenterology and Hepatology, Mayo Clinic, Rochester, MN, USA

Key points

- Diabetic enteropathy refers to all the gastrointestinal (GI) complications of diabetes, which can affect the entire gastrointestinal tract.
- GI symptoms in diabetes include dysphagia, dyspepsia, gastroparesis, abdominal pain, constipation, diarrhea, and fecal incontinence. Some GI disturbances (e.g. delayed gastric emptying) are often asymptomatic.
- Although these GI symptoms are not uncommon among persons with diabetes in clinical practice, the prevalence of GI manifestations among such people in the community is not substantially higher than in the general population.
- These GI manifestations can reduce quality of life and nutrition and also impair glycemic control.
- These symptoms are attributed to GI sensorimotor dysfunctions resulting primarily from extrinsic and intrinsic nerve (i.e. enteric) dysfunction.
- The investigations are tailored to the presenting symptoms, and require tests to exclude an organic disorder (e.g. gastric outlet obstruction in gastroparesis), to confirm GI sensorimotor dysfunctions (e.g. delayed gastric emptying), and to identify complications (e.g. small intestinal bacterial overgrowth).
- The management of GI symptoms in diabetes relies primarily upon improving control of glycemia and symptomatic measures, in addition to attention to the individual's state of hydration and nutrition.

Introduction

Although most attention has traditionally been focused on the stomach, diabetes can affect the entire gastrointestinal (GI) tract. The term *diabetic enteropathy* refers to all the GI complications of diabetes. GI involvement may be asymptomatic or manifest as symptoms, i.e. dysphagia, heartburn, nausea and vomiting, abdominal pain, constipation, diarrhea, and fecal incontinence. These manifestations may affect quality of life, impair nutrition, and affect glycemic control.

Epidemiology

Studies in selected groups, often from tertiary referral centers, suggest that GI symptoms are common in diabetes [1, 2]. However, these studies are prone to selection and other biases, which are avoided by studies conducted among people with diabetes in the community, where the prevalence of GI symptoms is either not different from or only slightly higher than for people without diabetes. Thus, in the Rochester Diabetic Neuropathy Study, only 1% of people with diabetes had symptoms of gastroparesis and only 0.6% had nocturnal diarrhea [3]. In another study from Olmsted County, Minnesota, the prevalence of GI symptoms (i.e. nausea and/or vomiting, dyspepsia, heartburn, irritable bowel syndrome, constipation, and fecal incontinence) was not significantly different between individuals with either type 1 (T1DM) or type 2 diabetes mellitus (T2DM) and age-matched people without diabetes [4]. However, people with T2DM and men with T1DM used laxatives more frequently than people without diabetes. Moreover, that study and a Finnish population-based study reported that people with T1DM had a lower prevalence of heartburn [5]. In contrast to these studies, a study in Australia found that the prevalence of several upper and lower GI symptoms was higher in 423 people with predominantly (95%) T2DM than in people without diabetes [6].

Compared with those studies, which were anchored by symptoms alone (i.e. not diagnostic tests), the cumulative 10-year incidence of gastroparesis has been estimated at 5.2% in T1DM and 1% in T2DM in a community sample of people with diabetes [7]. In that study, gastroparesis was documented by physician diagnosis based on delayed gastric emptying with scintigraphy, or by symptoms and retained food at endoscopy. However, because gastroparesis was identified only in people who presented for care, people who had an asymptomatic delay in gastric emptying may not have been identified. Hence the estimated incidence and prevalence of gastroparesis are critically dependent on definition [8].

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

Studies of the natural history of gastroparesis have been limited by relatively small numbers of participants, potential referral bias, or short follow-up periods. One study suggested that delayed gastric emptying and symptoms are both relatively stable over 12 or 25 years [9]. In a clinic-based study, diabetic gastroparesis was associated with severe symptoms, nutritional compromise, impaired glucose control, and a poor quality of life, independently of other factors such as age, tobacco use, alcohol use, or type of diabetes [10]. Two studies have investigated the association between diabetic gastroparesis and mortality or morbidity. The first, among 86 people with diabetes, of whom 56% had delayed emptying of solids and 28% had delayed emptying of liquids, ~25% had died by follow-up at least 9 years later. Gastroparesis was not associated with mortality after adjustment for other disorders [11]. However, this study did not ascertain the relationship between diabetic gastroparesis and other medical conditions. In another study that compared three parallel cohorts of people with diabetes (i.e. 94 with symptoms and delayed gastric emptying, 94 with classic symptoms of delayed gastric emptying but normal scintigraphy, and 94 with no symptoms of gastroparesis), diabetic gastroparesis was associated with cardiovascular disease, hypertension, retinopathy, and increased hospitalization [12]. Compared with those with GI symptoms alone, people with diabetic gastroparesis also had more hospital days; mortality was also greater, but differences were not statistically significant. In the National Institute of Diabetes, Digestive and Kidney Diseases Gastroparesis Clinical Research Consortium, the incident death rate was significantly higher in persons with diabetes compared with idiopathic cases (0.0266 vs. 0.0094), and in those with delayed compared with normal gastric emptying (0.0189 vs. 0.0031) [13].

Taken together, these data suggest that GI manifestations are not uncommon among persons with diabetes presenting for care. However, in the general population, the prevalence of GI manifestations is not substantially higher among people with diabetes, perhaps partly because the prevalence of GI symptoms, mostly attributable to functional GI disorders (e.g. irritable bowel syndrome), among people without diabetes in the community is relatively high, and approaches 20%. Among people with GI symptoms, the gastric emptying assessment can identify those with a worse prognosis. Whether this increased morbidity is driven by gastroparesis is unknown. Data on long-term natural history in the community are lacking.

Pathophysiology

Gastrointestinal dysmotility in diabetes is caused by extrinsic (i.e. sympathetic and parasympathetic) neural dysfunction, hyperglycemia, and hormonal disturbances. More recently, a role for intrinsic (i.e. enteric) neuronal dysfunctions, resulting from loss of excitatory and inhibitory neurons and interstitial cells of Cajal, has also been implicated [14]. Neural dysfunctions have been attributed to several mechanisms (e.g. oxidative stress) described below and detailed elsewhere [15].

Normal gastrointestinal motor functions

GI motor function is primarily controlled by the intrinsic or enteric nervous system (i.e. the "little brain" in the digestive tract) and modulated by the extrinsic (i.e. parasympathetic and sympathetic) nervous system (Figure 50.1) [16]. While intrinsic and extrinsic controls are independent, the prevertebral ganglia integrate afferent impulses between the gut and the central nervous system and provide additional reflex control of the abdominal viscera. The parasympathetic arm is excitatory to

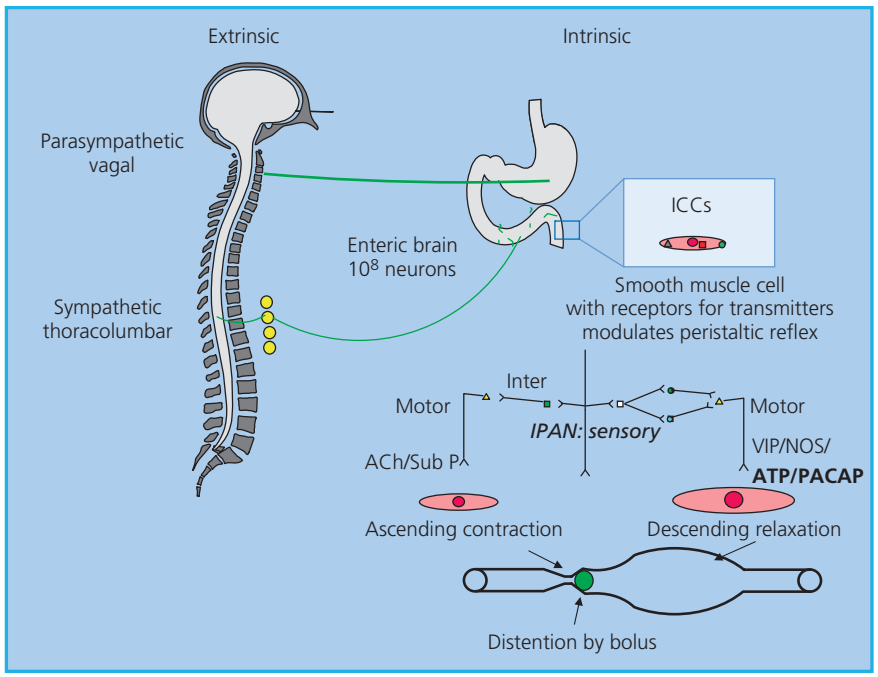

Figure 50.1 Control of gastrointestinal motility. Note that the extrinsic or autonomic nervous system modulates the function of the enteric nervous system, which controls smooth muscle cells through excitatory (i.e. acetylcholine [Ach], substance P [SubP]) or inhibitory (nitric oxide [NO], vasoactive intestinal peptide [VIP], pituitary adenylate cyclase activating peptide [PACAP]) neurotransmitters. ICC, interstitial cells of Cajal; IPAN, intrinsic primary afferent neurons. Source: Adapted from Camilleri M, Phillips SF. Disorders of small intestinal motility. *Gastroenterol Clin North Am* 1989; **18**:405–424.

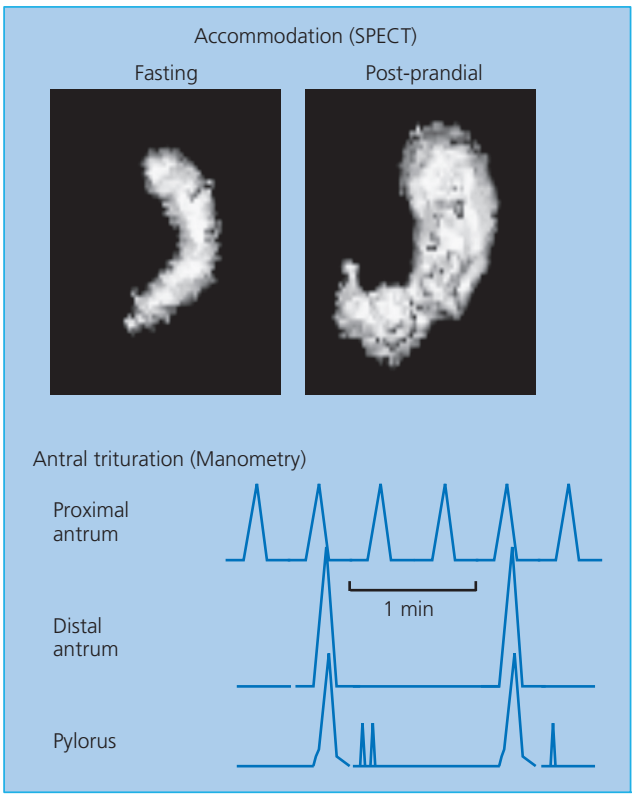

Figure 50.2 Assessment of gastric motor functions. Gastric accommodation can be assessed by measuring the postprandial change in gastric volume using single photoemission computed tomography (SPECT) (top). The stomach wall is labeled with intravenous [^{99m}Tc]pertechnetate. Food is subsequently transferred to the antrum. Manometry (bottom) demonstrates that the distal antrum and pylorus contract synchronously to grind food into smaller particles. Only particles 2 mm or smaller can be emptied through the pylorus.

non-sphincteric muscle and inhibits sphincters. The sympathetic component has opposite effects. The enteric nervous system consists of 100 million neurons that are organized in distinct ganglionated plexi, including the submucous plexus, which is primarily involved in absorption and secretion, and the myenteric plexus, which regulates motility. The interstitial cells of Cajal serve as pacemakers and also convey messages from nerve to smooth muscle. As with the somatic and autonomic nerves elsewhere, the gut's autonomic and enteric nervous system can be affected in diabetes. Derangements of the extrinsic nerves at any level may alter GI motility and secretion [17].

GI digestion and absorption require GI motility, gastric and pancreatic secretion, and GI hormonal release, which in turn modulate motor, secretory, and absorptive functions in the upper gut [18]. Traditionally, these processes are considered in three phases, i.e. cephalic, gastric, and intestinal, which are integrated and overlap. Normally, liquids, particularly non-caloric liquids, empty rapidly from the stomach in a linear fashion. In contrast, gastric emptying of solids follows an exponential pattern. During the first 45-min postprandial period (i.e. the lag phase), the gastric antrum grinds solids into particles smaller than 2 mm in size, so they can be emptied through the pylorus. During the lag phase, the stomach relaxes or accommodates, providing room for digestion to occur (Figures 50.2 and 50.3). Thereafter, solids are emptied in a linear fashion, with ~50% emptying in 2 h and 100% emptying in 4 h.

Pancreatobiliary secretions and mechanical processes ensure small intestinal digestion, which precedes absorption. The small intestine transports solids and liquids at approximately the same rate; the head of the column of liquid chyme may reach the cecum as early as 30 min after ingestion. As a result of the lag phase for the transport of solids from the stomach, liquids typically arrive in the colon before solids. However, it takes about 150 min for half the solid and liquid chyme of similar caloric density (assuming solids are presented in a triturated form to the small bowel) to traverse the small bowel. Complex carbohydrates or fat in the distal small intestine exert feedback control of proximal small intestinal motility (i.e. the small intestinal brake). Chyme is transferred from the ileum to colon in intermittent boluses. On average, it takes 36 h, with an upper limit of 65 h, to transfer contents from the cecum to the rectum. Compared with the stomach and small intestine, colonic transit is relatively prolonged, permitting digestion (i.e. fiber) and absorption (i.e. of water and electrolytes) to be completed.

Pathophysiology of diabetic enteropathy: insights from animal studies

In animal models, extrinsic neural dysfunction has been primarily ascribed to a loss of myelinated and unmyelinated fibers without much neuronal loss [19, 20]. The loss of nerve fibers is often multifocal, suggestive of ischemic injury. Within the enteric nervous system, reduced neuronal staining and, to a lesser extent, neuronal loss, particularly inhibitory neurons expressing nitric oxide synthase (NOS), have been described in several animal models of diabetes [15]. In theory, this reduction in nitrergic inhibitory functions may contribute to impaired gastric accommodation and accelerated intestinal transit in diabetes. Reduced sympathetic inhibition may also contribute to accelerated intestinal transit. Since nitric oxide (NO) is a mediator of pyloric relaxation, loss of NOS may impair pyloric relaxation, and thereby retard gastric emptying. Loss of interstitial cells of Cajal, documented in several animal models and case reports of diabetes, may also contribute to gut dysmotility [14, 21]. In addition, loss of interstitial cells of Cajal and increase in CD45 and CD68 immunoreactivity are the most common enteric neuropathological abnormalities in diabetic and idiopathic gastroparesis [22, 23].

Several mechanisms, including apoptosis, oxidative stress, advanced glycation end products, and neuroimmune mechanisms, may be responsible for neuronal loss and gut dysmotility [15]. The loss of interstitial cells of Cajal has been attributed to a reduction in heme–oxygenase (HO-1) and other protective mechanisms against hyperglycemia [14]. The effects of diabetes on neuronal morphology and functions are reversible. Insulin or pancreas transplantation improved glycemic control and the axonopathy affecting autonomic nerves in rats with diabetic

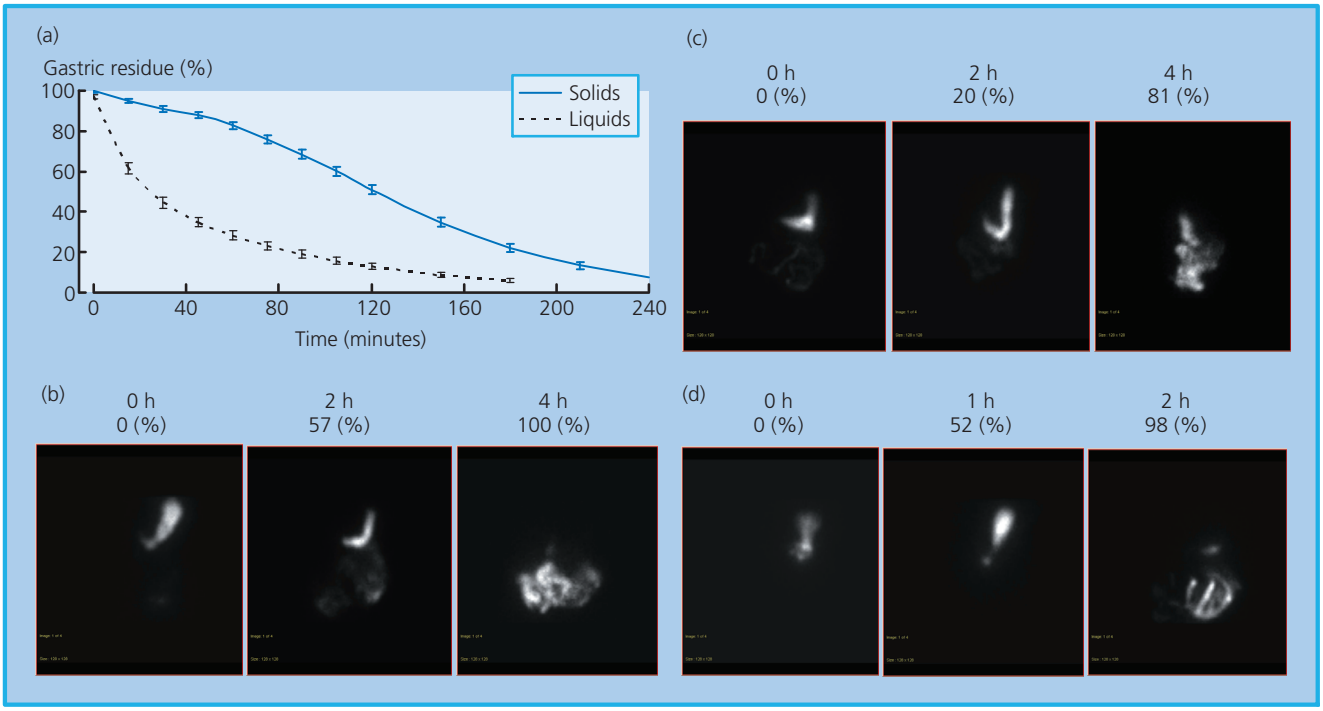

Figure 50.3 Assessment of gastric emptying by scintigraphy. Normally liquids are emptied in a linear manner whereas solid emptying has an exponential profile, characterized by an initial lag phase, followed by a more rapid, linear emptying (a). The lag phase corresponds to the time required for antral trituration and gastric accommodation, during which ~10% of solids are emptied (b), (c), (d). Representative examples of normal, delayed, and accelerated gastric emptying, respectively, of an egg meal, labeled with ^{99m}Tc, in people with diabetes. At time 0 (i.e. first image in each panel), the entire meal was in the stomach. Thereafter, the normal ranges for gastric emptying are 11–39% at 1 h, 40–76% at 2 h, and 84–98% at 4 h.

autonomic neuropathy [24]. Insulin also restored expression of NOS and gastric emptying in animal models of diabetes whereas insulin and insulin-like growth factors prevented the loss of interstitial cells of Cajal in cultures [25, 26]. Since interstitial cells of Cajal do not express receptors for either hormone, these effects are perhaps mediated by smooth muscle secretion of stem cell factor, which is the most important growth factor for interstitial cells of Cajal, rather than directly by insulin and insulin-like growth factors [14]. Overexpression of glial cell line-derived neurotrophic factor, a trophic factor for enteric neurons, in transgenic mice reversed hyperglycemia-induced apoptosis of enteric neurons and improved gastric emptying and intestinal transit [27].

Pathophysiology of diabetic enteropathy in humans

Gastric dysfunctions

Neuropathy

Diabetes is associated with accelerated or delayed gastric emptying, increased and reduced gastric sensation, and impaired gastric accommodation (Figure 50.4). A vagal neuropathy can cause antral hypomotility and/or pylorospasm, which may delay gastric emptying [28]. The pathophysiology of rapid gastric emptying in diabetes is less well understood. Conceivably, impaired gastric accommodation resulting from a vagal neuropathy [29] may increase gastric pressure and thereby accelerate gastric emptying of liquids. However, the relationship between rapid gastric emptying and impaired gastric accommodation has not been substantiated. The relationship between vagal neuropathy and impaired postprandial accommodation is unclear, since accommodation may be preserved even in persons with diabetes with vagal neuropathy [30], perhaps reflecting non-vagal adaptive mechanisms involving enteric neurons [31]. Some persons with diabetes and gastroparesis also have small intestinal dysmotility, more frequently characterized by reduced than by increased motility [32]. Small bowel dysmotility may also contribute to gastric stasis.

Hyperglycemia

Acute hyperglycemia delays gastric emptying in healthy individuals and in people with T1DM [33–36]. These effects may be explained by hyperglycemia-induced suppression of antral motility and migrating motor activity (i.e. the intestinal "housekeeper") [37–39]. However, the effects of acute hyperglycemia on gastric emptying are modest. Indeed, even in T1DM, severe acute hyperglycemia (i.e. 16–20 versus 4–8 mmol/L) prolonged the gastric emptying half-time by only 17 min (i.e. from 124 to 141 min). Acute modulation of blood glucose within the physiological postprandial range (4–8 mmol/L) can also delay gastric emptying, to a lesser extent [36]. Cross-sectional studies suggest that higher glycated hemoglobin concentrations are associated with a higher prevalence of GI symptoms and slower gastric emptying among

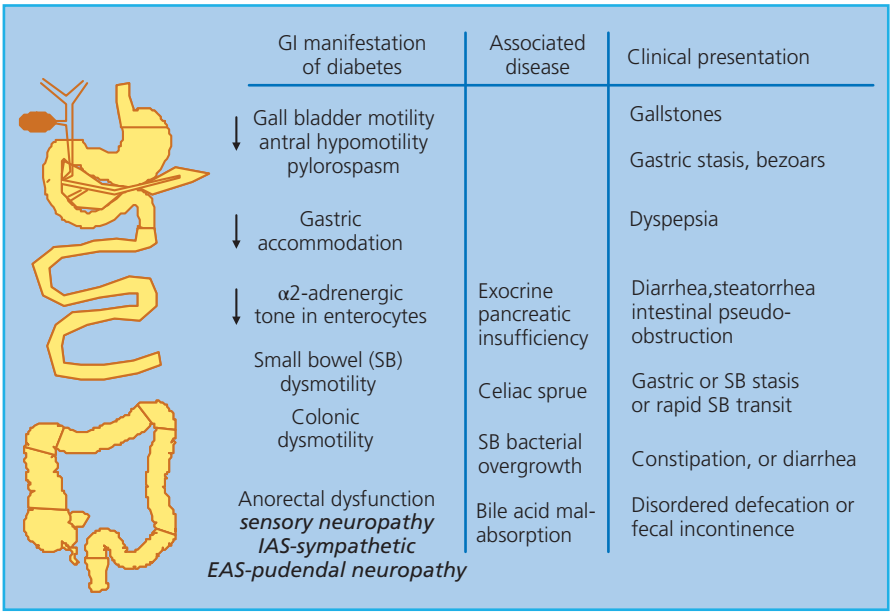

Figure 50.4 Pathophysiology of diabetes enteropathy in humans. IAS, internal anal sphincter; EAS, external anal sphincter. Source: Adapted from Camilleri M. Gastrointestinal problems in diabetes. *Endocrinol Metab Clin North Am* 1996; **25**:361–378.

people with diabetes in the community [6, 40]. Although strict glycemic control improves neural, renal, and retinal functions in diabetes, the impact on gastric emptying is unclear [41]. Indeed, in the only study that addressed this question, improved glycemic control did not improve gastric emptying 1 week later in 10 people with T2DM [42]. In addition to hyperglycemia, electrolyte imbalances due to diabetic ketoacidosis (e.g. hypokalemia) and uremia may also aggravate impaired motor function in persons with diabetes. Iatrogenic gastroparesis may result from treatment with amylin analogs such as pramlintide [43] or GLP-1 receptor agonists (such as liraglutide and exenatide). The latter has been documented in the literature in the gastric emptying of liquids [44, 45], with preliminary data proving clinically relevant delays in the gastric emptying of solids [46].

Diabetic diarrhea

It is useful to categorize the pathophysiology of diabetic diarrhea into conditions that are or are not associated with malabsorption (Figure 50.5). Involvement of sympathetic fibers, which normally inhibit motility and facilitate absorption via α_2-adrenergic

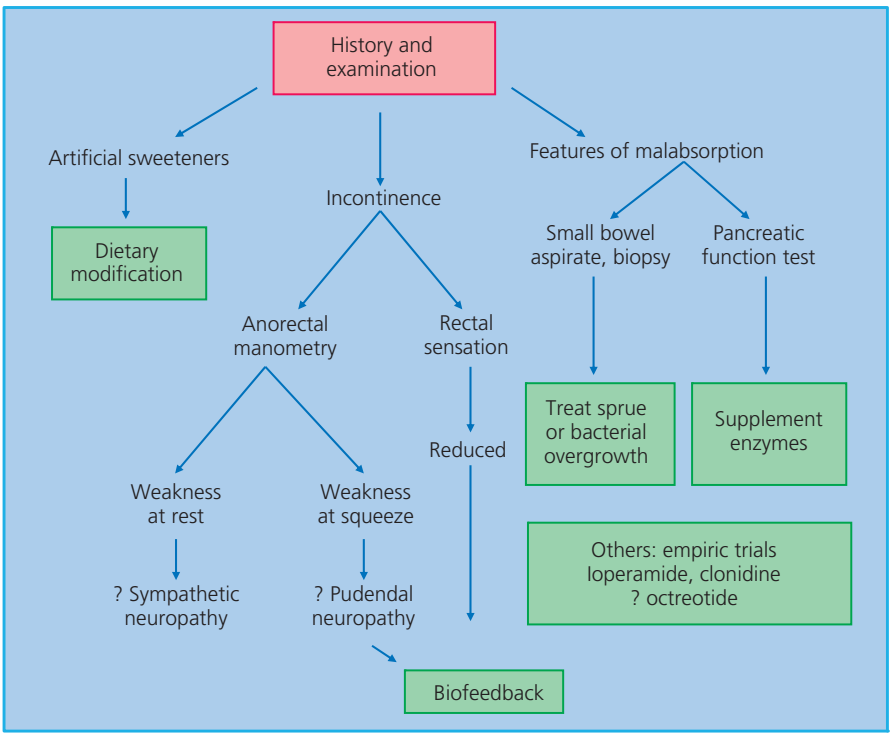

Figure 50.5 Management of diarrhea in diabetes mellitus. Source: Adapted from Camilleri M. Gastrointestinal problems in diabetes. *Endocrinol Metab Clin North Am* 1996; **25**:361–378.

receptors, can result in accelerated small intestinal transit and cause diarrhea [47]. Artificial sweeteners such as sorbitol may also contribute to diarrhea. People with rapid ileal transit may have bile acid malabsorption [48, 49] and deconjugated bile acids induce colonic secretion.

Features suggestive of malabsorption such as anemia, macrocytosis, or steatorrhea should prompt consideration of bacterial overgrowth, small bowel mucosal disease, or pancreatic insufficiency. Small intestinal dysmotility predisposes to bacterial overgrowth, which can cause bile salt deconjugation, fat malabsorption, and diarrhea. Although T1DM is associated with celiac disease, most people with celiac disease and T1DM in the community are asymptomatic [50]. Chronic pancreatic insufficiency may result from pancreatic atrophy, disruption of cholinergic enteropancreatic reflexes, or elevated serum hormonal levels of glucagon, somatostatin, and pancreatic polypeptide, which reduce pancreatic enzyme secretion [51]. However, the association between chronic pancreatic insufficiency and diabetes is uncommon. Moreover, because there is sufficient pancreatic reserve, only 10% of pancreatic function is sufficient for normal digestion.

Fecal incontinence

Loose stools and anorectal dysfunctions contribute to fecal incontinence in diabetic diarrhea. Compared with continent persons with diabetes and people without diabetes, people with diabetes and fecal incontinence have a higher threshold for rectal perception of balloon distention (i.e. reduced sensation) [52, 53]. A sympathetic neuropathy may impair internal anal sphincter functional and anal resting pressures and a pudendal neuropathy may result in reduced anal squeeze pressure.

Constipation

The mechanisms of constipation in diabetes have not been carefully studied and are poorly understood. Clinical observations suggest that, similarly to idiopathic chronic constipation, both colonic dysmotility and anorectal dysfunctions (i.e. impaired anal sphincteric relaxation during defecation) may contribute to constipation in diabetes [54]. Persons with colonic dysmotility have an impaired colonic contractile response to a meal and delayed colonic transit [55]. People with reduced rectal sensation may not perceive the desire to defecate. Compared with euglycemia, acute hyperglycemia inhibited the colonic contractile response to gastric distention and proximal colonic contraction elicited by colonic distention in healthy people without diabetes [56]. However, acute hyperglycemia did not significantly affect fasting or postprandial colonic tone, motility, compliance, and sensation, or rectal compliance and sensation in healthy people [57].

In addition to these factors, it is also important to consider the role of psychological factors in the perception of GI symptoms. Indeed, psychosomatic symptoms are significantly associated with the reporting of GI tract symptoms [4]. Several medications have GI side effects, e.g. metformin can cause diarrhea, and among other medications, verapamil and anticholinergic agents can cause constipation.

Clinical manifestations

Dysphagia and heartburn

Esophageal dysmotility, typically characterized by impaired peristalsis with simultaneous contractions, is common, may cause dysphagia, and may be related to cardiovascular autonomic neuropathy [58]. The amplitude of peristaltic contractions and basal lower esophageal sphincter pressures are generally normal. Symptoms of gastroesophageal reflux are also common, particularly in persons with impaired gastric emptying who have vomiting. Rarely, recurrent vomiting may lead to Mallory–Weiss tears and bleeding.

Dysphagia and heartburn should prompt upper GI endoscopy to exclude reflux and other incidental mucosal diseases (e.g. candidiasis, neoplasms). Although manometry may reveal esophageal peristaltic disturbances in persons with significant dysphagia that is not explained by a structural lesion, it is unlikely to alter management, except for rare people in whom another disorder (i.e. achalasia) is responsible for dysphagia. Because of the high prevalence of coronary atherosclerosis in diabetes, testing for coronary artery disease should be considered when necessary in those with chest pain.

Dyspepsia and gastroparesis

Although gastroparesis refers to a syndrome characterized by symptoms (i.e. nausea, vomiting, early satiation after meals, and impaired nutrition) and objective evidence of markedly delayed gastric emptying, gastric retention may be asymptomatic [59], perhaps because of the afferent dysfunction associated with vagal denervation [60]. Nausea and vomiting often occur in episodes lasting days to months or in cycles. Nausea and vomiting may be associated with impaired glycemic control and often cause hypoglycemia, perhaps because delivery of food into the small bowel for absorption is not sufficient to match the effects of exogenous insulin.

Consistent with the concept of a paralyzed stomach, the term gastroparesis should be restricted to people with markedly delayed gastric emptying. When the delay in gastric emptying is not severe, the term diabetic dyspepsia is perhaps more appropriate. Dyspepsia is characterized by one or more, generally postprandial, upper GI symptoms (i.e. bloating, postprandial fullness, and upper abdominal pain). Typically, vomiting is not severe, but significant weight loss secondary to reduced caloric intake is not unusual in people with dyspepsia. In addition to delayed gastric emptying, impaired gastric accommodation and abnormal (i.e. increased or decreased) gastric sensation may also contribute to symptoms in diabetes [61, 62]. Nonetheless, the distinction of dyspepsia from gastroparesis is challenging since there is no official distinction between moderately and severely delayed gastric emptying. Clinical experience suggests that gastric emptying of <65% at 4 h reflects a significant delay, as it is often associated with nutritional consequences, the need for nutritional supplementation, jejunal feeding, or gastric decompression [63].

Table 50.1 Symptoms and signs of autonomic dysfunction.

Sympathetic	Parasympathetic
Failure of pupils to dilate in the dark	Fixed, dilated pupils
Fainting, orthostatic dizziness	Lack of pupillary accommodation
Constant heart rate with orthostatic hypotension	Sweating during mastication of certain foods
Absent piloerection	Decreased gut motility
Absent sweating	Dry eyes and mouth
Impaired ejaculation	Dry vagina
Paralysis of dartos muscle	Impaired erection
	Difficulty with emptying urinary bladder
	Recurrent urinary tract infections

Gastric retention may be asymptomatic in some people, possibly owing to afferent dysfunction in the setting of vagal denervation, and delayed gastric emptying may be associated with recurrent hypoglycemia in people without upper GI symptoms.

Persons with diabetic gastroparesis frequently have longstanding T1DM with complications (i.e. retinopathy, nephropathy, peripheral neuropathy, and other forms of autonomic dysfunction, including abnormal pupillary responses, anhidrosis, gustatory sweating, orthostatic hypotension, erectile dysfunction, retrograde ejaculation, and dysfunction of the urinary bladder) (Table 50.1). In contrast, it has been suggested that rapid gastric emptying of liquids is a relatively early manifestation of T2DM [64–68]. Clinicians have relied on these manifestations, and on certain symptoms (e.g. vomiting of undigested food eaten several hours previously and weight loss) and signs (e.g. a gastric succussion splash or features of an autonomic neuropathy) to predict delayed gastric emptying in people with diabetes who present with upper and GI symptoms. However, several studies have shown that symptoms are of limited utility for predicting delayed gastric emptying in diabetes [69–75]. Similarly, the type and duration of diabetes, glycated hemoglobin levels, and extraintestinal complications were, in general, not useful for discriminating normal from delayed or rapid gastric emptying. However, significant weight loss and a neuropathy were risk factors for delayed and rapid gastric emptying, respectively [76]. In summary, upper GI symptoms in persons with diabetes may result from accelerated gastric emptying, often in association with vagal neuropathy and impaired proximal gastric accommodation. Hence it is essential to measure gastric emptying in people with upper GI symptoms.

Persons with diabetic gastroparesis may have other features caused by autonomic neuropathy. Table 50.2 provides a summary of commonly performed autonomic tests.

In persons with upper GI symptoms, an upper GI endoscopy is necessary to exclude peptic ulcer disease and neoplasms, either of which can cause gastric outlet obstruction. Upper endoscopy may reveal gastric bezoars, which suggest antral hypomotility. Metabolic derangements, such as diabetic ketoacidosis or uremia, and medications, particularly opiates, calcium channel blockers, and anticholinergic agents, may contribute to dysmotility. Rarely, people with gastroparesis present with retrosternal or epigastric pain, and cardiac, biliary, or pancreatic disease may be considered.

Barium X-rays of the small intestine or enterography with computed tomography should be considered only when the clinical features raise the possibility of small intestinal obstruction. Gastric emptying of solids should be quantified by scintigraphy or stable isotope breath test [77, 78], and antroduodenal manometry may be considered in selected circumstances. Measurement of pressure profiles in the stomach and small bowel can confirm the motor disturbance and may facilitate the selection of patients for enteral feeding (Figure 50.6). People with gastroparesis due to predominant antral hypomotility as a result of the diabetic enteropathy may tolerate feeding delivered directly into the small bowel whereas those with a more generalized motility disorder may not.

Diarrhea and constipation

The term *diabetic diarrhea* was first coined in 1936 by Bargen at the Mayo Clinic to describe unexplained diarrhea associated with severe diabetes [79]. Diabetic diarrhea is typically chronic, may be episodic, and can be severe. Diarrhea can occur at any time but is often nocturnal and may be associated with anal incontinence, which may indicate internal anal sphincter dysfunction. Persons with diarrhea often have symptoms of delayed gastric emptying such as early satiety, nausea, and vomiting.

Constipation may occur in isolation or alternate with episodes of diarrhea. Many physicians regard constipation to be synonymous with infrequent bowel movements. It is important to characterize symptoms because many people have misconceptions about normal bowel habits. For example, it is not necessary to have a bowel movement daily—the normal range varies from three bowel movements every week to every day. Moreover, by constipation, people refer to one or more of a variety of symptoms (i.e. infrequent stools, hard stools, excessive straining during defecation, a sense of anorectal blockage during defecation, the need for anal digitation during defecation, and a sense of incomplete evacuation after defecation) [80]. Some of these symptoms (e.g. a sense of anorectal blockage during defecation) may suggest disordered evacuation. A careful rectal examination during relaxation and straining is needed to exclude rectal mucosal lesions and to detect the presence of rectal prolapse, rectocele, and disordered defecation. Normally, voluntary contraction is accompanied by upward and anterior motion of the palpating finger toward the umbilicus as the puborectalis contracts. Conversely, the puborectalis should relax and the perineum should descend (by 2–4 cm) during simulated evacuation. The rectal examination may suggest features (i.e. reduced or increased perineal descent, paradoxical contraction of puborectalis) of defecatory disorders.

Abdominal pain

Persons with diabetes are obviously susceptible to the usual causes of abdominal pain seen in the general population. There is an increased prevalence of gallstones because of altered gallbladder contractility and of mesenteric ischemia caused by generalized

Table 50.2 Commonly performed autonomic tests.

Test	Physiological functions tested	Rationale	Comments/pitfalls
Sympathetic function			
1. Thermoregulatory sweat test (% surface area of anhidrosis)	Preganglionic and postganglionic cholinergic	Stimulation of hypothalamic temp. control centers	Cumbersome, whole body test
2. Quantitative sudomotor axon reflex test (sweat output, latency)	Postganglionic cholinergic	Antidromic stimulation of peripheral fiber by axonal reflex	Needs specialized facilities
3. Heart rate and blood pressure responses			
Orthostatic tilt test	Adrenergic	Baroreceptor reflex	Impaired responses if intravascular volume is reduced
Postural adjustment ratio	Adrenergic	Baroreceptor reflex	Impaired responses if intravascular volume is reduced
Cold pressor test	Adrenergic	Baroreceptor reflex	Impaired responses if intravascular volume is reduced
Sustained hand grip	Adrenergic	Baroreceptor reflex	Impaired responses if intravascular volume is reduced
4. Plasma norepinephrine response to:			
Postural changes	Postganglionic adrenergic	Baroreceptor stimulation	Moderate sensitivity, impaired response if intravascular volume is reduced
Intravenous edrophonium	Postganglionic adrenergic	Anticholinesterase "stimulates" postganglionic fiber at prevertebral ganglia	False negatives caused by contributions to plasma norepinephrine from many organs
Parasympathetic function			
1. Heart rate (RR) variation with deep breathing	Parasympathetic	Vagal afferents stimulated by lung stretch	Best cardiovagal test available, but not a test of abdominal vagus
2. Supine/erect heart rate	Parasympathetic	Vagal stimulation by change in central blood volume	Cardiovagal test
3. Valsalva ratio (heart rate, max./min.)	Parasympathetic	Vagal stimulation by change in central blood volume	Cardiovagal test
4. Gastric acid secretory or plasma pancreatic polypeptide response to modified sham feeding or hypoglycemia	Parasympathetic	Stimulation of vagal nuclei by sham feeding or hypoglycemia	Abdominal vagal test, critically dependent on avoidance of swallowing food during test
5. Nocturnal penile tumescence	Pelvic parasympathetic7	Integrity of S2–4	Plethysmographic technique requiring special facilities
6. Cystometrographic response to bethanechol	Pelvic parasympathetic	Increase in intravesical pressure suggests denervation supersensitivity	Tests parasympathetic supply to bladder, not bowel

atherosclerosis. However, there is little evidence that altered gallbladder contractility per se (i.e. in the absence of gallstones) causes symptoms. Thoracolumbar radiculopathy may result in pain in a girdle-like distribution that does not cross the midline. Specific tests are indicated if the clinical features of pain suggest these disorders. It is essential to elicit a careful history.

Diagnostic tests

Typically, diagnostic testing is primarily guided by symptom pattern and severity. However, since persons with delayed gastric emptying are often asymptomatic, gastric emptying assessments should also be considered in those with unexplained hypoglycemia. After initial testing to identify disturbances of transit, more detailed testing with intraluminal techniques (i.e. manometry and/or a barostat) may be useful for characterizing motor dysfunctions and guiding therapy. Delayed gastric emptying can be documented by scintigraphy, stable isotope breath test, or the presence of a large amount of retained food in the stomach. Barium studies and scintigraphy using labeled liquid meals are of limited value for identifying dysmotility because the gastric emptying of liquids and semisolids (e.g. mashed potatoes) frequently is normal, even in the presence of moderately severe symptoms. The tests that are available to measure gastric emptying non-invasively are summarized in Table 50.3.

Assessment of solid emptying by means of a radiolabel that tags the solid phase of the meal is a more sensitive test with a well-defined normal range. The proportion of radioisotope retained in the stomach at 2 and 4 h distinguishes normal function from delayed gastric emptying with a sensitivity of 90% and a specificity of 70% [81]. The importance of obtaining scans for 4 h

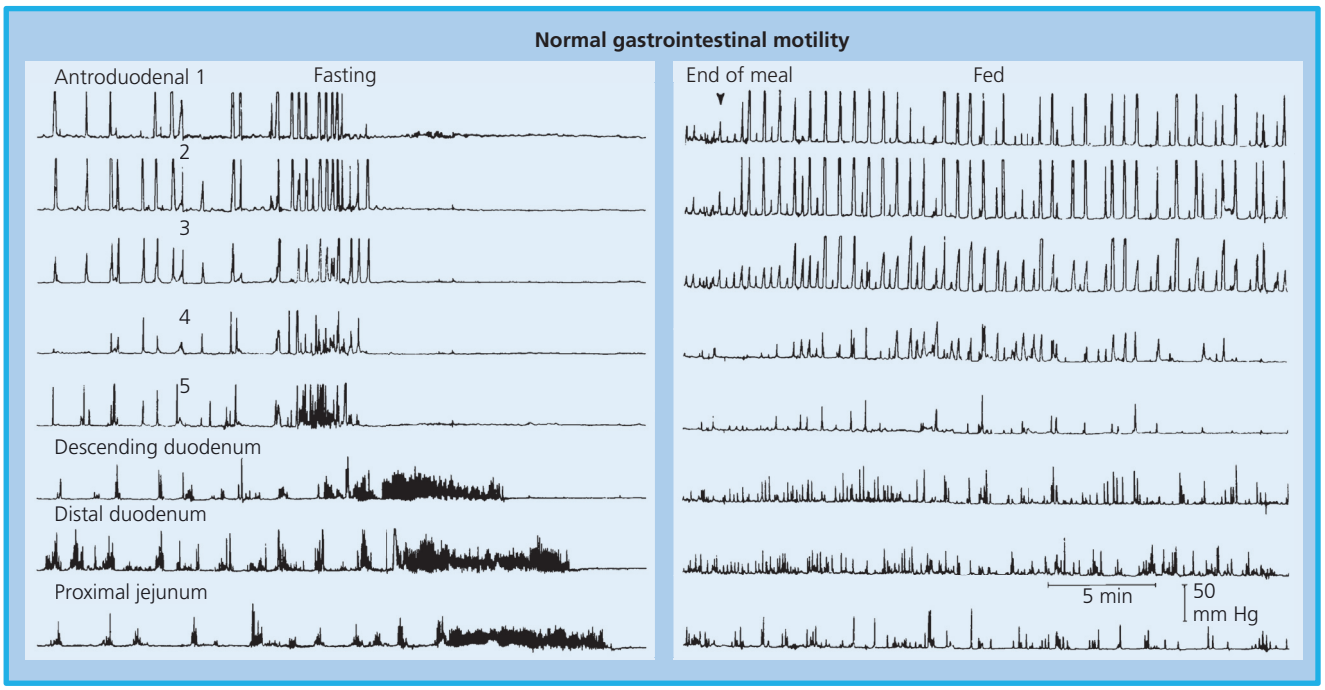

Figure 50.6 Normal manometric profile (fasting and postprandial). The migrating motor complex characteristic of fasting state is demonstrated by presence of quiescence (phase I), intermittent activity (phase II), and an activity front (phase III). The postprandial profile shows high-amplitude, irregular, but persistent phasic pressure activity at all levels. after a meal cannot be overemphasized. Since gastric emptying is slow initially, it is not accurate to extrapolate emptying from scans taken for a shorter duration. Another useful test for measuring solid-phase gastric emptying utilizes a standardized meal with biscuit enriched with ^{13}C, a substrate containing the stable isotope. When metabolized, the proteins, carbohydrates, and lipids of the *Spirulina platensis* or the medium-chain triglyceride octanoate give rise to respiratory CO_2 that is enriched in ^{13}C. Measurement of $^{13}CO_2$ breath content (a reflection of the amount of biscuit remaining in the stomach) by isotope ratio mass spectrometry allows the estimation of gastric emptying half-life [77, 78].

The wireless motility capsule using the SmartPill has been approved by the US Food and Drug Administration (FDA) for the evaluation of gastric emptying and colonic transit time in

Table 50.3 Non-invasive measurements of gastric emptying.

Feature	Gastric emptying by scintigraphy	Stable isotope breath test	Wireless pressure and pH capsule
Indication/function measured	Gastric emptying	Gastric emptying	Emptying and pressure amplitude
Device, assembly or special requirements	External gamma camera and isotope-labeled meal	Breath collection vials and stable isotope-labeled meal	Intraluminal capsule with miniaturized strain gauge and pH measurement
Placement of device	–	–	Capsule swallowed
Performance/versatility/ interpretation	Excellent, standardized meals, data acquisition and interpretation	Becoming standardized Performance related to mathematical analysis	Standard acquisition, delayed emptying fairly valid; pressures of unclear significance
Duration of study	Typically 4 h, could be added to small bowel and colon transit	3–4 h	6 h, could be added to small bowel and colon transit
Availability/potential use	+	+++	+
Costs	++	+	++

people with suspected slow transit constipation, and for the measurement of pH, temperature, and pressure throughout the GI tract [82]; it is a safe and practical alternative to gastric electrical stimulation [83]. Sensed data are transmitted by the single-use capsule to a receiver worn by the patient, and pH values from 0.5 to 9.0, pressure activity, and temperature are recorded. Gastric emptying time is defined as the time from capsule ingestion to a rise in pH from gastric baseline to >4.0, marking the passage of the capsule from the antrum to the duodenum. Normal emptying of the capsule should occur within 5 h of ingestion. If it does not occur within 6 h, a maximum gastric emptying time value of 6 h is assigned [82]. The gastric emptying results with the wireless motility capsule are not as accurate as those using scintigraphy with a digestible solid meal. Its advantages include point-of-care use in ambulatory settings and avoidance of pitfalls of gastric electrical stimulation, such as radiation exposure, need for a gamma camera, and lack of standardized practices across centers [82]. The utility of the wireless motility capsule testing has been enhanced with data [84] showing that pressure profile measurements recorded by the capsule can differentiate persons with diabetic gastroparesis from healthy individuals by the significantly lower numbers of contractions and motility indices.

However, healthy individuals and (more likely) persons with gastroparesis may not have a phase III migrating motor complex contraction within 6 h, when the next meal is given, and capsule emptying may be inhibited by the suspension of the migrating motor complex by the meal. Other limitations include possible difficulty with capsule ingestion and the potential for capsule retention or obstruction. Use of the capsule is contraindicated in children and those with a known history of esophageal stricture.

For people with severe upper GI symptoms, antropyloroduodenal manometry is a specialized technique that assesses pressure profiles in the stomach and small bowel and also guides management. Manometry may also reveal hypomotility of the gastric antrum and/or an intestinal neuropathy (Figures 50.6 and 50.7). Individuals with selective or dominant abnormalities of gastric function may be able to tolerate enteral feeding (delivered directly into the small bowel), unlike those with a more generalized motility disorder.

Gastric accommodation in response to meal ingestion may be impaired in diabetes [85]. This may contribute to the GI symptoms of nausea, bloating, and early satiety. Imaging of the stomach wall using [^{99m}Tc]pertechnetate allows measurement of gastric volume after meal ingestion.

For persons with constipation, colonic transit, anorectal manometry, and rectal balloon expulsion tests provide a useful start. Anorectal manometry and the rectal balloon expulsion test generally suffice to diagnose or exclude defecation disorders; magnetic resonance imaging or barium proctography is required only in selected cases. Colonic transit is often delayed in people with defecatory disorders. Therefore, in those with slow colonic transit, slow transit constipation can only be diagnosed after excluding defecatory disorders. Intraluminal assessments of colonic phasic motility (by manometry) and tone (by barostat) often reveal other dysfunctions (e.g. impaired contractile responses to a meal) and/or pharmacological stimuli (e.g. bisacodyl or neostigmine) in persons with slow transit constipation. Colonic transit can be characterized by radiopaque markers, which, depending on the technique, takes 5–7 days, or by scintigraphy, which takes 24–48 h. Both techniques are equally accurate for identifying slow or rapid colonic transit.

Small intestinal dysmotility may manifest as one or more of the following features: abnormal migrating motor complexes, failure to convert from fasting to postprandial motor pattern, and/or

features of a vagal neuropathy (i.e. excessive number of fasting migrating motor complexes or persistent postprandial migrating motor complexes). Assessment of stool fat provides a useful differentiation point for diabetic diarrhea, as it indicates malabsorption as the pathophysiology leading to diarrhea. An upper endoscopy provides an opportunity to obtain duodenal aspirates for bacterial overgrowth and small bowel biopsy to exclude celiac disease. Lactose or glucose hydrogen breath tests rely on substrate metabolism by bacterial overgrowth in the small intestine with hydrogen release and breath excretion. However, studies have shown that the early peak is frequently due to rapid delivery of the substrate to the colon with bacterial metabolism by normal colonic flora rather than small bowel bacterial overgrowth [86]. To reduce the potential impact of this confounding factor (i.e. rapid intestinal transit), a more restricted definition to diagnose small intestinal overgrowth may be preferable, i.e. an early hydrogen peak (20 ppm), due to small intestinal bacteria, occurring at least 15 min before the later prolonged peak, corresponding to the passage of the remaining lactulose into the colon. However, even with more restricted definitions, the sensitivity and specificity of the lactulose hydrogen breath test in detecting small bowel bacterial overgrowth have been reported to be only 68 and 44% and for the glucose breath test 62 and 83%, respectively [86].

Management

The principles of management are to address fluid and nutritional requirements, improve glycemic control, and treat symptoms [87].

Gastroparesis and dyspepsia

Although nutritional requirements and symptoms can be addressed to a variable extent in persons with mild and compensated gastroparesis, those with severe gastroparesis often require hospitalization for one or more of the following measures: intravenous hydration and correction of metabolic derangements (ketoacidosis, uremia, hypoglycemia, hyperglycemia), nasoenteric decompression, and/or enteral nutrition to manage vomiting and nutritional requirements [63]. Parenteral nutrition may become necessary in cases of malnutrition. Bezoars may be mechanically disrupted during endoscopy, followed by gastric decompression to drain residual non-digestible particles.

Erythromycin at a dose of 3 mg/kg body weight intravenously every 8 h can accelerate gastric emptying [88, 89]. When oral intake is resumed, treatment with oral erythromycin 250 mg t.i.d. daily for 1–2 weeks is worthwhile. Thereafter, the prokinetic effects of erythromycin are limited by tachyphylaxis. Anecdotal findings suggest that erythromycin may be effective if courses are separated by a drug-free period, e.g. lasting 2 weeks. Hyperglycemia interferes with the prokinetic effect of intravenous erythromycin on gastric emptying in people with and without diabetes [39]. Since both liquids and homogenized solids are more readily emptied from the stomach than solids, liquid or blended food will be better tolerated. Frequent monitoring of blood glucose is essential during this phase but improved control of glycemia did not improve gastric emptying in people with poorly controlled T2DM [90].

For individuals with severe gastroparesis who do not respond to the measures outlined above, it may be necessary to bypass the stomach with a jejunal feeding tube. This procedure should be preceded by a trial of nasojejunal feeding for a few days with infusion rates of at least 60 mL of iso-osmolar nutrient per hour. It is preferable to place jejunal feeding tubes directly into the jejunum either by endoscopy or, if necessary, by laparoscopy or mini-laparotomy, rather than via percutaneous endoscopic gastrostomy tubes. Such tubes allow restoration of normal nutritional status but they are not without adverse effects. There is no evidence to suggest that gastrectomy relieves symptoms or enhances quality of life. People with gastroparesis often have concomitant small intestinal denervation, which is likely to cause persistent symptoms after gastrectomy [32, 91].

If the patient remains symptomatic, other prokinetic agents may be considered as adjuncts. In the United States, the only available medication is metoclopramide, a peripheral cholinergic and antidopaminergic agent. During acute administration, it initially enhances gastric emptying of liquids in diabetic gastroparesis, but its symptomatic efficacy is probably related to its central antiemetic effects. However, its long-term use is restricted by a decline in efficacy and by a troubling incidence of central nervous system side effects. Therefore, we prefer to prescribe a dose of 10 mg t.i.d., administered 30 min before meals, for a short duration; the higher dose is 20 mg t.i.d. A systematic review of trials concluded that there was limited evidence to support the use of domperidone, which is another dopaminergic antagonist not approved for use in the USA [92]. Endoscopic injection of botulinum toxin into the pylorus was not effective in controlled studies primarily of idiopathic gastroparesis [93, 94].

Although the FDA recognizes gastric electrical stimulation as a humanitarian use device for refractory gastroparesis, its use for this indication is controversial. Although published data suggest that the device reduces vomiting frequency only when the device is on, data submitted to the FDA indicated that electrical stimulation reduced vomiting frequency to a similar extent with the device turned off or on, suggesting a placebo response [95, 96]. Moreover, the device is expensive and does not accelerate gastric emptying. Between 10 and 20% of patients have device-related complications.

New motilin agonist

Although erythromycin is currently used "off-label" as a gastric prokinetic, it may induce antibiotic resistance, it is associated with tachyphylaxis [97], and it may inhibit cytochrome P-450 CYP3A4, leading to unwanted drug interactions. In addition, because erythromycin is extensively metabolized by cytochrome P-450 3A (CYP3A) isozymes, commonly used medications that inhibit the effects of CYP3A may increase plasma erythromycin concentrations, thereby increasing the risk of ventricular arrhythmias and sudden death [98]. These factors all point towards an

urgent need for a more selective motilin receptor agonist. A novel motilin agonist (camicinal) has significant promise, based on the hypothesis that the motilin receptors can be induced to preferentially signal ("biased agonism"), via particular pathways, to evoke different responses with therapeutic advantages/disadvantages, such as preferentially activating the β-arrestin pathway, enhancing the ability to recover faster from desensitization of the receptor [99].

GSK962040 (or camicinal) is a selective small-molecule motilin receptor agonist that has been shown to induce phasic contractions and increase GI motility in conscious dogs [100]. A separate study has shown that GSK962040 has a greater effect in mediating cholinergic activity in the antrum than the fundus and the small intestine [101]. Results of a phase II 28-day clinical study of effects on gastric emptying and symptoms, safety, tolerability, and pharmacokinetics in persons with T1DM and T2DM diabetes with gastroparesis are awaited.

New ghrelin agonist

Relamorelin (RM-131) is a novel pentapeptide ghrelin receptor agonist with greater potency in increasing GE in animal pharmacology studies than other ghrelin mimetics [102].

In two randomized, double-blind, placebo-controlled, crossover studies conducted in 10 people with T2DM or T1DM and prior documentation of delayed gastric emptying, relamorelin accelerated the gastric half-emptying time of solids [103, 104]. In a phase II study of persons with T1DM, relamorelin reduced upper GI symptoms, with the most impressive effects being observed in those with high baseline vomiting [105]. In individuals with chronic constipation, relamorelin also accelerated colonic transit [106].

Diabetic diarrhea

Diabetic diarrhea is treated symptomatically with loperamide, preferably administered 30 min before meals, in the dose range 2–16 mg per day. Consumption of artificial sweeteners that contain the osmotically active sugar substitute sorbitol should be reduced. Second-line approaches are clonidine, 0.1 mg orally [107] or by patch in those who do not experience significant postural hypotension. Amitriptyline, which has anticholinergic effects, may reduce intestinal cramping and transit. Octreotide (25–50 μg subcutaneously 5–10 min before meals) delays small intestinal transit [108] and may also reduce secretory diarrhea associated with rapid intestinal transit [109]. Although it has been suggested that octreotide reduces small bowel bacterial overgrowth in chronic intestinal pseudo-obstruction[110], the study assessed bacterial overgrowth by breath testing. Indeed, by delaying small intestinal transit, octreotide may predispose to bacterial overgrowth. Regulating stool consistency may also improve fecal continence. In addition, pelvic floor retraining with biofeedback therapy can improve rectal sensation and enhance coordination between perception of rectal distention and contraction of the external anal sphincter [53]. However, biofeedback therapy is less effective in people with markedly reduced rectal sensation. A descending colostomy may be required and may improve the quality of life in those with severe diarrhea associated with fecal incontinence.

Constipation

For people without pelvic floor dysfunction, chronic constipation can be generally managed with pharmacological agents (i.e. osmotic and stimulant laxatives) [111]. Pelvic floor retraining by biofeedback therapy is the cornerstone for managing defecatory disorders; laxatives are used as an adjunct to pelvic floor retraining [112]. Fiber supplementation, either with dietary supplementation or with fiber products (e.g. psyllium, 15–18 g daily), should be considered in people with inadequate fiber intake. Of the osmotic laxatives, polyethylene glycol (up to 17 g in 8 oz [225 mL] of water once or twice per day) is a widely used and safe over-the-counter agent. Although lactulose is a poorly absorbed disaccharide, lactulose syrup contains small amounts of absorbable sugars and may increase hyperglycemia. Magnesium compounds are safe, but individuals with impaired renal function may develop magnesium retention. Bisacodyl or glycerin suppositories are useful rescue agents in people who have not had a bowel movement for 2 days. If possible, suppositories should be administered 30 min after a meal to synergize pharmacological therapy with the physiological response to a meal. By activating chloride channels and inducing colonic secretion, lubiprostone accelerates colonic transit in healthy individuals and improves symptoms in functional constipation [113–115]. Although there have been no studies in people with diabetes and constipation, lubiprostone should be considered in those who have not responded to osmotic agents.

The anticholinesterase pyridostigmine is efficacious in relief of constipation in individuals with diabetes and constipation, and the effect is also observed in those with autonomic neuropathy [116, 117].

51 Diabetes and Non-Alcoholic Fatty Liver Disease

Shivakumar Chitturi and Geoffrey C. Farrell
Gastroenterology and Hepatology Unit, The Canberra Hospital and the Australian National University Medical School, Australian Capital Territory, Australia

Key points

- Non-alcoholic fatty liver disease (NAFLD) is characterized by intrahepatic fat accumulation with varying degrees of hepatic inflammation and fibrosis.
- NAFLD is present in up to 20% of the general population worldwide.
- NAFLD is the hepatic manifestation of prediabetes and the metabolic syndrome, with strong links to obesity and type 2 diabetes (T2DM).
- There is a three- to fivefold increase in the incidence of diabetes within 5 years of the diagnosis of NAFLD.
- The spectrum of NASH includes simple steatosis, non-alcoholic steatohepatitis (NASH), and cirrhosis.
- The outcome of NAFLD varies by histologic subtype, from benign (simple steatosis) to liver failure (cirrhosis). A proportion of people with NASH progress to cirrhosis.
- Cardiovascular disease and malignancies are the main causes of death but there are increasing numbers of people developing hepatocellular carcinoma even in the absence of cirrhosis.
- The key pathogenic process involved in the transition from steatosis to NASH is hepatic lipotoxicity (especially from free cholesterol). Hepatic injury results from recruitment of inflammation through activation of pattern recognition receptors (Toll-like receptors, the NLRP3 inflammasome).
- Lifestyle measures, involving exercise and weight reduction, and optimizing metabolic control remain the cornerstone of management. Drugs such as vitamin E can improve NASH in some but not all people with NASH.
- Liver transplantation is indicated for those with end-stage liver disease.
- The disease recur in transplanted livers. Aggressive measures to optimize metabolic control are imperative to prevent this.

Introduction

Non-alcoholic fatty liver disease (NAFLD, "fatty liver") is a relatively recent addition to the list of systemic disorders associated with diabetes, although the two conditions have long been known to be pathogenically interrelated. NAFLD encompasses a spectrum of liver disorders characterized by intrahepatic fat accumulation (steatosis), with or without varying degrees of hepatic inflammation and fibrosis (non-alcoholic steatohepatitis, NASH), through to cirrhosis. These histologic features closely resemble alcoholic liver disease (hence the name "non-alcoholic") and a definition of NAFLD requires exclusion of "significant" alcohol intake.

NAFLD is important for several reasons. It is widely prevalent in the community. Though mostly benign, serious liver injury including cirrhosis and liver cancer can occur in certain subgroups (type 2 diabetes [T2DM], obesity). Fatty liver can also worsen other liver diseases including alcoholic liver disease, hemochromatosis and hepatitis C. Finally, NAFLD is an independent predictor and possible contributor to extrahepatic disorders such as ischemic heart disease and chronic kidney disease.

Definition and epidemiology

Non-alcoholic fatty liver disease is defined by hepatic fat accumulation in persons without a history of significant alcohol use [1, 2]. An operational definition of significant alcohol use restricts alcohol use to 140–210 g/week for men (2–3 standard drinks/day) and 70–140 g/week (1–2 standard drinks/day) for women [3, 4]. It is important to verify the lifetime track record of alcohol usage. Secondary causes of steatosis also need to be excluded [Table 51.1] [5].

NAFLD is the most common liver disorder worldwide [6–11] [Table 51.2]. In the USA, the community prevalence of NAFLD was initially reported as 2.8% to 8% and 18.8% to 30%,

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

Table 51.1 Secondary causes of hepatic steatosis.

Nutritional disorders	**Metabolic disorders**
Malnutrition	Abetalipoproteinemia
Total parenteral nutrition	Type 1 glycogen storage disease
Rapid weight loss, bulimia	Wilson disease
Celiac disease	Partial and total lipodystrophy
Drugs	**Bariatric surgery**
Amiodarone	Jejuno-ileal bypass
Perhexiline maleate	
High-dose glucocorticosteroids	**Other causes**
Tamoxifen	Chronic hepatitis C infection
Methotrexate	Toxicant-associated steatohepatitis
Highly active antiretroviral treatment	

respectively [12]. However, NAFLD was defined by criteria that are insensitive to mild steatosis (serum aminotransferases, liver ultrasound criteria). Using the more accurate method of proton magnetic resonance spectroscopy in the Dallas Heart Study (USA), up to a third of the population was shown to have NAFLD [6]. Significant ethnic differences were observed, with prevalence rates of 24%, 33%, and 45% among African Americans, non-Hispanic Whites, and Hispanics, respectively. Mirroring the global rise in obesity and T2DM, the prevalence of fatty liver now exceeds 15% in Asia and elsewhere [7, 13].

In most NAFLD studies, men outnumber women by 2 to 1 between the ages of 20 and 50 years. This trend is reversed in postmenopausal women, likely reflecting the withdrawal of a protective effect of estrogens [14]. NAFLD is also now reported (~10%) in children and adolescents [15].

NASH autopsy data show that NASH is present in 3% and 18% of lean and obese individuals, respectively [16]. Here too, there are ethnic differences. In Texas (USA), where the overall prevalence rate for NASH is ~12%, the frequencies of NASH vary among Hispanic (19.4%), non-Hispanic White (13.5%), and African Americans (9.8%), respectively [17]. These differences are partly attributed to differences in frequencies of the patatin-like phospholipase domain-containing protein 3 (PNPLA3) gene.

NAFLD and the metabolic syndrome

In most NAFLD case series, over half the individuals are obese, 30–40% have T2DM and 30% have dyslipidemia. Likewise, NAFLD is frequent in people with obesity (50%, rising to 90% in morbid obesity), T2DM (50–74%) [17], and dyslipidemia (up to 50%) [18]. NAFLD is also reported in 7–9% of lean individuals [19]. However, many of these individuals have central obesity or have been misclassified as "lean" because ethnic-specific anthropometric criteria were not used. Others may be "metabolically obese" lean individuals who have recently gained weight or become sedentary; anecdotally, most such individuals have a strong family history of T2DM.

NAFLD is the hepatic manifestation of the metabolic syndrome, with the majority (up to 87%) fulfilling criteria for the full syndrome [20]. Likewise, people with the metabolic syndrome are also 4 to 11 times more likely to develop NAFLD, which is also less likely to resolve [21]. Finally, the metabolic syndrome is a predictor of histologic severity, with an increased likelihood (OR 3.0) of NASH and advanced hepatic fibrosis (OR 3.5) [22].

NAFLD and diabetes

Type 2 diabetes

Over a third of people with NAFLD have T2DM. In people without diabetes, a family history of diabetes is obtained in over 50% and abnormalities of glucose tolerance are common [20]. In one study, 24 (33%) of 76 people with NAFLD but without diagnosed diabetes undergoing an oral glucose tolerance test had abnormalities of glucose tolerance; 7 had T2DM and 17 had impaired glucose tolerance [23]. Further, fatty liver is also an independent predictor of the future development of prediabetes [24] and T2DM (OR 3.0) [25]. The links with T2DM are important because the latter is a consistently reproducible predictor of histologic severity, including NASH (OR 2.48), any fibrosis (OR 2.94), advanced hepatic fibrosis (OR 6.03) [26], and hepatocellular carcinoma (relative risk (RR), 2.0–3.0) [27].

Table 51.2 Population-based studies assessing prevalence of non-alcoholic fatty liver disease.

Author [ref]	Year of study	Location	Sample size	Criteria used to define NAFLD	Prevalence (%)
Browning [6]	2000–2002	Dallas, USA	2287	MRS	24–45
Wong [7]	2012	Hong Kong, China	922	MRS	27
Bedogni [8]	2002–2003	Modena, Italy	3345	Hepatic ultrasound	16 (lean), 76 (obese)
Nomura [9]	1984	Okinawa, Japan	2574	Hepatic ultrasound	14; 3.6 (lean), 58 (obese)
Lazo [10]	1988–1994	NHANES III, USA	12,454	Hepatic ultrasound	19
Clark [11]	1988–1994	NHANES III, USA	15,676	Raised aminotransferases	8

MRS, proton magnetic resonance spectroscopy; NHANES III, National Health and Examination Survey III.

Type 1 diabetes

Although not as well appreciated, fatty liver is also prevalent among people with T1DM. Elevated ALT levels are seen in 10–35% of people with T1DM [28] and up to 44% have evidence of hepatic steatosis on liver ultrasound [29]. Many (48–80%) have normal ALT levels. However, ALT or ultrasound-derived prevalence data may not be accurate. Further, ultrasonography cannot differentiate hepatic steatosis from glycogenosis, a frequent finding in this group. Detailed histologic data are lacking. In Nottingham (UK), 11 (19%) of 57 people among a cohort of 4000 individuals with T1DM undergoing a liver biopsy had NAFLD. More than half (53%) had steatosis, 20% had NASH, similar to those with T2DM (54% and 35%, respectively), and one individual had cirrhosis [29].

The pathogenesis of NAFLD in T1DM is not unclear but is likely related to whole body [30] and hepatic insulin resistance [31], even in the face of insulin deficiency. Poor glycemic control is also an important contributor. Hyperglycemia promotes hepatic steatosis through activation of transcription factors involved in lipogenesis, carbohydrate response element-binding protein [32], while insulin activates sterol regulatory element-binding protein-1c (SREBP-1c) (for fatty acid synthesis), SREBP-2 (for cholesterol uptake) and upregulates glucose transporter 2 to facilitate hepatic glucose uptake [33].

Histologic subtypes

The underlying liver histologic characteristics have a strong bearing on the outcome. These include simple steatosis at one end, non-alcoholic steatohepatitis (NASH) in the middle, and cirrhosis at the other (Table 51.3) [34].

Simple steatosis is characterized by *intrahepatic fat accumulation* alone. The fat (triglyceride) deposition is predominantly macrovesicular (large fat globules) and is diffusely distributed. In severe cases, over two-thirds of all hepatocytes are involved.

NASH, the inflammatory subtype of NAFLD, is defined by hepatic steatosis *along* with *hepatic inflammation/hepatocyte injury* and varying degrees of *fibrosis* (Figures 51.1 and 51.2). Swollen hepatocytes (*ballooning*), a consequence of liver cell injury, are a characteristic finding. Some may carry eosinophilic cytoplasmic inclusions (Mallory–Denk bodies) but these are not essential for diagnosis. The hepatic inflammatory cell infiltrate is predominantly composed of lymphocytes and macrophages. The fibrotic changes are initially conspicuous in zone 3, in the vicinity of the terminal hepatic venule ("perivenular" fibrosis) and often encircle individual hepatocytes in a "chicken-wire" configuration or line the hepatic sinusoids ("perisinusoidal fibrosis"). In time, the fibrotic process involves the portal and periportal areas, leading to portal-central bridging fibrosis and cirrhosis. In children, an alternative histologic pattern with hepatic steatosis and portal fibrosis is recognized.

Hepatic nodules and diffuse hepatic fibrosis define NAFLD-associated cirrhosis. Curiously, hepatic fat or steatohepatitis may be absent, leading to mislabeling of these cases as representing "cryptogenic cirrhosis." However, people with cryptogenic cirrhosis are more often obese (55% vs. 24%) and have T2DM (47% vs. 22%) than those with other causes of cirrhosis, suggesting that these may represent cases of "burnt-out" fatty liver [35].

For accurate histologic subtyping, the pathologist's overall assessment of the liver biopsy remains critical [34]. For clinical trials, liver biopsies are also scored using a detailed scoring system [36] (Table 51.4).

Table 51.3 The spectrum of non-alcoholic fatty liver disease and definitions.

	Histologic subtype	Natural history
Simple steatosis	Fat accumulation within hepatocytes (steatosis) with no hepatocyte ballooning or fibrosis.	Mostly non-progressive.
Non-alcoholic steatohepatitis (NASH)	Hepatic steatosis with varying degrees of lobular inflammation, hepatocyte ballooning and/or fibrosis.	Can progress to cirrhosis. Associated with increased overall and liver-related mortality.
NASH cirrhosis	Cirrhosis with current or past evidence of hepatic steatosis or NASH. In cases of cryptogenic cirrhosis, features of NAFLD may be absent but NASH as the underlying cause may be suspected by the presence of obesity/type 2 diabetes and metabolic syndrome.	Usually progressive disorder leading to liver failure and liver cancer.

Why does NASH occur?

In non-alcoholic steatohepatitis (NASH), fatty liver from overnutrition is complicated by liver injury and inflammation [37, 38]. Genetic factors, as shown by ethnic differences in prevalence and familial clustering, are also important in the development of NASH. A number of candidate genes involved in aspects of innate immunity, cell metabolism, anthropometric traits, fibrogenesis, oxidative stress have been implicated. The most important of these is PNPLA3, identified by genome-wide association studies, which contributes to a threefold variation in the risk of NASH and fibrosis [13].

As discussed later, NASH confers adverse liver outcomes. This is because inflammation connects liver cell injury with fibrosis progression, the three elements of NASH pathology (vs. simple steatosis) [39]. The difference between NASH and "not NASH" NAFLD pathology is the type of lipid molecules that accumulate, and how they are processed by hepatocytes. NASH is now conceptualized as "liver lipotoxicity" [38, 39]. As informed by lipidomic analyses in NASH livers from man and mouse [40, 41], free

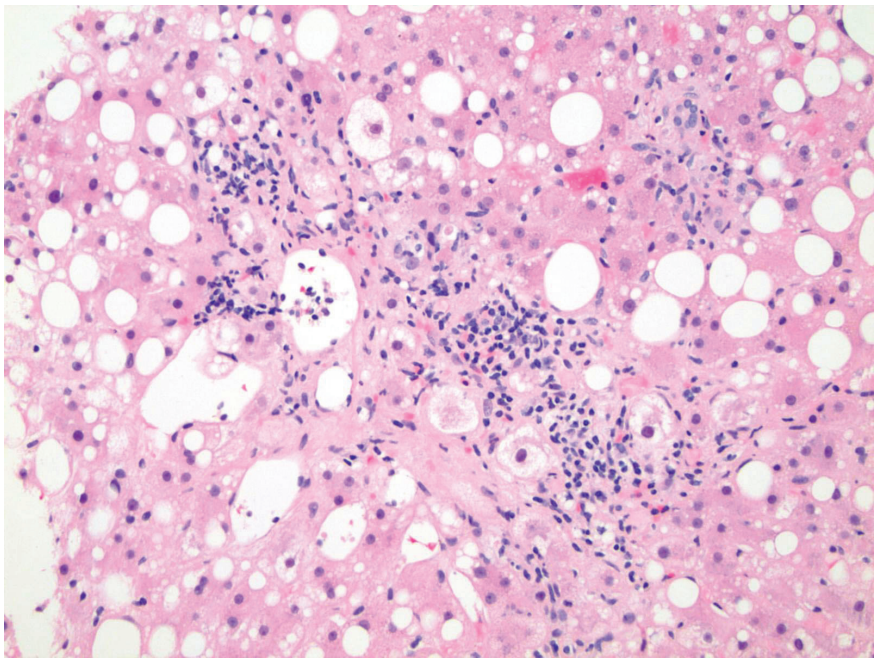

Figure 51.1 Nonalcoholic steatohepatitis. This slide illustrates diffuse hepatic steatosis, lobular inflammation, and ballooning. (H. and E. stain, × 200). Source: Slide provided by Prof. Matthew Yeh, University of Washington School of Medicine, Seattle, USA.

cholesterol seems the most likely lipotoxin [40, 42]. In obese mice with T2DM and metabolic syndrome (hypercholesterolemia, hypertension), and studies in primary hepatocytes have implicated free cholesterol in pathways to hepatocyte apoptosis and necrosis. Similar studies have shown that saturated free fatty acids and lysophosphatidylcholine exert similar lipotoxicity but the weight of evidence implicates free cholesterol as a more likely mediator of hepatocyte cell death *in vivo*. It is important to note that lipotoxicity to hepatocytes causes them to release danger associated molecular patterns (DAMPs) such as high mobility group box 1 (HMGB1), for which there is recent evidence [43]. Alternatively (or additionally) whether pathogen-associated molecular patterns (PAMPs), such as lipopolysaccharide (endotoxin) arising from a "leaky gut," are more important for inciting recruitment, and activation of macrophages to the liver in NASH is unresolved [44]. This "controversy" aside, most in this field now accept that the inflammatory response in NASH arises from innate immunity [44, 45], that is, an interaction of DAMPs and/or PAMPs with pattern recognition receptors. Greatest interest has focused on Toll-like receptors (TLRs) 4 and 9, but there is

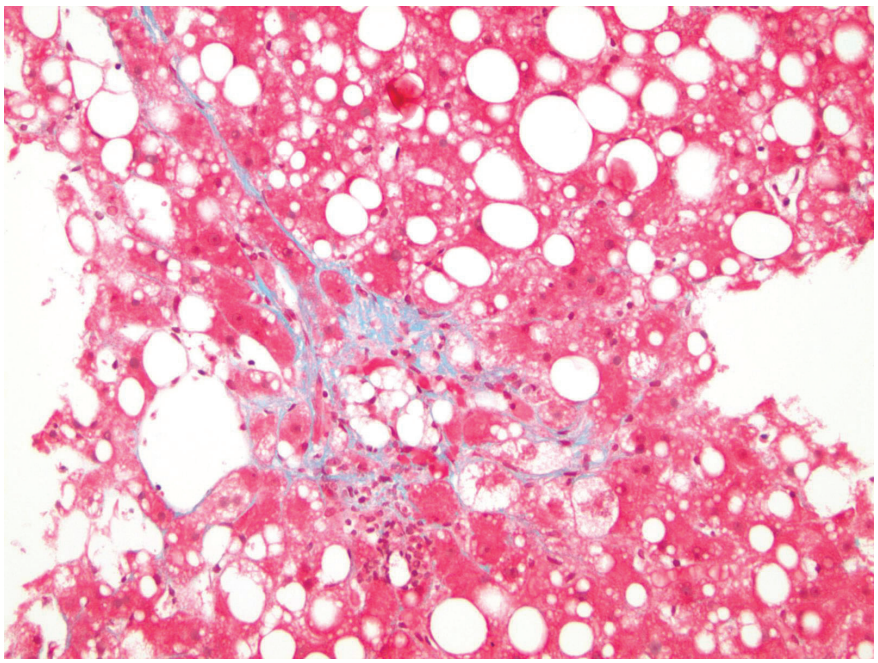

Figure 51.2 Nonalcoholic steatohepatitis. This slide shows perivenular (zone 3) and pericellular hepatic fibrosis (Masson trichrome stain, × 200). Source: Slide provided by Prof. Matthew Yeh, University of Washington School of Medicine, Seattle, USA.

Table 51.4 NAFLD histological classification developed by the Non-alcoholic Steatohepatitis Clinical Research Network.

Histological feature	Score	Category definition
Steatosis (percentage of liver parenchyma involved by steatosis under low- to medium-power evaluation)	0	<5%
	1	5–33%
	2	34–66%

emerging evidence for inflammasome activation in NAFLD [45], as shown in alcoholic hepatitis [46].

NLRP3 (NOD-like receptor protein 3) belongs to a family of cytosolic receptors for DAMPs that facilitate aggregation of apoptosis-associated speck-like protein containing CARD (ASC) to form a scaffold for assembly and dimerization of pro-caspase-1 [47]. This activates caspase-1 to cleave pro-IL-1β and pro-IL-18. Secreted IL-18 activates macrophages. IL-1β directs neutrophil recruitment, and may activate stellate cells directly into matrix-depositing cells. NLRP3 activation has been noted in dietary models of steatohepatitis [46], while *Nlrp3*, *Asc*, or *caspase-1* deletion protects against steatohepatitis in an amino acid deficiency model. Inflammatory response to biomaterials requires plasma membrane cholesterol [48], which is increased in NASH. In atheroma, cholesterol crystals activate NLRP3 in macrophages [49]. Cholesterol crystals have recently been noted in human, as well as in obese, diabetic mice with NASH, and caspase-1 activation in the latter NASH livers co-locates with crystal-laden hepatocytes [50]. Of interest, the pattern of lobular inflammation in NASH is predominantly one of macrophages (and activated Kupffer cells) surrounding injured hepatocytes to form crown-like structures, the likely source of macrophage and neutrophil chemokines. Such macrophages likely accumulate in response to lipotoxicity and/or cholesterol crystals. Phase 2b trial of a macrophage chemokine inhibitor is currently underway.

Clinical features

Most people with NAFLD are asymptomatic, with the diagnosis being suggested by liver ultrasonography or by abnormal liver tests. Occasionally, individuals may complain of discomfort over the right upper quadrant and a soft, enlarged liver may be palpable. A firm or hard liver should raise suspicion of significant liver fibrosis. Jaundice, splenomegaly, ascites, bruising, encephalopathy are usually absent. When present, these signs are often accompanied by typical biochemical and imaging characteristics of cirrhosis.

Extrahepatic-associations of NAFLD

People with NAFLD have an increased risk (OR 2–4.0) of non-fatal and fatal ischemic heart disease, beyond what is predicted by traditional cardiovascular risk factors. An association with atherosclerosis markers (e.g. carotid intima-media thickness) has also been demonstrated [51]. Not all studies have shown an increased risk but this inconsistency may result from differences in case definition. However, the links with cardiovascular mortality have also been emphasized in hospital-based case series, which have also correlated cardiovascular risk with liver disease severity (risk for NASH > simple steatosis > matched controls) [52]. Potential contributory mechanisms include oxidative stress, and an altered cytokine, fibrinolytic, and atherogenic profile (small dense LDL, reduced HDL) [51]. Targher et al. have observed a similar relationship between NAFLD and microvascular complications of diabetes ([retinopathy, OR 3.3; 95% CI: 1.4–7.6]; nephropathy, [OR 1.87; 95% CI: 1.3, 4.1]) [53] but there have been conflicting results. Other systemic disorders that are highly prevalent among individuals with NAFLD include chronic kidney disease, obstructive sleep apnea, colorectal adenomas/cancer, and polycystic ovarian syndrome [25].

Natural history of NAFLD

The histologic subtype dictates the outcome of people with fatty liver. Individuals with simple steatosis have an excellent outcome, with a very low risk of developing cirrhosis and liver failure. In a Danish study that followed 417 people with non-alcoholic and alcoholic steatosis over 13 to 20 years, the rates of cirrhosis were 0.6% and 22%, respectively [54]. Most people with simple steatosis can be reassured and managed by primary care physicians. The only caveat is that transition of simple steatosis to NASH can occur, as can resolution of NASH to simple steatosis, but the "deterioration" transition seems uncommon (rapid weight gain

and development of diabetes could be relevant) [70]. What is clear is that the existence of liver fibrosis (any severity) is a more important predictor of progression to cirrhosis than even the presence of NASH versus "not NASH" NAFLD.

In contradistinction to simple steatosis, those with NASH can progress to cirrhosis and hepatic decompensation. Over a period of 15 years, the risk of developing cirrhosis is at least 10% (4–14%) and the overall liver-related mortality is ~7% (2.8–18%) [55, 56]. The outcome of people, with NAFLD-associated cirrhosis, who have decompensated, is similar to that observed with chronic hepatitis C and other chronic liver diseases [56]. Over a 10-year period, the mean overall and liver-related mortality is 18% (7–44%) and 25% (19–89%), respectively [55]. Overall, there is a 1.7-fold increase in standardized mortality, and liver disease ranks third among the causes of death, preceded only by cardiovascular disease and malignancy [57].

Hepatocellular carcinoma

Several studies have highlighted the association between T2DM (relative risk (RR), 2.0 to 3.0) and obesity (RR 1.89) and the risk of hepatocellular carcinoma (HCC) [27, 58]. Most HCCs are associated with viral hepatitis and alcohol-related cirrhosis but the contribution of NAFLD may have been previously underestimated in small short-term studies [56].

Most but not all NAFLD-associated HCCs arise in the setting of cirrhosis. While some tumors in "non-cirrhotic" livers could represent sampling errors (with greater degrees of fibrosis having being missed), there are strong confirmatory liver explant data. In one Japanese series, only 51% had cirrhosis, with significant gender differences (men 39%, women 70%). The risk of HCC with NAFLD-cirrhosis is lower than that for chronic hepatitis C and is estimated between 2.4% over 7 years (0.34%/year) to 13% in 3 years (4.3%) [59, 60]. This is related to differing patient characteristics (age, body weight, alcohol intake) between studies. The overall risk of HCC is still low, especially in the absence of cirrhosis, but its widespread prevalence raises concerns about a potential public health crisis. In Newcastle (UK), a third of all HCC cases are now attributed to NAFLD [61].

Over two-thirds of HCCs occur in men, with a median age of 72 years. Most of these tumors are often solitary (75%) and well differentiated, with an average size of 3 cm. Many of these people have not been on surveillance programs.

Diagnosis and assessment

It is important to seek supportive evidence to make a positive diagnosis of NAFLD (metabolic syndrome features) (Tables 51.5 and 51.6) and to exclude those that negate this possibility (Table 51.1).

Liver enzymes

The entire histologic spectrum of NAFLD has been described in people with normal liver tests [62]. Therefore, aminotransferase changes are unreliable in predicting liver histology or response to treatment. When increased, serum alanine aminotransferase (ALT) values typically exceed those of aspartate aminotransferase (AST) (unlike for alcoholic liver disease) and are usually less than 10-fold above the upper limit of normal. In cases with advanced hepatic fibrosis or cirrhosis, the AST : ALT ratio approaches 1. Cases with ALT values exceeding 1000 IU/L are unusual and suggest the possibility of viral, autoimmune, or drug-induced liver injury. Occasional people present with an isolated increase in alkaline phosphatase and/or gamma glutamyl transferase [63].

Antinuclear and/or smooth muscle antibodies can be present in 25% of cases [64] and a liver biopsy may be necessary to exclude autoimmune hepatitis. An elevated serum ferritin (with a normal

Anthropometry	**Serology**
Height, weight, waist circumference	Hepatitis B surface antigen, hepatitis C antibody
Blood pressure	Anti-nuclear, smooth muscle, liver-kidney microsomal and mitochondrial antibody
Liver function tests	Serum ceruloplasmin, alpha-1 antitrypsin
Full blood count, prothrombin time	**Other tests**
Serum bilirubin	Transglutaminase antibody (celiac disease)
Serum alanine aminotransferase, aspartate aminotransferase	Iron studies, thyroid function tests
Serum alkaline phosphatase, gamma glutamyl transferase	**Imaging**
Serum albumin, globulins	Abdominal ultrasound, transient elastography (if available)
Serum fasting lipids, blood glucose, insulin (optional)	
75 g oral glucose tolerance test if fasting blood glucose ≥ 5.6 mmol/L	

Table 51.6 Metabolic syndrome (as defined by the International Diabetes Federation).

The metabolic syndrome is defined by central obesity plus any two of the following:	
Central obesity	Waist circumference ≥ 94 cm (Europid men); ≥ 80 cm (Europid women); ≥ 90 cm (Asian men); and ≥ 80 cm (Asian women)
Fasting blood glucose	Elevated fasting plasma glucose ≥ 5.6 mmol/L or previously diagnosed type 2 diabetes
Elevated triglyceride level	≥1.7 mmol/L or receiving specific treatment for this lipid abnormality
Reduced HDL-cholesterol level	≤ 1.03 mmol/L (men) and ≤ 1.29 mmol/L (women) or receiving specific treatment for this lipid abnormality
Raised blood pressure	Systolic BP > 130 mmHg or diastolic BP > 85 mmHg or receiving treatment for hypertension

BP, blood pressure. Source: Alberti KG, Zimmet P, Shaw J; IDF Epidemiology Task Force Consensus Group. The metabolic syndrome – a new worldwide definition. *Lancet* 2005; **366**:1059–1062. Copyright 2005 Elsevier.

transferrin saturation) is often present in people with NASH but this is usually unrelated to iron overload [65]. Hyperferritinemia has been suggested as a marker of histologic severity and as an indication for liver biopsy but its performance is inferior to other non-invasive diagnostic methods [66] (e.g. NAFLD fibrosis score).

Imaging

Hepatic ultrasound (US), abdominal computerized tomography (CT) and magnetic resonance imaging (MRI) can all identify fatty liver and detect advanced cases of cirrhosis with portal hypertension but are insensitive to mild steatosis (<33% of hepatic steatosis) [67] and cannot differentiate simple steatosis from NASH nor accurately assess fibrotic severity.

On liver ultrasound, fatty liver is defined by increased hepatic echogenicity relative to the right kidney ("bright" liver), blurring of the hepatic vasculature and poor visualization of the diaphragm (Figure 51.3). Liver ultrasonography has high specificity (>90%) but is insensitive to mild steatosis (<33%). On abdominal CT, hepatic steatosis is defined by decreased hepatic attenuation alone or by comparison with the spleen (liver-spleen attenuation difference >10 Hounsfield units) or by the liver : spleen attenuation ratio (>1.1) [68]. On an MRI scan, the fatty liver exhibits lower signal intensity than the surrounding muscle. Magnetic resonance spectroscopy (MRS), performed on MRI systems of >1.5 Tesla, is the most accurate non-invasive method of determining quantifying liver fat content by evaluating water- and triglyceride-derived proton signals within a small liver volume (2 cm^3). MRS is expensive and remains a research tool but it has been useful in selecting an intrahepatic triglyceride fat threshold of ≥5.56% to define NAFLD [8].

Of the newer imaging modalities, *transient elastography* (TE) using a dedicated instrument (Fibroscan,™ EchoSens, Paris, France) or conventional ultrasound equipment (*acoustic radiation force imaging*, ARFI) are used in staging liver fibrosis [69]. A shear wave is generated using a cutaneous probe placed over the liver area and then velocity of its passage across a defined block of the liver is measured. This estimate of liver stiffness (*liver stiffness measurement*, LSM) correlates with the fibrosis stage. The negative predictive value for cirrhosis is high (>90%) and some liver biopsies can be avoided. However, there is a "gray" zone of LSM where there is uncertainty about the fibrosis stage and a liver biopsy is still necessary. Failure to obtain adequate readings may occur in obese individuals but a new XL probe can be useful in such cases. Also promising is the ability to detect mild steatosis (10%) and grade steatosis using the same equipment. This is scored by the *controlled attenuation parameter* (CAP), which reflects ultrasound beam attenuation by liver fat [70]. Magnetic resonance elastography is also being evaluated as a fibrosis staging tool [71].

Liver biopsy: indications and limitations

Liver histology is the "gold standard" against which other diagnostic tests are compared. The indications for liver biopsy are listed in Table 51.7. In recent years, the place of liver biopsy is being re-evaluated. Besides the inconvenience, pain, risk of bleeding, visceral injury and rarely death from this procedure, there are other technical issues. The sample size should be adequate (length 2 cm, containing at least 10 portal tracts). Fair to good agreement between observers is noted for steatosis (k = 0.79) and fibrosis (k = 0.84) but there is less agreement in interpreting ballooning (0.56) and lobular inflammation (k = 0.45) [36]. These

Table 51.7 Indications for liver biopsy.

Indication	Typical settings
Presence of demographic, laboratory or imaging features that predict an higher likelihood of NASH or advanced hepatic fibrosis (age >50 years, type 2 diabetes, obesity, metabolic syndrome, hypothalamic-pituitary disease, AST : ALT ratio ≥1, low platelet count, features suggestive of cirrhosis on imaging); increasingly, derived scores (e.g. NAFLD score) or special techniques such as transient elastography have been used to assess fibrotic severity.	In some cases, the results of non-invasive tests may obviate the need for a liver biopsy. A liver biopsy is usually reserved for those cases where the stage of fibrosis cannot be determined with certainty. In other cases, where there is a high likelihood of advanced fibrosis, a biopsy is still useful if the diagnosis of cirrhosis could have an impact on managing comorbid conditions, e.g. cardiac or major surgery, renal transplantation
To exclude other liver disorders where the diagnosis is uncertain	Some examples 1. In people with chronic viral hepatitis B or C where there is suspicion that abnormal liver tests may relate to coexisting NAFLD rather than to active viral replication. 2. To exclude autoimmune hepatitis in the presence of anti-nuclear/smooth muscle antibodies, raised globulins.
In clinical trials	To document treatment response

limitations have stimulated a search for alternative assessment methods.

Non-invasive methods of assessing NAFLD

These include serum biomarkers and newer imaging techniques. There are two principal objectives: to distinguish between cases with simple steatosis from those with NASH, and to assess fibrotic severity. In addition, in population-based studies, several indices have been developed to identify people with NAFLD.

Screening for NAFLD

Neither population-screening nor screening in high-risk groups (obesity, diabetes) is officially endorsed. In population-based studies, indices that can predict NAFLD use a combination of anthropometric (body weight, waist circumference), standard (triglycerides) and non-standard (apolipoprotein A1, haptoglobin) lab tests and imaging (ultrasound). These population-based screening indices are less reliable when applied to individual cases.

Separating simple steatosis from NASH

Tests include combinations of markers of inflammation and cell death with other biologic and standard lab tests. Their applicability is limited by sample size and lack of independent validation. The limitation of serum aminotransferases has been discussed earlier. Measuring serum markers of inflammation such as highly sensitive C-reactive protein, interleukin-6, tumor necrosis factor α (TNF-α) lack sensitivity (<65%) in identifying NASH [72].

Hepatocyte apoptosis is an important mode of cell death in NASH. Its final steps involve the effector caspases 3 and 7, which also cleave a major cytoplasmic intermediate filament cytokeratin-18 (CK-18) to yield measurable serum fragments. The current CK-18 assays measure these fragments alone (M-30 assay) or as a combination of whole and cleaved CK-18 fragments (M-65 assay). The initial results were promising (area under the curve of 0.9) [73] but subsequent studies have been disappointing (sensitivity/specificity 58%/68%, AUROC 0.65), with significant overlap between cases with steatosis and those with NASH [74]. The terminal peptide of procollagen III (PIIINP) is also being evaluated as a biomarker that separates cases with simple steatosis from those with NASH and/or advanced fibrosis (AUROC of 0.85–0.87) [75].

Identifying fibrosis stages

Several different systems have been used to assess fibrotic severity, the best correlate of clinical outcome [76–82] (Table 51.8). These combine demographic variables such as age with routine laboratory tests. Of these, the NAFLD score has been extensively validated [76]. The score can be used to rule in or rule out hepatic fibrosis. A liver biopsy is needed for those with scores between -1.4 and 0.676. In the original study, over 75% of liver biopsies could have been avoided.

Another scoring system (original European liver fibrosis score, ELF Score) developed in the UK [78] includes age and three fibrosis markers: hyaluronic acid, N-terminal peptide of procollagen III (PIIINP), and tissue inhibitor of matrix metalloproteinase 1 (TIMP-1). Age was later omitted from the scoring system. More recently, PIIINP has been used as a standalone marker [75].

There are only limited data comparing individual scores. Some have found complex scores [83] to perform better than simple scores [BARD, APRI] while others have found comparable results [84]. Negative predictive values of over 90% were reported with APRI, BARD score, FIB-4, and NAFLD fibrosis score. However, 30–60% fall into the category of "indeterminate" and liver biopsy is still needed [83].

Current practice

There is no single non-invasive test that can accurately separate simple steatosis from NASH or assess fibrotic severity. In practice, combinations of serum biomarkers or clinical scores and/or transient elastography are used as "screening" tools. Liver biopsies are recommended for those who fall into the "indeterminate" and high-risk categories. Joint discussions with a gastroenterologist can help in selecting the appropriate diagnostic tests (including biopsy).

Table 51.8 Non-invasive scoring systems used in staging hepatic fibrosis.

Scoring system	Variables included	Interpretation of score	Reference
NAFLD fibrosis score	Age, BMI, IFG/diabetes, AST : ALT ratio, platelet count, albumin	2 cut-offs used. AUROC for 0.84 for advanced fibrosis. Lower cut-off has a NPV of 93% to exclude advanced fibrosis. Higher cut-off score has a PPV of 90% for ruling in advanced fibrosis	76
FibroTest	Age, alpha2-macroglobulin, total bilirubin, GGT and apolipoprotein 1	AUROC 0.75–0.86 for significant fibrosis; PPV 90% and NPV 73%	77
Original ELF score	Age, hyaluronic acid, PIIINP, TIMP-1	AUROC of 0.87; PPV 80%, NPV 95%	78, 79
(OELF)	Same as OELF except age excluded	Note: only 61 people with NAFLD included	
ELF score		AUROC same as OELF; PPV 42%, NPV 95%	
PIIINP	Serum PIIINP	AUROC 0.85–0.87 for distinguishing people with simple steatosis from those with NASH or advanced fibrosis	75
Fibrometer	Glucose, ferritin, platelet count, weight, age	AUROC 0.943 for significant fibrosis; PPV 88%, NPV 92%	79
FIB-4	Age, AST, ALT	AUROC for 0.802; NPV 90%	80
BARD	BMI > 28 kg/m^2, AST : ALT ratio, diabetes	AUROC 0.81, PPV 43%, NPV 96%	81
APRI	AST, platelet count	AUROC 0.85, NPV 93%	82

BMI, body mass index; AST, aspartate aminotransferase; ALT, alanine aminotransferase; GGT, gamma glutamyl transferase; AUROC, area under the curve; NPV, negative predictive value; IFG, impaired fasting glucose; PIIINP, N-terminal peptide of procollagen III.

Management

Diet and exercise

Lifestyle changes remain the cornerstone of management. Not only are they effective but also they are critical in managing the metabolic syndrome [85]. In fact, the "historical precedence" for lifestyle intervention in NAFLD is the structure and success of lifestyle intervention programs against T2DM among those with prediabetes (nearly all of whom will have NAFLD).

Diet

As a group, people with NAFLD consume high amounts of simple sugars (especially fructose), saturated fat, and lower amounts of omega-3 polyunsaturated fatty acids [PUFA] [86]. Therefore, dieticians recommend calorie restriction appropriate to gender, body mass index, and physical activity and restrict simple sugar and saturated fat (see Chapter 25). Pilot studies showing an improvement in NASH have encouraged consumption of PUFA-enriched diets or fish oil supplements [87]. However, a recent phase 2 placebo-controlled trial with ethyl eicosapentaenoic acid (EPA-E), a synthetic n-3 PUFA, showed no significant histologic benefits of EPA-E over placebo [88].

A 5% to 10% reduction in body weight can normalize liver tests, improve hepatic steatosis, lobular inflammation, and hepatocyte ballooning [89]. Crash diets achieving rapid weight loss (>1 kg/week) are discouraged because they can worsen steatohepatitis. Although there are initial quantitative differences in the amount of weight loss between the different diets available (e.g. low-carbohydrate, high-protein diets), these are not sustained at 2 years. Dietary adherence and an overall reduction in caloric intake are more important than macronutrient composition [90]. The effects on fibrosis are less pronounced but this may relate to the short study duration (often <1 year).

Physical activity

There is an inverse correlation between the intensity of physical activity and the risk of NAFLD. Current health recommendations are for at least 150 minutes of moderate intensity exercise a week. However, in a cross-sectional study of 813 people with NAFLD [91], only participants meeting the minimum criteria for *vigorous* exercise (75 minutes/week) were less likely to have advanced fibrosis (OR 0.53; 95% C.I: 0.29–0.97) or (NASH, OR 0.65; 95% C.I: 0.43–0.98). While increased exercise intensity is desirable, in this sedentary cohort, the target is likely to be achieved only through an incremental approach. A personal trainer and/or remote telephone or website support can help maintain adherence. When the effectiveness of such interventions were compared with a self-directed weight loss program, a greater proportion of people receiving support were successful in achieving 5% weight loss (38% to 41% vs. 5%, respectively) [92]. Whether the exercise prescription should involve aerobic or resistance training alone or a combination is unclear [93]. A pragmatic approach combines aerobic training on at least 5 days of week with two or three sessions of resistance training, with individual adjustments for comorbidities and overall conditioning.

Lifestyle intervention trials in people with NAFLD and T2DM

The Look AHEAD (Action for Health in Diabetes) study enrolled 5145 obese/overweight adults into two groups [94]. One group was assigned intensive lifestyle intervention (ILI) aimed at inducing a minimum of 7% weight loss while the other group received routine diabetes education support. An ancillary proton MRS study in 96 participants with NAFLD evaluated changes in liver fat (baseline vs. 1 year). The ILI group lost significantly more weight (8.3% vs. 0.03%), liver fat (51% vs. 23%), and had a greater reduction in HbA_{1c} (0.7 vs. 0.2%). There was a dose-response, with

the most striking reduction in hepatic steatosis confined to those showing a >10% reduction in body weight. Also, participants in the ILI arm without prior NAFLD were less likely to develop NAFLD (3% vs. 26% in the diabetes education support group).

The RAED2 trial compared aerobic exercise versus resistance training in 31 sedentary people with T2DM and NAFLD [95]. After 4 months, both groups showed improved insulin sensitivity and similar reduction in steatosis (by 26% to 32%), visceral and superficial subcutaneous adipose tissue content and HbA_{1c}. These studies endorse lifestyle measures as the first step in managing NAFLD.

Vitamin E

Oxidative stress is an important contributor to the pathogenesis of fatty liver. This has prompted randomized controlled trials of antioxidants such as vitamin E [96]. In the PIVENS study, participants were assigned to vitamin E (800 mg/day, $n = 84$), pioglitazone (30 mg/day, $n = 80$), or placebo ($n = 83$) for 96 weeks. Liver biopsies were obtained at baseline and at the end of treatment. The endpoint was an improvement in a composite score involving a combination of steatosis, lobular inflammation, and hepatocyte ballooning. The primary endpoint was only achieved by vitamin E (43% vs. 19% for placebo, $p = 0.001$). Pioglitazone also improved hepatic steatosis and lobular inflammation but not the composite score using the pre-specified p value of 0.025 (34% vs. 19% for placebo, $p = 0.04$). No significant changes in fibrosis were observed with either drug. Another pediatric trial (TONIC) comparing vitamin E with metformin and placebo [97] showed no significant inter-group differences with respect to the primary endpoint (ALT reduction) except for NASH resolution in the vitamin E group (58% vs. 28% for placebo, $p = 0.006$).

Although vitamin E is endorsed by some gastroenterology organizations, there are unresolved issues. Vitamin E has been linked to an increase in all-cause mortality, hemorrhagic strokes, and prostate cancer [4].

Thiazolidinediones ("glitazones")

Insulin resistance is also an important determinant of NAFLD. Rosiglitazone, now withdrawn, showed promise in NASH [98]. Subsequent studies have used pioglitazone (see PIVENS trial earlier). In a meta-analysis of seven randomized trials, thiazolidinediones were shown to improve steatosis, lobular inflammation and ballooning and even fibrosis. Inter-trial differences exist with regards to effects on ballooning and fibrosis [99]. Most of the benefits are seen in the first 1–2 years. Recurrence of NASH is frequent after discontinuation and side effects such as weight gain (mean 4.4 kg), an increased risk of bone fractures and bladder cancer are discouraging [4].

Metformin

Like thiazolidinediones, metformin is not recommended as a stand-alone drug for treating NASH. Small studies documented improvement in liver tests but there was little impact on liver histology as reiterated by a recent meta-analysis [100]. An emerging role is in the area of liver cancer prevention. In a meta-analysis of eight observational studies, metformin use was associated with a 50% reduction in the incidence of HCC (OR 0.5; 95% C.I: 0.34–0.73) [101]. *In vitro*, metformin (through AMP-activated kinase activation) has been shown to inhibit mTOR (mammalian target of rapamycin), a key signaling pathway that is upregulated in over 50% of HCCs [102].

Incretins

Incretin-based treatment strategies include drugs that mimic the action of endogenous glucagon-like peptide 1 (GLP-1). GLP-1 is secreted by intestinal L cells and is involved in blood glucose regulation through stimulation of glucose-dependent insulin release, decreased glucagon secretion, reduced gastric motility, and induction of satiety. Of relevance to fatty liver, GLP-1 also suppresses hepatic lipogenesis and increases hepatic fatty acid oxidation [103]. Further, an incretin-based approach to treatment is supported by the demonstration of GLP-1 receptors on hepatocytes [104] and evidence of diminished GLP-1 signaling in NAFLD.

GLP-1 has a very short half-life (1.5–2 min). Human studies involve analogs that mimic endogenous GLP-1 action (exenatide, liraglutide) or drugs that prolong its action by preventing its inactivation by dipeptidyl peptidase-4 (e.g. sitagliptin).

While preclinical data showed reduction in hepatic steatosis and studies in people with T2DM showed improvement in liver enzymes, human studies with histologic endpoints are lacking. In one 24-week study involving 10 people receiving liraglutide, a reduction in hepatic inflammation and fibrotic severity was seen in six and eight participants, respectively [105]. On the other hand, eight people with T2DM and NAFLD treated with exenatide improved their ALT levels but showed no histologic improvement [106]. Ongoing controversies relating to the risk of pancreatitis, pancreatic and thyroid cancer with these agents also need to be resolved (see Chapter 32).

Obeticholic acid (6-ethylchenodeoxycholic acid, OCA)

Lipophilic bile acids binding to farnesoid receptor X (FXR) improve insulin sensitivity, decrease hepatic gluconeogenesis and improve hypertriglyceridemia [107]. Further, a FXR agonist, such as OCA, also has antifibrotic effects and has been evaluated in human NASH. In a pilot study involving 41 people with diabetes ($n = 41$), OCA improved insulin sensitivity and ALT levels [108] and prompted a larger phase 2b randomized clinical trial (FLINT) involving 283 people with non-cirrhotic NASH [109]. Participants were randomized to OCA 25 mg ($n = 141$) or placebo ($n = 142$) daily for 72 weeks. Baseline and end of treatment liver biopsies were scheduled. The primary endpoint was an improved NAS score (Table 51.4) by 2 points without worsening of fibrosis stage. However, following an interim analysis, end of treatment biopsies were waived and ~20% did not undergo a second biopsy. Of those biopsied, an improved NAS score was noted in 45% and 21% in the OCA and placebo arms, respectively. However, resolution of NASH was modest (22% vs. 13%, $p = 0.08$). An improvement in fibrosis was also observed (35% vs. 19%) but again, there were

Table 51.9 Overview of current treatment approaches for managing NAFLD.

Treatment	Effects	Comments	Reference
Lifestyle measures (diet/exercise)	Improved aminotransferases, insulin sensitivity, and steatohepatitis	5% to 10% weight loss needed to achieve endpoints; high long-term attrition rates without supervision and reinforcement	89
Omega-3 polyunsaturated fatty acids	Improved aminotransferases, insulin sensitivity, and steatohepatitis	Not confirmed by a randomized controlled trial	88
Vitamin E	Improved aminotransferases, steatohepatitis	Concerns about increased all-cause mortality with long-term use	96
Pentoxifylline	Improved steatosis, lobular inflammation	Meta-analysis of 5 studies showed no significant histologic improvement	115
Insulin sensitizers			
Metformin	Improved aminotransferases, insulin sensitivity, weight loss	Improvement in steatohepatitis not different from placebo	100
Thiazolidinediones (pioglitazone)	Improved aminotransferases and insulin sensitivity; trend to improvement in steatohepatitis in randomized trial	Improvement in steatohepatitis not different from placebo Weight gain, need for long-term use, risk of bone fractures and heart failure	96
Glucagon-like peptide 1 agonists	Improved aminotransferases and insulin sensitivity	No randomized trials; limited data	105
Statins	Improved aminotransferases, variable effects on steatosis	No liver histology or randomized trial data Useful in managing dyslipidemia	3
Angiotensin-converting enzyme inhibitors (losartan)	Improved insulin steatohepatitis, steatohepatitis, and fibrosis	Small studies. Single randomized trial showed no benefit in comparison with rosiglitazone; no placebo arm in that study	116
Obeticholic acid	Modest improvement in steatohepatitis	Pruritus common; unfavorable effects on total/ LDL cholesterol	109
Bariatric surgery	Weight loss, steatohepatitis improved; slight worsening of fibrosis	Restricted to selected subgroups (morbidly obese); costs, side-effects need to be considered; increased risk in people with cirrhosis	113
Other agents			
Endocannabinoid antagonists (Rimonabant)	Improved aminotransferases, insulin sensitivity, and reduced steatosis	Causes depression; withdrawn	117
Ursodeoxycholic acid	Improved aminotransferases	No significant histologic benefit over placebo	118

no significant differences in the proportion of participants who had resolution of advanced (bridging) fibrosis (41% vs. 28%). Although well tolerated, pruritus was troublesome in the OCA group (23% vs. 6%, respectively). A further concern is a small increase in total and LDL cholesterol and a concomitant decline of HDL among those receiving OCA. In our opinion, these lipid changes among people with an already very high cardiovascular risk will limit enthusiasm for use of OCA in NASH.

Probiotics

The contributions of the gut microbiome to NASH (hepatic inflammasome activation by gut-derived bacterial endotoxin through TLR signaling) were alluded to earlier (also see Chapter 17). Studies have sought to manipulate the gut microbiota as a treatment strategy. In one, 48 children with NAFLD were given VSL#3 (a probiotic) or placebo for 4 months. VSL#3 contains a mixture of eight probiotic strains of Streptococcus thermophilus, Bifidobacteria, and Lactobacillus. The primary endpoint was a reduction in liver steatosis (by ultrasound). This was observed only in the VSL#3 group. At the end of treatment, there were fewer participants with moderate (9% vs. 55% at baseline) and severe steatosis (0% vs. 45%) in the VSL#3 arm [110]. Interestingly, significant weight loss and an increase in GLP-1 levels were noted in the VSL#3 arm alone. Further validation with histologic data is needed before probiotics can be recommended.

Statins and hyperlipidemia

Small case series noted improvement in serum aminotransferases and hepatic steatosis with statins. However, definitive histologic studies are lacking and therefore, they cannot be endorsed on their own for treating NAFLD.

Statins are often under-prescribed due to concerns of hepatotoxicity but these concerns are misplaced. The small increase in ALT seen in 2–3% of statin recipients is not a harbinger of serious liver injury. The latter (1/million) is very rare when considered in the context of their widespread use. Further, their safety is endorsed by studies involving people with normal or abnormal serum aminotransferases as well as those with established chronic liver disease [111]. Moreover, their impact on reducing cardiovascular events is particularly relevant to people with abnormal liver tests. In a *post hoc* analysis of the GREACE study, participants with abnormal liver tests receiving a statin had a 68% relative

risk reduction (10% vs. 30%) as compared with those not receiving them [112].

Bariatric surgery

This is currently indicated for people with a body mass index ≥40 kg/m^2 alone or ≥35 kg/m^2 with comorbid metabolic disorders. In addition to an improved metabolic profile, a reduction in hepatic steatosis and lobular inflammation are also observed. In a 5-year follow-up study of 381 people undergoing bariatric surgery, the proportion of participants with NASH was halved (14.2% vs. 27% at baseline). Some worsening of hepatic fibrosis was described but this was mostly mild (≤F1 in 96%) [113]. It should be noted that these procedures were done primarily for non-hepatic indications. People with cirrhosis were often excluded. While individuals with compensated cirrhosis are not barred from undergoing such procedures, they should be counseled about the potential for longer operating times, greater blood transfusion need, and operative risk [114].

Table 51.9 summarizes the different treatment strategies that been evaluated for NAFLD [115–118].

Managing people with cirrhosis

Patients should be monitored for signs of hepatic decompensation. They should undergo annual endoscopic screening for esophageal and gastric varices, annual bone densitometry, dietician, vaccination against hepatitis A and B, and seasonal influenza strains, and avoid hepatotoxic drugs, sedatives, complementary and alternative medicines, and non-steroidal anti-inflammatory drugs.

Hepatocellular carcinoma surveillance

The prevailing small but definite risk of HCC raises the question of routine surveillance. This is relevant because patients outside surveillance programs are more likely to present with larger tumors and receive curative treatment less often. Moreover, surveillance is cost-effective and thus recommended for people with cirrhosis [4], who should undergo 6-monthly abdominal ultrasound testing. The cost-effectiveness of HCC surveillance in the absence of cirrhosis is untested. Serum alfa-fetoprotein is insensitive (40% have normal AFP levels) and has been abandoned as a tumor marker.

Liver transplantation

People with decompensated liver disease should be referred for liver transplantation. Currently, NAFLD is the most common indication for liver transplantation in persons over 65 years. Overall, fatty liver is listed as the primary indication in ~10% of liver transplants [119] and is on course to becoming the leading indication within the next two decades. Short-term patient and graft survival rates are similar to people with alcoholic liver disease and better than that for those with chronic hepatitis C [120]. However, some studies have identified "high-risk" groups with a poor transplant outcome. Patients over 60 years, BMI ≥ 30 kg/m^2 with diabetes and hypertension had a 50% one-year mortality [121]. Moreover, recurrence of NAFLD is frequent. Nearly half will develop hepatic steatosis within 5 years. Seven to thirty percent will develop NASH and 10% will progress to cirrhosis within 10 years [121]. NAFLD is also seen in 10–20% of recipients undergoing liver transplantation for non-NAFLD indications. Therefore, aggressive preventive and treatment strategies aimed at optimizing metabolic control are critical.

Pediatric NAFLD

This is beyond the scope of this chapter and the reader is referred to recent reviews [122]. A few key points will be highlighted. The prevalence figures for NAFLD in children are ~10% (autopsy data) and 17% in adolescents [15]. Lower prevalence frequencies are reported in ALT/ultrasound-defined NAFLD studies. There are strong ties with obesity, with over half (53%) of obese children having NAFLD. Of these, up to 83% have at least one feature and up to 29% fulfill criteria for the metabolic syndrome [123]. Inherited genetic disorders presenting as steatosis are more prevalent in children than in adults and need to be considered. Indications for liver biopsy and diagnostic techniques are similar to those for adults. A typical pediatric pattern of NAFLD (hepatic steatosis with portal inflammation) is characteristically seen in up to half of the liver biopsies [34]. Natural history data with histological information are limited. While largely benign, advanced fibrosis, NASH, and cirrhosis can occur. The high frequencies of occurrence of severe disease (NASH in 84%, advanced fibrosis in 3%, need for liver transplantation) have been mostly in case series from tertiary centers and likely represent selection bias [123]. Treatment strategies are also similar with lifestyle intervention measures being the preferred approach. Although there are data (TONIC trial) supporting the use of vitamin E, long-term safety concerns preclude widespread use [97].

52 The Skin in Diabetes

Graham R. Sharpe[1] and Paul D. Yesudian[2]
[1] Department of Dermatology, Clatterbridge Hospital, Wirral, UK
[2] Consultant Dermatologist, Department of Dermatology, Glan Clwyd Hospital, Bodelwyddan, UK

Key points

- There are many skin manifestations associated with diabetes, some relatively specific while others are commoner amongst individuals with diabetes than those without.
- Acanthosis nigricans, pigmented papillomatous overgrowth of the epidermis seen in flexures, is associated with hyperinsulinemia.
- Many of the metabolic changes in the skin are related to glycation of structural proteins that occurs more extensively in diabetes.
- Necrobiosis lipoidica is most frequently seen in type 1 diabetes (T1DM), often on the shins in women. It remains problematic to treat.
- Thickening, loss of elasticity and yellowing of the skin are related to glycation of collagen and elastin in the skin.
- There are a number of vascular changes in cutaneous vessels with reddening and telangiectasia of the skin similar to premature degenerative aging of the skin.
- Skin infections, particularly *Candida,* may occur in poorly controlled diabetes.
- Necrolytic migratory erythema is a pathognomic sign of the rare glucagonoma syndrome.
- Reactions to recombinant human and analog insulin preparations and newer classes of antidiabetes agents are unusual.

Introduction

Many skin disorders are associated with diabetes. Some are relatively specific to the condition, usually caused by the metabolic changes in diabetes or side-effects of treatment, whilst others are non-specific but occur more frequently than in individuals without diabetes. The classification used in this chapter, including associated conditions and infections, is shown in Table 52.1.

Metabolic manifestations

This group includes a number of conditions that appear specific to diabetes (e.g. diabetic thick skin) or are much commoner than in the general population (e.g. necrobiosis lipoidica) [1]. The etiology of these conditions is largely related to the process of non-enzymatic glycation of cutaneous structural proteins or hyperinsulinemia.

Acanthosis nigricans

This condition is characterized by a velvety papillomatous overgrowth of the epidermis, which is usually hyperpigmented. The flexural areas, particularly the axillae, groins, inframammary region and neck, are most frequently affected and may become macerated or malodorous if severe [1] (Figure 52.1). Rarely, more generalized changes involve the knuckles, other extensor surfaces, palms, and soles. Histologic features include extensive hyperkeratosis, papillomatosis, acanthosis with retained keratotic material, which accounts for the dark color.

Acanthosis nigricans is associated with various endocrine disorders, which share the common features of insulin resistance and hyperinsulinemia: these include diabetes mellitus, acromegaly, Cushing disease, polycystic ovarian disease, obesity, metabolic syndrome, and genetic and autoimmune insulin receptor defects [2]. A severe malignant form is associated with gastric adenocarcinoma. It is believed that hyperinsulinemia induced by insulin resistance activates type 1 insulin-like growth factor receptors, on various tissues including epidermal cells and fibroblasts [3]. Stimulation of keratinocyte proliferation gives rise to hyperkeratosis and acanthosis (Figure 52.2).

Acanthosis nigricans, which can be disfiguring and upsetting, is most frequently seen in type 2 diabetes (T2DM) and obesity. Management is by reducing the underlying cause; particularly, weight reduction in obesity and increasing physical activity reverses the changes [4]. Topical retinoids, calcipotriol, and mild peeling agents such as salicylic acid or lactic acid may be helpful for limited involvement. Systemically metformin and rosiglitazone reduce insulin levels and give modest improvement in the condition [5].

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

Table 52.1 Cutaneous manifestations of diabetes.

Metabolic manifestations:		Acanthosis nigricans Diabetic bullae Eruptive xanthomas Diabetic scleredema	Achrochordons Necrobiosis lipoidica Diabetic thick skin Yellow skin and nails
Vascular changes		Diabetic dermopathy Periungual telangiectasia Lower limb vascular changes	Facial rubeosis Perforating disorders Calciphylaxis
Infections	*Bacterial*	Staphylococcus Erythrasma Malignant otitis externa	Streptreptococcus Necrotizing fasciitis
	Fungal/Yeast	Dermatophytosis Mucormycosis	Candida
Associated conditions		Pruritus Lichen planus Clear cell syringomas	Vitiligo Glucoganoma Disseminated granuloma annulare
Iatrogenic		Insulin-induced **a** Immediate: localized/generalized **b** Delayed: lipodystrophy Reactions to oral hypoglycemic agents	

Figure 52.1 Acanthosis nigricans, showing typical dark velvety appearance: (a) in the axilla; (b) in the groin. Source: (b) Courtesy of Dr. S. Mendelsohn, Countess of Chester Hospital, Chester, UK.

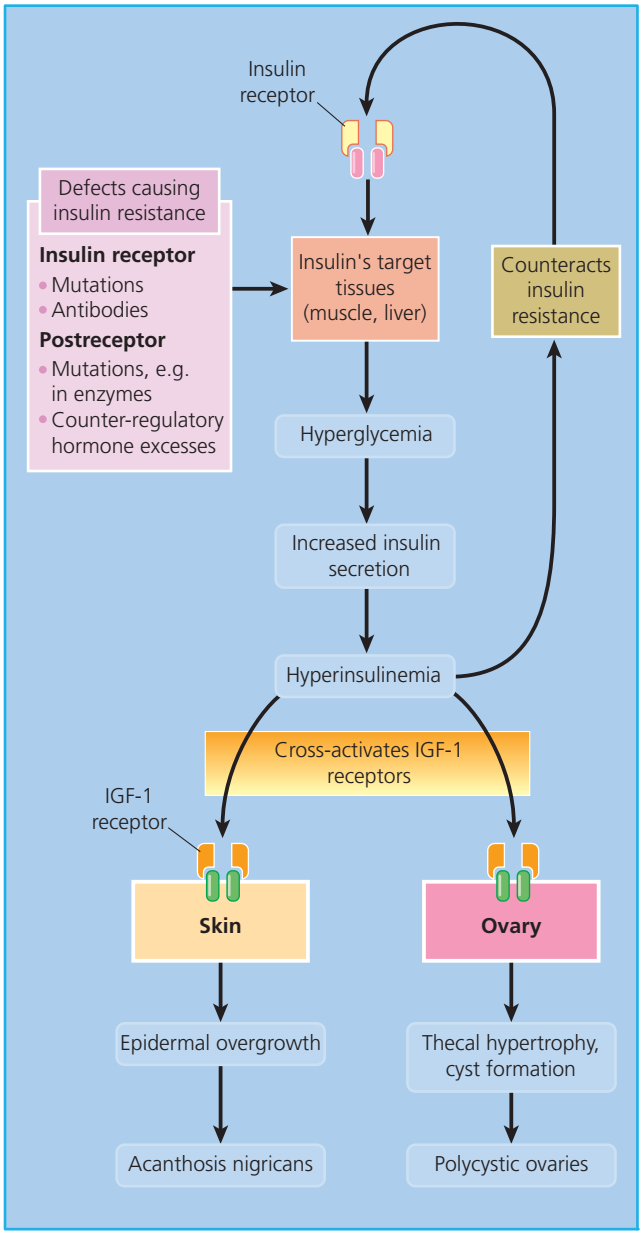

Figure 52.2 Suggested relationship of insulin resistance and hyperinsulinemia to acanthosis nigricans. Raised insulin levels may act on type 1 insulin-like growth factor receptors in the skin to cause epidermal overgrowth. Similar events in the ovary could lead to polycystic ovary disease, which is also associated with insulin-resistant states.

Achrochordons (skin tags)

Skin tags are benign, soft, fleshy skin-colored fibromas, which occur with increasing age and are particularly common in people with diabetes [6]. They may occur in at least 66% of individuals with diabetes and are probably related to the proliferative effect of hyperinsulinemia on keratinocytes and fibroblasts as in acanthosis nigricans [7]. Large numbers may be a marker of impaired glucose tolerance [8]. Skin tags occur predominantly in flexural regions around the eyes, neck, axillae, and in women in the inframammary area. Treatment is usually not required although if they cause discomfort through irritation or give cosmetic concern snip excision or electrodesiccation is effective.

Necrobiosis lipoidica diabeticorum

Necrobiosis lipoidica is a chronic granulomatous skin condition that most frequently affects the shins of those with T1DM. This is a rare condition with a 1% prevalence in people with diabetes [9, 10]. Although it is much commoner in individuals with diabetes, the relationship to diabetes and the etiology of necrobiosis lipoidica remains unclear. In a retrospective study only 22% of 65 participants with necrobiosis lipoidica had or developed diabetes in a 15-year follow-up. Necrobiosis lipoidica may precede the onset of diabetes by years, develop concurrently or years later. The presence of necrobiosis lipoidica is thus an indication for investigation of possible diabetes and future monitoring. Necrobiosis lipoidica usually develops in young adults or early middle life, but has been reported in children with T1DM [11]. Women are three times more commonly affected than men. There is no proven association with glycemic control, but people with diabetes and necrobiosis lipoidica appear to have a higher incidence of chronic diabetic complications such as retinopathy, neuropathy, and microalbuminuria [12].

Necrobiosis lipoidica has a distinctive appearance (Figure 52.3). Early lesions may be rounded, dull red, symptomless papules or plaques, which slowly progress to the typical chronic lesion—an oval or irregularly shaped indurated plaque with central atrophy. Necrobiosis lipoidica often has a shiny surface, with prominent telangiectatic vessels crossing over a waxy yellowish central area due to lipid deposition. The margin of lesions may be brownish or red and sometimes with comedo-like plugs, where necrotic material is extruded through the surface. The shin is the most commonly affected site, but the thighs, ankles, and feet may also be affected; lesions rarely occur on the trunk, upper limbs, or scalp [12]. Ulceration occurs in up to 35% of cases and may be very slow to heal. Necrobiosis lipoidica lesions are usually partially or completely anesthetic and alopecia is frequently present. Lesions are variable in number but usually few and most extend slowly over several years, sometimes coalescing with adjacent areas. Long periods of quiescence may occur or occasionally lesions may heal with scarring. The condition can lead to significant morbidity and cosmetic disfigurement. The diagnosis is usually clinical; a diagnostic skin biopsy is not normally required and may risk ulceration in atrophic lesions. The differential diagnosis of early lesions includes granuloma annulare, cutaneous sarcoid, necrobiotic xanthogranuloma, and diabetic dermopathy.

Histologically, necrobiosis lipoidica lesions consist of foci of degenerate collagen bundles with a hyalinized appearance (necrobiosis), surrounded by fibrosis, with diffuse or perivascular infiltrate of histiocytes, lymphocytes, and plasma cells. Frequently a palisading granulomatous reaction with giant cells is seen (Figure 52.4). These abnormalities occur throughout the dermis with telangiectasia and epidermal thinning [13]. There is considerable overlap between these features and those of granuloma annulare.

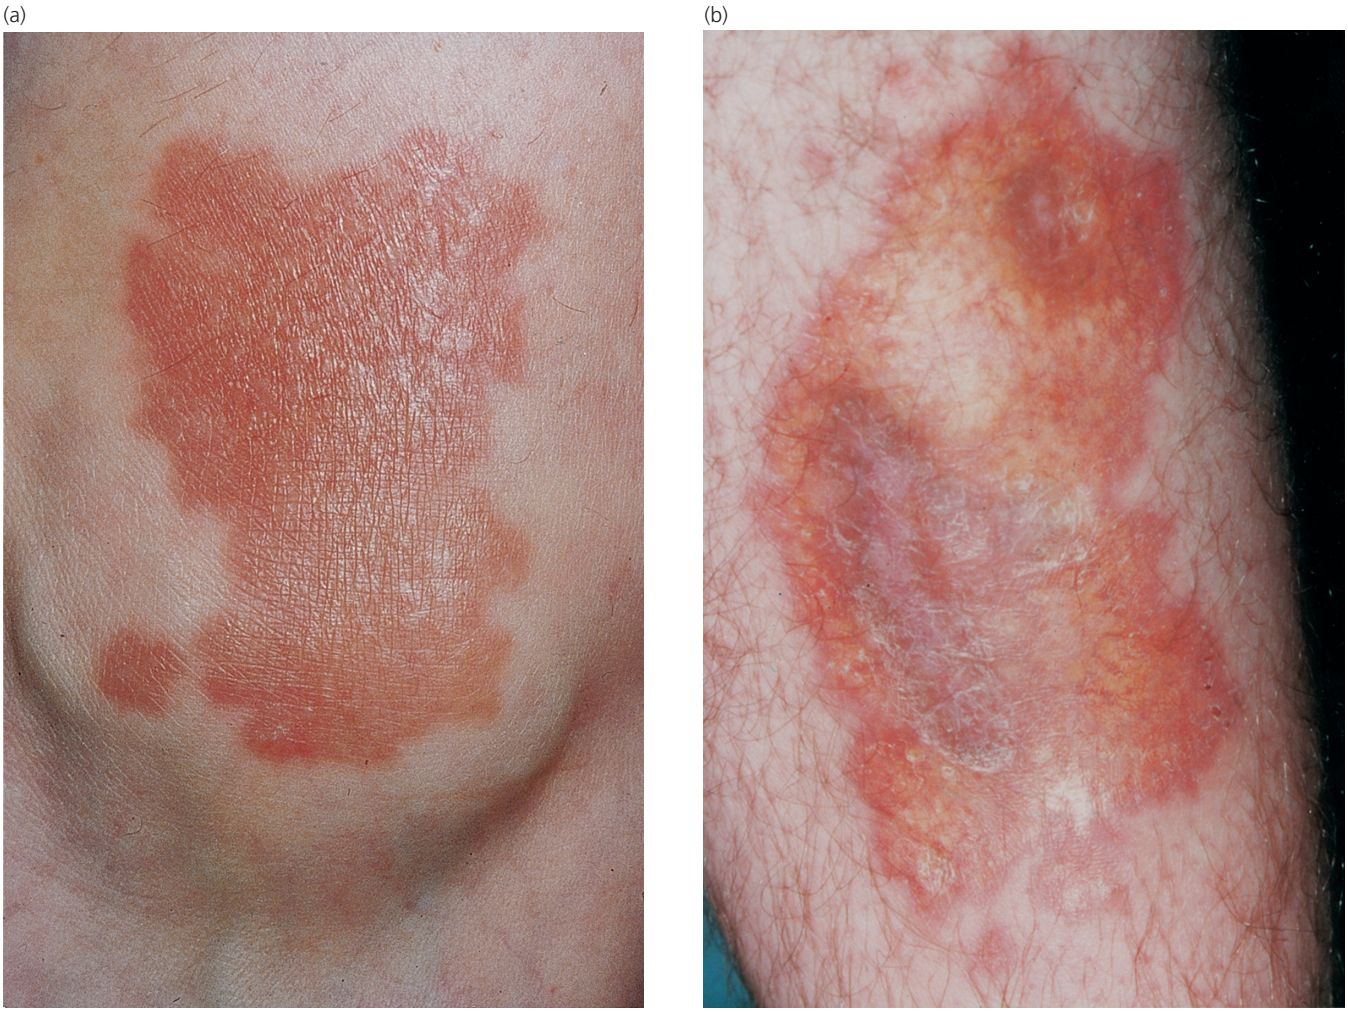

Figure 52.3 Necrobiosis lipoidica diabeticorum. (a) An early lesion on ankle showing the erythematous stage. (b) A long-standing area of necrobiosis lipoidica, note the typical yellow atrophic appearance with telangiectasia.

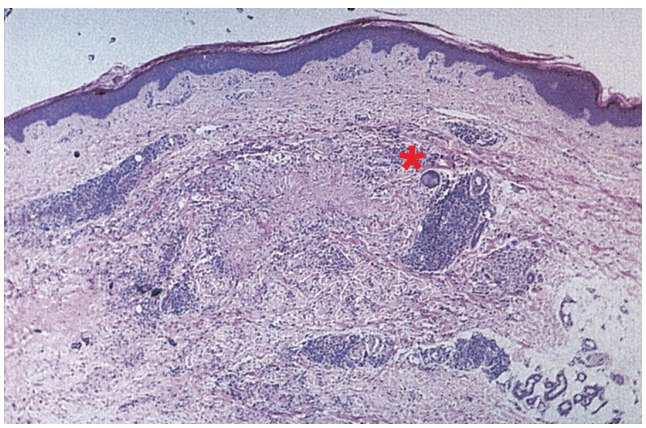

Figure 52.4 Histologic feature of necrobiosis lipoidica diabeticorum showing degeneration of the collagen (necrobiosis), associated with fibrosis and a granulomatous histiocytic infiltrate. A giant cell is indicated by an asterisk. Hematoxylin and eosin stain ×40.

The similarity contributed to the suggestion that localized granuloma annulare is associated with diabetes. Despite histologic similarities in the earlier stages of the two conditions, they run a very different clinical course and only the generalized form of granulare annulare is linked to diabetes [13].

No treatment for necrobiosis lipoidica has proved effective in double-blind placebo controlled trials and treatment remains unsatisfactory. Spontaneous remission is unusual and good diabetic control does not usually have a significant effect on the course of the condition. Patients should be encouraged not to smoke and to avoid trauma to the area, which may result in a painful and recalcitrant ulcer. The multitude of case reports of diverse treatments suggests that there is no established benefit for most of these [1]. In many cases, cosmetic camouflage may be the preferred option. Topical steroids, calcineurin inhibitors and psoralens with ultraviolet A (PUVA) are the most used therapies [14].

For early lesions corticosteroids either applied topically (perhaps under occlusion) or by intra-lesional injection may be

beneficial [15]. The inflammatory process extends beyond the clinical margins and topical steroids may halt or slow progression if applied to the periphery of lesions. Once atrophy has developed this is irreversible and topical steroids should not be used in chronic lesions because they may worsen skin atrophy. An alternative to steroids is the calcineurin inhibitor tacrolimus applied topically which will not cause atrophy. Several small open studies report an approximately 50% response rate to topical PUVA [16] while topical retinoids may be beneficial in atrophic cases [17]. Pulsed dye laser treatment may improve telangiectasia and erythema but there is a risk of skin breakdown. There are reports of good results following excision and grafting, although the disease may recur locally. The tumor necrosis factor α (TNF-α) antagonists infliximab and etanercept are reported beneficial for ulcerative necrobiosis lipoidica [18]. Most recently topical application platelet-rich plasma has shown encouraging results in ulcerated lesions. In an open study, all 15 participants showed marked reduction in ulcer size after 10 weekly applications [19].

Diabetic bullae (bullosis diabeticorum)

Diabetic bullae affect men more than women and are more common in older people and those with peripheral neuropathy [20]. The conditions usually present as tense sterile blisters, from a few millimeters up to several centimeters in size, on a non-inflammatory base, appearing rapidly and healing over a few weeks without scarring (Figure 52.5). The feet and lower legs are the commonest sites, followed by the hands. The condition is most commonly seen in long-standing T1DM with late complications. Electron microscopy studies demonstrate a subepithelial split at the level of the lamina lucida and immunofluorescence studies are negative [21]; however, the etiology of bullae is unclear. Other causes of subepithelial blisters, including the autoimmune blistering diseases porphyria cutanea tarda, pseudoporphyria, and infections such as bullous impetigo need to be excluded. Treatment is normally supportive to prevent secondary infection although surgical debridement and negative pressure dressing has been proposed [22]. Aspirating tense blisters to prevent rupture may be required and most heal within a few weeks.

Diabetic thick skin

The skin of individuals with diabetes is measurably thicker by ultrasound than in people without diabetes [23] and shows loss of elasticity [24]. Thickening is most often seen on the hands and feet and may progress to finger pebbles, groups of indurated papules on the extensor aspect of the fingers and knuckles. Milder changes are seen in a minority of older people without diabetes. The thickness of the skin is largely attributable to the filamentous proteins of the dermis, of which collagen is by far the most abundant. In people with diabetes, the collagen bundles are thickened and disorganized, as a result of irreversible non-enzymatic glycation, and cross-linking of protein. The formation of advanced glycation end-products (AGEs) damages the protein thereby reducing the ability of enzymes such as collagenase to remodel the fibers [25]. Gradual and irreversible modification of collagen, elastin and other structural dermal proteins is part of the physiologic aging process, but is accelerated in diabetes, especially if poorly controlled.

Skin thickness shows some correlation with duration of diabetes [26] and the presence of complications such as neuropathy and microangiopathy [9, 27]. Topical emollients help with the associated skin dryness, but there is no effective treatment. Tight glycemic control may slow the development of skin thickening. Whilst skin thickness is often clinically insignificant when advanced it may lead to the specific complications of "diabetic hand syndrome" and diabetic scleredema [28]. The combination of thick tight waxy skin and limited joint mobility has been called cheiroarthropathy and is present in up to a fifth of people with T1DM [29].

Diabetic hand syndrome usually occurs in those over 60 years of age (see Chapter 53) [30]. The early changes include thickening of the skin over the dorsum of the hands and digits, especially the proximal interphalangeal joints (sclerodactyly). More extreme cases present with a tight waxy appearance together with pebbly pads over the knuckles and distal fingers. The interphalangeal joints are particularly susceptible and involvement of periarticular connective tissue contributes to painful stiff fingers [31]. In a minority, the condition progresses to cause a fixed flexion deformity of the fingers and Dupuytren contracture, while soft tissue thickening of the wrist may cause carpal tunnel syndrome by compression of the median nerve.

Scleredema of diabetes

This is marked dermal thickening, commonly involving the posterior aspect of the neck and upper parts of the back, and extending to the face, arms, and abdomen with more severe involvement but sparing acral areas. It has a prevalence of 2.5–14% in diabetes and

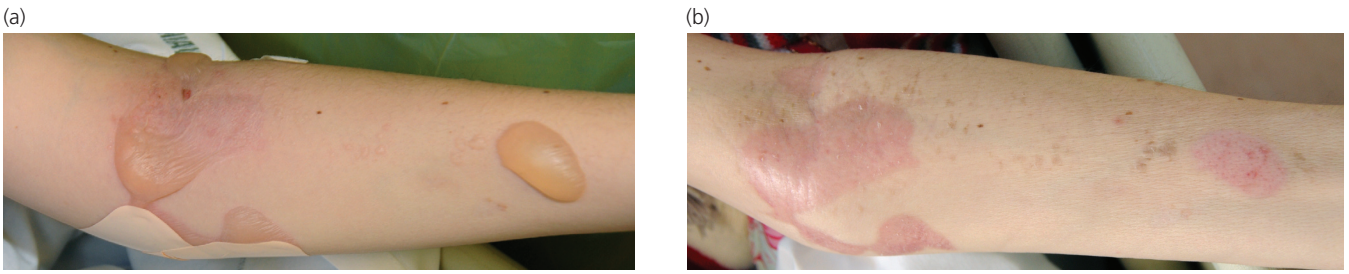

Figure 52.5 Diabetic bullae. (a) Acute bullae on an arm. (b) Resolving lesions 14 days later.

is found particularly in men with T2DM and those who are overweight and with poorly controlled diabetes [32]. The skin is hard, thick and may be indurated and erythematous. Histology of the condition shows dermal thickening that contains large collagen bundles and an increased number of mast cells [28]. Scleredema, with similar morphologic changes, may follow chronic streptococcal infection of the skin, often involving the lower legs. No therapy is very effective for scleredema although response to ultraviolet light or PUVA [33] has been reported. Strict glycemia control is recommended as this may slow the progression.

Yellow skin and nails

Individuals with diabetes develop yellowish skin and nails more frequently than the general population. This is most noticeable on the palms and soles. It has been referred to as carotenemia, but there is little evidence to support the theory that carotenoids are the cause [34]. The most probable explanation is that the discoloration is due to non-enzymatic glycation of dermal collagen. The end product 2-(2-furoyl)-4[5](2-furanyl)-1H-imidazole has a yellowish color. This occurs to a much greater extent in the hyperglycemia of diabetes compared to individuals without diabetes. Yellow nails have frequently been noted in persons with diabetes, particularly the distal hallux [35]. An early sign of diabetes may be the presence of a yellowish or brownish discoloration in the distal part of the hallux nail plate. The canary yellowish hue that can affect the toe and finger nails is distinct from the yellowish discoloration seen in association with onychomycosis. A study of fingernails has shown that people with diabetes have high levels of furosine-lysine, another marker of non-enzymatic glycation [36]. Whilst these appearances may give cosmetic concerns it is benign and there is no effective treatment.

Eruptive xanthomas

Eruptive xanthomas are rare and pathognomonic of hypertriglyceridemia. This can occur at the initial presentation of T1DM when there is insulinopenia [6]. Insulin is a stimulatory factor for lipoprotein lipase which if not activated leads to impaired clearance of very-low density lipoproteins and chylomicrons. Xanthomas present as clusters of yellowish papules of triglyceride up to 5 mm on extensor surfaces of the limbs and buttocks (Figure 52.6). The onset is usually rapid and lesions frequently occur in groups or crops with surrounding erythema initially). Men are more commonly affected. Although xanthomas may itch initially, they are usually asymptomatic. Lesions usually regress slowly within months after hypertriglyceridemia has been corrected by lipid-lowering drugs or improved glycemic control.

Vascular changes

Diabetic dermopathy (shin spots)

This is the commonest dermatological condition associated with diabetes, occurring in up to 50% of people with diabetes and nearly 3% of the adult general population, who usually have only one or two lesions. By contrast, most individuals with diabetes have four or more [37]. Men are more frequently affected. It is commoner in those over 50 years of age and in long-standing diabetes. The condition is associated with neuropathy, nephropathy, and retinopathy, and also coronary artery disease [38]. The presence of diabetic dermopathy is a subtle sign that suggests more serious complications [39]. Diabetic dermopathy does not correlate with obesity or hypertension in individuals with diabetes [40]. The presence of microvascular changes, notably thickening of arterioles and capillaries led to the term "diabetic dermopathy" [41]. It has been hypothesized that diabetic dermopathy arises from local abnormal blood flow. This was confirmed with laser Doppler technology, which revealed a functional abnormality in blood flow in 25 people with diabetes compared to 67 people without diabetes [42].

The lesions are well-circumscribed, atrophic, brownish scars often on the shins, giving the alternative name "diabetic shin spots" [37] (Figure 52.7). The forearms, thighs, and bony

Figure 52.7 Diabetic dermopathy, "shin spots." Source: Courtesy of Professor Julian Verbov, Royal Liverpool University Hospital, UK.

prominences may also be affected [40]. The lesions are usually bilateral and may appear in crops. Early lesions are oval, red papules measuring up to 1 cm in diameter, which slowly develop scaling and a brown color due to the presence of hemosiderin-laden histiocytes and extravasated erythrocytes in the superficial dermis. There is no recommended treatment as they are usually asymptomatic and tend to resolve over 1–2 years. However, it is worthwhile screening for other microangiopathic complications of diabetes [43].

Rubeosis faciei

Rubeosis faciei is the chronic flushed appearance in the face and neck of people with diabetes [44]. The intensity of coloration is dependent on the vascular engorgement in the superficial venous plexus [45]. The changes occur due to altered vascular tone or diabetic microangiopathy. It appears more obvious in fair-skinned individuals and can be difficult to distinguish from normal facial redness in the general population. The condition may be improved with glycemic control and avoidance of vasodilators (caffeine and alcohol) [43].

Periungual telangiectasia

Erythema of the skin surrounding the nail bed resulting from the dilatation of proximal nailfold capillaries is an excellent marker of functional microangiopathy [46]. It can occur in up to 49% of people with diabetes. Even though connective tissue diseases can exhibit similar periungual telangiectases, the lesions are morphologically different. In those with diabetes, isolated homogenous engorgement of venular limbs is seen, whereas mega-capillaries or irregularly enlarged loops are observed in connective tissue disease [47].

Lower limb vascular changes

An erysipelas-like erythema with well-demarcated patches of cutaneous reddening, occurring in the legs and feet of people with diabetes is described. It can be mistaken for erysipelas, but is differentiated by the lack of associated fever, leukocytosis, or elevated erythrocyte sedimentation rate [48]. Cutaneous signs of ischemia in the lower limbs include cold or cyanosed feet, erythema, hair loss, and atrophy. A sign of large-vessel disease is dependent rubor with delayed return of color (>15 s) after pressure has been applied to the skin. Individuals with diabetes who have both venous insufficiency of the lower legs and arterial disease are particularly prone to developing non-healing ulcers; these frequently become superinfected and can be very troublesome to manage. Neuropathy, with lack of pain sensation, also contributes to lower leg injury and ulceration. Repeated trauma and increased shear forces affect the skin without the usual protective mechanisms that are impaired by peripheral neuropathy, leading to further skin breakdown [49]. Compared to people without diabetes, the risk for gangrene and amputation is higher in those with diabetes [50].

Perforating dermatoses

Reactive perforating collagenosis (folliculitis) is a condition characterized by transepidermal elimination of degenerative collagen and is seen in end-stage renal disease caused not only by diabetes, but other conditions as well [51]. It presents with pruritic hyperkeratotic papules on the extensor surfaces of the lower limbs, but can occur on the trunk and face. Histology reveals an atrophic epidermis surrounding a plug of degenerate material consisting of elastin and collagen [47]. It is thought to be a disorder of keratinization that engenders a proliferation of epidermis to eliminate abnormal tissue. Although it appears to be an inflammatory condition, microvasculopathy has been noted in the underlying dermis of biopsy specimens [52]. The lesions can be exacerbated by injury or excoriation. It is notoriously difficult to treat but may be helped by topical steroids and retinoids, failing which phototherapy is an option. Management of the underlying renal insufficiency or diabetes may be beneficial. The effectiveness of doxycycline and allopurinol has also been documented [53, 54].

Calcific uremic arteriolopathy (calciphylaxis)

Calcific uremic arteriolopathy is a small-vessel vasculopathy occurring in renal failure and, sometimes, in persons with

diabetes. It is characterized by mural calcification, intimal proliferation, fibrosis, and thrombosis [55]. The lesions start as localized areas of erythema and tenderness of the skin that become ischemic forming a livedo-reticularis pattern. This leads to the development of subcutaneous nodules and poorly healing, necrotizing skin ulcers. They can serve as a portal of entry for infectious agents. It usually affects the extremities but can involve the abdomen and buttocks as well. The prognosis in those with calciphylaxis is poor due to impaired wound healing and infection leading to sepsis. Treatment is usually unsatisfactory. Aggressive analgesic therapy may be required for ischemic pain, along with optimal blood glucose control and weight reduction [56, 57]. Newer treatments in the setting of renal failure include sodium thiosulphate [58] and cinacalcet hydrochloride [59].

Infections

Studies have shown that there is no significant increase in the prevalence of infections in most people with diabetes and the strength of previously assumed associations have been questioned (see Chapter 55) [60]. However, poor glycemic control can increase the risk of infection by causing abnormal microcirculation, decreased phagocytosis, impaired leucocyte adherence, and delayed chemotaxis [61].

Bacterial infections

Furuncles, carbuncles, folliculitis, and erythrasma were particularly frequent before the introduction of insulin and antibiotics, and skin infections due to *Staphylococcus aureus* are still probably commoner in those with diabetes.

Severe ("malignant") otitis externa is an uncommon but potentially lethal infection caused by invasive *Pseudomonas* spp. It occurs in elderly people with diabetes and manifests as purulent discharge with severe pain in the external ear. It progresses from cellulitis to osteomyelitis, meningitis, and cerebritis. Subsequent cranial nerve damage can also occur and carries a high mortality [62]. Treatment involves ear canal irrigation, skin debridement and systemic antibiotics, particularly quinolones [63].

Erythrasma, caused by *Corynebacterium minutissimum*, is rare and occurs with increased frequency in obese people with diabetes. It presents as a red, shiny or scaly patch in the intertriginous areas and with UV light exhibits a characteristic coral-red fluorescence. Topical or systemic erythromycin is curative. Unusual infections with coliforms or anaerobes occur in those with diabetes as can *Pseudomonas* infections of the toe web spaces or nail-fold (paronychia) and secondary infection of venous ulcers [64.] Anaerobic cellulitis with *Clostridium* species can occur in people with diabetic ketoacidosis, requiring aggressive debridement of devitalized tissue, and intravenous antimicrobial therapy [55].

Necrotizing fasciitis is a potentially lethal skin and soft tissue infection that is commoner in people with diabetes [65]. The infection has mixed flora including *Streptococcus pyogenes*, anaerobic *Streptococci*, *Bacteroids*, and *Stapylococcus aureus* and may arise from trivial wounds like injection sites, or begin from decubitis ulcers. It presents initially with the triad of pain, swelling, and erythema [66] and can be misdiagnosed as cellulitis (Figure 52.8). An initial clue to necrotizing fasciitis is that the pain is out of proportion to the swelling or erythema with tenderness beyond the apparent involved area. Rapid progression ensues with extensive tissue destruction and severe systemic toxicity, leading to death. Necrotizing fasciitis should be treated with extensive surgical debridement of necrotic tissue and high-dose antibiotics, with blood and tissue culture. The mortality remains high in spite of optimal treatment [67]. This condition should be considered in those with cellulitis who have associated systemic features like tachycardia, leucocytosis, marked hyperglycemia, or acidosis.

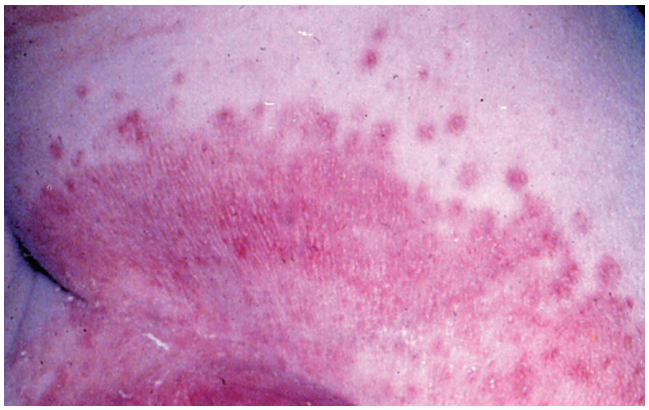
Figure 52.8 Severe infection in a person with diabetes that led to necrotizing fasciitis.

Fungal/yeast infections

Candida

Infection with *Candida albicans* may be a presenting feature of diabetes or manifest as a complication of poorly controlled diabetes. The infection appears as erythematous papules, coalescing to form glazed plaques, with satellite pustules affecting the flexural areas in the body, the vulva, and penis (Figure 52.9a). In women, vulvovaginitis is the commonest manifestation and presents with pruritus vulvae that can be intense and distressing. The vulva appears erythematous and fissured with peripheral pustulation in severe cases and may be particularly troublesome in hyperglycemia with

(a)



(b)

Figure 52.9 *Candida* infections in people with diabetes. (a) Flexural infection showing satellite lesions. (b) Chronic paronychia caused by *Candida albicans*. Note swollen and erythematous nailfolds.

glycosuria [65]. Candida balanitis, balanoposthitis, and phimosis occurs less commonly in men, but may be a presenting feature [68]. Candida angular stomatitis and an atrophic tongue resembling median rhomboid glossitis are oral manifestations of diabetes. Oral candidiasis occurs more commonly in people with diabetes who smoke or wear dentures [69]. Candida intertrigo occurs on opposing surfaces under the breast, in the groins and axillae, or in the folds of the abdominal skin.

Candida infection of the hands and feet are probably equally seen in people with diabetes as those without, but tends to be more severe in the former. Chronic paronychia presents as swelling and erythema around the lateral nailfold, with more severe involvement leading to onycholysis (Figure 52.9b). Microscopic examination and culture of the extruded material will confirm the infection. Less common than paronychia is infection of the web space between the middle and fourth finger (erosion interdigitale blastomycetica) [70]. Exclusion of moisture is an essential aspect to the treatment, and systemic antifungal drugs (e.g. oral fluconazole or itraconazole), rather than topical preparations may be required.

Dermatophytosis

Dermatophyte skin infections are probably not commoner in people with diabetes [60]. However, epidemiological studies have shown a higher incidence of onychomycosis in individuals with diabetes; the severity of the nail disease correlates with the duration of diabetes [71]. Fungal skin infection can serve as a portal of entry for other infectious agents, particularly in those with neurovascular complications. *Trichophyton rubrum* is the commonest pathogen, causing erythematous lesions that are often annular with scaly edges. Intertrigo or interdigital infection presents as maceration and superficial scaling. The diagnosis is confirmed by finding fungal hyphae in the superficial scale, ideally taken from the edge of the lesion. Treatment is with a topical imidazole antifungal or terbinafine, although extensive systemic itraconazole or terbinafine may be required. Severe onychomycosis can contribute to foot ulcers and hence require treatment with topical and systemic antifungal therapy, proper nail maintenance, and aggressive debridement [72].

Phycomyces infections

Poor metabolic control, resulting in hyperglycemia and ketoacidosis, may permit organisms that are normally non-pathogenic to establish infections in traumatized skin [73]. Leg ulcers or non-healing surgical wounds may have super-added phycomycete infections. Deep phycomyces infection like rhinocerebral mucormycosis is a rare but life-threatening complication of diabetes. Early manifestations include facial or ocular pain and nasal stuffiness, which progresses to fever, facial cellulitis, periorbital edema, proptosis and rarely, blindness [74]. The infection spreads along the turbinates, septum, palate, maxillary and ethmoid sinuses and can extend into the frontal lobe, cavernous sinus, or carotid artery. It should be suspected in anyone with diabetes presenting with sinusitis, purulent nasal discharge, altered mentation, and infarcted tissue in the nose or palate. Treatment involves correction of acid-base imbalance, aggressive debridement of devitalized tissue and intravenous antifungal therapy.

Associated conditions

These are a group of dermatoses that are reported more commonly in individuals with diabetes.

Vitiligo

Vitiligo is a common autoimmune condition characterized by complete loss of pigment in the skin. The exact pathogenesis is unknown. It is seen more frequently in T1DM, but can occur in type 2 diabetes as well. Polyglandular autoimmune syndrome type 2 is characterized by adrenal failure, autoimmune thyroid disease and T1DM, and can be associated with vitiligo [75]. It manifests as patchy, symmetrical depigmented areas of skin and although asymptomatic, can cause significant emotional distress.

Treatment is unsatisfactory although topical steroids and calcineurin inhibitors can be used. Patients should be advised on photoprotection.

Lichen planus

Lichen planus is an inflammatory disorder of the skin recognized by the presence of violaceous flat-topped polygonal papules, distributed in the flexural aspects of the limbs. An increased incidence of diabetes has been reported in people with lichen planus, particularly the erosive oral lichen planus variant [76, 77]. Impaired glucose metabolism is present in half of patients and 25% will have overt diabetes [78]. However, most studies have examined the presence of diabetes in those with lichen planus rather than the reverse. The link between diabetes and lichen planus is therefore still unproven, especially since both are relatively common conditions.

Pruritus

Even though there is a common assumption that itching is a symptom of diabetes, this is questionable. Studies have failed to link the presence of generalized pruritus with diabetes [79, 80]. Localized itching, particularly in the genital area, can be associated with candidal infections. The presence of xerotic skin, a feature present in individuals with and without diabetes, can also predispose to pruritus. It has been hypothesized that sympathetic nerve dysfunction leading to hypohidrosis and dry skin and peripheral sensory neuropathy can contribute to pruritus [81]. The regular use of emollients ameliorates the itch to a certain extent [82].

Clear-cell syringomas

Syringomas are adnexal non-neoplastic lesions that are derived from the intra-epidermal part of the sweat duct. They present as yellowish papules distributed around the eyes and are asymptomatic. Clear-cell syringoma is an unusual variant which has two features of note: the histological preponderance of clear cells and the frequent coexistence with diabetes mellitus [83, 84]. It has been postulated that in those affected, there may be a phosphorylase deficiency secondary to hyperglycemia that in turn results in the formation of clear cells. Generalized eruptive clear-cell syringomas have also been associated with diabetes [85].

Glucagonoma

The glucoganoma syndrome is caused by tumors of the α cells of the pancreas that secrete glucagon (Chapter 20). Even though the syndrome is rare, it needs to be considered in people with diabetes who present with diffuse atypical rashes. It consists of four major components: increased glucagon levels, diabetes (usually mild), weight loss, and necrolytic migratory erythema. Necrolytic migratory erythema occurs in 70% of cases, manifesting as an annular erythematous and figurate erythema with peripheral vesicles, pustules, and erosions (Figure 52.10). It involves the intertriginous areas and face, but can affect acral sites as well. The dermatosis can be a presenting clue, occurring 1–6 years before the diagnosis of glucoganoma [86]. It can be associated with other physical findings, including glossitis, stomatitis, dystrophic nails, and alopecia. A skin biopsy shows suprabasal acantholysis, and psoriasiform hyperplasia with pallor, ballooning and necrosis of the upper spinous layer of the epidermis [87]. The role of hyperglucagonemia in the cause of the skin eruption is unclear. Deficiency of essential fatty acids, zinc, and amino acids may be important in the pathogenesis. Resection of the pancreatic islet cell tumor clears the rash, sometimes within 48 hours. Management may also involve chemotherapy, essential amino acid and fatty acid supplementation, and the use of somatostatin or its analog octreotide, which suppresses glucagon levels and improves skin lesions.

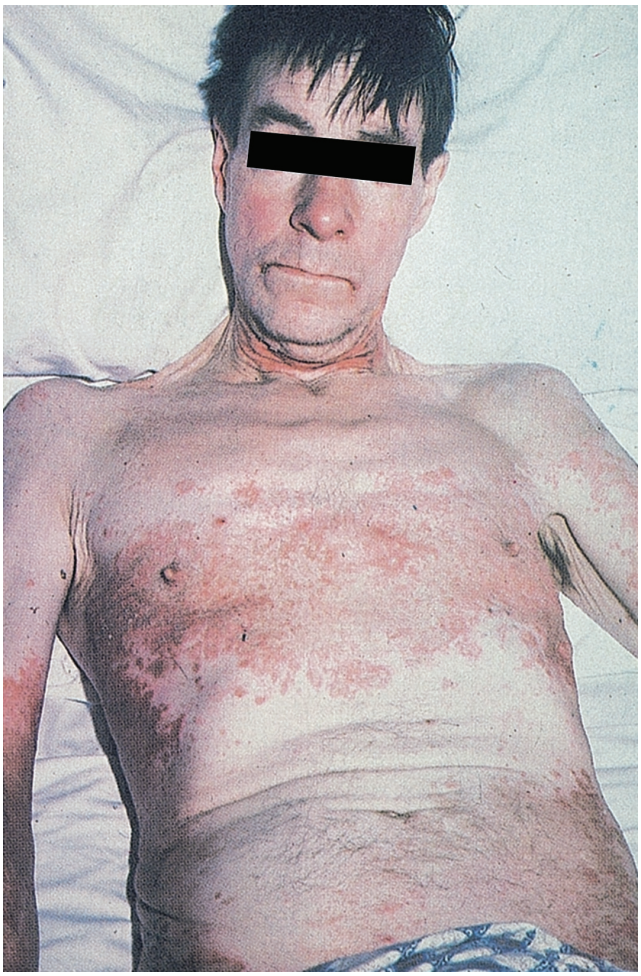


Figure 52.10 Necrolytic migratory erythema in a person with the glucagonoma syndrome. Source: Courtesy of S. Bloom, Royal Postgraduate Medical School, London, UK.

Disseminated granuloma annulare

Granuloma annulare is an inflammatory condition in the skin characterized by annular erythematous plaques with central normal skin, usually distributed in the extensor aspect of the limbs, particularly in the dorsal hands. The uncommon disseminated form of granuloma annulare has been reported with diabetes

mellitus [88, 89]. The lesions in the disseminated form are usually asymptomatic and may lack the typical annular morphology. Histology reveals granulomatous infiltration with lymphocytes and histiocytes with central areas of degenerated collagen associated with giant cells. Lesions can resolve spontaneously or persist for prolonged periods. Treatments include topical steroids, phototherapy, systemic retinoids, and topical calcineurin inhibitors [90]. The link of diabetes with generalized granuloma annulare is controversial with some authors questioning the association [91].

Iatrogenic

Reactions to insulin

Insulin allergy

Reactions to insulin were previously common due to the presence of impurities of cow or pig proteins, and preservatives or additives. The use of human and analog recombinant insulin has decreased the incidence of insulin allergy and it is now less than 1% of people with insulin-treated diabetes [55]. Allergic reactions to insulin can be classified as immediate-local, general, delayed, or biphasic. Immediate-local reactions occur within a few minutes of injection and subside within an hour. Erythema with urtication can occur and is possibly IgE mediated. Treatment of the immediate local reaction is to change the insulin to a more purified product. Systemic reactions include generalized urticaria, and rarely, anaphylaxis. Generalized urticarial reactions to purified insulins are rare [92], but a few people sensitized to animal insulins have suffered anaphylaxis with human insulin [93]. Delayed hypersensitivity reactions are the commonest, appearing about 2 weeks after the start of insulin therapy. Itchy nodules are evident at the sites of injections, 4 to 24 hours after injection. Biphasic responses have been reported in some individuals, with immediate urticaria followed by a delayed reaction several hours later. They are considered Arthus-immune complex reactions. The hypersensitivity may be to insulin itself, or to preservatives, such as aminobenzoic acid or to zinc [94]. Allergic reactions can be managed by antihistamines, addition of glucocorticoids, discontinuation of therapy, or a change in the insulin delivery system.

Lipoatrophy

Lipoatrophy occurs at sites of insulin injections and is particularly prominent with the longer-acting preparations [95]. It is characterized by a loss of subcutaneous fat and can be a cosmetic concern. This complication is less common with the advent of purer insulins. It is more common in young women with diabetes. The pathogenesis is secondary to an immunological reaction as biopsies from affected sites show immunoglobulin M and complement. Repeated injections to the same site may predispose to this problem [96].

Lipohypertrophy

Lipohypertrophy presents as soft, subcutaneous nodules or thickening at sites of repeated injections [97]. It occurs due to the lipogenic action of insulin, with repeated local stimulation of adipocytes being causative. As lipohypertrophic areas are relatively painless, young people with diabetes tend to inject the same site repeatedly, worsening the hypertrophy [10]. Insulin absorption may be delayed at such sites, potentially resulting in disruption of glycemic control [98]. It resolves spontaneously by changing the site of insulin injections. Hyperkeratotic verrucous variants of lipohypertrophy have also been described [99].

Other complications of insulin allergy

Granulomatous lesions that have a furuncular or pustular appearance can occur following insulin injections [100]. Keloids, hyperkeratotic papules, purpura, and localized pigmentation are also reported. Post-inflammatory pigmentation following insulin injection is commoner in Asian skin and may take 6–12 months to fade. Epidermal inflammation around an injection site gives hyper-pigmentation [10] and contributory factors include intradermal or intra-epidermal injections, reuse of needles, non-rotation of injection sites, and occasional injections through clothing. People using insulin pumps for subcutaneous insulin delivery can experience local infections at the site of needle insertion, contact allergy to the associated tape and tubing material, and rarely subcutaneous nodules [101]. Acanthosis nigricans can occur as

Figure 52.11 Drug rash with chlorpromazine.

(a)

(b)

Figure 52.12 Erythema multiforme. (a) Showing the varied appearance of the condition: annular, arcuate and blistering lesions and confluent erythema on the ears. (b) Mouth ulceration in Stevens–Johnson syndrome, the severe form of erythema multiforme.

a local cutaneous side effect to insulin injections; the proliferation of the type 1 insulin-like growth factor receptor, epidermal growth factor receptor and fibroblast growth factor receptor may be causative [10].

Reaction to oral antidiabetes agents

Sulfonyureas

Sulfonylureas are the most common oral antidiabetes agents that cause skin reactions. About 1–5% of those taking first-generation sulfonyureas develop cutaneous reactions within 2 months of treatment [55]. Maculopapular, morbilliform, urticarial or generalized erythematous reactions are common and resolve with discontinuation of the medication (Figure 52.11). Photosensitive reactions, usually of the photoallergic type, as well as lichenoid eruptions have also been reported. Erythema multiforme, characterized by erythematous and hemorrhagic skin lesions associated with "target" lesions, can be a severe manifestation of drug reactions (Figure 52.12). Extensive blistering that includes the mucosal surfaces can occur and if the conjunctiva are involved, urgent ophthalmological opinion is mandatory. The chlorpropamide alcohol flush is a disulfiram-like effect occurring in 10–30% of those taking this drug. Patients experience facial erythema, headache, and palpitations about 15 minutes after drinking alcohol and it subsides in about an hour. Endogenous opioids may be important as the flush is blocked by naloxone [102]. Second-generation sulfonylureas like glipizide and glimepiride are less likely to cause cutaneous side effects. Glipizide has rarely been associated with photosensitivity, rash, urticarial, and pruritus. Glimepiride can similarly cause lichenoid skin reactions [103]. Pemphigus and psoriasiform eruptions can be precipitated by glibenclamide [104, 105].

Other oral antidiabetes agents

Rashes with other oral antidiabetes agents are much less common compared to sulfonylureas. Transient erythema or urticaria may occur with metformin. It is also reported to cause a psoriasiform drug eruption, erythema multiforme [106], photosensitivity, and leucocytoclastic vasculitis [107]. Acarbose can cause a generalized erythema multiforme. As it is minimally absorbed from the gut, it may be the degradation products of acarbose that cause the allergic reaction [108]. Acute generalized exanthematous pustulosis, a dermatosis characterized by generalized pustules all over the body, has been reported to be induced by acarbose [109]. Thiazolidinediones are not commonly associated with reactions but can cause edema, transient erythema and urticaria, as can the glinides such as repaglinide [55].

53 Bone and Rheumatic Disorders in Diabetes

Andrew Grey and Nicola Dalbeth
Department of Medicine, University of Auckland, Auckland, New Zealand

Key points

- Musculoskeletal disorders may cause pain and disability, and adversely affect management of diabetes.
- Fibroproliferative disorders of soft tissue such as limited joint mobility, frozen shoulder, Dupuytren's contracture, trigger finger, and carpal tunnel syndrome occur more commonly in diabetes and may lead to upper limb disability.
- Charcot joint is an infrequent but serious complication of diabetic peripheral neuropathy, and is characterized by disordered osteoclastogenesis. Bisphosphonate therapy may be a useful adjunct to standard treatment.
- Individuals with diabetes are at high risk of developing gout, particularly in the presence of renal impairment and diuretic use.
- Osteoarthritis is an important cause of poor health-related quality of life in people with diabetes.
- The prevalence of diffuse idiopathic skeletal hyperostosis (DISH) is increased in people with type 2 diabetes.
- Fracture risk is increased in both type 1 and type 2 diabetes.
- Bone mineral density is decreased in type 1 diabetes, and increased in type 2 diabetes.
- Disease complications increase fracture risk by increasing risk of falls and causing regional osteopenia.
- Thiazolidinediones decrease bone formation and bone mineral density, and increase fracture risk in type 2 diabetes.
- Fracture healing may be impaired in diabetes.

Musculoskeletal disease in diabetes

Background

A variety of musculoskeletal disorders are associated with diabetes. These disorders may cause pain and disability, and influence the ability of people with diabetes to adhere to other aspects of diabetes treatment, particularly exercise and weight management. Therapies commonly used in the treatment of rheumatic disease, particularly corticosteroids and non-steroidal anti-inflammatory drugs (NSAIDs), may be particularly problematic in people with diabetes. The important bone and joint disorders associated with diabetes are discussed in this chapter and are outlined in Table 53.1.

Fibroproliferative disorders of soft tissue

Cheiroarthropathy–limited joint mobility

Limited joint mobility refers to a syndrome of joint contractures resulting in decreased passive mobility of the joints in people with diabetes [1]. Flexion contractures of the proximal interphalangeal (PIP) joints and metacarpophalangeal (MCP) joints of the hands are characteristic, with the fifth PIP joint affected first (Figure 53.1). The skin on the dorsum of the hands typically appears tight and waxy [2]. Large joints such as the wrists, elbows, ankle, and cervical spine may also be affected, and reduced lung volumes have been reported in severe cases [3, 4]. Pain is usually mild or absent early in disease, and features of synovitis such as joint swelling, effusion, warmth, and tenderness are typically absent. The disorder can be readily differentiated from systemic sclerosis by lack of Raynaud's phenomenon and other systemic features, normal nail fold capillary examination, and negative autoantibodies [5, 6].

The presence of limited joint mobility of the hands is detected clinically by assessing for the prayer sign or the table-top sign. The prayer sign is positive if patients are unable to oppose the palmar surfaces at any interphalangeal or MCP joints, when the hands are placed in the prayer position. For assessment of the table-top sign, the patient places both hands on a table top with the palms down and the fingers fanned out. The fingers are then viewed at table level. In stage 0, the entire palmar surface of the fingers makes contact with the table. In stage 1, one finger is affected (usually the fifth PIP joint of one or both hands). In stage 2, two or more fingers of both hands are affected, (usually the fourth and fifth PIP joints). In stage 3, there is involvement of all the fingers and also restricted movement in a larger joint, usually the wrist or elbow [7]. Passive joint movement should also be assessed to confirm limitation of joint mobility [8].

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

Table 53.1 Bone and joint disorders in patients with diabetes mellitus.

Fibroproliferative disorders of soft tissue
Cheiroarthropathy
Frozen shoulder
Dupuytren's contracture
Stenosing tenosynovitis (trigger finger)
Carpal tunnel syndrome
Disorders of joint tissue
Charcot joint
Gout
Osteoarthritis[1]
Rheumatoid arthritis genetic risk and type 1 diabetes[1]
Disorders of bone
DISH
Osteoporosis and fractures
Disordered fracture healing

[1]Direct association not proven. DISH, diffuse idiopathic skeletal hyperostosis.

Figure 53.1 Limited joint mobility with flexion contractures affecting the finger proximal interphalangeal joints. Source: Courtesy of Dr. Tim Cundy.

Prevalence estimates for limited joint mobility in type 1 diabetes (T1DM) range from 9% to 66%, and from 25% to 75% in type 2 diabetes (T2DM) [1, 9–12]. There is some evidence that prevalence rates have declined in individuals with T1DM in the last 20 years, due to improvements in glycemic control [13].

Limited joint mobility is an important entity primarily because of its clinical associations. It is one of the earliest complications of diabetes and is strongly associated with the presence of microvascular complications such as retinopathy and nephropathy in T1DM [1, 13–16], and macrovascular complications in T2DM [10]. It is also associated with other fibroproliferative disorders affecting the upper limb such as frozen shoulder, Dupuytren's contracture, and carpal tunnel syndrome [12, 16–19]. In general, limited joint mobility does not severely impact on hand function, but combinations of these upper limb disorders may cause upper limb disability [20–22]. In addition to microvascular complications, risk factors for development of limited joint mobility in people with diabetes include older age, puberty (in T1DM), disease duration, and cigarette smoking [10, 23–25].

Advanced imaging techniques have demonstrated thickening of skin, tendons and tendon sheaths in those with limited joint mobility [26, 27]. Histological examination of the skin shows altered mucopolysaccharide distribution, elastin and collagen, and reduced vascular lumen [28]. Non-enzymatic glyclation and accumulation of collagen have been implicated in the pathogenesis [29]. Disordered glycosaminoglycan metabolism is also a feature; skin biopsies from individuals with severe limited joint mobility show pronounced hyaluronan expression in the epidermis and diminished expression in the dermis and basement membrane, compared with skin from people without diabetes and people with diabetes but without limited joint mobility [30]. In addition, increased urinary glycosaminoglycan excretion has been reported in patients with limited joint mobility [31]. Reduced circulating insulin-like growth factor 1 (IGF-1) is associated with limited joint mobility, implicating the GH-IGF axis in the pathogenesis of this complication [32]. Microvascular abnormalities also contribute to disease, with reports of disordered palmar microvascular flow in response to thermal challenge [33].

The mainstay of therapy remains obtaining excellent glycemic control, and reduced prevalence of this disorder has been reported with such interventions [13, 34]. Physiotherapy, particularly hand therapy, may be of benefit to improve joint contractures and function. Corticosteroid injection of flexor tendon sheaths has been reported to lead to resolution of finger contractures in almost two-thirds of cases related to limited joint mobility, and should also be considered [35].

Frozen shoulder

This disorder is characterized by shoulder pain, stiffness, and severely restricted range of motion in all planes [36]. Three phases of the disorder are well recognized; first, the painful freezing stage with associated nocturnal pain (lasting 4–8 months), followed by the adhesive phase with improvement in pain but severely

restricted range of motion (lasting 8–24 months), and finally the resolution phase [37]. The mean time to resolution is 30 months [37]. Plain radiographs of the shoulder are typically normal. Although the condition is usually self-limiting, some people have persistent shoulder pain and restricted range of motion many years after assessment [38, 39].

Imaging and histological studies have demonstrated that the pathological features of frozen shoulder are thickening of the capsule and synovium with contracted joint volume. Affected tissue is characterized by dense type I and type III collagen deposition with proliferating fibroblasts and a chronic inflammatory infiltrate comprising of T cells, macrophages, and mast cells [40, 41]. Disordered collagen synthesis and vascular endothelial growth factor (VEGF-1) mediated angiogenesis have also been implicated [42, 43].

Treatment is tailored to the stage of the disorder [36]. In the painful freezing stage, analgesics, including NSAIDs if tolerated, are indicated. Early use of intra-articular corticosteroids is associated with improved outcomes [44], and physiotherapy with exercise within the limits of pain is of greater benefit than more intensive physiotherapy such as stretching and mobilization [45, 46]. NSAIDs and intra-articular steroids may have similar outcomes over 6 months [47]. Although oral corticosteroids provide short-term relief in the painful freezing stage, they are not routinely recommended due to lack of long-term benefit and risk of adverse events [48]. In the adhesive phase, more intensive physiotherapy is indicated. For those who fail to respond to physiotherapy and have persistent shoulder restriction, interventions such as radiographic-guided hydrodilatation, manipulation under anesthesia, or arthroscopic release should be considered [49, 50].

Diabetes is a major risk factor for frozen shoulder. The prevalence of frozen shoulder is 11–19% of people with diabetes, compared with 2–3% age-matched controls [17, 20, 51, 52]. Individuals with diabetes are also more likely to have bilateral disease. Key risk factors for frozen shoulder in people with diabetes are older age, duration of diabetes, previous myocardial infarction, retinopathy and peripheral neuropathy [53]. The presence of other fibroproliferative musculoskeletal disorders such as limited joint mobility and Dupuytren's contracture is strongly associated with frozen shoulder in people with diabetes [53]. Furthermore, frozen shoulder in individuals with diabetes is more difficult to treat due to persistent disease and worse outcomes following surgical interventions [50, 54, 55].

Dupuytren's contracture

Dupuytren's contracture is a fibroproliferative disorder of the palmar fascia leading to formation of palmar nodules, development of a palmar aponeurosis cord with tethering of the overlying skin, and eventually flexion contractures particularly affecting the ring and little fingers [56]. Elderly men of Northern European ancestry are most frequently affected. Disordered fibroblast and myofibroblast function has been described, with deposition of type III collagen, potentially mediated by growth factors such as transforming growth factor-β (TGF-β) and basic fibroblast growth factor [57–59].

Surgical treatment is the mainstay of therapy, although nonsurgical options, particularly local injection of collagenase are promising [60]. People with diabetes have similar responses to collagenase injections as individuals without diabetes [61]. Splinting and intralesional corticosteroids are frequently ineffective [62]. Surgical referral should be considered in the presence of contracture. Various surgical approaches are available, including fasciotomy (division of the affected palmar fascia) or fasciectomy (excision of the affected palmar fascia). Percutaneous needle fasciotomy is a minimally invasive technique with good short-term outcomes, although recurrence is a frequent problem [63, 64].

Risk factors for Dupuytren's contracture include advanced age, male sex, cigarette smoking, manual labor, and alcohol consumption. Diabetes is also an important risk factor for Dupuytren's contracture, which is present in up to 26% of people with diabetes [20, 21, 65]. Age and disease duration are the major risk factors for development of Dupuytren's contracture in those with diabetes [66]. Dupuytren's contractures are also associated with microvascular complications in T1DM and macroalbuminuria in T2DM [67, 68]. Rapidly progressive contractures are less frequently seen in people with diabetes [66]. Coexistent fibroproliferative disease is frequent in individuals with diabetes-associated Dupuytren's contracture, with higher rates of limited joint mobility [68].

Stenosing tenosynovitis (trigger finger)

Trigger finger is a condition in which the flexor tendon is "prohibited from gliding through the tendon sheath because of thickening of the synovial sheath over the tendon" [69]. This disorder most frequently affects the ring finger, but may also affect the other fingers and the thumb. The patient may report a clicking sensation when moving the finger, discomfort over the palm, or overt triggering when the finger is locked in flexion [70]. Nodular or diffuse flexor tendon sheath swelling may be palpable.

The syndrome occurs due to a discrepancy between the flexor tendon and its sheath in the A1 pulley at the level of the metacarpal head [70]. The pulley becomes thickened with increased extracellular matrix and fibrocartilage metaplasia [71]. These pathological changes may be induced by repetitive trauma.

Corticosteroid injection into the tendon sheath is an effective therapy for the majority of patients, particularly in the presence of nodular disease. For people with nodular disease for less than 6 months, local injection has a reported success rate of 90% [72]. Splinting and hand therapy are useful adjuncts to local injection. If conservative therapy fails, release using a percutaneous needle approach or open surgery is indicated [73].

People with diabetes are at higher risk of trigger finger, with a lifetime risk of 10% compared with 2.6% of the general population [70]. Multiple finger involvement is also more common in people with diabetes, and is associated with presence of limited joint mobility and carpal tunnel syndrome [74]. A person's age, diabetes duration, and presence of microvascular complications

are all associated with increased risk of trigger finger in diabetes [66, 75]. Outcomes are typically worse when trigger finger is associated with diabetes, with lower responses to corticosteroid injection and greater need for surgery [76–78]. Furthermore, T1DM is associated with higher prevalence of disease, more affected digits, greater need for surgery, and higher risk of recurrence [66, 76, 78].

Carpal tunnel syndrome

Carpal tunnel syndrome is a common compressive neuropathy affecting the median nerve as it traverses with the flexor tendons through the carpal tunnel, an anatomical space comprising the carpal bones and the transverse carpal ligament [79]. The most common histological appearance is non-inflammatory tenosynovial fibrosis, with increased fibroblast number and type III collagen deposition, most likely mediated by TGF-β [80]. Compression within the carpal tunnel leads to disordered microvascular supply of the nerve, causing demyelination and axonal degeneration. The typical presentation is hand paresthesia, particularly affecting the thumb, index finger, and middle finger. Paresthesia is often more frequent at night, and may wake the patient from sleep. Wrist and hand pain may also occur, and patients frequently report hand clumsiness.

Clinical examination may be normal, but in the presence of severe and prolonged disease there may be features of median nerve denervation, including thenar wasting, weakness of thumb abduction and sensory loss over the median nerve distribution. Provocative tests including Phalen's test and Tinel's test may be positive, and if present have relatively high specificity for carpal tunnel syndrome. Phalen's test is positive if paresthesia in the median nerve distribution is reported following flexion of the wrist at 90° for 60 seconds. Tinel's test is positive if paresthesia is reported after tapping the volar wrist over the carpal tunnel. The diagnosis is confirmed by nerve conduction testing, with the typical findings of prolonged latencies and delayed conduction velocities affecting the median nerve across the wrist [81].

Treatment consists of maintaining the wrist in a neutral position using a removable wrist splint. Splinting is particularly useful for nocturnal symptoms, and may be sufficient to treat mild disease [82]. Although oral corticosteroids have short-term efficacy, side effects are usually unacceptable [83]. Local corticosteroid injection provides good short-term relief [84]. Surgical release under local anesthesia is a well-tolerated and effective therapy, which should be considered in those who have failed conservative therapy, or who have severe symptoms and signs of nerve compression [85]. Open release and endoscopic approaches have similar clinical outcomes [86].

Carpal tunnel syndrome may be caused by a number of factors including non-specific flexor tenosynovitis affecting the wrist, rheumatoid arthritis and other inflammatory synovial arthropathies, obesity, pregnancy, and disordered wrist anatomy [79]. Diabetes is one of the most common metabolic disorders associated with carpal tunnel syndrome, being present in 16% of affected patients [87]. Most studies have shown increased risk of carpal tunnel syndrome in people with T1DM or T2DM [66, 88, 89]. A survey using clinical and neurophysiological assessment reported a prevalence of carpal tunnel syndrome of 2% in a reference population without diabetes, 14% in people with diabetes but no diabetic polyneuropathy, and 30% in people with diabetic polyneuropathy [90]. Carpal tunnel syndrome is associated with duration of diabetes, and is more frequently present in those people with microvascular complications such as retinopathy, nephropathy, and polyneuropathy [66, 91]. Carpal tunnel syndrome is also more common in individuals with limited joint mobility, and it has been postulated that this disorder occurs at higher frequency in diabetes due to accelerated thickening and fibrosis of the flexor tendon sheaths within the carpal tunnel [19]. Glyclation of collagen may also reduce compliance of connective tissue within the carpal tunnel [89]. In addition, the presence of existing microvascular disease may further increase the risk of endoneural ischemia as the median nerve travels through the carpal tunnel. Carpal tunnel syndrome may be more difficult to assess in people with coexistent diabetic neuropathy, due to atypical presentation and neurophysiological assessment [90, 92]. Treatment options for those with diabetes and carpal tunnel syndrome are similar to people without diabetes, and responses to surgery are usually good [93, 94].

Disorders of joints

Charcot joint

Charcot joint is a destructive arthropathy, most commonly affecting people with diabetes in the presence of severe peripheral neuropathy. This disorder affects 0.1–0.4% of people with diabetes and may lead to severe foot deformity and disability, ulceration, and limb amputation (see Chapter 48) [95].

Several stages of disease are described [96, 97]. The developmental stage presents as acute inflammation with swelling, warmth, and erythema of the foot. Pain may be a feature, despite the presence of peripheral sensory neuropathy. Peripheral pulses are usually easily palpable. Gradually worsening deformity occurs, with bone resorption, fracture and dislocation, leading to instability of the foot and the classic rocker-bottom dislocation of the midfoot. Plain radiographs may appear normal early in the acute phase of disease (Stage 0), but MRI scans show florid bone marrow edema, subchondral cysts and microfractures, and bone scintiscan shows increased uptake on the bony phase [97]. As deformity develops, radiographs show severe osteolysis, bone fragmentation and disordered architecture (Stage 1). In the coalescence (Stage 2) phase, hyperemia resolves, swelling reduces, and skin temperature normalizes. Bone debris is resorbed and bone sclerosis may occur. The reconstructive stage (Stage 3) is characterized by remodeling of bone, ankylosis and proliferation of bone, and formation of a stable foot. The acute phase (Stages 0 and 1) typically lasts 2–6 months, and the reparative phase (Stages 2 and 3) lasts up to 24 months. During both the acute and the reparative phases of disease, bony deformity may lead to abnormal load bearing, with ulceration of overlying skin and secondary osteomyelitis.

Five separate patterns of foot involvement are identified in people with diabetes [98]: (1) affecting the forefoot with osteolysis of the MTP and IP joints of the feet, leading to the "sucked candy"

Figure 53.2 Plain radiograph of Charcot foot. Note the osteolysis, bone fragments, subluxation, and fracture affecting the tarsometatarsal joints of the foot. Source: Courtesy of Dr. Tim Cundy.

appearance on plain radiography; (2) affecting the tarsometatarsal (Lisfranc's) joint leading to instability, subluxation, and fracture (Figure 53.2); (3) dislocation and fracture affecting the midtarsal and naviculocuneiform joints; (4) affecting the ankle and subtalar joints, often with severe osteolysis; (5) affecting the calcaneus. The most common patterns are (2) and (3), and combinations of patterns may be present. Bilateral disease is present in one-quarter of patients. Rarely, other joints such as the knees, elbows, and shoulders are affected.

The etiology of the disease remains controversial [99]. Minor trauma frequently precipitates onset of disease, and may lead to subclinical bone injury that triggers an aberrant inflammatory response [100]. It is likely that disordered weight-bearing in joints affected by peripheral neuropathy leads to repetitive injury and instability (the neurotraumatic hypothesis). Additionally, autonomic dysfunction causing vasodilatation, arteriovenous shunting, and hyperemic bone resorption has been implicated (the neurovascular hypothesis). Development of osteopenia and osteolysis increases risk of fractures in the presence of abnormal load-bearing with a cycle of joint instability and fracture development, causing further abnormal load-bearing [101]. Recent work has focused on the role of local inflammation in disease pathogenesis. Advanced imaging and histological analysis have demonstrated that inflammation of synovium and bone is evident in Charcot joint, and is characterized by increased expression of the pro-inflammatory cytokines TNF-α and interleukin-1 (IL-1) [102–105]. Large numbers of osteoclasts are present within affected bone, and people with Charcot joint have greater circulating pre-osteoclast cells with increased ability to form peripheral blood-derived osteoclasts *in vitro*, compared with people with diabetes but without Charcot arthropathy and those without diabetes [105–107]. Markers of bone resorption are increased in people with acute Charcot joint [108]. Interestingly, acute phase markers are not significantly elevated, indicating an apparent dissociation between local and systemic inflammatory disease [109]. These data implicate RANKL-mediated osteoclastogenesis, driven locally by pro-inflammatory cytokines, and provide a rationale for the use of agents that target the osteoclast in treatment of the disease.

Management of Charcot joint depends on the stage of disease. Treatment during the acute phase consists of immobilization which reduces inflammation, prevents abnormal load-bearing, and stabilizes the foot in a position of least deformity. The standard immobilization method during the acute phase is a non-weight-bearing total contact cast. This treatment requires close monitoring and regular adjustment, and should be maintained until swelling and temperature normalize, and radiographs show no further bony destruction [110]. Some recent uncontrolled reports have indicated that use of a weight-bearing total contract cast may be an acceptable alternative to the non-weight-bearing option, but controlled trials are not yet available [111, 112].

The recognition that the acute phase of Charcot joint is associated with excessive osteoclast activity has led to the testing of agents targeting bone turnover for treatment of this condition. Clinical trials of bisphosphonate treatment have shown varying results, with improvement in skin temperature and bone turnover markers, but no clear benefit in immobilization rates [113]. One recently published randomized placebo-controlled trial reported increased immobilization times following zoledronate (three 4 mg infusions) [114]. A randomized trial of intranasal calcitonin demonstrated efficacy with respect to bone turnover markers, but no differences in clinical measures were reported [115]. The efficacy of TNF-inhibitors and other anti-resorptive agents such as the RANKL inhibitor denosumab has not yet been studied in Charcot joint.

Surgery is generally not considered first-line therapy, although one study has reported good surgical outcomes following débridement, open reduction, and internal fixation with autologous bone grafting in the acute phase of disease [116]. In general, surgical management is currently recommended for patients in the reparative (rather than the acute) phase of disease, and particularly for those with deformities associated with chronic foot ulcers and joint instability. Many different surgical approaches to arthrodesis have been described, including open reduction with both internal and external fixation, depending on the presence of local infection and other anatomical variables [117]. Other surgery includes exostotomy, osteotomy, intramedullary rodding, and amputation. Infection, non-union and triggering of an acute Charcot reaction are important post-operative complications, and careful post-operative management is essential.

Outcomes in people with Charcot foot are frequently poor. An analysis of 115 patients reported that non-operative management was associated with a 2.7% annual rate of amputation, a 23% risk of requiring bracing for more than 18 months, and a 49% risk of recurrent ulceration [118]. The presence of open ulcers at initial presentation or chronically recurrent ulcers is associated with increased risk for amputation.

Gout

Gout is an inflammatory arthritis caused by intra-articular deposition of monosodium urate crystals [119]. This disorder

Figure 53.3 Tophaceous gout of the hands in a person with type 2 diabetes.

is the most common form of inflammatory arthritis affecting men, and affects 1–2% of the white European adult population [120]. In early disease, gout presents as recurrent episodes of self-limiting acute inflammatory attacks ("flares") of arthritis. These attacks most often affect the 1st MTP joint, midfoot, and ankle. In the presence of prolonged hyperuricemia, some individuals develop recurrent polyarticular attacks, tophaceous disease, and erosive arthritis (Figure 53.3).

The key risk factors for gout are hyperuricemia, male sex, chronic renal impairment, hypertension, obesity, diuretic use, coronary heart disease, and seafood, meat and alcohol intake [121–123]. The relationship between gout and metabolic syndrome is well recognized. Serum urate concentrations and gout are strongly associated with abdominal adiposity, and have been shown to predict the development of T2DM [124–126]. People with gout have high rates of the metabolic syndrome and T2DM compared to individuals without gout [127]. Promotion of renal tubular reabsorption of uric acid by insulin is thought to mediate this relationship [128]. Recent identification of the glucose and fructose transporter SLC2A9 as a key regulator of serum urate concentrations suggests a further etiological link between hyperuricemia and hyperglycemia [129]. The gout prevalence of up to 22% has been described in people with T2DM treated in secondary care [130]. Key risk factors for gout in this population were male sex, renal impairment, and diuretic use. Interestingly, severe hyperglycemia may reduce urate concentrations, as glycosuria has a uricosuric effect. Thus, as glycemic control improves in patients initiating treatment for diabetes, there is a potential risk of increasing serum urate concentrations and worsening gout attacks [131, 132].

Long-term urate-lowering therapy is indicated for individuals with gout who have recurrent flares, tophi, chronic kidney disease or urolithiasis [133]. Serum urate lowering to a concentration of <0.36 mmol/L (6 mg/dL) is needed to dissolve monosodium urate crystals, prevent flares and achieve tophus regression. Allopurinol is the mainstay of urate-lowering therapy, but may be ineffective at recommended doses. If the serum urate target is not achieved with allopurinol alone, further options include dose escalation of allopurinol, addition of a uricosuric agent such as probenecid or benzbromarone, or consideration of the newer xanthine oxidase inhibitor febuxostat, which provides effective urate lowering in people with diabetes and gout [134]. Options for treatment of acute gout flares include NSAIDs, corticosteroids, and/or colchicine [135]. Initiation of urate-lowering therapy is frequently associated with exacerbation of gout flares; this side effect can be avoided by commencement of urate-lowering therapy once the acute flare has resolved, gradual introduction of the urate-lowering drug, and co-prescription of low-dose colchicine.

The presence of coexistent gout has several implications for individuals with T2DM. Poorly controlled gout may hinder attempts at exercise and weight loss. For those with morbid obesity and diabetes, bariatric surgery may have beneficial effects not only on glycemic and blood pressure control, but also on control of serum urate [136]. Diuretic therapy may exacerbate hyperuricemia and should be avoided in individuals with gout unless absolutely required. Drugs such as losartan and fenofibrate have weak urate-lowering effects and may be of particular benefit in people with diabetes and gout if antihypertensive or lipid-lowering therapy is required [137, 138].

Osteoarthritis

Osteoarthritis is the most common form of arthritis and is a major cause of pain and disability worldwide. In people with diabetes, the presence of osteoarthritis leads to substantially lower health-related quality of life [139]. Increased load-bearing of articular cartilage is a key risk factor for development of osteoarthritis, and a strong positive relationship has been reported between

obesity and the risk of developing osteoarthritis [140–143]. There has been substantial uncertainty about whether T2DM is an independent risk factor for development of osteoarthritis [140, 142, 144, 145], or whether the association between T2DM and osteoarthritis is primarily mediated through increased body mass index (BMI). Recent data have suggested that diabetes itself may increase the risk for osteoarthritis independent of elevated BMI and increased joint loading. Magnetic resonance imaging studies of knee cartilage have shown that diabetes is associated with higher T2 relaxation times (indicating increased cartilage degeneration), even after adjusting for other metabolic features including abdominal circumference [146]. Diabetes is also an independent risk factor for severe osteoarthritis requiring arthroplasty, even after adjusting for BMI [147]. Furthermore, the presence of metabolic syndrome and diabetes increases the risk of knee osteoarthritis in obese women, even after adjusting for age and joint asymmetry [148]. Chondrocytes express glucose transporters and hyperglycemia has a number of deleterious direct and indirect effects on articular cartilage [149]. Inadequately controlled osteoarthritis pain is more frequently observed in people with diabetes both at the knee and hand [150, 151].

A holistic approach to osteoarthritis management is recommended, with education, exercise, and weight loss if overweight within the core management recommendations for all people with osteoarthritis [152]. Analgesic approaches include topical nonsteroidal anti-inflammatory drugs, which are generally well tolerated in people with diabetes [153]. Intra-articular steroids may provide short-term analgesia in symptomatic knee osteoarthritis, but can lead to short-lived elevations in blood glucose among people with diabetes [154]. For those undergoing hip and knee arthroplasty, diabetes is associated with higher risk of prosthetic infection, post-operative activity limitation and need for early revision [155–157].

Rheumatoid arthritis

Rheumatoid arthritis and T1DM share several genetic associations such as *PTPN22*, *HLA-DR9*, the chromosome 4q27 region, the *IDDM5* region and the *IDDM8* region [158–162]. There is evidence of familial clustering of these disorders; 2.8% of first-degree relatives of probands with rheumatoid arthritis have T1DM, compared with 0.35% of the general population [163]. The presence of T1DM is a risk factor for a particular subset of rheumatoid arthritis; anti-cyclic citrullinated peptide (CCP) positive disease [164]. Anti-CCP antibodies are associated with increased risk of persistent arthritis in patients presenting with early inflammatory arthritis [165] and development of erosive disease in those with established rheumatoid arthritis [166]. The association between T1DM and anti-CCP positive rheumatoid arthritis is in part related to the effects of *PTNP22* variants on the risk of both conditions [164].

Skeletal disease in diabetes

Diffuse idiopathic skeletal hyperostosis (DISH)

DISH is a disorder characterized by increased bone formation, particularly at the entheses (the insertions of ligaments and tendons into bone) [167]. Ossification of the anterior longitudinal ligament of the spine occurs, most commonly in the thoracic spine (Figure 53.4). Extraspinal ossification may also be identified. The prevalence has been reported to be as high as 15% in women and 25% in men over the age of 50 [168]. Patients may present with back pain and stiffness, although it remains controversial whether DISH is associated with increased back pain, and the disorder is frequently detected as an incidental finding on chest radiographs [169, 170]. Rare complications such as dysphagia, vocal cord paralysis, compression of the inferior vena cava, and neurological compression syndromes have been described in patients with florid hyperostosis [171]. Spinal fracture may occur after relatively minor injury and cause significant neurological compromise [172]. The diagnosis is made radiographically, according to the Resnick criteria, in brief: (1) presence of flowing calcification and ossification along the anterolateral aspects of at least four contiguous vertebral bodies, (2) relative preservation of intervertebral disc height and the absence of extensive degenerative disc disease, (3) absence of features of spondyloarthropathy [173].

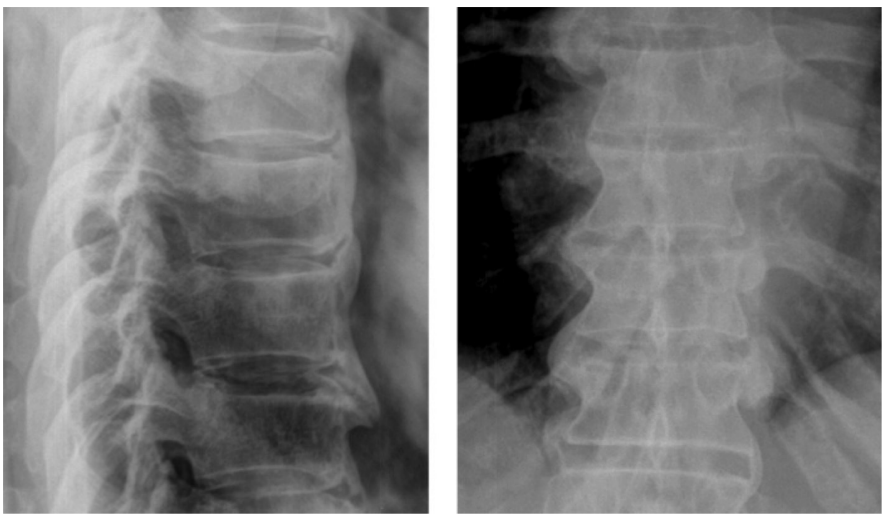

Figure 53.4 Plain radiographs of diffuse idiopathic skeletal hyperostosis (DISH) affecting the thoracic spine. Source: Courtesy of Dr. Anthony Doyle.

There have been no controlled trials of therapies in patients with DISH. For symptomatic patients, analgesics and physiotherapy are standard therapy. A small uncontrolled study of patients reported that a physiotherapy program focusing on spinal mobility, stretching and strengthening had some benefits in improving lumbar spinal mobility after 24 weeks, with no significant benefits in pain or functional outcomes [174]. Surgery is rarely required, but may be indicated for compressive syndromes caused by florid hyperostosis.

Obesity and T2DM are key risk factors for DISH [175–178]. The presence of additional metabolic disorders such as dyslipidemia or hyperuricemia further increases the risk of DISH associated with diabetes [179]. People with DISH have higher rates of hyperglycemia and higher circulating insulin levels particularly after a glucose load [176, 180]. It is likely that obesity has direct biomechanical effects, due to increased load at the entheses. Additionally, systemic factors may contribute to the development of DISH, as people with this disorder have evidence of increased bone mineral density (BMD) elsewhere in the skeleton [181, 182]. Insulin, growth hormone, and IGF-1 have been implicated in the pathogenesis of DISH, and high circulating concentrations of these hormones may contribute to the development of hyperostosis [180, 183, 184]. High expression of NF-κB, platelet-derived growth factor BB and TGF-β1 has also been reported in affected tissue in people with DISH, implicating these factors in osteoblast activation and new bone formation [185].

Osteoporosis and fractures

Background

Fragility fractures are a major cause of morbidity and public health expenditure. The most devastating fracture, that of the proximal femur, is associated with a 20% risk of dying within 6 months of the event, and a substantial risk of loss of independence [186]. Individual fractures are associated with considerable periods of disability and loss of productivity [187]. Important risk factors for fragility fracture include older age, low BMD, female gender, light body weight, previous fracture during adulthood, cigarette smoking, falls, and glucocortocoid use [186]. Dual-energy X-ray absorptiometry (DEXA) is the preferred modality for measurement of BMD. Recently, absolute fracture risk algorithms have been developed, using these risk factors, to provide 5–10-year estimates of the risk of major osteoporotic fracture, or specifically of hip fracture [188, 189].

Insight into the mechanisms by which bone loss occurs can be gained by measurement of biochemical markers of bone turnover, which reflect either osteoblast function/bone formation or osteoclast function/bone resorption. At present, bone markers are important tools in evaluating the pathogenesis and treatment of osteoporosis in clinical studies, but their utility in the management of individual patients is limited by assay variability, low predictive value for skeletal events and high cost [190].

In recent years, evidence has accrued that suggests that the risk of fragility fractures is increased in both types of diabetes, albeit perhaps by different mechanisms. In addition, attention has focused recently on the skeletal effects of treatments for T2DM, in particular the thiazolidinediones.

Fracture epidemiology in diabetes

Type 1 diabetes

Meta-analyses of observational studies have examined the relationship between T1DM and risk of fracture [191, 192]. Hip fracture is the only fracture type evaluable in these analyses, because of the paucity of studies of other fracture types. Both meta-analyses demonstrated a substantially increased (six- to ninefold) relative risk of hip fracture in T1DM [191, 192] (Figure 53.5). Studies of other fracture types in T1DM are few in number and many include only a small number of events, but they generally support the notion that non-vertebral fracture risk is increased, with relative risk estimates of 1.3–3 for any fracture [193, 194] and of 2.4 for foot fractures [195]. The only study to date to assess vertebral fractures found no increase in risk in T1DM [196].

Type 2 diabetes

Recent epidemiological studies have also suggested that fracture risk is increased in T2DM. Meta-analyses of these observational studies report increased risk of all fractures, and also those of the hip, forearm, and foot [191, 192] (Figure 53.5). Relative risk estimates for hip fracture are lower in T2DM (1.4–1.7) than in T1DM, and estimates of fracture risk at other sites in T2DM range from 1.2 to 1.4. Since the meta-analyses were published, the WHI Observational Study, which included >5000 postmenopausal women with T2DM, reported increased risks of any fracture and of fractures at several specific sites, including the hip, spine, foot, and upper arm [197]. Risk estimates ranged from 1.2 to 1.5 across the skeletal sites. The WHI study was one of the few with the capacity to evaluate vertebral fractures. Although there was an increased risk of spine fractures in the WHI study, it remains uncertain whether risk of this fracture type is higher in T2DM, as other studies have not found an association [198].

Mechanisms of skeletal fragility in diabetes

Although fracture risk appears to be increased in both T1 and T2DM, important differences might exist in the pathogenesis of skeletal fragility in the two diseases (Table 53.2). At least two mechanisms underlie the increased skeletal fragility in T1DM. The majority of cross-sectional studies of T1DM report decreased BMD throughout the skeleton, although there is no consistent association between age of participants, duration of disease, and magnitude of BMD deficit [199, 200]. Interestingly, studies performed in children and young adults demonstrate lower than normal BMD at hip and spine at the time of diagnosis [201, 202]. Taken together with the observations from longitudinal studies that BMD does not progressively decline in T1DM [203–206], and cross-sectional studies of middle-aged people with T1DM that report normal levels of markers of bone turnover [207–209], these data suggest that the observed deficit in BMD in T1DM occurs early in the course of the disease, and perhaps prior to its

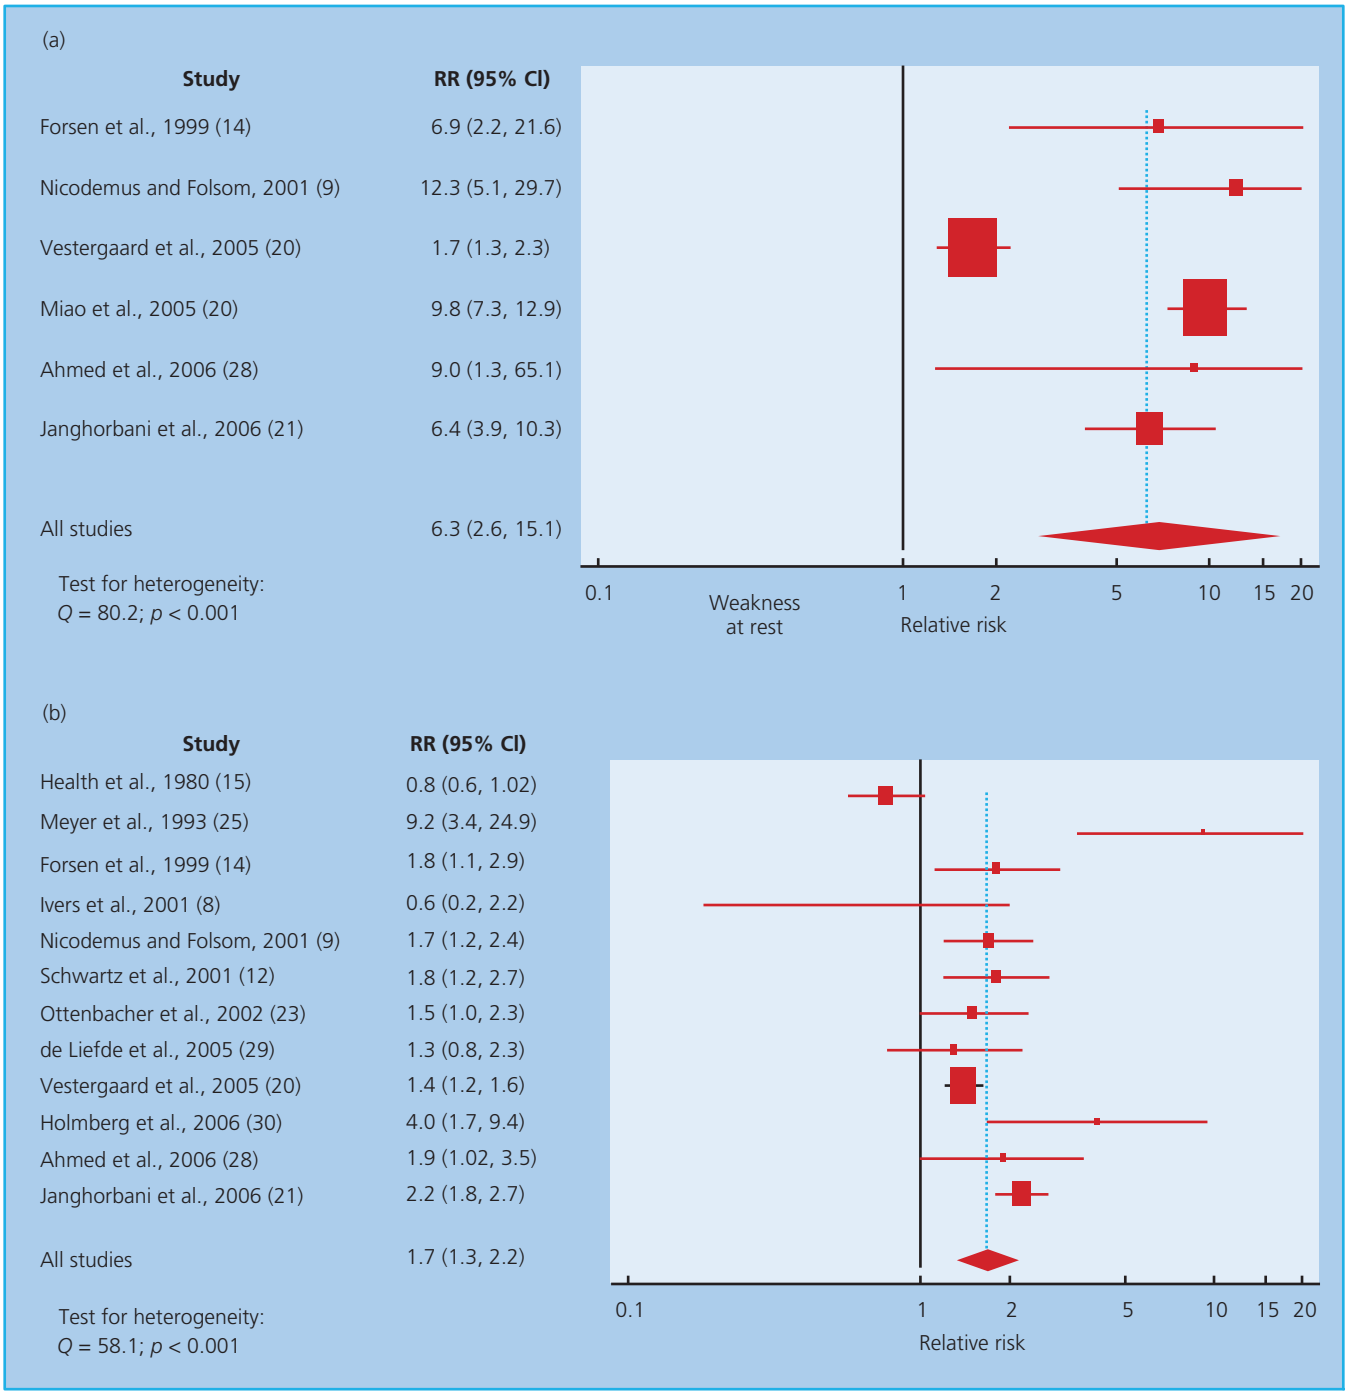

Figure 53.5 Association of type 1 diabetes (a) and type 2 diabetes (b) with hip fracture risk in meta-analyses of case–control and cohort studies. Each square shows the study-specific relative risk (RR) estimate (the size of the square reflects the study-specific statistical weight, that is, the inverse of the variance), and the horizontal line shows the related 95% CI. The diamond shows the summary RR estimate, and its width represents the corresponding 95% CI. Reproduced with permission of Oxford University Press.

clinical presentation. It is possible that deficiency of insulin and other pancreatic β cell hormones such as amylin and preptin, each of which has been implicated in skeletal homeostasis [210–213], contributes to the decreased BMD observed in T1DM. Recent data also implicate low levels of IGF-1 in the pathogenesis of cortical bone loss in T1DM [214]. Insulin deficiency alone is probably not sufficient to explain the lower BMD, since insulin therapy does not normalize BMD. Lower body weight may also be a factor, as

Table 53.2 Mechanisms of increased skeletal fragility in diabetes.

there is a strong positive relationship between weight and BMD [215, 216].

However, the magnitude of the reduction in BMD (3–8%) is probably not sufficient to explain the higher rates of fracture in T1DM [200]. A second mechanism by which skeletal fragility is likely to be increased is via an increased propensity to falls as a result of disease complications. Neuropathy, visual impairment, cerebrovascular disease, and hypoglycemia are likely to increase falls risk. In the only study to date that has evaluated this possibility, substantially higher risks of hip fracture were observed in individuals with T1DM with a range of disease complications than in those without complications [217]. Neuropathy may also impact adversely on BMD in the distal limbs, as people with T1DM and neuropathy have lower cortical bone mass in the distal limbs than those without neuropathy [218]. Animal studies suggest that interruption of nerve supply to bone decreases regional bone mass independent of changes in mechanical loading [219]. The presence of regional osteopenia may contribute to the increased risk of distal limb and foot fractures in T1DM.

The mechanisms by which skeletal fragility is increased in T2DM is uncertain (Table 53.2). The observation that fracture risk in increased is in some ways surprising, because the higher body weight that commonly accompanies T2DM might be expected to preserve bone mass and protect against adverse skeletal outcomes. In fact, BMD in the axial skeleton *is* higher in people with T2DM than in those without diabetes [191, 197, 198]. However, BMD remains an important risk factor for fracture in T2DM, since incident fractures occur more frequently in people with T2DM and decreased BMD than in those with normal BMD [220]. The limited available evidence suggests that people with T2DM who have neuropathy and nephropathy have lower BMD than those free of these complications [191, 221].

As in T1DM, it is likely that complications of T2DM, such as neuropathy, vascular disease and impaired vision, increase the risk of falling, and thereby of fracture. In the Study of Osteoporotic Fractures, a prospective study of fracture epidemiology in older American women, participants with T2DM had a 22% higher risk of non-spine fractures than participants without diabetes [198]. Participants with T2DM who were treated with insulin had both a higher prevalence of disease complications and a higher risk of fracture than those with T2DM who were not treated with insulin. In the Health ABC study, a prospective study of older (>70 y) American men and women, there were strikingly higher prevalences of neuropathy, cerebrovascular disease, and falls in participants with T2DM who suffered a fracture, compared to those with T2DM who did not fracture [220]. Many risk factors for falls, including use of medications associated with increased falls risk, are more commonly present in populations with T2DM than in those without diabetes [222]. Low-impact falls are more frequent in individuals treated with insulin [223]. Curiously, however, adjusting for diabetes complications and/or falls risk does not necessarily attenuate the increased fracture risks observed in T2DM [198, 220].

It is possible that aspects of bone strength and/or quality that are not captured by DEXA assessment are abnormal in people with either type of diabetes, and contribute to increased bone fragility. At present, there are no validated methodologies for assessing these aspects of bone quality. Several cross-sectional studies have evaluated bone microarchitecture in small numbers of people with T2DM using high-resolution computed tomography [224–228]. Four of five studies found similar bone structural variables between participants with and without T2DM, while one reported increased porosity of cortical bone at the radius but not the tibia in the group with T2DM. In one study, microindentation analysis suggested a lower bone mechanical strength in the group with T2DM [226]. It therefore remains unclear whether abnormality of bone structure or quality exists in diabetes.

Potentially relevant to the notion that bone quality is impaired in diabetes is evidence that advanced glycation end products (AGE), products of non-enzymatic glycation, are present in greater amounts in the skeletons of diabetic animals than those of control animals [229]. The glycation of matrix proteins in bone may alter biomechanical properties in such a way as to decrease bone strength [230, 231]. *In vitro* studies suggest that AGEs inhibit differentiation of osteoblasts [229, 232] and increase differentiation of osteoclasts [233], thereby potentially altering bone remodeling and/or strength in a detrimental fashion. There may be AGE-specific effects on bone remodeling, as pentosidine decreases osteoclast development *in vitro* [234]. Mice deficient in the receptor for AGE exhibit increased bone mass and decreased osteoclast function, suggesting that the overall effect of increased AGE signaling in bone is likely to be detrimental [235]. A pivotal role for AGEs in the increased risk of fractures in diabetes implies that improved glycemic control should ameliorate the risk. However, a secondary analysis of a randomized trial of intensive glycemic control in T2DM did not find such an effect [236].

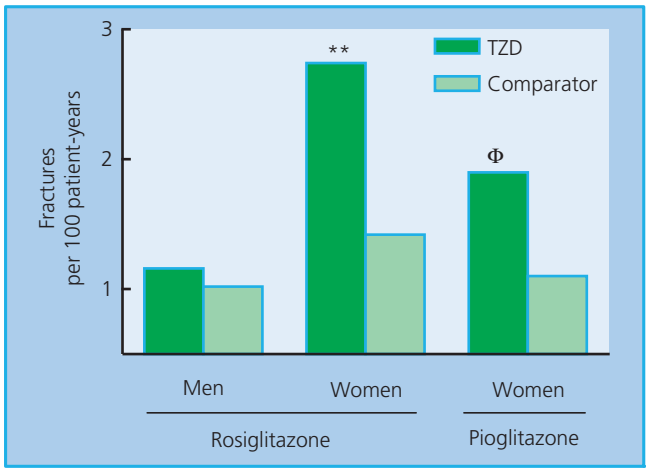

Figure 53.6 Fracture rates, captured as adverse events, in randomized, controlled trials of thiazolidinedione (TZDs). **, $p < 0.01$ vs. comparator; φ, significantly higher than comparators. Source: Reproduced with permission of A. Grey.

Finally, in T2DM, there is clear evidence that treatment with either of the currently available thiazolidinediones, rosiglitazone and pioglitazone, increases fracture risk, at least in the appendicular skeleton in women [237, 238]. Data collected as adverse events during randomized controlled trials of each thiazolidinedione in middle-aged populations with T2DM demonstrated a twofold increase in risk of distal limb fractures in women, although not in men [239–241] (Figure 53.6). However, observational data from an older cohort of individuals with T2DM suggest that fracture risk is also increased in men exposed to thiazolidinediones, and that the incidence of "classical" osteoporotic fractures (hip, forearm, humerus) is also higher in thiazolidinedione users [242].

The mechanisms underlying the adverse skeletal effects of thiazolidinediones are complex, and may involve both direct and indirect pathways (Figure 53.7). Of primary importance is the effect of the thiazolidinediones to directly inhibit bone formation, by diverting mesenchymal stem cell precursors from the osteoblast to the adipocyte lineage [237]. In addition, thiazolidinediones increase or maintain bone resorption at inappropriately elevated levels, via direct actions on osteoclast development [237, 243]. Indirect actions of thiazolidinediones that potentially contribute to their detrimental skeletal effects include decreasing systemic and skeletal production of IGF-1, modulating production of skeletally active adipokines, and decreasing levels of pancreatic β-cell hormones with known skeletal activity [238]. A substantial body of preclinical studies in rodents demonstrates that thiazolidinediones decrease bone formation and BMD *in vivo* [237]. In humans, randomized controlled trials have reported that thiazolidinediones reduce BMD over 12–18 months, although not markedly [244–247]. There was not a consistent pattern of changes in markers of bone turnover.

The skeletal toxicity of thiazolidinediones has prompted interest in the effects of other oral antidiabetes agents on bone health. At present, the available data suggest that metformin, sulfonylureas, agents that modulate glucagon-like peptide 1 signaling, and sodium-glucose co-transporter 2 inhibitors are neutral in regard to the skeleton [248].

Investigation and management of osteoporosis in diabetes

Diabetes of either type should be regarded as a risk factor for fragility fracture, and included in clinical fracture risk assessment, along with recognized risk factors such as age, gender, body weight, previous fracture, cigarette smoking, glucocorticoid use, and BMD. Recently developed fracture risk algorithms assist determination of an individual's short- to medium-term absolute fracture risk [188, 189], although they may underestimate risk in populations with diabetes [228]. Although BMD is on average

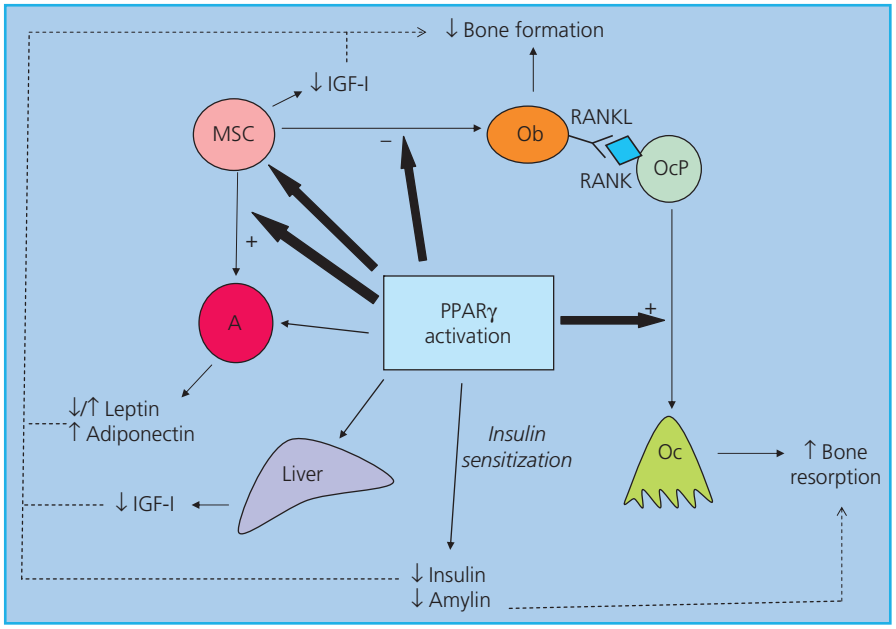

Figure 53.7 Mechanisms by which PPARγ regulates bone metabolism. Within the bone microenvironment (black arrows), activation of PPARγ signaling promotes differentiation of mesenchymal stem cells (MSC) into adipocytes (A) at the expense of osteoblasts (Ob), decreases stromal cell production of IGF-1, and promotes differentiation of osteoclast precursors (OcP) into mature bone-resorbing osteoclasts (Oc). The net effect is to decrease bone formation and increase bone resorption. Activation of PPARγ signaling at extraskeletal sites such as adipose tissue and the liver, and the ensuing effects of insulin sensitization on the β cells of the pancreas (regular arrows) may indirectly impact on the skeleton (interrupted arrows) by altering circulating levels of several hormones and cytokines, as indicated. RANKL, receptor activator of NF-κB ligand; RANK, receptor activator of NF-κB. Source: Reproduced with permission of A. Grey.

increased in T2DM, measurement of BMD in people with T2DM is still helpful in defining that person's fracture risk. Prescription of thiazolidinediones to people with T2DM who are found to be at high risk of fracture should be avoided unless there are compelling reasons to do so. Minimizing falls risk is an important component of skeletal management in diabetes; this can be achieved by targeting both macrovascular and microvascular disease complications, minimizing the risk of hypoglycemia, optimizing visual acuity, and minimizing use of other medications known to be associated with falls. Although there are no data from interventional studies on the effects of pharmacological treatments on fracture risk in diabetes, it is reasonable to assume that agents known to prevent fractures in osteoporotic populations without diabetes, such as bisphosphonates, will also be effective in diabetes [186].

Fracture healing in diabetes

Some evidence suggests that fracture healing is abnormal in diabetes. In rat models of T1DM, the mechanical and structural properties of the healing bone are inferior in the diabetic rats when compared to control animals, findings which are accompanied by evidence of both decreased callus size and collagen content [249, 250]. Interventional studies demonstrate that therapy with insulin to achieve normoglycemia is associated with fracture healing that is indistinguishable from that observed in non-diabetic animals [251, 252]. Subsequently, administration of insulin at the site of skeletal injury was also shown to promote fracture healing, without altering serum glucose, implying a role for insulin in directly mediating bone repair [253]. Few data are available from human studies, but increased rates of fracture non-union in both T1 and T2DM have been reported [254], as have higher than expected rates of serious complications in people with diabetes with open ankle fractures [255]. Diabetes is associated with a doubling of the risk of fracture-healing complications (delayed union, non-union, or malunion) [256], although long-term recovery might not be affected [257]. It is not known whether interventions specifically targeted to populations with diabetes lead to improved post-fracture outcomes. Further investigation of the influence of diabetes and its treatment on fracture repair in humans is needed.

54 Diabetes and Cancer: Evidence for Risk, Methodology and Implications

Ellena Badrick and Andrew G. Renehan

Institute of Cancer Sciences, University of Manchester; Health eResearch Centre, Farr Institute, Manchester Academic Health Science Centre, University of Manchester, Manchester, UK

Key points

- Type 2 diabetes (T2DM) is associated with increased risk of several adult cancer types, independent of common risk factors such as obesity.
- The extent of the cancer risk may be overinflated in many studies due to failure to take account of several biases, including detection time bias. When these are accounted for, diabetes–cancer associations are generally very modest.
- Two hypotheses seek to explain the pathophysiological mediation between diabetes and cancer risk, namely hyperglycemia and hyperinsulinemia. There is no strong argument favoring either.
- Early studies implicated a number of glucose-lowering drug classes in either increased (insulins, TZDs, incretin-based agents) or decreased (metformin) cancer risk. In hindsight, many of these earlier analyses probably overestimated the effect sizes. Using more robust methodological approaches to reduce confounding and biases, most of the recent evidence to these questions indicates little or no effect.
- There is now a large volume of laboratory evidence supporting the plausibility of effects of glucose-lowering drug classes on tumor development. While these might not translate at an epidemiological level, there is a need to continue research on these agents to better define their efficacy.

Background

Diabetes and cancer are common chronic conditions, and they frequently coexist. Worldwide, there are 415 million people with diabetes [1]; and there are 14.1 million with new diagnoses of cancer per year [2]. In the United Kingdom (UK), it is estimated that 5 million people will have diabetes by 2025 [3], and among these, there are an estimated 730,000 people with T2DM newly diagnosed between 2007 and 2012, of whom, there will be 103,000 new cancer diagnoses in the next 10 years (personal estimates). There is recent evidence that, in T2DM populations where deaths from cardiovascular disease are declining, cancer is becoming the most common cause of death [4]. Thus, morbidity and mortality from cancer among people with T2DM is an important and common clinical problem. Estimates of co-occurrence of prevalent diabetes and cancer are age-, sex-, population, and cancer-type specific but, for example, in the Danish population, some 35% of the population will have a diagnosis of diabetes in their lifetime, 44% a diagnosis of cancer, and about 15% will have both diagnoses [5].

A link between diabetes and cancer was noted in print as early as 1914 [6], but diabetes–cancer associations were glanced over as secondary findings in papers for nearly a century and seldom were the primary outcome of interest. However, in a 1991 paper focusing specifically on this link, using population data from Sweden, Adami and colleagues [7] noted significant increases in risk of liver, endometrial, and pancreatic cancer among people with diabetes. While (in hindsight) the occurrence of pancreatic cancer was thought to be due to reverse causality (i.e. the cancer causing metabolic changes that manifest themselves as symptoms of T2DM), the other findings were higher than expected. Interest in the diabetes–cancer link peaked again in 2009, after four epidemiological studies evaluating links between diabetes therapies and cancer risk were published simultaneously in *Diabetologia*, the official journal of the European Association for the Study of Diabetes (EASD) [8]. The 2009 controversy brought together researchers from diabetes and oncology communities, and focused attentions on the methodological complexities underpinning the links between diabetes and cancer [9]. These methodological issues and their importance for clinical interpretation will be highlighted.

This chapter describes the epidemiological evidence evaluating associations between diabetes, cancer incidence and mortality, followed by a section on the interpretation of these data. The chapter will then discuss the two prevailing mechanistic hypotheses

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

linking diabetes and cancer, namely hyperglycemia versus hyperinsulinemia. The central tenet of antidiabetes therapy is glucose control. From the pharmaco-epidemiological literature, there is some evidence that glucose-lowering medications might influence cancer risk, but again, discussion is required around interpretation of these data. Finally, a short section will cover the impact of diabetes in people diagnosed with cancer. Here, there are additional complexities in the interpretation of the data, beyond the scope of this chapter.

Diabetes and cancer risk: the epidemiological evidence

Cancer incidence

Over the past decade, a large volume of epidemiological evidence has accumulated of studies evaluating associations between diabetes and cancer risk, and summarized in several meta-analyses, listed in Table 54.1. In the main, the bulk of this evidence applies to populations with T2DM. These summary analyses are broadly consistent and show that diabetes is associated with an increased incident risk of the following cancer types: breast [10, 11], notably post-menopausal breast [11, 12]; colorectal [10, 13]; endometrial [14]; renal [15]; bladder [16, 17]; pancreas [18, 19]; liver [20, 21]; and non-Hodgkin lymphoma [22]. Many studies, from mainly Western populations, suggest that diabetes is inversely associated with risk of prostate cancer [23, 24], though recent analyses from studies in Asia-Pacific populations suggest the diabetes–prostate cancer relationship is the opposite, that is, a positive association [23, 25]. The reasons for these differences is an area of active research.

The above-listed relationships have been accepted by a number of international organizations, including a joint consensus statement from the American Diabetes Association, American Cancer Society, with the EASD and the European Cancer Organization [26], and a report from the American Association of Clinical Endocrinologists and American College of Endocrinology [27].

Cancer-related mortality

Findings for associations between diabetes and cancer-related mortality are broadly consistent with those for cancer incidence. There have been four major analyses (reviewed in [28]). These studies report positive associations between baseline diabetes and mortality from cancers of the colorectum (or colon), liver, pancreas, and bladder. However, associations for diabetes and mortality from prostate, breast, and endometrial cancers are less consistent than those observed for incidence of these cancers. For lung cancer (where there is no link between diabetes and cancer incidence), one large pooled analysis of 97 prospective cohorts [29], reported a significant positive association, but this was not replicated in the other analyses.

At a public health level, the mortality data are helpful as an index of disease burden. However, at a clinical level, there are limitations as mortality from cancer is conditional on the occurrence of cancer, but these studies fail to disentangle the impact of diabetes on incidence versus treatment outcome, treatment-related

Table 54.1 Summary estimates from meta-analyses of risk of incidence cancers in populations with type 2 diabetes.

Cancer type	Authors (year) (ref.)	Cohorts/case-control studies	Summary risk estimates (95% confidence intervals)
All breast cancer	Larsson et al. (2007) [11]	15/5	1.20 (1.12, 1.28)
	De Bruijin et al. (2013) [10]	unclear	1.23 (1.12, 1.34)
Post-menopausal breast cancer	Larsson et al. (2007) [11]	unclear	1.16 (1.09, 1.24)
	Boyle et al. (2012) [12]	25/15	1.27 (1.16, 1.39)
Colorectal cancer	Larsson et al. (2005) [13]	9/6	1.30 (1.20, 1.40)
	De Bruijin et al. (2013) [10]	unclear	1.26 (1.14, 1.40)
Endometrial cancer	Friberg et al. (2007) [14]	3/13	2.10 (1.93, 3.24)
Renal cancer	Larsson & Wolk (2011) [15]	9/0	1.42 (1.06, 1.91)
Bladder cancer	Larsson et al. (2006) [16]	3/7	1.24 (1.08, 1.42)
	Yang et al. (2013) [17]	15/8	1.68 (1.32, 2.13)
Pancreatic cancer	Huxley et al. (2005) [18]	19/17	1.82 (1.71, 1.94)
	Ben et al. (2011) [19]	35/0	1.94 (1.66, 2.27)
Hepatocellular carcinoma	El-Serag et al. (2006) [20]	13/13	2.50 (1.93, 3.24)
	Wang et al. (2012) [21]	32/17	2.31 (1.87, 2.84)
Non-Hodgkin lymphoma	Mitri et al. (2008) [22]	5/11	1.19 (1.04, 1.35)
Prostate cancers: Western populations	Kasper et al. (2006) [24]	12/7	0.84 (0.76, 0.93)
	Bansal et al. (2013) [23]	37*	0.81 (0.76, 0.85)
Prostate cancer: Asia-Pacific populations	Long et al. (2012) [25]	4/3	1.31 (1.12, 1.54)
	Bansal et al. (2013) [23]	8*	1.64 (1.00, 2.28)

*Unclear how many were cohort and case-control design.

morbidities and impact of T2DM on quality of life in people with cancer (see later). Furthermore, the observation that there were differences for some cancer sites between mortality and incidence suggest that some residual confounding may be present.

Type 1 diabetes and cancer

Is there a link between type 1 diabetes (T1DM) and cancer risk? This question is not always readily answered as studies often are unable to distinguish between T1DM and T2DM, and reviews on this question yield mixed results [30]. As T1DM presents in childhood, very long-term follow-up is required to detect sufficient numbers of common adulthood epithelial cancers for meaningful association analyses. Probably, for this reason, when some shorter-term studies address this question, they tend to find increases in risk of malignancies of early adulthood—such as lymphoma [31].

Large cohorts of people with T1DM are now surviving into their middle and late adulthood. A recent collaborative analysis from five countries identified 8800 cancers in populations with T1DM followed for 3.7 million person-years, and report that the pattern of increased incident cancer types mirrors that for T2DM [32]. However, overall the effects sizes are very modest and smaller than those for T2DM and cancer risk. As all these people are on long-term insulin therapy, this study concluded that they could not exclude an effect from this medication.

Interpretation of the epidemiological evidence

As a prelude to this discussion, we first define and distinguish confounding and bias, using the definitions from the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) reporting group [33]. *Confounding* literally means confusion of effects. An apparent association or lack of association is due to other factors that determine the occurrence of the disease but that are also associated with the exposure. Confounding produces relations that are factually correct, but that cannot be interpreted. *Bias* is a systematic deviation of a study's result from a true value. Typically, it is introduced during the design or implementation of a study and cannot be remedied later. Bias and confounding are not synonymous. Bias arises from flawed information or subject selection so that a wrong association is found.

Diabetes and cancer: potential confounding

A schematic representation of the causal mechanisms between diabetes and cancer risk is shown in Figure 54.1. Excess weight, commonly expressed as elevated body mass index (BMI), is a mutual risk factor for the development of T2DM and for several cancer types [34], and it is conceivable that the positive associations between T2DM and cancer incidence may simply reflect excess body weight or obesity as a confounder. There are many pathophysiological mechanisms in obesity that are common to T2DM, and may be important mediators of tumorigenesis [35]. These include alterations in sex hormone pathways, adipokines,

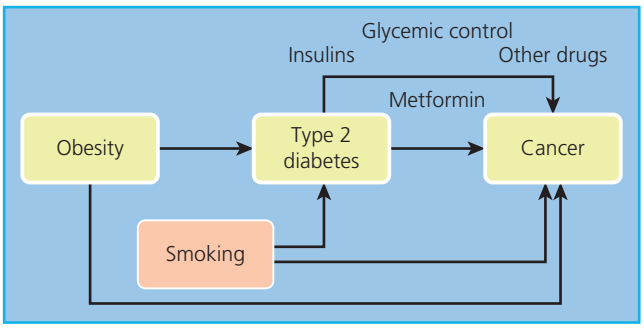

Figure 54.1 Schematic representation of the complexities of the link between obesity, diabetes, and cancer. Obesity is a mutual risk factor for type 2 diabetes and cancer, and might confound the relationship between diabetes and risk of incident cancer. Smoking is another potential mutual risk factor.

and subclinical inflammation; hyperinsulinemia and aberrations in the insulin-like growth factor (IGF) system [35].

However, it is generally held that the relationship between T2DM and cancer risk is independent of BMI [36]. There are number of justifications to support this tenet. First, whilst the list of diabetes-related cancers and obesity-related cancers overlaps, there are some exceptions. For example, there are associations between diabetes and bladder cancer, but in general, associations between obesity and bladder cancer are absent or very modest [37]. Elevated BMI is associated with increased risk of advanced prostate cancer [35], but diabetes appears to be inversely associated with prostate cancer, at least in Western populations. Second, in cohort studies where risk estimates have been specifically reported with and without adjustment for BMI, positive diabetes-cancer associations have remained for breast [38], colorectal [39], and endometrial [40] cancers.

Similarly, cigarette smoking is a mutual risk factor for the development of both diabetes and several cancer types. Although, this question is understudied, as few diabetes-related cancers are smoking-related cancers, it would seem that smoking is not a major confounder. Nonetheless, smoking status is important to consider in the interpretation of BMI-cancer associations as smokers tend to have lower mean BMI compared with non-smokers; and smoking is important in studies where mortality is the endpoint as smoking-related non-neoplastic causes of death (e.g. cardiovascular disease) might compete with neoplastic causes of death.

A note on ethnicity is pertinent. In the United States, compared with non-Hispanic whites (11%), the age-standardized prevalence of diabetes is higher among non-Hispanic blacks (22%), non-Hispanic Asians (21%), and Hispanic persons (23%) [41], but cancer incidences are generally lower in the latter three ethnic groups compared with white populations. An exception is the incidence of prostate cancer, which is higher among non-Hispanic blacks compared with white populations. Finally, cancer screening is an additional confounder—as there may be differential rates of cancer detection and diagnosis between populations with and without diabetes, if there were differential rates of cancer

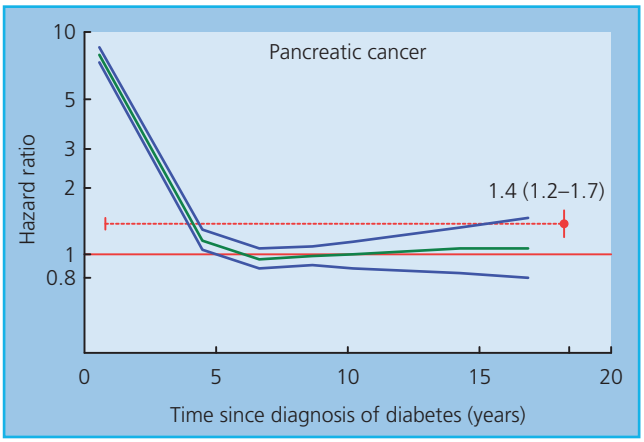
screening. Thus, with colorectal cancer as an example, there are several trial-proven effective approaches to colorectal cancer screening—including fecal occult blood testing (FOBT), once-only flexible sigmoidoscopy, and colonoscopy—but some evidence (reviewed in [28]) that people with T2DM underutilize colorectal cancer screening programs. For breast cancer screening, similarly, data indicate lower rates of attending mammographic screening among those with diabetes than those without (reviewed in [28]). As a final note to cancer screening, it is important to note that the risk estimates in Table 54.1 are relative (rather than absolute) risk. These are very modest elevated risks at an individual level and people with T1DM and T2DM do not require enhanced cancer screening.

Diabetes and cancer: potential biases

There are a number of potential biases important to the interpretation of the diabetes–cancer association. These include:

1 Detection time bias: This bias arises due to the co-diagnoses in the same time window of the disease exposure of interest (here, diabetes) and outcome of interest (here, cancer). Thus, there is a peak co-diagnosis of diabetes and cancer in the first 2 to 3 years after initial diagnosis of diabetes. However, these cancers diagnosed shortly after a new diagnosis of diabetes are generally not caused by diabetes. Inclusion of these cancers temporarily early post diagnosis of diabetes exaggerate the risk estimates for the diabetes–cancer associations (see Figure 54.2). This "co-diagnosis peak" (and potential detection bias) is common for several cancer types after a new diagnosis of diabetes [42]. Some investigators refer to this as protopathic bias [43], and argue that it is a serious cause of inflated risk estimates between diabetes and cancer incidence. Within the "co-diagnosis peak," there are at least three underlying causal relationships: (i) reverse causality, (ii) heightened clinical investigations (ascertainment bias) from diabetologists, and (iii) heightened clinical investigations from the oncology team. The simple methodological solution is to use an incident diabetes cohort and exclude cancers diagnosed in the first 2–3 years. An alternative solution is to use time-varying hazard models as shown in Figure 54.2.

2 Immortal time bias: This refers to a period of follow-up during which, by design, death or the study outcome cannot occur [44]. This bias is common and well known in the pharmaco-epidemiology literature, but not always appreciated in the general clinical epidemiology literature. In pharmaco-epidemiology studies, immortal time typically arises when the determination of an individual's treatment status involves a delay or wait period during which follow-up time is accrued. This wait period is considered immortal because individuals who end up in the treated or exposed group have to survive (be alive and event free) until the exposure definition is fulfilled—for example, at least two prescriptions of an antidiabetes therapy. If they have an event before starting treatment, they are placed in the untreated or unexposed group. Bias is introduced when this period of "immortality" is either misclassified (a misclassification bias) with regards to treatment status or excluded from the analysis (a selection bias). Immortal time bias is particularly problematic because, first, it biases the results in favor of the treatment under study by conferring a spurious survival advantage to the treated group (a misclassification bias), and second, by excluding the survival time in persons who later take up the treatment, the survival times of the narrowly defined non-treatment group is disadvantaged (selection bias) (Figure 54.3). These principles can be readily expended to diabetes as the exposure and incident cancer is the event of interest. Immortal time bias should be suspected in fixed cohort analyses where the covariate diabetes is handled as an "ever/never"



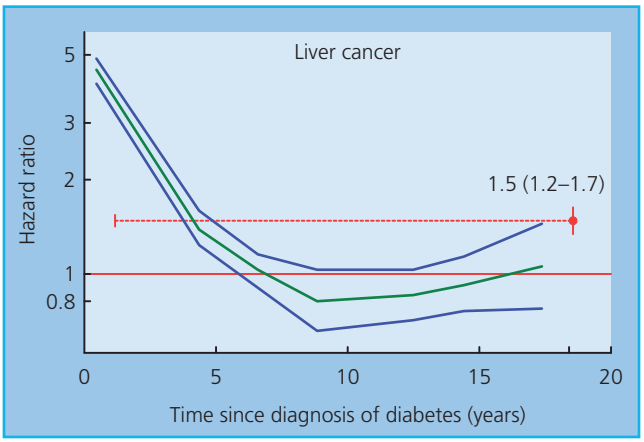


Figure 54.2 Detection time bias. This bias arises due to the co-diagnosis in time of the disease exposure of interest (here, diabetes) and outcome of interest (here, cancer). The hazard plots here are based on data from Adami et al. 1991 [7] and show how the hazard varies with time since diagnosis of diabetes, shown for pancreatic and liver cancers. There is a peak co-occurrence of the diabetes and cancer in the first 2 to 3 years. However, these cancers are not caused by diabetes. If we include these cancers in the risk association model (fixed cohort analysis: shown as a red dotted line), the net risk estimates are 1.4 and 1.5, respectively, and 95% confidence intervals (CIs) are greater than one, suggesting a significant positive association. However, in the preferred time-varying model (shown as a green line and 95% CIs as blue lines), the hazard between 5 and 15 years after diabetes diagnosis is close to one, that is, null association. It is only 15 years after diabetes diagnosis, that there is a suggestion of a positive "causal" association between diabetes and risk of pancreatic and liver cancers.

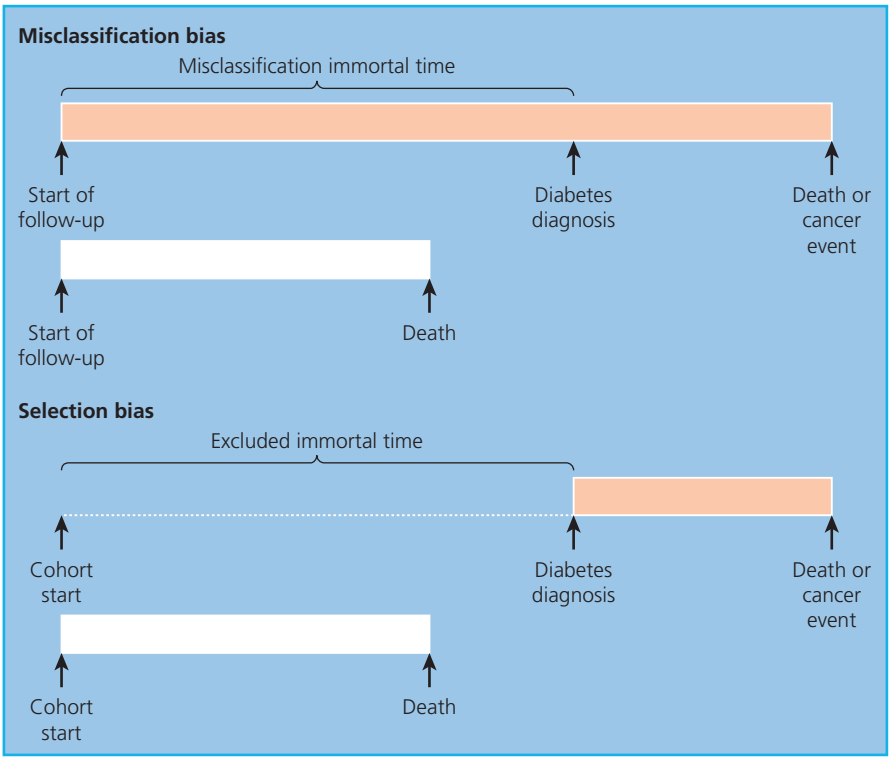

Figure 54.3 Immortal time bias is introduced in cohort studies when the period of immortal time is either incorrectly attributed to the treated group through a time-fixed analysis (top) or excluded from the analysis because the start of follow-up for the treated group is defined by the start of treatment and is, by design, later than that for the untreated group (bottom). Source: Schematic diagram adapted from [45]. Reproduced with permission of BMJ Publishing Group Ltd.

term. A methodological solution is to use time-varying models [45, 46].

3 Allocation bias: This is particularly prevalent in pharmacoepidemiological studies (discussed later) and is sometimes referred to as confounding by indication. An example might be where insulin therapy is generally prescribed late in the course of diabetes when patients are older and "sicker." Not surprisingly these biases result in an apparent increased cancer risk [47]. Methodological solutions require advanced methods such as inverse probability weighting, which is to model the data with two time-updated terms in the model [48].

4 Survival bias: This bias is due to differential survival (or differential loss to follow-up) in those undergoing the index exposure (here, diabetes or diabetes therapies) compared with that of the comparator group. In turn, this will differentially influence the number of individuals at risk of developing the index event of interest (here, subsequent incident cancer). This is sometimes referred to as susceptibility bias, and is a specific form of selection bias. The methodological solution here is to use competing risk analyses.

Hyperglycemia versus hpyerinsulinemia hypotheses

What are the drivers of cancer development in people with diabetes? There are broadly two theories: (i) hyperglycemic, and (ii) hyperinsulinemic hypotheses [49].

Excess blood glucose is the hallmark of diabetes and could be a major risk factor for cancer development [50]. Pre-diabetes is also associated with an increased risk of cancer [51]. This hypothesis suggests that hyperglycemia is a confounder in the observed increased risk of cancer outcomes associated with increasing use of "late pathway" drugs, for example, insulin therapy. When looking at evidence from *in vivo* studies, it is true that transformed cells have a high glucose requirement, in keeping with their high rates of glycolysis relative to normal cells, as first recognized by Otto Warburg, and it is still conceivable that hyperglycemic conditions would give cancer cells a relative growth advantage. However, most cancer cells have a constitutively high level of glucose uptake, and are able to fully satisfy their glucose requirements under normoglycemic conditions [52]. Experimental studies exploring dose–response relationships between glucose concentration and tumor growth generally show that increasing glucose concentration does increase proliferation, but with a plateau occurring around 5 mmol/L. There is some population-level evidence that very high or low levels of HbA_{1c}, the marker of average glucose in the blood, is related to mortality [53]. However, cancer risk does not appear associated with the duration or intensity of hyperglycemic exposure, and glucose-lowering therapy does not appear to diminish the risk of cancer in people with diabetes. For example, a meta-analysis of major trials into intensive glycemic control and cancer risk concluded that it is unlikely that hyperglycemia plays a role in cancer development [54]. Further evidence comes from data comparing antidiabetes therapies and categorizing drugs that increase insulin levels (exogenous insulin or secretagogues) and comparing these to drugs that lower insulin levels such as

metformin and thiazolidinediones. If within the drug groups one stratifies the populations by glycemic control and see no difference by HbA_{1c} status, this evidence would dispute the hyperglycemia theory [55].

T2DM is characterized, in the early stages, by insulin resistance and consequent hyperinsulinemia. The latter promotes tumor cell growth directly via insulin receptors [56], but effects may additionally be mediated indirectly via the type 1 IGF receptor [56]. In turn, many cancer cell lines express insulin and IGF receptors. Therefore high endogenous insulin levels or administration of exogenous insulin could theoretically have a promoting effect on neoplastic disease. Insulin resistance may also promote cancer risk via other mechanisms, such as decreased sex-hormone binding globulins leading to excess estrogen and stimulation of estrogen-dependent tumors or inflammation. Insulin resistance is also associated with a higher production of NEFA, interleukin-6, plasminogen activator inhibitor-1, leptin, and tumor necrosis factor α [35]. Notably, cancers are heterogeneous and insulin responsiveness is not universal. Nonetheless, the accumulation of experimental and epidemiological evidence is consistent with a hyperinsulinemia hypothesis, but overall, there is no strong argument favoring either hyperinsulinemia or hyperglycemia as the single key driver of tumorigenesis.

Pharmaco-epidemiology: glucose-lowering agents and cancer risk

Interpretation

All the confounding and biases described earlier, in relation to interpretation of epidemiological studies evaluating diabetes and cancer risk, also apply to pharmaco-epidemiology. Specific to diabetes therapies and cancer, these have been addressed in a concept paper from the Diabetes and Cancer Research Consortium (DCRC), an international group mainly focusing on pharmaco-epidemiological queries in the complex relationships between diabetes, diabetes treatment, and cancer risk [47]. In this framework document, two important methodological features were emphasized: (i) the need to account for detection time bias; and (ii) the need to set up data to account for time-varying exposures. The interpretations of many early "first-generation" reports were limited by failure to take account of these key analytical issues [46].

Allocation bias deserves specific comment. To address this bias, one solution advocated by the DCRC group is to model the data with two time-updated terms in the model: (i) a binary term for ever exposure up to that time point, and (ii) a continuous term for cumulative exposure [48]. Further methodological work from DCRC members came when Walker and colleagues [57] summarized the problems of capturing drug exposure from observational datasets and described optimal methodology to reduce this bias. For instance, they illustrated that different drugs are administered to control glucose as T2DM progresses, making direct "trial-like" comparisons between drug classes uninterpretable. In this setting, the use of ever/never drug exposure categories only should be avoided, and cumulative exposure handled statistically as a time-varying covariate—we refer to these as "second-generation" studies [46]. These points are worth remembering when reading the next sections.

Table 54.2 Anti-tumor mechanisms of action of metformin in the laboratory.

Mechanisms of action
• Activation of LKB1/AMPK pathway
• Induction of cell cycle arrest and/or apoptosis
• Inhibition of protein synthesis
• Reduction in circulating insulin levels
• Inhibition of the unfolded protein response
• Activation of the immune system

Metformin and cancer risk

For almost a decade, there have been suggestions in the epidemiological literature that, among people with T2DM, use of metformin is associated with a reduced risk of certain cancers [58]. Coupled with these observations, there are now many laboratories across the globe exploring the role of metformin in cancer, and several novel anti-cancer mechanisms have been demonstrated and validated, beyond its well-known clinical glucose-lowering effects [59] (Table 54.2). In an era when oncologists are encouraged to repurpose inexpensive licensed drugs, metformin seemed a strong candidate, and led one UK mainstream newspaper to headline "A diabetes pill that costs just 2p a day could prevent thousands dying from Britain's biggest cancer killers" [60].

However, we now understand that many of the earlier epidemiological studies on this question contained time-related biases that artificially made metformin look "protective." Most important of these was immortal time bias, described earlier. The net result of this bias is an advantage to the users of the drug of interest (here, metformin) when the analysis is simply categorized by ever/never use. This was well illustrated by Suissa and colleagues [61], who found that immortal time bias was prevalent among many studies that reported a reduced cancer risk associated with metformin use. By contrast, those studies that used methods to avoid these biases reported no effect of metformin use on cancer incidence.

Here again, treatment allocation bias is a potential pitfall to interpretation. For example, metformin is first-line treatment for diabetes, and is therefore used earlier in the disease course than other medications. Those who achieve control with metformin alone differ in disease severity from those who require additional medication. Differential allocation of drugs based on such confounding factors tends to exaggerate the "protective" benefits of metformin. Differential allocation is an inevitable bias in observational studies and has to be addressed within a randomized trial framework. Primary cancer prevention trials are currently impractically huge and thus investigators have selected to test the hypothesis that metformin is cancer protective in the

secondary cancer prevention setting. An example is an adjuvant trial in early breast cancer, NCIC MA.32, with a primary endpoint of 5-year invasive cancer-free survival [62]. The recruitment target (3582 women without diabetes) was completed in early 2013—the results of this trial are soon to be reported.

The third key appreciation in the story of metformin and cancer lies in the biology. It has become clear that many preclinical *in vivo* studies use concentrations of metformin higher than those safely obtained in the clinical setting. Most *in vitro* studies report using doses of metformin between 1 and 40 mM, which is well above the feasible therapeutic plasma levels (0.465–2.5 mg/L or 2.8–15 mM) in humans [63]. It is possible that metformin causes an energy stress in these studies that far exceeds effects seen clinically.

Insulins and cancer risk

There are hypothetical physico-chemical reasons why some insulins might be pro-tumorigenic. Specifically, molecular engineering of the insulin molecule to form some insulin analogs results in a molecule that "looks" more like IGF-I, with high affinity for the type 1 IGF receptor [64] (Figure 54.4). This receptor and its downstream pathway are important for tumor development.

In the late 2000s, several observational studies evaluated the putative link between insulin glargine and cancer risk, and were subsequently meta-analyzed in several reviews (reviewed elsewhere [65]). In general, there are many inconsistencies in the findings of these meta-analyses. In turn, these reflect important design differences in the included studies. For example, some studies evaluated any insulin use versus non-insulin therapies in people with diabetes, while others evaluated glargine versus non-glargine insulin use. As insulins are generally prescribed late in the course of diabetes, patients are older and "sicker" and not surprisingly these biases result in an apparent increased cancer risk. None of the meta-analyses directly addressed the problem of time-related biases. For similar reasons, lumping data from case-controls (where time-varying exposures generally cannot be modelled) with cohorts is problematic.

The publication of the ORIGIN trial in 2012 brought some clarity to the above inconsistencies (this debate is expanded upon elsewhere by the authors [65]). This trial randomly assigned 12,537 people with impaired glucose tolerance or T2DM to receive insulin glargine versus standard care [66]; the largest trial of its type. Although the protocol endpoints were cardiovascular non-fatal events or deaths, following the concerns emerging about cancer links in the late 2000s, the investigators additionally detailed risk per cancer type by treatment allocation. There were no differences between treatment arms for all cancer incidence or deaths, and no differences between treatment arms for specific reported cancer types. These data seem definitive, although there are some caveats. First, although median follow-up was 6.2 years in the ORIGIN trial, there is a rapid drop-off thereafter such that only 14% of recruited participants were followed to the seventh year. Many cancer epidemiologists would consider this lag period too short to assess associations between an exposure and cancer incidence. Second, there was considerable contamination of insulin use across the trial arms.

Pioglitazone and cancer risk

Pioglitazone and rosiglitazone are thiazolidinediones, which act as PPARγ agonists and are used as second-line therapies in the treatment of T2DM. However, their use has been questioned owing to safety concerns. In preclinical studies, exposure of male rats to pioglitazone was associated with an increased risk of bladder cancer. In 2005, the ProActive trial (a large European randomized controlled trial evaluating the effects of pioglitazones on cardiovascular outcomes) found a non-significant increase in the incidence of bladder cancer in the pioglitazone-treated group. Based on these animal studies and trial data, the U.S. Food and Drug Administration (FDA) commissioned the manufacturer to carry out a 10-year observational cohort study to further examine this risk. An initial mid-term analysis showed that 2 or more years of cumulative exposure to pioglitazone was associated with an increased risk of bladder cancer [67]. Around the same time, a similar increase in risk was observed in a French cohort [68], which led to the withdrawal of pioglitazone from France and Germany.

More recently, two large analyses suggest a lack of association between pioglitazone and bladder cancer. Levin and colleagues

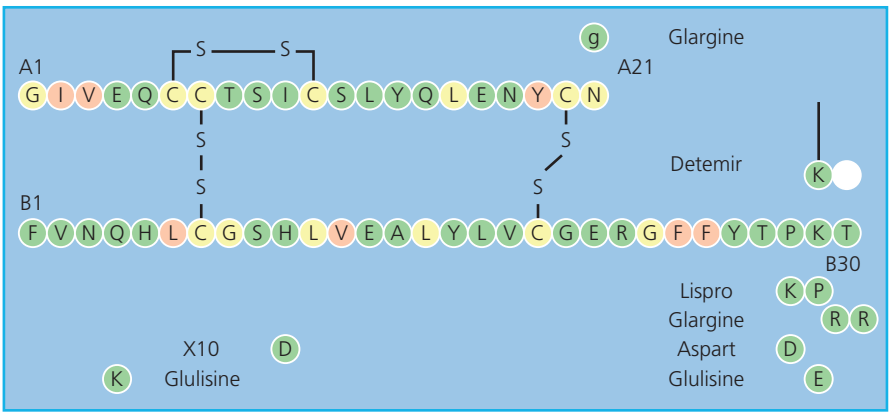

Figure 54.4 Schematic representation of molecular engineering of the insulin molecule. Most of the engineering is in the B chain, except for glargine, which also has an amino acid substitution in the A chain. These molecular changes make insulin glargine more IGF-I "like." The net results are twofold: increased affinity for the mitogenic IGF-I receptor (IGF-IR) and slower dissociation time off the IGF-IR. Source: Modified from [64].

[48], on behalf of the DCRC, performed an international (six populations) cumulative exposure analysis on 1.01 million persons with diabetes with 3248 incident bladder cancers; while Lewis et al. [69] reported a lack of association between pioglitazone use in persons with diabetes and incident bladder cancer in the 10-year follow-up of a Kaiser Permanente Northern California (KPNC) cohort (193,099 persons: 1261 bladder cancers). Both analyses found no associations between pioglitazone use and incident bladder cancer risk. An additional study from the KPNC group indicated that proteinuria testing in people with diabetes may be a confounder in studies of pioglitazone and bladder cancer [70].

Incretin-based drugs and cancer risk

Incretin-based glucose-lowering medications were introduced to the US market in 2005 and have proven to be effective glucose-lowering agents, both as glucagon-like peptide 1 receptor agonists (GLP-1RA) and as dipeptidyl peptidase 4 (DPP-4) inhibitors. From 2011, surveillance from the US FDA adverse events reporting system started to identify significantly higher risk of pancreatic cancer for GLP-1R agonists and DPP-4 inhibitors, and significantly higher risk of thyroid cancer for GLP-1R agonists. A hypothesis emerged that both drug classes promote acute pancreatitis, and then initiate histological changes suggesting subclinical chronic pancreatitis with associated pre-neoplastic lesions (e.g. ductal proliferation), and potentially, in the long run, pancreatic cancer [71]. These data initially came from pharmaco-vigilance databases and are particularly challenging to interpret for several reasons: long-term use of incretin-based glucose-lowering is limited, and there had been inadequate adjustment and modelling to take account of the biases and confounding outlined in the early paragraphs. Additionally, it is unclear whether or not pre-clinical animal model data translate directly to human cancer development.

Since these initial reports, subsequent studies have failed to demonstrate associations between incretin-based drug use and pancreatitis (reviewed in [72]), with one study pointing out that associations with pancreatitis might reflect diabetes severity rather than drug use per se [73]. For cancer, animal studies suggest a role of GLP-1R activation in the development of pancreatic cancer and thyroid cancer in rodents, but such an effect in humans seems less likely as there is relative lack of expression of GLP-1R on pancreatic ductal cells and thyroid tissues [72]. Elevated risk of pancreatic or thyroid cancers have not been replicated in human observational studies or analyses of data from clinical trials. Based on current evidence, continuous monitoring of the cancer issues related to incretin-based therapies is required.

Other medications

It is important to note that people with diabetes are commonly on several other medications, in addition to those specifically prescribed as glucose-lowering drugs. There include aspirin, statins, and antidepressants, all of which have been implicated in cancer risk reduction in other settings. The time-dependent interrelationships between the use of these drugs is clearly complex to model, and with a few exceptions [74], is currently understudied.

Impact of diabetes on outcome after cancer diagnosis

While the link between diabetes and incident cancer risk is now established, it is less clear, and indeed, more complex, to interpret whether diabetes at or after cancer diagnosis, impacts adversely on outcome. In general terms [detailed elsewhere (28)], there are two distinctive study designs: (i) inception cohort studies evaluate the effect of baseline diabetes on cancer-related mortality in general populations; whereas (ii) the oncology literature often uses cohorts of patients with a cancer diagnosis and pre-existing T2DM and evaluates the endpoints of cancer-specific survival (or mortality). Some epidemiologists refer to the latter as case fatality studies. The clinical implications of the findings from these study types differ considerably; in statistical terms, time zero is at baseline cohort entry in the former; whereas time zero is date of cancer diagnosis or cancer initial treatment in the latter.

Within the above two study types, there are multiple levels of potential confounding and biases of cancer morbidity and mortality studies. A methodological group of the DCRC has identified nine levels on the cancer pathway at which confounding may arise [28]: cancer screening use; stage at diagnosis; cancer treatment selection; cancer treatment complications and failures; peri-treatment mortality; competing risks for long-term mortality; effects of T2DM on anti-cancer therapies; effects of glucose-lowering treatments on cancer outcome; and differences in tumor biology.

In the face of the above limitations, the current evidence on the impact of diabetes on outcome after cancer diagnosis is as follows: (i) diabetes is associated with increased all-cause mortality in people with cancer, but the evidence that it influences cancer-specific mortality is inconsistent (reviewed elsewhere [28]); (ii) for some cancers, there is evidence that people with T2DM present with more advanced disease, receive suboptimal treatment, and have poorer oncological outcomes [75]; and (iii) compared with people with cancer but without diabetes, people with cancer and diabetes have a poorer quality of life and reduced physical activity [76].

Clinical implications

For day-to-day clinical practice, there are a number of key messages. First, T2DM is associated with increased risk of several adult cancer types, independent of common risk factors such as obesity. However, these elevated risks are generally very modest. While it is important that people with diabetes partake in cancer screening

programs, in common with the rest of the general population, they do not require enhanced cancer screening. This is best illustrated by colorectal cancer screening, where some commentaries have advocated high-risk screening colonoscopy for people with diabetes [77]. The British Society of Gastroenterology [78] classify risk in individuals with a family history of colorectal cancer (and without a hereditary syndrome) as moderate and subdivide this into *high-moderate* risk (lifetime risk: 1 in 6 to 10) and *low-moderate* risk (lifetime risk: 1 in 12). The recommendation in these individuals is early screening colonoscopy. The lifetime risk for colorectal cancer in people with diabetes is 1 in 20 to 40. There is therefore no need for screening colonoscopy above and beyond the general population.

Second, two hypotheses seek to explain the pathophysiological mediation between diabetes and cancer risk, namely hyperglycemia and hyperinsulinemia. There is no strong argument favoring either. In terms of general management of people with diabetes and the minimization of cancer risk, the extrapolation of recommendations applicable to the risk reduction of cardiometabolic complications seem appropriate. There is no strong case to have cancer prevention-specific recommendations among people with diabetes. Thus, shared (cardio-metabolic) recommendations including weight management, optimal glucose control, and treatment of elevated blood pressure and dyslipidemia are applicable.

Third, a number of glucose-lowering drug classes have been implicated in either increased (insulins, thiazolidinediones, incretin-based agents) or decreased (metformin) cancer risk. Most of the recent evidence to these questions has been reassuring. This information can be conveyed to people already on these medications or about to commence these as new therapies.

Finally, there is now a large volume of laboratory evidence supporting the plausibility of effects of glucose-lowering drug classes on tumor development. While these might not translate at an epidemiological level, there is a need to continue research on these agents to better define their efficacy in cancer modulation. These drugs might have an impact (either beneficial or harmful) at a clinical level in subpopulations of patients.

Acknowledgments

The authors acknowledge the many colleagues and other researchers around the world who have shared with them, over many years, their thoughts, experiences, and methodological insights into the details and concepts described in this chapter.

Conflict of interest

AGR has received lecture honoraria and advisory board consultant fees from Novo Nordisk, manufacturer of several insulin analogs. EB has no conflict of interest.

55 Diabetes and Infections

Clive S. Cockram and Bonnie C.K. Wong
Chinese University of Hong Kong, Hong Kong

Key points

- Diabetes is associated with an increased overall risk of infections.
- The presence of diabetes also modifies the course of many infections and increases morbidity and mortality.
- Multiple disturbances in innate immunity have a role in the pathogenesis of the increased prevalence of infections in people with diabetes.
- Impaired phagocytosis by neutrophils, macrophages and monocytes, impaired neutrophil chemotaxis and bactericidal activity, and impaired innate cell-mediated immunity appear to be the most important disturbances of the immune system.
- Humoral immunity appears relatively unaffected, hence plasma levels of antibodies and responsiveness to vaccination are relatively unaffected.
- In general, better regulation of the diabetes leads to an improvement in cellular immunity and function.
- Increased skin and mucosal carriage of *Staphylococcus aureus* and *Candida* species may increase risk of infection with these organisms.
- Some microorganisms become more virulent in a high glucose environment; examples include certain *Klebsiella* serotypes and *Burkholderia pseudomallei*.
- Viral infections such as hepatitis C are associated with a higher prevalence of diabetes.
- Highly active antiretroviral therapy for HIV/AIDS may also precipitate diabetes.
- Vascular disease such as microangiopathy can further impair the expression of the immune response as well as affecting the overall function of the microcirculation. It is commonly a factor in severe infections such as malignant otitis externa, emphysematous pyelonephritis, and necrotizing fasciitis.
- Diabetes increases the risk of tuberculosis approximately threefold and also increases the risk of treatment failure. Unusual or extrapulmonary sites of infection may be important and cavitatory disease is more common.
- Urinary tract infections and asymptomatic bacteriuria are more common in people with diabetes. Autonomic neuropathy is a common and important underlying factor.
- Skin and soft tissue infections are more common, with the infected diabetic foot as a prime example. Vascular disease and diabetic neuropathy are important underlying factors in the vulnerability of the foot to infection. Skin infection or infections of the external genitalia are common presenting features of diabetes. Necrotizing fasciitis is also associated with diabetes.
- Some uncommon but life-threatening infections occur almost exclusively in people with diabetes. Examples include the rhinocerebral form of mucormycosis, malignant otitis externa, Fournier gangrene and emphysematous forms of cystitis, pyelonephritis, and cholecystitis.
- Other factors that can predispose to infection include renal failure, obesity, need for hospitalization, indwelling catheters and delayed wound healing.

Introduction

People with diabetes develop infections more often than those without diabetes and the course of the infections is also more complicated. Historically, infections have been well recognized as an important cause of death in diabetes and remain a very important cause of morbidity and mortality. This is particularly true in less well-developed countries and areas, where infections are commonly the first manifestation of previously unknown diabetes. The infected diabetic foot remains a prime example of this phenomenon.

While the association between diabetes and infections is well recognized, the relationships are complex, not always clear-cut, and often controversial. Data on the true incidence of certain infections are lacking and a number of factors complicate efforts to assess risk of infections and outcomes. Studies are often retrospective and uncontrolled in nature.

Some infections, which occur predominantly in people with diabetes, are uncommon and inevitably have limited data. Examples include malignant otitis externa, mucormycosis, emphysematous forms of cholecystitis, cystitis and pyelonephritis, and Fournier gangrene.

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

In the case of more common infections that, while not limited to people with diabetes, have diabetes as a complicating factor, many variables make for considerable heterogeneity in the clinical course. Examples include duration of disease, presence of diabetic complications, glycemic control (both recent and longer term), access to and provision of medical services, and presence or absence of other concurrent illnesses.

A study from Utrecht has confirmed that, in general terms, people with type 1 (T1DM) and type 2 diabetes mellitus (T2DM) are at increased risk of lower (but not upper) respiratory tract infection, urinary tract infection, and skin and mucous membrane infections [1]. In this study, the well-documented increased risk of urinary infection was extended to include both risk of recurrence in both sexes and risks in men (perhaps explained by prostatitis).

A study, conducted in Ontario, Canada, compared people with diabetes with matched individuals without diabetes [2]. The investigators calculated the risk ratios, both for contracting an infection and for death from infection. Forty-six percent of people with diabetes had at least one hospitalization or outpatient visit for infections compared with 38% of those without diabetes, the relative risk ratio being 1.21. However, the risk ratios for infectious disease-related hospitalization or death were noticeably higher at 2.17 and 1.92, respectively. This may be attributable to increased severity and presence of complications. In the case of hospitalization, it could also reflect a lower threshold on the part of physicians to admit people with diabetes to hospital when they have intercurrent illnesses. A study, also from Canada (Calgary Health Region), conducted a population-based assessment of severe bloodstream infections requiring intensive care admission. Demographic and chronic conditions that were significant risk factors included diabetes, with a relative risk ratio of 5.9. The most common organisms were *Staphylococcus aureus*, *Escherichia coli*, and *Streptococcus pneumoniae* [3].

Bertoni et al. [4] also suggest that adults with diabetes are at greater risk for infection-related mortality, and that the excess risk may be mediated by cardiovascular disease (CVD). When diabetes was combined with CVD, the relative mortality risk was 3.0 (1.8–5.0), compared to 1.0 (0.5–2.2) in the absence of CVD.

Increased hospitalization rates due to bacterial infections have also been reported in adults (>14 years, $n = 4748$; RR 2.3) with T1DM and correlates with severity of any coexistent nephropathy. It was also noted that each percent unit of HbA_{1c} rise equated to a 6–10% increase in annual antibiotic purchases [5].

Further evidence that the presence of diabetes can worsen the outcome of infections comes from a number of sources. For example, T2DM is associated with an increased mortality from community-acquired pneumonia. While much of this may be explained by factors such as age and coexisting comorbid illnesses, admission hyperglycemia has been shown to be a particularly important predictor of death. Also, even in people without previously diagnosed diabetes, glucose levels in general assume importance [6].

The evidence extends also to the area of recently emerging infectious diseases. During the outbreaks of severe acute respiratory syndrome (SARS) in 2003 in Toronto, the presence of diabetes was an independent risk factor for poor outcomes (intensive care unit admission, mechanical ventilation, and death) with a threefold increase in relative risk [7]. A recent report, from Saudi Arabia, of Middle Eastern respiratory syndrome (MERS) coronavirus infection shows a 60% overall fatality rate, with underlying diabetes being present in 68% of cases, the commonest of a number of important comorbidities [8]. Increased severity of the clinical presentation of Dengue fever is also described, with increased representation of Dengue hemorrhagic fever among people with diabetes [9]. These, and other examples, emphasise the importance of diabetes both in new and emerging infectious diseases and in those that are expanding their range in response to factors such as globalization and climate change.

Both host- and organism-specific factors appear implicated in the increased susceptibility and risk. From the host perspective, defects in innate immunity are particularly important, notably decreased functions (chemotaxis, phagocytosis and killing) of neutrophils, monocytes and macrophages. Other factors include effects of diabetic complications, poor wound healing, the presence of chronic renal failure, and frequent hospitalizations, with the attendant risk of nosocomial infection.

Infections may also precipitate metabolic derangements, producing a bidirectional relationship between hyperglycemic states and infection. Some infections may also be implicated more directly in the etiology of diabetes.

Physicians working in primary care need to have high awareness of the relationships between diabetes and infection, and of the important infections that may be involved. Infections involving the foot, soft tissues, skin and nails, as well as the urinary tract, are of particular importance as they are commonly encountered in people with diabetes, may be present at diagnosis and may be the presenting feature that leads to the diagnosis of diabetes. Infections of the foot and skin will receive additional attention elsewhere in this textbook so, in order to avoid duplication, coverage in this chapter is curtailed. This should not be taken as an indication of lack of relative importance, the opposite being the case. The other chapters concerned should be taken as forming part of the overall coverage of the topic of diabetes and infections (see Chapters 17, 48 and 52).

Diabetes, the immune system and host factors

Host immune response

The increased susceptibility of people with diabetes to bacterial (and other) infections is well established. Although the mechanisms remain incompletely understood, deficiencies in the host innate immune response appear relatively more important than changes in adaptive immunity.

The presence of diabetes has multiple effects upon innate immune responses, including effects upon neutrophils, monocytes, and other components of innate immunity, which have important roles in the increased prevalence and enhanced severity of infections. The effects include reduced chemotaxis, phagocytosis and impaired bactericidal activity.

Some disturbances in the complement system and in cytokine responses have also been described in people with diabetes (e.g. low complement factor 4 and decreased cytokine responses after stimulation), but their role in the increased susceptibility to infection is less clear [10]. Consistent defects have not been demonstrated. No clear disturbances in adaptive immunity have been described. Cell-mediated immune disturbances may be minimized by good glycemic control. Humeral adaptive immunity, in particular, appears relatively unaffected as exemplified by the relatively normal antibody responses to most vaccinations and the fact that serum antibody concentrations and responses are generally normal, despite the potential for glycation of antibodies such as IgG. For example, people with diabetes respond to pneumococcal vaccine equally as well as controls without diabetes [11, 12].

The complexity of the component systems involved in the immune system makes comparison between studies difficult and it is obviously simplistic to study individual components in isolation given their interdependency.

Many studies have used i*n vitro* or animal model methodology to identify the mechanisms of immune impairment and a full review of these studies is outside the scope of this chapter. However, the following observations may serve as examples from within the range of abnormalities that have been found.

Neutrophil chemotaxis, neutrophil adherence to vascular endothelium, phagocytosis, intracellular bactericidal activity, opsonization, and other aspects of innate immunity are all depressed in hyperglycemic individuals with diabetes [13–15]. These changes lead to reduced host defense in response to infection with extracellular bacteria. Both impaired chemotaxis and phagocytosis have also been described in monocytes of people with diabetes [16].

Defects in innate immunity have been shown to predispose *db/db* mice to *S. aureus* infections. Interestingly, however, these mice show a heightened inflammatory response which occurs in association with an impaired neutrophil respiratory burst, and the recruited neutrophils fail to resolve the infection [17]. Such a heightened inflammatory response may be a factor in humans with tuberculosis. In this context also, while release of tumor necrosis factor and interleukin-1 from lipopolysaccharide-stimulated macrophages has been shown to be reduced in diabetic mice compared with control mice [18], study of monocytes from humans with diabetes indicates upregulation of the secretion of the same inflammatory mediators [19]. This further illustrates the difficulty in comparing studies conducted in different settings and species.

Some innate (e.g. cytokines, complement) immune functions are decreased while others remain unaffected. For example, while unstimulated cytokine concentrations may be higher, cytokine responses to stimuli are often reduced [20]. Interpretation of the complexity of the underlying mechanisms may also need to take into account potential underlying proinflammatory effects associated with diabetes itself.

The level of macrophage inflammatory protein 2, a mediator of lung neutrophil recruitment, is significantly decreased in diabetic mice compared to control mice [21]. The deficiency causes a delay in neutrophil recruitment in the lungs. This may be an important factor influencing the susceptibility of people with diabetes to infections of the lower respiratory tract.

Hyperglycemia impairs opsonophagocytosis by diverting nicotinic acid adenine dinucleotide phosphate (NADPH) from superoxide production into the aldose reductase-dependent polyol pathway [22], providing one further example of a mechanism by which hyperglycemia directly impairs phagocytosis.

Diabetic mice show greater than twofold induction of genes that directly or indirectly induce apoptosis [23]. By contrast, blocking of apoptosis allows for a significant improvement in wound healing and bone growth. This may influence many aspects of responses to infection, including impaired wound healing, which are important in the setting of diabetes.

These examples, while somewhat piecemeal, serve to demonstrate the range of abnormalities in the immune system that may result from hyperglycemia. Of particular importance are those spanning macrophage, monocyte and neutrophil function, and which impair adherence to endothelium, chemotaxis, phagocytosis and bactericidal activity. They also point to other abnormalities (e.g. involving apoptosis), wound healing, and cytokine responses to infection. The antioxidant systems involved in bactericidal activity may be compromised. These impairments, which are exacerbated by hyperglycemia and acidemia, may be reversed substantially, if not entirely, by normalization of pH and blood glucose levels. It needs to be emphasized, however, that the severity of effects correlates somewhat unpredictably with direct contemporaneous measures of glycemic control such as HbA_{1c}, perhaps reflecting longer term or persistent changes such as accumulation of advance glycation end products (AGEs) [24]. A role for AGEs is postulated as a component in the pathogenesis of the impaired neutrophil function. In general, a better regulation of the diabetes leads to an improvement of the cellular aspects of immune function, both innate and adaptive, despite variable correlations with HbA_{1c}.

Many questions remain as to the nature of the defects produced by diabetes, their effects upon infection risk, and their exact relationship to both long- and short-term glycemic control, very much confounded by differences in experimental methodology.

Other host-related factors

Other host-specific factors, over and above impairment and disruption of immune defenses, can further the predisposition to infection. These include vascular insufficiency (microangiopathies and macroangiopathies), sensory peripheral neuropathy, autonomic neuropathy, and skin and mucosal colonization

with pathogens such as *S. aureus* and *Candida* species. Abnormalities of the structure and function of the microcirculation can also have additional indirect adverse effects on the immune responses themselves. Thus, immunologic responses may be further compromised by microangiopathy, and additional factors related to diabetes complications specifically increase the risks of certain infections, especially those involving the foot and the urinary tract.

Obesity, which is commonly associated with diabetes, also increases the risk of certain infections. These include nosocomial infections, wound and surgical site infections, respiratory infections and infections involving the gastrointestinal tract. The presence of obesity also correlates with infected diabetic foot ulcers in people with diabetes [25].

Diabetic complications

Vascular disease is an important component in the etiology of the diabetic foot and the attendant complications of infection, ulceration, and gangrene. Micro- and macrovascular disease is very common in diabetes. Macrovascular disease may be premature, extensive, severe and present in unusual sites. Vascular insufficiency results in local tissue ischemia that can, in turn, enhance the growth of micro-aerophilic and anaerobic organisms, while simultaneously depressing the oxygen-dependent bactericidal functions of leukocytes. The antioxidant systems involved in bactericidal activity may be compromised by the combination of microvascular disease and the diabetic metabolic derangement itself. Hyperglycemia and acidemia are important predisposing factors to this latter effect and are reversed substantially by normalization of pH and blood glucose levels. Vascular disease related to diabetes may also further impair the local inflammatory response and the tissue penetration of antibiotics.

Neuropathy, both peripheral and autonomic, also contributes to the risk of foot infections and ulceration, as well as to certain other infections. Sensory peripheral neuropathy masks the recognition of trauma. Minor local trauma in people with peripheral neuropathy may result in skin ulcers, which, in turn, can become infected. Skin lesions are often either unnoticed or ignored until infection occurs. Autonomic neuropathy contributes to the etiology of foot infections by mechanisms such as decreased sweating, which predisposes to drying and fissuring of the skin, and by further exacerbating abnormalities in the control of the microcirculation. Both sensory and motor neuropathy can lead to deformity and alter the dynamics of the function of the foot. Fuller discussion of the etiologic factors related to sepsis and the diabetic foot is provided in Chapter 48.

People with diabetes-associated autonomic neuropathy may develop urinary retention and stasis in association with loss of innervation to the bladder. This predisposes them to urinary tract infections. This risk is particularly high in women. Autonomic neuropathy can also impair the function of the gastrointestinal tract, predispose to certain gastrointestinal tract infections and contribute to risk of aspiration pneumonia (in the context of gastroparesis). Renal papillary necrosis can also contribute to the risk of renal failure as well as to infection within the urinary tract.

Thus, a number of factors contribute to the vulnerability of people with diabetes to infections. Over and above the abnormalities of the immune response, vascular disease and neuropathy can greatly enhance susceptibility (e.g. in the lower limb and urinary tract). Hyperglycemia per se may specifically heighten susceptibility to certain fungal and bacterial infections, the number of which is being increasingly recognized.

Organism-specific factors

Certain organisms may show increased adherence to diabetic cells [15] and others may demonstrate increased virulence in hyperglycemic environments. Specific factors that predispose people with diabetes to infection with specific organisms include the following examples.

Candida albicans and fungi

Glucose-inducible proteins produced by *Candida albicans* are homologous to a complement receptor on phagocytes. These proteins may promote adhesion of *C. albicans* to buccal or vaginal epithelium. This adhesion, in turn, impairs phagocytosis, giving the organism an advantage over the host [15].

Ketone reductases produced by *Rhizopus* species allow these species to thrive in high glucose, acidic conditions typically present in diabetic ketoacidosis [26].

Klebsiella spp.

A bacterial genus of note in the context of diabetes is *Klebsiella*. *Klebsiella* infections are the second most common causes of Gram-negative sepsis (after *E. coli*). In a report from Taiwan, diabetes was the most commonly associated underlying condition in people presenting with community-acquired *K. pneumoniae* bacteremia [27]. The percentage of individuals with underlying diabetes was 49%, which is even higher than in earlier reports [28, 29]. Apart from the high proportion with diabetes, associations were also observed with serotype K1 (associated with impaired phagocytosis), liver abscess and other metastatic complications (endophthalmitis, meningitis, brain abscess) [27]. Primary liver abscess in other parts of Asia is also increasing in incidence, with 40% reportedly associated with diabetes [30]. Bacteremia is present in 50%, and 8–10% have metastatic complications (endophthalmitis, meningitis, brain abscess, pneumonia, skin and soft tissue infections, lung abscess, septic arthritis, renal abscess, peri-anal abscess, and prostatic abscess).

Melioidosis

A combination of organism-specific factors together with the changes in innate immunity may explain the increased susceptibility of people with diabetes to melioidosis. About 50% of cases of melioidosis occur in people with diabetes. The responsible organism, *Burkholderia pseudomallei*, has been shown to be selectively resistant to phagocytosis in the presence of diabetes.

In a study from Thailand, where melioidosis is relatively common, neutrophil responses to *B. pseudomallei*, in both people with and without diabetes showed that *B. pseudomallei* displayed reduced phagocytosis by neutrophils compared to *S. enterica typhimurium* and *E. coli*. In addition, intracellular survival of *B. pseudomallei* was detected throughout a 24-hour period, indicating intrinsic resistance of *B. pseudomallei* to killing by neutrophils. Furthermore, neutrophils from people with diabetes displayed reduced migration in response to IL-8 and an inability to delay apoptosis. Thus, *B. pseudomallei* appears to be intrinsically resistant to phagocytosis and killing by neutrophils. When added to the impaired migration and apoptosis seen in diabetes, the combination seems sufficient to explain the increased susceptibility to melioidosis [31].

Bidirectionality: the effect of infections on diabetes

Bidirectionality exists in the relationship between diabetes and infections. The effect of infections upon diabetes includes the effects of certain infections on the etiology and pathogenesis of diabetes itself, adverse effects upon hyperglycemia in established diabetes and exacerbation of diabetes complications. The importance of the potential adverse effects upon hyperglycemia in established diabetes needs to be emphasised. Infections remain an important predisposing cause of both diabetic ketoacidosis and hyperosmolar hyperglycemia syndrome.

The importance of certain viral infections in the possible etiology of diabetes has received increasing attention in recent years with respect to both T1DM and T2DM.

Viral infections have been implicated in the etiology of T1DM for many years. Although this complicated topic is beyond the general scope of this chapter and is considered in detail in Chapters 3 and 10, it is noteworthy that type 1a (autoimmune) diabetes is increasing in prevalence globally, providing strong evidence that environmental factors are involved in the clinical expression of the disease. Viruses have long been included in the list of putative environmental triggers. Enteroviruses (especially Coxsackie B viruses, B4 in particular), rubella, mumps, rotavirus, parvovirus, and cytomegalovirus have all been implicated and continue to be reported [32, 33]. Although correlations between the presentation of diabetes and the occurrence of a preceding viral infection have been recognized, a direct causal relationship, with fulfillment of Koch postulates, remains difficult to prove, possibly because other inflammatory factors are also required. In this context, it is interesting to note that the process may be associated with a dominant CD4 T-helper type 1 immune response, whereas the dominance of a T-helper type 2 response, as seen in the face of certain infectious and parasitic agents, may protect against T1DM and other autoimmune diseases. Thus, the increasing freedom from such infections, especially in more developed areas of the world, may allow increased expression of an underlying genetic predisposition. Infection by certain viruses, such as the Coxsackie B viruses, may then be associated with the appearance of (and persistence of) β-cell antigens, mediated by mechanisms such as molecular mimicry and activation of Toll-like receptors. Lack of exposure to infection and infestation in early childhood appears to dilute the ability of the innate immune system to withstand autoimmune responses and challenges. T1DM is not alone in this respect and the general concept has become known as the "hygiene hypothesis" [34]. The potential role of alterations in the gut microbiome is also receiving increasing attention and is dicscussed further in chapter 17.

The high prevalence of T2DM in association with hepatitis C infection and the progression of certain diabetes complications (e.g. diabetic nephropathy) in association with hepatitis B are other noteworthy examples. The treatment of HIV/AIDS with protease inhibitors predisposes to diabetes, metabolic syndrome, and increased cardiovascular risk. The public health implications of these issues are considerable given the concordance of the diabetes epidemic with these other highly prevalent diseases.

All infections, especially if severe, have the potential to exacerbate hyperglycemia by a number of mechanisms (e.g. worsening of insulin resistance by production of "stress" or counter-regulatory hormones and production of cytokines such as IL-1 and tumor necrosis factor) [35]. Infection remains a major factor in the pathogenesis of diabetic ketoacidosis or hyperosmolar hyperglycemia. Infections can also precipitate hypoglycemia if symptoms, such as anorexia, nausea and vomiting, lead to reduced food intake. Malaria and its treatment with quinine can also induce hypoglycemia.

Hepatitis C

A number of reports from North America, Europe, and the Middle East consistently demonstrate an increased prevalence of diabetes (ranging from 24% to 62%) among people with chronic hepatitis C virus (HCV) infection compared both with persons with other forms of liver disease and with other control groups. Among HCV-infected individuals reported prevalence of diabetes (21–50%) is much higher when compared with other forms of chronic liver disease (2–12%) or those without liver disease (2–6%) [36–41].

In the USA, T2DM occurs more often in persons with HCV infection who are above 40 years of age, particularly those aged between 40–49 years where the relative risk ratio is 3.8. Apart from age, the prevalence of diabetes is greatest in people who are non-white, have a high body mass index, are below the poverty level, and have a family history of diabetes. The prevalence of T1DM appears to be unaffected [42].

The suggestion that HCV infection predisposes to T2DM as a result of progressive liver damage is supported by the observations that the association is most marked in the older age groups (>40 years), and that there is higher risk among those with advanced HCV cirrhosis. The presence of diabetes is also associated with more severe hepatic fibrosis. The higher prevalence of diabetes in comparison with that seen in other liver diseases suggests an additional mechanism specific to hepatitis C. Tumor necrosis factor has been suggested as one possible candidate [43].

HCV infection is also strongly associated with diabetes among intravenous drug users and this is independent of HIV infection or use of highly active antiretroviral therapy (HAART) [44]. Thus,

it is important to monitor people with chronic HCV infection for development of diabetes. Bidirectionality again applies with weight loss and good glycemic control improving hepatitis outcomes.

HIV/AIDS

Although HIV/AIDS has not in itself been reported to increase the risk of diabetes, the treatment of HIV/AIDS with antiretroviral therapy (ART) predisposes to T2DM, other metabolic risks, and premature cardiovascular disease. In the Multicenter AIDS Cohort Study, HIV-infected men had a greater odds of insulin resistance than HIV-negative men, regardless of ART exposure, and diabetes mellitus incidence was four times higher among HIV-infected men on ART compared with uninfected men [45, 46]. The incidence of diabetes increases with cumulative exposure to ART [47].

This has become a major problem in the management of this already very complicated disease. The effects occur via disturbances in lipid homeostasis and fat partitioning (lipodystrophy), insulin resistance, insulin secretion, and mitochondrial dysfunction. Insulin resistance is more important than impaired insulin secretion. ART for HIV-1 infection is frequently complicated by lipodystrophy (peripheral fat loss and relative visceral obesity), dyslipidemia and insulin resistance, especially with zidovudine, stavudine, and didanosine. HIV-infected adults receiving ART also have an increased incidence of hypertension, as well as cardiovascular morbidity.

Whether ART-naïve individuals have altered risk of subsequent CVD or T2DM remains unclear, although insulin resistance has been reported among protease inhibitor (PI)-naïve persons with HIV infection, in association with fat redistribution. Exposure to antiretroviral therapy for more than 1 year is associated with increasing risk of T2DM. Although the risk is greatest among individuals treated with PI, attributed to a direct inhibitory effect on cellular glucose transport by PI medications [44], an increased prevalence of diabetes among those receiving a PI-sparing regimen has also been found. Nucleoside analog-induced mitochondrial toxicity is probably of importance. Cessation of PI appears to have little beneficial effect in reversing lipodystrophy, although it may improve the metabolic control in diabetes. Alteration of thymidine analog nucleoside reverse transcriptase inhibitors may, however, confer benefit on lipodystrophy [48, 49]. Another study in HIV-infected persons initiating ART reported that higher levels of the inflammatory markers high-sensitivity C-reactive protein, sTNFR1 and sTNFR2 were associated with an increased risk for diabetes mellitus despite suppressive ART. These data suggest that the inflammatory milieu of HIV infection may also contribute to the development of insulin resistance [50].

In a study of almost 900 people with HIV-infection, initiation of ART was evaluated for prevalence and incidence of metabolic syndrome and subsequent diagnosis of CVD and T2DM over a 3-year period. The prevalence of baseline metabolic syndrome was 8.5% and 7.8% (ATP-III and IDF criteria, respectively). Substantial progression to metabolic syndrome occurred within 3 years following initiation of ART. The presence of metabolic syndrome at baseline was significantly associated with an increased risk of T2DM while metabolic syndrome occurring during the 3-year period was associated with an increased risk of both CVD and diabetes [51, 52].

In another study [53], 123 of 6513 people with HIV-infection developed diabetes during almost 28,000 person-years of follow-up, an incidence of 4.4 cases per 1000 person-years. An increased incidence rate ratio was found for men, older age, obesity and African American, or Asian ethnicity. Strong associations were observed with treatment using nucleoside reverse-transcriptase inhibitors (NRTI), NRTI + PI, and NRTI + PI + non-nucleoside reverse-transcriptase inhibitors (NNRTI), but not with an NRTI + NNRTI regimen.

Lipodystrophy is a crucial aspect of the association of ART with insulin resistance, leading to relative preponderance of visceral fat, hepatic steatosis, and fat deposition at other "ectopic" sites. HIV-infected persons with lipodystrophy, compared with those without lipodystrophy, have a reduction in plasma adiponectin and adipose tissue adiponectin mRNA levels of approximately 50%, correlating with insulin resistance and increased cytokine levels [52].

Because baseline and incident metabolic syndrome identifies individuals at risk for both CVD and T2DM, evaluation in all people commencing ART is warranted. A fasting plasma glucose concentration should be checked before initiation of therapy and monitored every 3–6 months, especially in those receiving changes in treatment or who have significant risk factors for insulin resistance. An oral glucose tolerance test may be required, particularly in the presence of risk factors or equivocal glucose concentrations. Dietary guidelines established for the general population remain relevant for the management of glucose disorders in the context of HIV infection. Weight loss through increased activity and caloric restriction should be recommended for overweight individuals with HIV-infection.

Metformin improves insulin sensitivity in people with HIV lipodystrophy and is an effective antidiabetes medication; however, it should be used with caution in those receiving an NRTI (in particular zidovudine, didanosine, and stavudine), and in persons with impaired renal function because of the possibility of lactic acidosis. The newer integrase strand transfer inhibitor, dolutegravir, will increase the level of metformin by decreasing renal clearance. Close monitoring is warranted and dosage adjustment of metformin may be needed. Thiazolidinediones (pioglitazone) may also improve insulin sensitivity in people with HIV lipoatrophy. Insulin therapy should be used according to standard recommendations. Substitution of an NNRTI for a PI has been observed to improve insulin resistance but this needs to be balanced against any risk to virus control. Careful discussion with the HIV physician is therefore essential and it may be deemed safer to increase the antihypoglycemic treatment rather than changing the components of the ART regimen [54–56].

Hepatitis B

Although, in contrast to hepatitis C, hepatitis B virus (HBV) has been less consistently associated with an increased prevalence of

diabetes, the presence of hepatitis B markers may nevertheless influence the natural history of diabetes and its complications and the relationship may be bidirectional as the presence of diabetes is associated with more severe fibrosis and cirrhosis. However, there is uncertainty as to cause and effect given the general association of diabetes with liver cirrhosis [57].

Chinese people with HBV-infection and T2DM have been shown to be more likely to develop end-stage renal disease than non-HBV infected people with T2DM (8.7 vs. 6.4%) with a hazard ratio of 4.5. The association of chronic HBV infection with increased risk of end-stage renal disease was independent of other potential confounding factors. People with HBV-infection also reported earlier onset of diabetes and had a higher frequency of diabetic retinopathy than those without HBV-infection (28% compared to 22%). Cardiovascular complications appeared unaffected [58].

Specific infections either strongly associated with diabetes or in which the presence of diabetes is important

Infections involving the head and neck

Two head and neck infections that are associated with high rates of morbidity and mortality, malignant otitis externa and rhinocerebral mucormycosis, are particularly noteworthy in people with diabetes.

Malignant otitis externa

Malignant otitis externa is an invasive infection of the external auditory canal and skull base that typically arises in elderly people with diabetes. An early series was described in 1968 [59]. Most cases (86–90%) have been reported in people with diabetes. *Pseudomonas aeruginosa* is nearly always the causal organism (>98% of cases) although *Aspergillus* species or other fungi, are occasionally responsible. Microangiopathy in the ear canal has been suggested as a predisposing factor.

Presenting features include severe intractable headache and otalgia, otorrhea, and deafness, often over a period of weeks to months. Intense cellulitis is combined with edema of the ear canal. Focal neurologic signs and cranial nerve palsies may occur. The pain may involve the temporomandibular joint and be aggravated by chewing. Osteomyelitis of the skull base and temporomandibular joint is a potentially life-threatening complication and the mortality in the pre-antibiotic era exceeded 50%. On otoscopy, granulation tissue may be seen in the floor of the ear canal, often in association with edema and intense cellulitis. The tympanic membrane is usually intact. Computed tomography (CT) and magnetic resonance imaging (MRI) studies are essential for defining the extent of bone and soft tissue involvement, together with the bony destruction of the skull base that may be seen in advanced cases.

Systemic antipseudomonal antibiotics are the primary therapy. Early referral to an otorhinolaryngologist is essential and allows diagnostic confirmation by surgical biopsy. Debridement of necrotic tissue can also be carried out if necessary, although the introduction of effective antibiotic therapy has reduced the requirement for surgery. With the introduction of quinolones, the cure rate has increased to 90%, with few adverse effects reported and oral therapy rendered possible. Prolonged treatment for 6–8 weeks is recommended, as for osteomyelitis [60]. Thus, treatment consists of prolonged administration (6–8 weeks) of an antipseudomonal agent (typically, an orally administered quinolone). The emergence of ciprofloxacin resistance is a potential problem. It is recommended that systemic quinolone use be reserved for treatment of invasive ear infections caused by susceptible pathogens. For otitis externa caused by *Aspergillus* species, treatment would include surgical debridement; treatment with voriconazole, posaconazole, or amphotericin B. An example of invasive aspergillosis involving the skull base is shown in Figure 55.1.

Mucormycosis (zygomycosis)

The term mucormycosis is used to describe a variety of infections caused by fungi of the *Rhizopus* and *Mucor* species which belong to the order Mucorales (class Zygomycetes). These fungi are ubiquitous saprophytes and infections produced by them are essentially confined to immunocompromised individuals. The fungi have a predilection to invade blood vessels. Ketone reductases produced by *Rhizopus* spp. allow them to thrive in high glucose, acidic conditions as are typically present in diabetic ketoacidosis [26]. Rhinocerebral, pulmonary, gastrointestinal, cutaneous and disseminated forms of the infection are described. The rhinocerebral manifestation (and with sinus involvement) has the highest frequency and is potentially the most lethal in the context of people with diabetes.

The close connection with diabetes is becoming increasingly diluted as other causes of an immunocompromised state become increasingly common or survivable (notably hematologic cancer and bone marrow transplant recipients). Nevertheless, diabetes remains the most common underlying factor in most reports. In a review of 49 cases of pulmonary mucormycosis, diabetes was the underlying cause of the immunocompromised state in 9 (25%) [61]. In another study, the prevalence and mortality in people with diabetes were 36% and 44%, respectively [62]. It typically, although not exclusively, occurs in association with ketoacidosis, severe hyperglycemia and/or a debilitated state.

Rhinocerebral mucormycosis is a life-threatening fungal infection. Untreated it is universally fatal; if recognized early there is a 20% survival rate. Presenting features include facial or ocular pain and nasal stuffiness. Generalized malaise and fever may also be present. Intranasal black eschars or necrotic turbinates may be found and, if present, provide sites that can be biopsied. Treatment consists of surgical debridement of the involved sinuses and prolonged intravenous therapy with amphotericin B or alternative antifungal agents such as some newer azoles.

Acute invasive fungal sinusitis can also result from aspergillosis, as can malignant otitis externa. Biopsy confirmation of the microbiologic diagnosis is therefore useful [63].

(b)

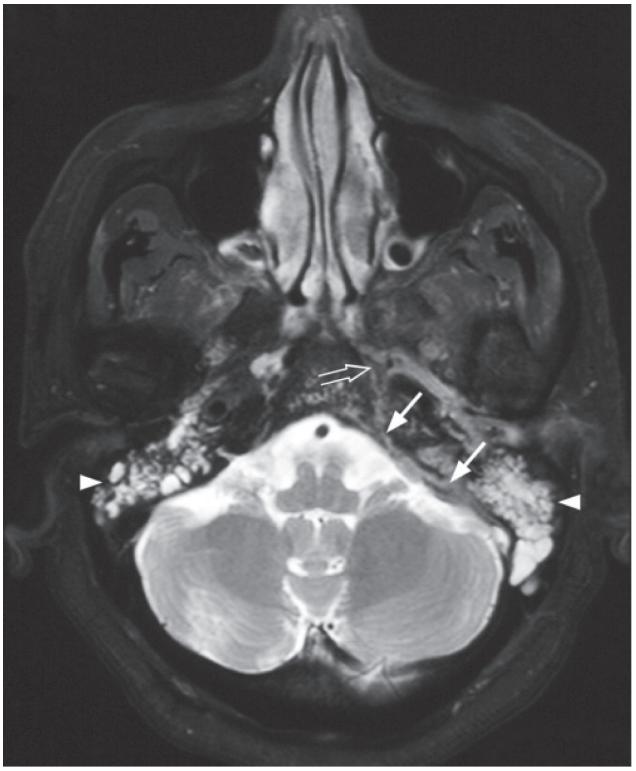

Figure 55.1 Magnetic resonance imaging (MRI) scan of skull base in a 59-year-old man with a 20-year history of diabetes (with nephropathy), treated with insulin who developed severe extensive invasive aspergillosis. He presented with headache and vertigo followed by left sixth and seventh nerve palsies. He subsequently developed bilateral sensorineural hearing impairment and blindness secondary to extensive skull base infiltration by the invasive aspergillosis. MRI demonstrated enhancing soft tissue closely related to the left posterolateral wall of the nasopharynx with parapharyngeal, skull base, perineural and dural infiltration. Biopsy showed inflamed fibrous tissue with degenerated fungal filaments. Culture confirmed *Aspergillus flavus*. He is receiving lifelong therapy with voriconazole. He remains blind. MRI of skull base in the axial plane with: (a) T1-weighted; and (b) post-gadolinium T1-weighted sequences. These show marked dural thickening (arrows) with enhancement in the left posterior cranial fossa. An abnormal signal with enhancement is also noted in the adjacent left petrous apex (open arrow). Note also the presence of inflammatory fluid within both mastoid air cells (arrow-heads). Source: Acknowledgments to Dr. K.T. Wong, Consultant Radiologist, for preparation and reporting of the figures, and to Professor A. Ahuja for permission to use the figures. Both are placed at the Department of Diagnostic Radiology and Organ Imaging, Prince of Wales Hospital, Chinese University of Hong Kong, Hong Kong.

Endophthalmitis

Secondary endophthalmitis may occur as a rare but devastating metastatic complication of septicemia and in this setting is almost entirely confined to people with diabetes. *E. coli* and *Klebsiella* are the more likely pathogens and urinary tract infection is reported as the most common underlying source of infection [64].

People with diabetes are also more prone to postoperative infections following eye surgery or infections secondary to eye trauma. Overall, the most common cause of endophthalmitis is as a postoperative complication of cataract surgery [65], a procedure commonly carried out in people with diabetes.

Periodontal disease

People with diabetes are very prone to periodontal disease compared to the general population, with a two- to fourfold relative increase in prevalence and a particular predilection for those whose diabetes is poorly controlled.

The associated periodontitis, if left untreated, can result in loss of attachment of ligament fibers and supporting alveolar bone which in turn can increase the mobility of teeth and necessitate extraction. Tooth abscesses and episodes of bacteremia also become more likely. Diabetes may complicate the pathogenesis of periodontitis by causing abnormalities in the vasculature of the gingival tissues, in addition to the effects upon immune responses described earlier. Aggressive and difficult to treat forms of periodontitis are also more common in adults with diabetes. Periodontal health is influenced by glycemic control to the extent that the prevalence of periodontal diseases among people with well-controlled diabetes is not increased [66].

A bidirectional relationship has also been suggested whereby the presence of periodontal disease adds to the overall burden of chronic inflammation, thereby adversely affecting glycemic control as well as overall risk of CVD and diabetic nephropathy.

Respiratory tract infections and tuberculosis

The increased risk of mortality and morbidity from community-acquired pneumonia has been described earlier and includes pneumonia either directly resulting from, or secondary to, common infections such as influenza and *S. pneumoniae* and also includes *Legionella* infections [67]. The risk of bacteremia following pneumococcal infection is increased [68]. Viral shedding may be more prolonged following influenza infections in people with comorbidities including diabetes, which may influence decisions regarding initiation and duration of antiviral therapy [69].

Lower respiratory tract infections, resulting from *S. aureus* and Gram-negative organisms such as *K. pneumoniae*, are more common in people with diabetes. Melioidosis has also been discussed earlier as an example of organism-specific factors that interact with diabetes to increase risk of infection. People with diabetes are also thought to be at increased risk for *S. aureus* pneumonia and this may result from higher rates of nasal carriage of *S. aureus* in people with diabetes (up to 30%) compared to healthy individuals (11%) [70].

Any respiratory infection in people with diabetes is associated with increased mortality. In the USA, people with diabetes are reportedly four times more likely to die from pneumonia or influenza than are people without diabetes [71].

The importance of diabetes as the most common underlying predisposing factor for thoracic empyema has also long been recognized. *Klebsiella* spp are again notable as the most common pathogens, while other important pathogens include streptococci, *S. aureus* and anaerobes [72].

Diabetes and tuberculosis

An association between diabetes and tuberculosis has been widely accepted in the past, and solid epidemiological evidence has emerged in the last decade to establish firmly a close link. Systemic reviews have confirmed that people with diabetes are approximately three times more likely to develop active tuberculosis than are people without diabetes, albeit with varying estimates of overall risk (ranging from two- to 11-fold) [3–5, 73, 74].

The importance of the association is often neglected in the larger arena of public health, for example when compared with the risk of tuberculosis associated with HIV/AIDS. The increase in risk appears consistent across geographical regions, and regardless of both study design and background incidence of tuberculosis. It appears greatest among younger people in areas of high tuberculosis incidence and in non-North American populations [73]. The public health impact may be particularly high in low-income or middle-income countries or areas that are at the forefront of the diabetes epidemic and where tuberculosis remains endemic [74–76] and may therefore be particularly high in countries such as China and India.

The impact of the diabetes epidemic on tuberculosis incidence in India has been modeled by Stevenson et al. [77]. They suggest that diabetes accounts for 14.8% (range 7.1–23.8%) of pulmonary tuberculosis and 20.2% (8.3–41.9%) of smear-positive tuberculosis, with an excess risk of the latter in urban areas. This can be compared to an overall estimate of 3.4% for the proportion of adult tuberculosis incidence ascribed to HIV/AIDS in India [78].

The association of tuberculosis with diabetes reflects impaired innate immunity as well as a reduced adaptive T-helper type 1 response with reduced secretion of T-helper type 1-related cytokines, thereby increasing the risk of progression from tuberculosis infection to active disease as well as increasing the risk of latent tuberculosis following initial primary infection. Regarding the clinical presentation, extrapulmonary or unusual manifestations of tuberculosis are more common in the context of diabetes. People with tuberculosis and diabetes are more likely to develop opacities over the lower lung fields, extensive parenchymal lesions, any cavity, multiple cavities and large cavities compared to those without DM and these radiological abnormalities are more common in the presence of poorer glycemic control [79, 80].

In addition to the increased risk, there is evidence that people with diabetes are at increased risk of worse outcomes, including treatment failure, relapse, and mortality [81]. People with diabetes are more likely to remain smear positive after 2–3 months of treatment as shown in six of nine studies evaluating sputum conversion [81]. A study from Indonesia indicated a doubling of the risk of remaining smear positive at the end of treatment [82]. The same group has also shown that the presence of T2DM may adversely affect the bioavailability of rifampicin and lead to an increase in dose requirement [83]. A study from Brazil found that those with tuberculosis and diabetes had poorer treatment outcomes even after adjusting for confounding factors [84].

One of the options to improve treatment outcomes might be to extend the period of treatment. In Hong Kong, an area with much pioneering experience of tuberculosis treatment since the 1950s, the Centre for Health Protection recognizes the risk of a worse outcome, and its guidelines recommend a more prolonged period of treatment for people with diabetes compared to those without. For example, when treating pulmonary tuberculosis using a standard regimen of four drugs for the first 2 months followed by two drugs, a total treatment duration of 9 months, rather than 6 months, is recommended.

Two examples of individuals with tuberculosis in association with diabetes are shown in Figure 55.2. It is perhaps noteworthy that neither was receiving regular follow-up care for the diabetes.

Bidirectionality again needs to be remembered because the presence of tuberculosis is very likely to have a negative impact upon hyperglycemia. Tuberculosis, as with other infectious diseases, can lead to deterioration of glycemic control and complicate the management of diabetes. Unpredictable effects upon glycemic control may result from alterations in inflammatory processes, changes in appetite and body weight and, importantly, through drug–drug interactions. Rifampicin, the most important drug, increases the hepatic metabolism of sulfonylurea drugs, although with great inter-individual variation. It may also lead to an enhanced glucose-lowering effect of metformin [85].

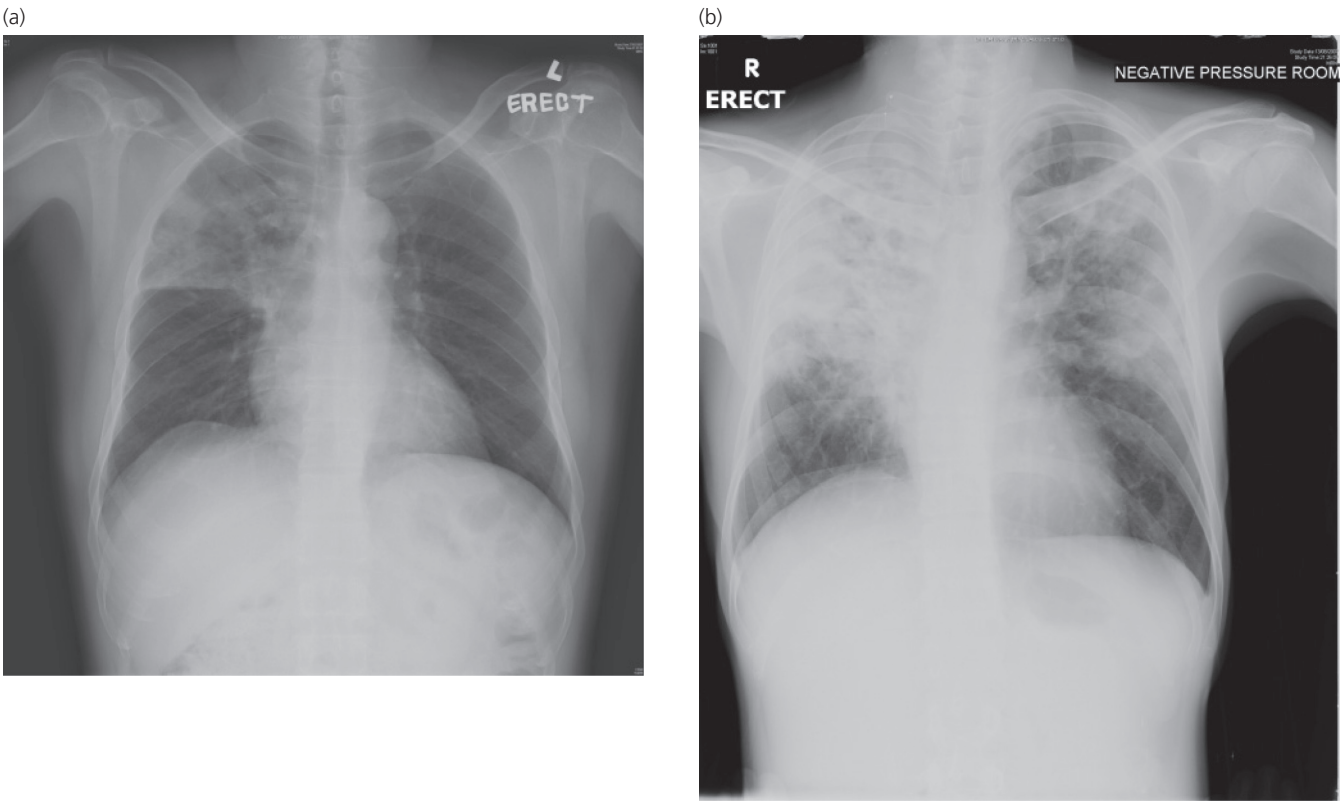

Figure 55.2 (a) A 49-year-old man with diabetes and obesity, not receiving regular follow-up, and presenting with hemoptysis, sputum smear positive for tuberculosis. Chest X-ray shows extensive right upper lobe pneumonic changes. (b) A 30-year-old man with diabetes but no regular follow-up, presents with a cough for 4 months with weight loss, sputum smear positive for tuberculosis. Chest X-ray shows extensive bilateral and cavitatory disease.

Some national treatment guidelines (e.g. Indonesia) strongly recommend the use of insulin therapy since insulin has no direct pharmacokinetic interactions with rifampicin or other anti-tuberculous agents. Thus people with concurrent diabetes and tuberculosis may have specific needs during treatment, including close monitoring of glycemic control, renal and hepatic function, as well as counselling and education. There is therefore a strong case to be made for integrated care together with service and policy development [85]. The issue of screening is pertinent, both for diabetes in people with tuberculosis and for tuberculosis in people with diabetes.

Infections of the urinary tract

Epidemiology and risk factors

Urinary tract infection (UTI) is frequently encountered in people with diabetes. Asymptomatic bacteriuria also occurs with a higher frequency. One study has demonstrated a prevalence rate for asymptomatic bacteriuria of 26% in women with diabetes, compared to 6% in women without diabetes [86, 87].

A randomized controlled trial of antibiotic treatment for asymptomatic bacteriuria revealed no differences in the development of symptomatic UTI, time to onset of symptoms, risk of pyelonephritis or need for hospitalization [86]. On this basis, diabetes does not appear to warrant either screening for, or treating, asymptomatic bacteriuria. However, this remains a controversial issue and, from the practical standpoint, ascertaining "asymptomatic status" with confidence, particularly in older women with diabetes, can be difficult or impossible.

A number of studies confirm the increased risk of symptomatic UTI in association with diabetes. In one study of more than 600 women [88], those with T2DM had an overall risk of 20%. A recent study has extended the risk to include recurrence rates as well as risk to men [1].

Diabetes is a risk factor for cystitis in postmenopausal women, leading to a two- to threefold increase in risk [89]. An increased prevalence of asymptomatic vaginal *E. coli* colonization has also been reported in postmenopausal women who are receiving insulin treatment. This vaginal colonization may be mediated by greater adherence of type 1 fimbriated *E. coli* to uroepithelial cells in women with diabetes, may be related to impaired cytokine secretion, or may reflect a reduced polymorphonuclear inflammatory response [86, 90].

Diabetes also increases the risk of complications of UTI, serious or unusual forms of infection, and need for prolonged hospitalization [91]. It is a risk factor for acute pyelonephritis in women (odds ratio 4.1), and is the strongest of the various risk factors

examined. Among hospitalized patients, 16.7% reported having diabetes compared with 5.8% of non-hospitalized patients [86]. A three- to fivefold increase in risk also exists in people with diabetes aged less than 44 years [88].

Diabetic autonomic neuropathy is an important predisposing factor to UTI. This affects the sympathetic and parasympathetic afferent fibers to the bladder and causes decreased reflex detrusor activity. Impaired bladder sensation results in bladder distension, increased residual urine volume, vesicoureteric reflux and recurrent upper UTI [92, 93]. Some cases are related to urinary catheterization or instrumentation [86, 92, 93]. Additional factors predisposing to UTI include: glycosuria, sexual intercourse, history of previous UTI, obstruction, longer duration of diabetes, poor glycemic control, decreased urinary cytokine excretion, increased *E. coli* adhesion, macroalbuminuria, and neutrophil dysfunction [92, 93]. Renal papillary necrosis and chronic renal failure also contribute to the complex array of risk to the urinary tract.

Microbiology

E. coli is the most commonly reported organism. *Klebsiella* is also a problem, especially among individuals with uncommon severe forms of UTI, such as emphysematous pyelonephritis. Other organisms include *Acinetobacter* species, group B streptococci, and *P. aeruginosa* [86]. The latter should be suspected particularly if there is a history of recent instrumentation or hospitalization.

C. albicans in the urine can be associated with incomplete bladder emptying and high glucose concentrations in the urine. Diabetes has been shown to be present in 39% of hospitalized patients with funguria [86]. Candiduria may signify contamination of the urine specimen, benign saprophytic colonization (± catheter), or may be indicative of true invasive infection of the upper and/or lower urinary tract [94]. Diabetes is also a risk factor for multidrug-resistant UTI, perhaps related to recurrent or increased exposure to antibiotics [95].

Clinical features of urinary tract infection in diabetes

Uncomplicated UTIs may be asymptomatic. Symptoms, when present, are generally similar to those experienced by the non-diabetic population. Infection of the lower urinary tract usually presents as dysuria, frequency or urgency. Fever, flank pain, chills and rigors, vomiting and costovertebral angle tenderness raise the suspicion of upper tract infection with renal involvement. Bilateral renal involvement is also more frequent and bilateral pyelonephritis is twice as common in people with diabetes. Bacteremia may be present.

A poor response to appropriate antibiotic therapy should raise the suspicion of the presence of complications. These may include renal papillary necrosis and perinephric abscess. The symptoms of renal papillary necrosis include flank and abdominal pain (which mimic both pyelonephritis and ureteric colic), together with fever. Renal functional impairment is commonly found. Features such as a persisting high fever despite antibiotic treatment, hypotension or septicemic shock, and a palpable tender renal mass may point to the presence of a perinephric abscess. In one series of patients with perinephric abscess, 36% had diabetes [96].

Figure 55.3 Example of emphysematous cystitis in a 67-year-old woman with diabetes and end-stage renal disease requiring hemodialysis. She developed septic shock with lower abdominal tenderness. Blood and urine cultures showed *E. coli*. Computed tomography (CT) scan shows air pockets inside the urinary bladder (arrows). Source: Sun JT, et al. Life-threatening urinary tract infection. *Q J Med* 2009; **102**:223. Reproduced with permission of Oxford University Press.

Emphysematous cystitis and emphysematous pyelonephritis

Although uncommon, the severity of these infections warrants their special consideration. Emphysematous cystitis is an uncommon complication of lower UTI characterized by the presence of gas in the bladder wall (Figure 55.3). It presents with hematuria, pneumaturia, and abdominal pain. Plain abdominal radiography or CT scan are indicated to detect the presence of gas. Surgical intervention may be required in up to 20% of cases and mortality is reportedly up to 10%. Emphysematous cystitis requires aggressive treatment in hospital and intravenous antibiotic therapy [97].

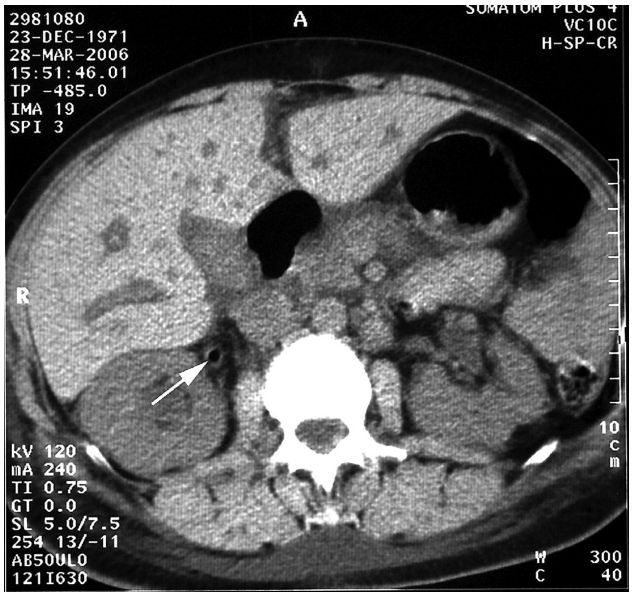

Figure 55.4 Emphysematous pyelonephritis: computed tomography tomography (CT) scan demonstrating gas in the right ureter (indicated by arrow) and a moderate hydronephrosis in a 34-year-old woman with type 1 diabetes. The responsible was organism was *E. coli*. She responded to antibiotics and drainage by nephrostomy, followed by ureteroscopy during which obstructing necrotic slough was removed. Source: Clark T, et al. A case of emphysematous pyelonephritis. *J R Soc Med* 2009; **102**:75–77. Copyright © 2009 SAGE Publications.

Emphysematous pyelonephritis is an infection that is almost exclusively limited to people with diabetes, who account for 90% of cases (Figure 55.4). It predominantly occurs in women and carries a grave prognosis [98]. It is a necrotizing infection of the renal parenchyma and surrounding areas which can be focal or diffuse and may spread to the collecting system or perinephric tissues. The formation and presence of gas in the renal parenchyma, collecting system or perinephric area may be contributed to by fermentation of glucose when present at high concentrations, by the presence of gas-forming organisms and by impaired renal perfusion. Mixed acid fermentation of glucose by Enterobacteriaceae has been suggested as a major pathway of gas formation [99].

A lengthy list of pathogens has been reported; however, as with other UTIs in the context of diabetes, the most common pathogens are *E. coli* (in 70%) and *Klebsiella* (in 30%). Vasculopathy of the renal circulation is believed to be a major factor in the pathogenesis, once again emphasizing the importance of vascular disease in the clinical manifestation of the more severe forms of infection related to diabetes.

Presenting features include fever, abdominal pain, nausea and vomiting, and drowsiness or stupor. As a result of these nonspecific symptoms the diagnosis is often delayed. The presence of features such as renal angle tenderness, pyuria or pneumaturia should lead to a high index of suspicion. A flank mass may be detected, often accompanied by crepitus. Disseminated intravascular coagulation, septicemic shock, and acute renal failure are all associated with a poor prognosis.

The diagnosis is established by radiologic identification of gas in renal tissue. This is best demonstrated by CT. The plain abdominal X-ray sensitivity is lower. Ultrasonography can also be used, but CT should be regarded as the investigation of choice. In a report of 46 cases in Taiwan, 96% had diabetes with HbA_{1c} higher than 8% (>64 mmol/mol), and 22% also had features of obstruction [100]. Mortality can exceed 50% in patients treated with antibiotics alone. Medical therapy alone is therefore not recommended. Patients may require percutaneous drainage (for localized cases with abscess formation or obstruction) or nephrectomy (in extensive cases). The advent of CT has allowed a more rational approach to the use of these surgical interventions, by allowing more accurate delineation of factors such as gas distribution, obstruction and abscess formation [101].

Diagnosis of urinary tract infection

A high index of suspicion is required, with particular attention in the presence of diabetic neuropathy, renal dysfunction, or renal papillary necrosis. Microscopic examination of the urine may reveal leukocytosis and pyuria. Urine culture and sensitivity should always be carried out. In febrile patients or in suspected upper tract infection, blood culture is essential to detect bacteremia or Gram-negative septicemia.

Plain abdominal radiography is useful to help rule out obstructive uropathy, stones and emphysematous infection. Ultrasonography is a sensitive, safe, and inexpensive technique for initial screening. Ultrasound or CT can confirm the diagnosis of renal abscess, mass, presence of air in the urinary tract and the extent of perinephric spread of infection. The diagnosis of renal papillary necrosis may require ultimate confirmation by retrograde pyelography.

Treatment of urinary tract infection

Treatment should be tailored to take account of local antibiotic resistance patterns (if known), as well as previous history of UTI, previous antibiotic exposure (and possible allergies) together with other risk factors such as recent instrumentation or catheterization. Uncomplicated UTI may be treated with co-trimoxazole (if the local resistance rate is <15–20%), fluoroquinolones, nitrofurantoin, ampicillin, amoxicillin +/– clavulanate, or sulbactam. Increasing resistance to fluoroquinolones has been noted recently. Co-trimoxazole may potentiate the hypoglycemic effect of some oral antidiabetes agents and should be used with caution.

Complicated infections require hospitalization and parenteral antibiotics. Intravenous therapy is continued until fever resolves, following which oral antibiotics can be substituted to complete at least 2 weeks of treatment. Second- or third-generation cephalosporins, β-lactam/β-lactamase inhibitor combinations, or fluoroquinolones may need to be considered in individuals with risk factors, and the possibility of infection with *Pseudomonas* may influence this choice, particularly in the setting of nosocomial exposure or recent instrumentation.

Upper urinary tract involvement with UTI may be up to five times more frequent in people with diabetes compared with

people without diabetes and may be unsuspected or asymptomatic. More prolonged courses of antibiotics (7–14 days) may be considered wise even in the context of apparently uncomplicated UTI [84]. This may also reduce the risk of subsequent relapse. Repeated urine culture to document bacteriologic cure 2–4 weeks post-treatment is advisable given high rates of relapse or treatment failure.

Distinguishing *Candida* infection from colonization is difficult. Removal of an indwelling catheter, if present, is recommended as an initial intervention. Antifungal agents such as fluconazole may be considered in patients with invasive disease.

Intra-abdominal infections other than those within the urinary tract

The potential for interaction between diabetes and various infections of the gastrointestinal tract is considerable. A few examples may be considered. In this context, although the presence of increased risk of *Helicobacter pylori* infection in people with diabetes remains controversial, the presence of diabetes may, in turn, reduce the effectiveness of antibiotic regimens aimed at eradicating the infection. The presence of gastritis may also influence the endocrine functions of the gut, and may also influence the absorption and handling of oral glucose-lowering drugs such as metformin.

Emphysematous cholecystitis

Cholecystitis is probably no more common in people with diabetes than in the general population; however, severe fulminating infection, especially with gas-forming organisms (enteric Gram-negative rods and anaerobes) is more common.

Emphysematous cholecystitis is a rare variant of acute cholecystitis caused by ischemia of the gallbladder wall and infection with gas-producing organisms. It is strongly associated with diabetes (35–55% of cases have underlying diabetes) [102].

Gangrene and perforation of the gallbladder are more frequent, and the overall mortality is substantially higher (at least 15% compared to less than 4%) when compared with acute cholecystitis. *Clostridium perfringens*, *E. coli*, and *Bacillus fragilis* are the most frequently encountered pathogens. Emphysematous cholecystitis is thought to result from acalculous cystic duct obstruction, associated with inflammatory edema, which can eventually lead to cystic artery occlusion. Colonization by gas-forming organisms contributes to necrosis of the mucosa, venous congestion, gangrene and, eventually, gallbladder perforation. Gallstones are present in only about half of patients.

The early clinical manifestations may be indistinguishable from those of acute cholecystitis. Right hypochondrial pain and fever are present in all cases, and other important features include nausea and vomiting, septic shock, jaundice, and peritonitis. Toxicity is marked, and jaundice may develop in the later stages from biliary obstruction. The gallbladder may be palpable in 25–50% of patients. It should be remembered that Murphy's sign (pain and inspiratory arrest on palpation of the right upper quadrant) might be absent in patients with underlying diabetic neuropathy. Crepitus on palpation is an ominous sign. Additional complications include pericholecystic abscess, gallbladder necrosis, generalized or biliary peritonitis, and localized perforation sealed by the omentum.

Plain abdominal X-ray or ultrasound can lead to diagnosis in 95% of cases. In a plain radiograph, gas may be visible in the gallbladder lumen or within the gallbladder wall as a gaseous ring. CT is the most sensitive modality for the detection of intraluminal or intramural gallbladder gas and also demonstrates local complications such as pericholecystic inflammatory changes, abscess formation or perforation. Initiation of appropriate antibiotics and early cholecystectomy is crucial. Emergency surgery is needed because of the high incidence of gangrene and perforation [103, 104].

Liver and other intra-abdominal abscesses

Although liver abscesses may occur in many situations not involving diabetes, the issue is of sufficient importance to justify inclusion in this section.

In keeping with the susceptibility to *Klebsiella* infections described earlier, associations between diabetes and *K. pneumoniae* liver abscess have been reported, notably from Taiwan and Korea [105–107]. Examples from Hong Kong are shown in Figure 55.5.

In Korea, invasive liver abscess is particularly associated both with *K. pneumoniae* (78% of the total, 40% of whom have diabetes) and with the K1 serotype (60%) [30].

Diabetes is the most common underlying risk factor specifically for the virulent K1 serotype, but not for non-*Klebsiella* abscesses [108]. In a population-based series of pyogenic liver abscess reported from Taiwan and including 29,703 participants [109], diabetes was a risk factor in 33% leading to an odds ratio of 9 and was associated with an increasing incidence. Liver abscess in people with diabetes was not, however, associated with increased mortality, particularly if therapeutic percutaneous drainage procedures are performed. Eighty percent were associated with *K. pneumoniae* and not as a mixed infection with other organisms. Primary liver abscess in other parts of Asia is also increasing in incidence [30], with 40% reportedly associated with diabetes. Bacteremia is present in 50%, and 8–10% of these cases have metastatic complications (e.g. endophthalmitis, meningitis, brain abscess, pneumonia, skin and soft tissue lesions).

In a series from Europe ($n = 1448$), the presence of diabetes was associated with a 3.6-fold increase in risk for pyogenic liver abscess, and also with a higher 30-day post-discharge mortality rate compared with people who did not have diabetes [110].

In the context of the K1 serotype of *Klebsiella* species, a pathogenic role for the magA gene in the serotype-specific region of the K1 capsule gene cluster, together with a K1 capsular polysaccharide per se, is considered as one of the virulence determinants essential for the development of invasive liver abscess. MagA, an outer membrane protein contributing to capsular polysaccharide

(b)

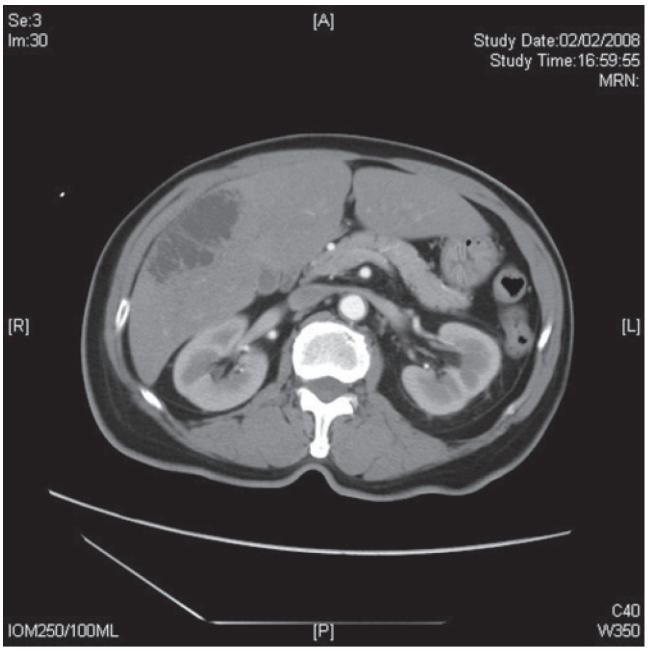

Figure 55.5 (a) CT-scan of an 82-year-old man with fever and newly diagnosed diabetes. Blood culture grew *Klebsiella pneumoniae*. The scan shows an 8 × 8.2 cm heterogeneous lesion in the right lobe of the liver composed of multiple rim-enhancing lesions, with septation and hypodense cystic components. A further three smaller similar lesions (1–2.5 cm) were also seen inferiorly. Overall features are suggestive of liver abscesses. He recovered with drainage and antibiotics. (b) CT-scan of a 77-year-old woman with underlying diabetes, fever and right upper quadrant pain. Both blood culture and pus (from the liver abscess) grew *K. pneumoniae*. The CT scan shows an irregular ovoid lesion with multiple locules and thin intervening septations in the periphery of liver segment V and measuring 7.3 × 3.2 × 6.1 cm. The features suggest liver abscess with signs of early liquefaction. The woman recovered with drainage and antibiotics. Source: The authors acknowledge the Department of Diagnostic Radiology and Organ Imaging, Prince of Wales Hospital, Chinese University of Hong Kong for kindly supplying the images and permitting their use.

formation, coexists with serotype K1 and has been identified as the major virulence factor of *K. pneumoniae* [109]. Poor glycemic control also has a role by impairing neutrophil phagocytosis of K1/K2 type *K. pneumoniae*, whereas it does not significantly affect the phagocytosis of non-K1/K2 *K. pneumoniae*. An rmpA-associated hypermucoviscosity phenotype has also been reported in invasive purulent diseases caused by *K. pneumoniae*.

Most isolates are susceptible to cephalosporins (especially third-generation agents) and fluoroquinolones; however, therapeutic drainage is also needed and also assists with obtaining specimens for culture and susceptibility testing.

Metastatic abscesses may occur elsewhere in the abdomen, either singly or in combination with other sites, as well as within the urinary tract. A notorious, although uncommon, example is psoas abscess where responsible organisms are likely to be *S. aureus*, *Mycobacterium tuberculosis*, *E. coli*, or *Klebsiella*.

Skin and superficial soft tissue infections

Skin and subcutaneous tissues

Infections involving the skin, nails, and subcutaneous tissues are very common, and the skin and subcutaneous tissues are frequent targets of infection in diabetes, particularly in association with poor glycemic control. Candidal infections, bacterial infections such as furunculosis, dermatophycoses, and onychophycoses are all commonly seen and may be the reason for diabetes being identified. Cutaneous forms of mucormycosis or other fungal infections may occur and be diagnosed following skin biopsy. More detailed consideration is given to these disorders in Chapter 52 and is not repeated here.

Sensory neuropathy, atherosclerotic vascular disease, and hyperglycemia predispose people with diabetes to skin and soft tissue infections. Additional risk factors for the development of cellulitis include a past history of cellulitis, edema, peripheral vascular disease, tinea infection, and dryness of the skin. The predominant organisms involved are group A streptococcus and *S. aureus*. Cellulitis can also occur in less usual settings. For example with *S. pneumoniae* (pneumococcal) infections, cellulitis may occur in association with extracutaneous foci of disease, the suggestion being that, in this setting, the cellulitis results from hematogenous spread rather than local infection [111].

People with diabetes, particularly those who inject insulin, often have asymptomatic nasal, mucosal and skin colonization with potential pathogens such as *S. aureus*. Nasal colonization may also contribute to increased risk of staphylococcal pneumonia, for example in association with influenza.

According to data from the National Health and Nutrition Examination Survey (NHANES), people with diabetes who are colonized with *S. aureus* are also more likely to have a methicillin- resistant *S. aureus* isolate than a susceptible one (odds ratio 2.6; 95% CI: 1.1–6.1) [112]. A recent increase in community-associated methicillin-resistant *S. aureus* (CA-MRSA) gives additional cause for concern. A recent report evaluating CA-MRSA in three communities found that 77% of skin or soft tissue infections were methicillin-resistant [113]. The underlying conditions identified included smoking (35%), previous skin infection (21%), and diabetes (19%).

Mucosal and skin colonization with *C. albicans* is also common and may involve numerous sites including the genitalia of both sexes as well as the mouth, skin, and nails [114]. Balanitis and vulval candidiasis are common presenting features of diabetes.

Colonization may predispose to cutaneous or incisional staphylococcal (or other bacterial) infections as well as transient bacteremia. Entry sites may also include areas of fungal skin infection (e.g. intertrigo). Infection at distant sites with abscess formation or septicemia may then ensue. In two relatively early studies (each from the 1960s) older people with diabetes were shown both to be at greater risk of staphylococcal septicemia and also to suffer a substantially higher mortality (69% in those with diabetes compared to 42% overall) [115, 116].

Deeper soft tissue infections

Deeper soft tissue infections also occur with increased frequency in people with diabetes. Examples include pyomyositis, necrotizing fasciitis, and Fournier gangrene. Pyomyositis, usually associated with infection by *S. aureus*, occurs in muscles that have undergone trauma, especially when associated with hematoma formation.

Necrotizing fasciitis

Necrotizing fasciitis is a deep-seated life-threatening infection of subcutaneous tissue. Progressive destruction of fascia, fat, and muscle ensues. Although relatively uncommon, necrotizing fasciitis is a life-threatening condition. Necrotizing fasciitis and Fournier gangrene (a form of necrotizing fasciitis involving the perineum), as well as other necrotizing soft tissue infections resulting from a variety of organisms, all have reported associations with diabetes. Diabetes is the most common of a number of conditions predisposing to necrotizing fasciitis, all of which are associated with compromise to the immune system.

As its name indicates, necrotizing fasciitis spreads initially along fascial planes; however, as infection and inflammation progress, necrosis of muscle, subcutaneous tissues and overlying skin occurs. Necrotizing fasciitis usually follows identifiable episodes of trauma such as burns, insect bites or abrasions, or can result from exposure of non-intact skin to a source of infection. The most common sites are the limbs, abdominal wall, and perineum. Involvement of the vulva in women with diabetes may begin as a Bartholin gland ductal abscess, usually associated with obesity [117].

Polymicrobial infection is most commonly observed, with streptococci and *Enterobacteriaceae* being the most common isolates. The great majority of cases result from infection with anaerobes together with one or more facultative aerobes, whereas about 10% are associated with group A streptococcus, with or without *S. aureus*. Thus, group A streptococcus is the most common cause of infection by a single organism and can also occur in combination with staphylococci, including CA-MRSA. A recent article describing necrotizing fasciitis caused by CA-MRSA showed that although current or past intravenous drug abuse underlay 43% of patients, 21% occurred in people with diabetes [118].

Vibrio, *Aeromonas*, *Haemophilus*, and *Salmonella* infections have also been reported. An interesting example is infection by halophilic marine *Vibrios* either following exposure of non-intact skin to seawater [119] or following bites by marine organisms, such as crabs, and this should be considered when a history of appropriate exposure is present.

Necrotizing fasciitis carries a high mortality, particularly when affecting the lower extremities or perineum, and is rapidly fatal unless diagnosed promptly and treated aggressively. It may be initially misdiagnosed as a benign soft tissue infection and a high index of suspicion is therefore required. Skin changes may be minimal in the early phase of infection.

Early disease may be characterized by severe local pain, which is either disproportionate to or precedes other clinical features such as local inflammation and cellulitis, fever and systemic toxicity. Cellulitis may spread rapidly, unseen in deeper fascial planes. Crepitus is present in about half of cases. Violaceous discoloration of the skin may be noticed and may progress into blistering and bullae. Thrombosis and vasculitis each contribute to necrosis of the superficial fascia and suppuration from liquefactive necrosis. Gangrene and ulceration can result. Anesthesia of overlying skin may indicate destruction of subcutaneous nerves.

Plain radiographs, ultrasound, CT and MRI scan can each assist in both diagnosis and management by identifying the presence of gas in the tissues and by delineating the extent of the disease. Aerobic and anaerobic cultures should be taken from within the lesion, as should blood cultures.

Surgical debridement and fasciotomy are the mainstays of therapy. The single most important issue influencing mortality is time to surgical debridement. Thus, timely diagnosis, empirical broad-spectrum antibiotic therapy (including anaerobic cover) and aggressive surgical debridement of affected tissue are crucial components of management. The antibiotic cover can subsequently be tailored according to culture and sensitivity results. Additional supportive therapy in an intensive care environment should be provided where possible and as necessary.

Fournier gangrene

Fournier gangrene is a specific form of necrotizing fasciitis involving the perineum, scrotum, and penis. Overall mortality is very high. As with other forms of necrotizing fasciitis, diabetes is the most common of a number of potential predisposing conditions with a reported presence ranging 32–60% of cases [120, 121].

Infection is usually polymicrobial with a lengthy list of potential pathogens which is similar to that seen in other forms of necrotizing fasciitis (*E. coli*, *Bacteroides* spp, staphylococci, streptococci, *Proteus* spp, *Pseudomonas* spp, enterococci). *C. perfringens* is present in the great majority (>90%) of cases in which myonecrosis is present.

Initial malaise and scrotal discomfort or pain is followed by systemic toxicity. Blistering ulceration and necrosis of the skin occur and in the later stages progress to scrotal swelling and a foul purulent discharge. Crepitus may be present. Sources of infection include abnormalities of the urogenital system (most notably urethral trauma, instrumentation or a chronic indwelling catheter, scrotal abscess or injury, insect bite) and local gastrointestinal abnormalities (e.g. ischiorectal or perianal abscess, incarcerated inguinal hernia).

Diagnosis is predominantly clinical. Radiologic imaging techniques may reveal subcutaneous gas and delineate the extent of involvement, as with other forms of necrotizing fasciitis.

Fournier gangrene is a surgical emergency, and extensive debridement is required. Urinary or fecal diversion may be required, as may laparotomy. Broad-spectrum antibiotic therapies with anaerobic cover, as well as general supportive measures are indicated as with other forms of necrotizing fasciitis. The results of microbiologic investigation may allow subsequent tailoring of antibiotics.

Infected diabetic foot

Foot infection is the most common soft tissue infection associated with diabetes and therefore is a topic of the utmost importance to all who deal with people with diabetes. However, a specific chapter (chapter 48) is devoted entirely to this topic. Thus, in order to avoid duplication, the topic receives only brief discussion in this chapter.

Disease-related peripheral neuropathy and peripheral vascular disease are both important in the etiology of foot infections, although the clinical presentations of the "predominantly ischemic" and the "predominantly neuropathic" foot differ. Serious complications include osteomyelitis, amputation, or even death. Infection often begins after minor trauma, which may be unnoticed, especially in the presence of sensory neuropathy. Cellulitis, soft tissue necrosis and extension into bone, leading to osteomyelitis, may then follow. Involved organisms most commonly include group A streptococcus and *S. aureus*, as well as aerobic Gram-positive cocci, Gram-negative rods and anaerobes.

The mainstays of management include exploration and debridement of the necrotic tissue and administration of appropriate antibiotics. In moderate to severe cellulitis or in the presence of osteomyelitis that places the limb at risk, the patient should be hospitalized for broad-spectrum antibiotic therapy and surgical intervention.

As in most diabetes-related infections, poor glycemic control plays an important part, and foot infections remain a common presenting feature of newly diagnosed diabetes, particularly in less developed parts of the world. Prevention of foot ulcers involves a multidisciplinary team approach. Foot care is an essential component of all diabetes education programs and should include proper foot care habits, protective footwear, and pressure reduction.

Bone and joint infections

Bone and joint infections remain a significant problem for people with diabetes and can be very difficult to treat. Diabetes is a risk factor for both osteomyelitis and septic arthritis.

The different types of osteomyelitis require differing medical and surgical therapeutic strategies. The three main types, classified according to etiology, include osteomyelitis secondary to a contiguous focus of infection (e.g. after trauma, surgery or insertion of a joint prosthesis); osteomyelitis secondary to vascular insufficiency (e.g. diabetic foot infections); or osteomyelitis secondary to hematogenous spread of infection. The most common reason for septic arthritis is following insertion of joint prostheses. All are more common in people with diabetes, with osteomyelitis of the foot at the forefront. Taking, as an example, osteomyelitis of the spine, then a recurring theme occurs with a combination of both increased risk of hematogenous vertebral osteomyelitis (two- to sixfold) and predisposition to infection involving unusual organisms [122]. Acute osteomyelitis can respond to antibiotics alone but prolonged courses are required for bone and joint infections given the physiologic and anatomical characteristics of the tissues involved. Early diagnosis, together with bone sampling for microbiologic and pathologic examination to allow targeted and long-lasting antimicrobial therapy, allows the best outcomes. As with the diabetic foot, a multidisciplinary approach is required for success, including expertise in orthopedic surgery and infectious diseases, together with vascular surgery. Surgical intervention should be considered if medical treatment fails, for diagnostic confirmation, or in the presence of complications.

Chronic osteomyelitis may be associated with avascular necrosis of bone and formation of sequestrum (dead bone), and surgical debridement is then necessary for cure in addition to antibiotic therapy. It is important to remember the possibility of infection by *M. tuberculosis* [123].

Iatrogenic and surgical site infections

Insulin injections

Infections at the site of insulin injections are very uncommon and remain so even when traditional hygienic practices are not applied. Although not advised, administration of insulin through clothing is also not associated with increased risk of infection. Abscesses at needle sites are occasionally seen in individuals receiving subcutaneous insulin infusions [124]. Likewise, pulp infection over the distal phalanges in association with self-blood glucose monitoring is exceedingly unusual.

Surgical site infections

An association between diabetes and an increased risk of surgical site infections has been known to exist for many years.

Studies addressing this question have frequently focused on the risk of postoperative infection following coronary artery bypass grafting. The association has been generally assumed to be causally related to the deleterious effect of hyperglycemia on immune function [125].

Three studies support an increased risk of postoperative infection associated with postoperative hyperglycemia among those with diabetes undergoing bypass grafting [126–128]; however, whether or not hyperglycemia imposes an independent risk for infection remains controversial. In none of the studies was mortality increased and, in one, postoperative hyperglycemia was correlated with a higher risk of infection while an elevated HbA_{1c} was not. The studies demonstrate, however, that improved glucose control during the operative and perioperative period can reduce the risk of postoperative infections in people with diabetes undergoing cardiac surgery. One retrospective study of 1574 patients undergoing coronary artery bypass grafting at a single institution found no increase in mortality or rates of infection among those with higher postoperative glucose levels and 34.6% of patients in this series had a diagnosis of diabetes. Nevertheless, increased glucose concentrations were associated with increased hospital charges and a longer postoperative stay.

Both allograft rejection and risk for infection appear to be higher in transplant recipients with diabetes. In one study, the risk of serious infection was higher in heart transplant recipients with diabetes in the early postoperative period [129]. In another study, renal transplant recipients had a greater risk of both acute allograft rejection and infection when perioperative glycemic control was poor [130].

Dialysis

Ambulatory peritoneal dialysis is a common form of treatment for end-stage renal disease in people with diabetes. For those receiving continuous ambulatory peritoneal dialysis, episodes of catheter-related peritonitis are common, although variable from individual to individual, with some developing multiple episodes. Overall, however, the rate of infection does not appear to be greater in people with diabetes than those without diabetes, perhaps reflecting impairment of immunity associated with end-stage renal disease per se.

The issue of peritonitis in people receiving continuous ambulatory peritoneal dialysis is an important one given the large number of people with diabetes receiving this treatment. It is well recognized that peritonitis, despite significant reductions in the last two decades, remains the most important complication of continuous ambulatory peritoneal dialysis with an overall mortality of about 3.5%, irrespective of both the underlying cause of the infection and the renal failure [131]. The degree to which the presence of diabetes adds to the already considerable infection risk remains uncertain. People with diabetes may, however, be generally more unwell and have additional factors and complications such as macrovascular disease, need for hospitalization and predilection to certain infections, such as candidiasis. All of these may, in principle, contribute to the already very considerable risk.

Principles of treatment, prevention, and general care

General principles

A high level of awareness is required in people with diabetes and in all healthcare providers, both to allow prevention and early, prompt recognition and diagnosis. Education, good glycemic control and general steps to maintain health and nutrition are all important measures aimed at minimizing risk. Careful attention to foot care is particularly emphasized. Vigilant measures should be instituted to prevent infection. When infections do occur, evolving antibiotic resistance patterns and other local factors must be considered, with CA-MRSA and tuberculosis both providing obvious examples of the importance of this.

The choice of antibiotic therapy follows the same general principles as for any other individual. Use of empirical broad-spectrum antibiotics is generally recommended until microbiologic results can guide treatment. Due caution should be applied in the presence of diabetic complications. For example, the use of potentially nephrotoxic agents in the context of diabetic nephropathy may aggravate renal dysfunction, and in turn impaired renal function requires caution with doses and monitoring of blood levels. The presence of gastroparesis or autonomic neuropathy may hinder, or render unreliable, the absorption of oral drugs. People who are blind or partially sighted as a result of eye complications may also be at increased risk, for example when exposed to drugs that impair hearing or balance. Longer courses of antibiotic therapy may be appropriate, for instance in treating UTI.

Antiviral agents are recommended in the setting of influenza, and a more aggressive treatment approach may be appropriate even when presentation is relatively late [69]. Responses to treatment should also be carefully monitored (e.g. in the case of tuberculosis) [82]. The importance of appropriate referral to surgical or other specialist colleagues has been stressed repeatedly. Examples include surgical debridement in the case of necrotizing fasciitis, and incision and drainage of abscesses.

People with diabetes generally have a normal response to vaccines and should receive immunizations according to established guidelines. None of the vaccines currently available are contraindicated on the basis of diabetes alone. Because of increased susceptibility to complications, routine immunization against pneumococcus and influenza is recommended, particularly for older people with diabetes or for those with additional comorbidity such as chronic respiratory disease. Influenza vaccination has been shown to reduce hospital admissions significantly during influenza outbreaks [132]. Hepatitis B vaccination is also important although some populations may require additional or booster doses over and above standard recommended regimens.

Glycemic control

All physicians need to be aware of the importance of careful monitoring of diabetic control in the presence of infection and should

be on guard against destabilization of control or development of complications. Interestingly, in people without diabetes following hospitalization, even mild degrees of hyperglycemia are associated with increased mortality in association with severe illness. Although depressed immune function correlates somewhat variably with traditional measures of glycemic control, there is sufficient evidence to indicate an inverse relationship between the two which is potentially reversible. Previously undiagnosed diabetes may also be first detected following hospitalization and then needs to be distinguished from hospital-related hyperglycemia which later reverts to normal.

People with T1DM or others receiving insulin need to be aware of the probability of changing insulin requirements in response to infection and to the risk of severe consequences such as diabetic ketoacidosis. Many people with T2DM, who are not on insulin, need to be transferred temporarily to insulin therapy as the stress of illness frequently adversely affects glycemic control. Hospital admission is mandatory if severe destabilization of glycemic control occurs, or if symptoms such as nausea and vomiting interfere significantly with oral food intake. In this situation, intravenous insulin-glucose regimens are recommended. While good glycemic control is important, it is also important to avoid hypoglycemia. Interaction between the diabetes care team and other involved specialists should be initiated as early as possible.

The importance of perioperative glycemic control in people with diabetes undergoing surgery also needs to be emphasized in order to minimize negative impacts upon postoperative infection rates and wound healing (see Chapter 34).

Attention to other risk factors (e.g. neurologic and vascular complications) is also important in order to minimize the risk of infections and infection-related complications. The importance of the presence of microangiopathy and neuropathy in the risk of the more severe forms of infection is again emphasized.

For more detailed description of these aspects of care, readers are referred to clinical practice recommendations, for example those of the American Diabetes Association or to other national or international guidelines, as well as to other relevant chapters in this textbook.

Awareness among physicians needs to be high, especially with regard to the unusual and severe forms of infection that may occur. The general approach to antibiotic treatment is the same as for people without diabetes, but details may differ (e.g. doses and duration of therapy). Responses to vaccination are generally normal, and influenza and pneumococcal vaccination is recommended. Careful attention to glycemic control and to other underlying factors is essential.

10 Psychosocial Aspects of Diabetes

56 Psychological Factors and Diabetes Mellitus

Frans Pouwer[1] and Jane Speight[2,3]

Key points

- People who report chronic stress, low stress resilience, sleeping problems, or depression are at increased risk of developing type 2 diabetes mellitus (T2DM). Recent evidence suggests that chronic stress is also a risk factor for the development of type 1 diabetes mellitus (T1DM). The mechanisms remain poorly understood.
- Both T1DM and T2DM can affect the psychological and neuropsychological status of children and adults. In most instances, these effects are modest in magnitude and are most likely to be associated with certain adverse events that occur during the course of diabetes or its management.
- Children show remarkable psychological resilience to the diagnosis of T1DM. About one-third report some psychological distress shortly after diagnosis but this generally subsides within 6 months. Problematic adjustment is characterized by increased depressive symptomatology, more anxiety, social withdrawal and sleep disturbances. A similar adjustment reaction is often seen in parents, particularly mothers, of children with newly diagnosed T1DM. Diagnoses of post-traumatic stress disorder are also more common in parents, occurring at rates comparable with that reported in children diagnosed with cancer.
- During the first 5–10 years of their diabetes, most children and adolescents show adequate psychological functioning; however, after 10 years of diabetes, their rates of anxiety, depression, or eating disorders are markedly increased, with as many as one-third of adolescents with diabetes meeting criteria for one or more psychiatric disorders.
- Macrovascular disease, chronic foot ulceration, and proliferative retinopathy increase the risk of psychopathology, an understandable reaction to serious complications; however, lifetime psychiatric disorders such as depression may also increase the risk of later development of complications such as retinopathy. Recurrent diabetic ketoacidosis, particularly in young women, is also predicted by poor psychological functioning, and by high rates of family dysfunction.
- Diabetes-specific distress and fear of hypoglycemia are both relatively common. The latter may lead to premature treatment as blood glucose levels begin to fall, resulting in persistent hyperglycemia.
- Generic health-related quality of life and health status for those with diabetes does not differ from people with other chronic conditions, such as arthritis. Lower health-related quality of life is associated with diabetes complications, being female, physical inactivity, low income, and recurrently hypoglycemia.
- Diabetes-specific quality of life can be impaired by intensive diabetes management or improved with flexible approaches to intensification of treatment.
- Interventions such as individual or group therapy or counseling based on the principles of cognitive behavioral therapy (CBT) or mindfulness-based therapies are effective in improving mental well-being. Web-based CBT is also effective.
- Diabetes management and health outcomes are influenced by reciprocal relationships between glycemic control and psychological variables. The latter include enduring psychological traits such as locus of control, coping style, temperament, and transitory psychological states (stress, anxiety, depression). Diabetes is also strongly related to family functioning, especially in children and adolescents: low family conflict, good communication, cohesion, and marital satisfaction relate to better diabetes control.
- Self-care behaviors (medication-taking, self-monitoring of blood glucose, healthy eating, physical activity) are only weakly related to glycemic control, but this may reflect the inaccuracy of self-reported behaviors, the crudeness of the self-report measures or the discrepancy between "typical" recent behaviors (e.g. past 2 weeks) and HbA_{1c} (the average blood glucose over the past 8–12 weeks).
- Effective interventions to improve psychological well-being, self-care, and health outcomes include empowerment-based approaches, structured training/education, as well as psychotherapy and family therapy. The components of effective programs include (with various emphasis) goal-setting, problem-solving, coping, managing stress, self-motivation, and self-management skills.
- Cognitive dysfunction in diabetes is generally mild, but when diabetes is diagnosed in the first 5–7 years of life, children have an elevated risk of

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

manifesting clinically significant impairments in all cognitive domains. Those with a later onset of diabetes show modest effects, most evident on measures of intelligence, academic achievement, and psychomotor efficiency. Deficits appear early in the course of the disease, and are evident within 2–3 years after diagnosis. Hypoglycemia was long considered to be the major cause of this neurocognitive dysfunction but more recent research suggests that adverse effects on cognition usually occurs only when hypoglycemia extends over a prolonged period of time. Although the etiology of neurocognitive changes in children remains poorly understood, a growing body of evidence implicates chronic hyperglycemia and, in particular, the development of microvascular and macrovascular complications.

- In adults with T1DM, neurocognitive deficits are quite modest and are most apparent on measures of intelligence, psychomotor speed, and executive function. Older adults with T2DM manifest marked reductions in memory function and, in both groups, the strongest predictor of cognitive dysfunction is chronic hyperglycemia and the presence of biomedical complications, particularly retinopathy and peripheral neuropathy.
- Structural damage to the brain is also common in both children and adults with either T1DM or T2DM. Not only is there a reduction in cortical gray matter density, but white matter structures may be disrupted. Cerebral atrophy is often present, neural slowing is evident on electroencephalography and regional cerebral blood flow is altered.

Introduction

Diabetes and psychology have long been linked. Areteus of Cappadocia (1st or 2nd century) described life with diabetes as "disgusting and painful." In the 17th century, Thomas Willis mentioned long grief and melancholia as potential causes of diabetes. More than three centuries later, a meta-analysis of modern longitudinal epidemiological studies confirmed that Willis was right. This chapter examines four major points of intersection: (1) psychological risk factors for diabetes, (2) psychological impact of diabetes and its complications, (3) psychological factors that influence, or are influenced by, the everyday management of diabetes, and (4) the neuropsychological or cognitive consequences of diabetes.

Psychological risk factors for the development of diabetes

Longitudinal epidemiological studies have shown that not only depression and anxiety, but also general emotional stress, sleeping problems, anger, and hostility, are associated with increased risk of developing type 2 diabetes (T2DM) [1–3]. Using data from the British Household Panel Survey ($n > 9000$), Mommesteeg et al. [4] found that, compared to adults reporting a low level of psychological distress, those with higher levels were at 33% increased risk of developing T2DM during the 18-year follow-up. Additional analyses showed that this association might be mediated by a low energy level and impaired health status. Both sleep quality and quantity (too much and too little) predict the onset of T2DM. In a systematic review of 10 longitudinal studies, involving >107,000 men and women without diabetes at baseline [5], short sleep duration (≤5–6 hours per night) increased diabetes risk by 28%, while long duration (>8–9 hours/night) increased risk by 48%; difficulty in initiating and maintaining sleep increased diabetes risk by 57% and 84%, respectively [5]. For other psychological factors (such as childhood neglect, a large number of adverse life events, and elevated work stress), there are conflicting findings [2].

Only one prospective study so far has investigated stress as a risk factor for type 1 diabetes (T1DM). In an updated analysis of the All Babies In southeast Sweden (ABIS) study, 58 children from the 10,495 participants developed T1DM, with childhood experience of a serious life event being associated with a higher risk (HR 3.0; 95% CI: 1.6–5.6) [6, 7]. Chapter 57 will describe how depression is an important risk factor for the development of T2DM.

The majority of studies have focused on emotional problems or psychological factors as transient states, such as current depression or stress levels. However, if psychological factors do indeed have an impact on the development of T2DM, this is most likely a process over several years. Therefore, personality factors or traits may also play an important role. The role of stress resilience in the onset of T2DM was investigated prospectively in a national cohort study of 1.5 million male military conscripts in Sweden (from 1969 to 1997) with follow-up over 25 years (from 1987–2012) [8]. Stress resilience was assessed using a "gold standard" interview by psychologists (with high inter-rater reliability). Controlling for family history of T2DM and baseline BMI, those with low stress resilience were 51% more likely to be diagnosed with T2DM than those with greater innate ability to cope with stress [8]. Chronic stress was associated with a number of unhealthy behaviors (e.g. physical inactivity, unhealthy diet, sleep problems, smoking) as well as activating the innate immune system (i.e. increased interleukin 6 and other cytokine mediators of stress response, which are also involved in mediating insulin resistance). A recent systematic review of 10 longitudinal and 13 cross-sectional studies investigated whether various personality characteristics are associated with having, or the risk of developing, metabolic syndrome but there is conflicting evidence for high hostility, neuroticism, or Type D (distressed and socially inhibited) personality as risk factors, possibly reflecting publication bias [9]. Consequently, we need new epidemiological cohort studies with a prospectively published study protocol to further our knowledge about the role of chronic emotional stress, depression/anxiety, and personality traits as risk factors for the development of T2DM. One example is the Maastricht Study [10], which will investigate not only depression and anxiety, but also various personality factors in relation to T2DM. Future research also needs to focus on

identifying behavioral and physiological mechanisms linking various forms of stress and incident T2DM.

The psychological impact of diabetes and its complications

Psychological distress shortly after diagnosis

People with diabetes ought to manifest significant psychological distress, or so goes conventional clinical wisdom. The term psychological distress refers not only to depressive and anxiety symptoms, but also to diabetes-specific distress. Depression and anxiety are both common general mental health disorders, while diabetes-specific distress reflects a person's negative emotional response to the burden of living with diabetes, not the presence of a psychiatric condition [11]. Depression, anxiety, and diabetes-specific distress partly overlap, but are not interchangeable constructs. People with diabetes live with a condition that shortens their life expectancy, can lead to debilitating biomedical complications (e.g. blindness or neuropathy), and requires them to take daily responsibility for managing their health (e.g. with medications or insulin injections, and careful monitoring of diet, physical activity, and blood glucose levels) for the remainder of their lives. Interestingly, however, in the Hoorn Study, a diagnosis of screening-detected T2DM was not associated with significant psychological distress [12].

Children and their parents

In contrast to many expectations, children and adults show remarkable psychological resilience to a diagnosis of diabetes. In what may be the most comprehensive prospective psychological study of children with T1DM and their families, Kovacs et al. [13] assessed 95 children, 8–13 years of age, shortly after discharge from their initial hospitalization, and followed them for 6–10 years. Within 3 months of diagnosis, 36% of the children experienced sufficient psychological distress to meet criteria for a diagnosable psychiatric disorder [14]. Most had "adjustment disorder," defined as a transient reaction that exceeds the normal and expected response to a stressor, which develops within 3 months of onset of the stressor and lasts no more than 6 months. The occurrence of such a disorder signals that the child is beginning to come to terms with the diabetes, and can be considered a component of the "mourning process" that often accompanies the development of any chronic illness [15]. As expected, recovery was rapid, with 93% showing complete remission of psychiatric symptoms within 9 months.

Greatly elevated rates of post-traumatic stress disorder (PTSD) have also been reported in a prospective study of parents evaluated at 6 weeks, and 6 and 12 months after their child's diagnosis. Depending on the time point, 16–22% of mothers and 8–14% of fathers met DSM-IV criteria for a PTSD diagnosis [16]. These rates were significantly higher than symptoms in the general population but are comparable with those seen in mothers of children diagnosed with cancer. The best predictor of PTSD severity at 12 months was PTSD severity at 6 months; episodes of hypoglycemia were also associated with an increased severity of PTSD.

In a systematic review of eight cross-sectional studies that focused on fear of hypoglycemia in parents of children under the age of 12 with T1DM, fear of hypoglycemia was common, especially among mothers [17]. Moreover, fear was related more to hypoglycemia severity than frequency, particularly if the child had experienced a hypoglycemic convulsion [17].

Adults

The onset of diabetes during adulthood ought to produce similar adjustment disorders within several months of diagnosis in both the individual and partners or close family members. A German study used structured interviews that provided diagnoses according to DSM-IV in a sample of adults (aged 17–40 years) with newly diagnosed T1DM and compared them with a large reference group, comprising a representative population sample of 2046 persons of a similar age. Persons with T1DM had a rate of major depressive episodes twice that of the reference group (5.8% vs. 2.7%) [18]. A more careful analysis showed that these differences were statistically significant only for women with T1DM (9.3% vs. 3.2% in the reference group), with no differences in men (3.6% vs. 2.2%), nor for other psychiatric disorders [18]. Studies of adults with T2DM report mixed findings regarding psychological morbidity in the first year following diagnosis. A meta-analysis has demonstrated the prevalence of depression to be higher in adults with diagnosed T2DM compared to those with undiagnosed T2DM, impaired glucose metabolism or normal glucose metabolism [19]. The recent LifeLines study was a large epidemiological study of 90,686 participants who underwent diagnostic psychiatric interviews and had fasting glucose levels taken [20]. In contrast with the earlier meta-analysis [19], LifeLines shows that depression is independently associated with T2DM, both diagnosed (odds ratio [OR] = 1.4:1.1–1.8; $p = 0.006$) and undiagnosed (OR = 1.8:1.3–2.6; $p = 0.001$), while anxiety is independently associated with diagnosed T2DM (OR = 1.4:1.2–1.7; $p < 0.001$) but not undiagnosed T2DM [18]. A smaller clinical study of 71 participants reported that more than 50% expressed no emotional reaction to the diagnosis and felt that they could cope [21]. In a prospective study of 116 adults with newly diagnosed T2DM identified by a targeted population-screening program, the diagnosis had no substantial impact on psychological well-being, shortly after, and 6 and 12 months after diagnosis [12].

Psychological reactions emerging in the course of diabetes

Living with and managing diabetes is a complex endeavor. People with T1DM or insulin-treated T2DM must take responsibility for administering insulin doses and checking blood glucose levels (often several times per day), carefully monitoring food intake and physical activity, and then readjusting insulin, food and/or exercise in response to high or low blood glucose values or during acute illness. For those with T2DM not using insulin, the treatment regimen can be less onerous but adopting and sustaining

healthy lifestyle behaviors can also be burdensome, and not understanding how to adjust diet and physical activity to improve outcomes can be frustrating and demoralizing. In either instance, people with diabetes and their families assume primary responsibility for these self-care behaviors, all of which are directed at achieving or maintaining optimal glycemic control and quality of life.

Depression, anxiety, and diabetes-specific distress in children and adolescents

As duration of T1DM increases, it appears that many children and adolescents function well psychologically, although small increases may be evident in depressive and anxiety symptomatology and internalizing behaviors, such as somatic complaints, social withdrawal, and sleep disturbance. In school-aged children [22], this is evident after 2–3 years of T1DM, yet the magnitude of these changes does not reach clinically significant psychopathology. Somewhat higher rates of externalizing, or aggressive, behaviors have also been reported, with this phenomenon especially pronounced in boys [22], and strongly associated with persistent hyperglycemia [23].

Children who report more difficulties in managing their T1DM also show more symptoms of psychological distress. Level of psychological distress shortly after T1DM onset is often a good predictor of psychological problems later [24]. This suggests that it is helpful to assess psychological well-being shortly after diabetes onset and to monitor this routinely thereafter. De Wit et al. reported a randomized controlled trial that confirmed the utility of monitoring psychological well-being in adolescents with diabetes, for example with the MY-Q questionnaire [25, 26]. The frequency of assessments can be adjusted to the needs of the young person with diabetes, and intensified where indicated to guide further clinical actions and initiate stepped care [27].

When a structured psychiatric interview is used to assess for clinically significant psychopathology, marked elevations are found in rates of psychiatric disorder. Not only are girls more often affected than boys [28, 29], but their risk for recurrence of depression is also greater. In a cohort of Australian children with newly diagnosed T1DM assessed over a 10-year period, 37% had at least one DSM-IV diagnosis [28]; of those, 60% met criteria for two or more disorders and 55% met criteria for three or more disorders [28]. Mood, anxiety, and eating disorders were each present in 17% of the sample and nearly 20% manifested a behavioral disorder. Those adolescents who met criteria for a DSM-IV psychiatric disorder were also more likely to have manifested significant externalizing problems shortly after diagnosis, which were likely to have preceded diagnosis. Other investigators have identified maternal psychopathology as a potent predictor of subsequent psychiatric disorder and increased depressive symptomatology in children and adults with T1DM [30].

Elevated rates of suicidal ideation have been reported for adolescents with T1DM, with lifetime prevalence rates of ~26%, compared to 9–12% for adolescents without diabetes [31]. Although the rate of actual suicide attempts is low among youth with diabetes (4%), suicidal ideation was associated with greatly increased rates of disengagement from medical treatment.

Relatively little is known about diabetes-specific distress in children and adolescents. Largely, this is due to the dearth of appropriate measures for this age group and lack of recognition, until recently, of the potentially important role of diabetes-specific distress. A recent systematic review [32] highlights that only three measures have been developed specifically for adolescents and prevalence of clinically relevant diabetes-specific distress is estimated to affect around one-third of adolescents. Diabetes distress appears to be associated with HbA_{1c} (particularly when age-appropriate measures of diabetes distress are used), although associations with self-care behaviors were mixed [32]. While parental emotional support appears to be associated with lower rates of diabetes-specific distress, neither age nor gender appear predictive of diabetes-specific distress [32]. Importantly, diabetes-specific distress was strongly associated with depressive symptoms [32], suggesting that these constructs are inter-related and perhaps that interventions to reduce diabetes-specific distress may improve general well-being of adolescents with diabetes.

Depression, anxiety, and diabetes-specific distress in adults

The process of psychological adaptation to the diagnosis of diabetes in adulthood remains incompletely understood, largely because few longitudinal studies have been conducted with adults [33]. The Diabetes Control and Complications Trial (DCCT) Research Group [34], which is the largest follow-up study of adults with T1DM, found no change in self-reported psychological symptomatology over a follow-up period of 6–9 years, and found no relationship between type of treatment (conventional or intensive insulin therapy) and levels of psychological distress [35]. In an early systematic review, rates of clinically significant depression were higher in both treatment groups (25%) compared with rates of depressive symptoms (measured by self-report questionnaire) in the general population (14%) [36].

Cross-sectional studies of adults with either T1DM or T2DM have demonstrated repeatedly that rates of psychological distress, particularly depressive symptoms and anxiety, tend to be higher than the general population, but are usually comparable to those reported in individuals with other chronic conditions [37–39]. Using self-report measures of psychological symptoms, Peyrot and Rubin [40] found greatly elevated rates of both depressive (41%) and anxiety symptomatology (49%), with 38% of their entire sample showing elevations in both domains; however, repeated reassessment of these individuals over a 6-month period indicated that these effects are quite unstable. Across all three assessments, only 13% of the sample was persistently disturbed. The strongest predictors of ongoing distress included being female, having less than a high school education, being middle-aged, and having more than two diabetes-related biomedical complications [41]. Nefs et al. clearly showed that the best predictor of future depressive symptoms is a history of depression [33].

The concept of diabetes-specific distress emerged in the adult diabetes literature around two decades ago, with the publication of the Problem Areas in Diabetes scale [42]. There was no significant difference in distress scores among those with T1DM or insulin-treated T2DM, and scores were only weakly associated with age and diabetes duration [42]. Sixty percent of study participants reported at least one diabetes-related problem as "serious," with the top five most frequently endorsed "serious" problems being:

- worries about the future and the possibility of serious complications;
- feeling guilty or anxious when you get off track with your diabetes management;
- feeling scared when you think about living with diabetes;
- feeling discouraged with your diabetes regimen; and
- feeling depressed with you think about living with diabetes.

This seminal study also found that diabetes-specific distress was associated negatively with self-care (after adjustment for age, diabetes duration, and general emotional distress) and correlated positively with HbA_{1c}. Various international and more recent studies corroborate these findings [43–45]. A recent review found that elevated diabetes-specific distress is experienced by 20–30% of adults with T1DM, and more likely in women and in those with longer T1DM duration, severe hypoglycemia and younger age [46]. While many of the key emotional problems may not discriminate by diabetes type [42], studies have noted that the distress experienced by adults with T1DM tends to relate to "worries about low blood sugar reactions" and "feeling burned out by the constant effort to manage diabetes," while that experienced by adults with T2DM relates more to "not having clear and concrete goals for your diabetes care" and "feeling constantly concerned about food and eating" [46].

Psychological reactions to acute biomedical complications

Acute complications of diabetes include diabetic ketoacidosis (DKA; Chapter 36) and severe hypoglycemia (Chapter 35), both of which may be rare or recurrent events for an individual, and be influenced by an individual's personal and treatment characteristics.

The frequency of DKA peaks in adolescence, and recurrent DKA remains an issue among only a minority of adults with T1DM, largely predicted by intentional insulin omission. In the only narrative review of this topic, Skinner notes that this is because of feelings of depression, resentment, denial, and rebellion against diabetes [47]. Many interventions have potential depending on the person's circumstances: changing insulin regimens (including nurse-led injections, insulin pump), cognitive behavioral therapy, and family therapy are all options. He described that an important step in resolving recurrent DKA is a multidisciplinary approach, with knowledge of the person with diabetes from a psychosocial perspective and, most importantly, not losing contact with the person experiencing recurrent DKA.

Acute hypoglycemic episodes are often uncomfortable and unpredictable. They are accompanied by autonomic arousal characterized by aversive symptoms such as trembling, sweating, light-headedness, pounding heart, nervousness, feelings of agitation and worries that this episode could lead to a seizure, coma or death if not treated promptly. Thus, the development of fear of hypoglycemia, and the corresponding effort to avoid any situation that may lead to a recurrence of a hypoglycemic event, is unsurprising and an adaptive psychological reaction. In the DAWN2 study, conducted in 17 countries, 56% of participants with diabetes reported being worried about hypoglycemic events [48]. Fear of hypoglycemia is, indeed, indiscriminate, occurring in children [49] and adults with diabetes [50, 51], but especially in parents [49] and spouses [52], who can be more fearful than the individual, as they are often more acutely aware of its impact, while the person is unconscious with little recall of the event. In the DAWN2 study, for example, 61% of family members of people with diabetes reported to be worried about hypoglycemia [53].

Adults with T1DM, who experience recurrent hypoglycemia, or even a single episode of severe hypoglycemia when accompanied by seizure or coma, have greater fear of hypoglycemia [54]. This can be accompanied by broader diabetes-specific distress and impaired generic emotional well-being [55]. This is likely to be a consequence of several factors, including pre-existing personality traits, particularly neuroticism or trait anxiety, and current level of psychological distress [56]. Recent work has begun to explore the relationship between fear of hypoglycemia, and risk of severe hypoglycemia, identifying four subgroups (e.g. low fear/low risk; high fear/high risk; low fear/high risk; high fear/low risk), demonstrating the complexity of such fear and the importance of understanding the nature of the fear for determining suitable clinical interventions [57].

Less is known about the impact of hypoglycemia on adults with T2DM, but a narrative review concluded that (recurrent) hypoglycemia has a negative impact on quality of life [58]. Hypoglycemia is associated with more depressive and anxiety symptoms, and also with impairments of the ability to drive, work, and function in ways that are important for quality of life [58].

In addition to being associated with higher levels of generalized psychological distress, fear of hypoglycemia may lead people with diabetes, and parents of children with diabetes, to avoid hypoglycemia by treating falling blood glucose prematurely and hence maintaining blood glucose at higher than optimal levels [59]. Other, much rarer, diabetes-specific fears include fear of injecting or self-testing [56, 60, 61]; the prevalence of a phobia to needles or blood and injury remains controversial but is likely between 1–10% [56, 60, 61].

Psychological reactions to long-term biomedical complications

Several international studies have now demonstrated that worries about the future and the possibility of serious complications are the foremost "problem areas" for people with diabetes [42–45]. This is unsurprising given that long-term complications (such as retinopathy, neuropathy, nephropathy) can have a devastating impact upon the individual's health [62]. Due to the emphasis

placed on the importance of managing diabetes optimally to prevent complications, their development may also be viewed by people with diabetes, their families, healthcare providers, and others as a sign that they have "failed" to self-manage the condition adequately. Thus, it is reasonable to consider that the onset of complications leads to psychological distress, due to the emotional impact and significance of a new health status but also to a change in self-perception or identity and to self-blame and guilt. This conjecture has not been tested empirically and it is unknown how adults react psychologically immediately after a complication appears. However, as a group, adults with complications usually have greater levels of depression [63, 64]. A prospective cohort study reported that 24% of adults with diabetes presenting with their first diabetic foot ulcer had clinically significant major depression, and this was associated with a threefold risk of death during an 18-month follow-up period [65]. Other studies have also demonstrated marked increases in depressive symptomatology with peripheral neuropathy, and have attributed this psychological distress to the physical distress associated with reduced feeling in the feet and unsteadiness, as well as its unpredictability [66, 67].

People who develop retinopathy, and with it varying degrees of vision loss, experience a range of adverse social impacts (including social isolation, increasing dependence on others, disruption to family functioning) as well as an array of emotional impact (including loss of confidence, fear, vulnerability, anger, stress, depression) [68]. However, the degree of psychological distress secondary to visual loss may not be unique to people with diabetes; at least one study of older adults has reported no significant difference in psychological adjustment between those with and without diabetes, either at the onset of visual loss or when re-evaluated 12 months later [69].

Quality of life

Psychological distress has so far been the primary focus of this discussion, but the extent to which diabetes affects the individual's perceived quality of life is also important. Defining and measuring quality of life remains controversial, although it is generally agreed that it is multidimensional (including physical, psychological, and social domains), subjective (domains will vary in importance and relevance for each individual), and dynamic (changing over time) [70]. A useful way to gain insight about this is to ask a person with diabetes "what aspects of life are important for your quality of life?" and, then "how does your diabetes affect these?"

Generic, health-related quality of life

Most attempts to assess quality of life actually assess health status, or what is commonly (and perhaps confusingly) referred to as "health-related quality of life," with the two most frequently used measures being the SF-36 and EQ-5D [70]. In people with diabetes, such measures are typically more sensitive to differences between those with and without macrovascular complications or other non-diabetes-related comorbidities [71], or following major procedures such as pancreas transplant [72], than to differences between those with and without microvascular complications or using intensive versus conventional treatment regimens [73]. Large-scale studies comparing the health-related quality of life of people with various chronic conditions have typically found little evidence that it is differentially disrupted in adults with diabetes. For example, when health-related quality of life was assessed in a large cohort of adults with diabetes using the Medical Outcome Study (MOS-36) questionnaire, people with diabetes reported more problems in physical and social functioning than those without chronic conditions, but tended to function better than people with cardiovascular, pulmonary, or gastrointestinal disorders [74]. For individuals with T1DM, poorer health-related quality of life is associated with being older, having biomedical complications, being female, being less physically active, and having a lower income [75]. Similarly, among individuals with T2DM, impaired health-related quality of life was associated with being female, the presence of diabetes-related complications, other non-diabetes-related comorbidities, and duration of diabetes [76].

Nieuwesteeg et al. [77] reviewed 17 studies that compared generic quality of life of children and adolescents with T1DM with that of their healthy peers. The authors concluded that the weighted effect sizes across all studies indicated no substantial differences in quality of life domains between children and adolescents with T1DM and healthy controls. On the other hand, disease-specific problems were certainly present.

Most recently, the DAWN2 study has shed light on the quality of life of 1368 adults with T1DM and 7228 adults with T2DM from 17 countries [48]. Overall, the impact of diabetes on various dimensions of quality of life was negative, with only 28% reporting a positive impact on at least one of the six life dimensions. A negative impact of diabetes on physical health was reported by 62% of respondents, followed by emotional well-being (by 46%), financial situation (by 44%), leisure activities (by 38%), work or studies (by 35%), and on relationships with family and friends by 21%. Approximately 40% of respondents (range: 19–65%) reported that their medication routine interferes with their ability to live a normal life.

Diabetes-specific quality of life

Diabetes-specific quality of life instruments do not enable comparisons between conditions but they are more likely to be sensitive in measuring the impact of diabetes and are also more responsive in assessing the consequences of treatment changes than generic or health-related measures [70]. This is because they include domains that are particularly relevant to diabetes, for example dietary freedom, and exclude other domains of less relevance, such as mobility.

The Diabetes Quality of Life (DQOL) measure was the first questionnaire to be developed specifically to assess the impact of diabetes upon quality of life [78]. It was designed for use in the DCCT to examine explicitly factors such as satisfaction, impact of diabetes, social and vocational worry and diabetes-related worry. The DCCT findings suggested that quality of life is unimpaired by type of treatment (conventional or intensive insulin

therapy) [79]. The apparently benign experience of being in the intensive-treatment arm of the DCCT (despite more injections, more blood glucose monitoring, and a threefold increase in severe hypoglycemia) may be a consequence of the greater level of psychological and medical support provided in such clinical trials. Alternately, it may reflect the relative insensitivity of the DQOL measure, which is capable of detecting the impact of major treatments (e.g. pancreatic transplantation) but is less sensitive to the more subtle differences between types of insulin regimen [70].

Another widely used tool to assess diabetes-specific quality of life is the ADDQoL [80]. While healthy adults with T1DM or T2DM typically report a good overall present quality of life, on average, they also indicate that the impact of diabetes on their quality of life is negative [80, 81]. In particular, the aspect of life most negatively impaired by diabetes is the freedom to eat as I wish, an item that captures eating what, when, how much or how little the person prefers and, importantly, not having to eat when he or she does not wish to do so [81, 82]. Diabetes-specific quality of life is typically more negatively impaired for those using insulin compared with other medications, and for those living with one or more long-term complications [80]. However, several randomized trials demonstrate that more flexible and convenient treatment regimens (even when insulin is required) improve diabetes-specific quality of life compared with treatment regimens that impose more rigidity in terms of timing of medications and meals [82, 83].

De Wit et al. have reviewed the instruments used to assess quality of life in young people with diabetes, identifying five diabetes-specific instruments, each with limited evidence regarding psychometric properties and various issues limiting their application in clinical practice [84]. They concluded that the PedsQL and the KINDL-R appear to be the most suitable instruments, but also that further research is needed to seek standardization of measurement in adolescents and to establish cross-cultural validity. In a review by Nieuwesteeg [77], boys with T1DM reported better diabetes-specific quality of life than the girls with T1DM. More recent studies evaluating changes in quality of life associated with the use of continuous subcutaneous insulin infusion have been mixed, with some indicating no benefit, while others suggested modest benefit [85], particularly amongst children and their parents [86]. Optimal metabolic control has sometimes [87], but not invariably [88], been found to be associated with better diabetes-specific quality of life in adolescents.

Age at onset of diabetes may also affect certain aspects of life quality. An early survey found that adults diagnosed with T1DM before 9 years of age were more satisfied with their marriage, and were more likely to have children than those diagnosed later [89]. The authors suggest that individuals diagnosed earlier in development may be more adept at integrating the condition as part of their lifestyle and, thus, find less disruption from diabetes later in life. More recent work also suggests that the linkages between marital satisfaction, higher levels of diabetes-related satisfaction and better glycemic control may reflect better psychosocial adaptation to a variety of illness-related and marital role stresses and strains [90]. Among older adults (mean age 81 years), the aspects of life most negatively impaired by diabetes are independence and dietary freedom [91].

The impact of psychological factors on diabetes management

The relentlessness of self-care, lack of immediate reward, unpredictability of blood glucose levels, and the feelings of guilt, anxiety, and failure that a person can experience when blood glucose levels are suboptimal (or unexplainable) can cause diabetes-specific distress, and may adversely affect general mood and emotional well-being. Conversely, certain personality traits or coping styles that are intrinsic to an individual's psychological make-up may modulate the person's ability to manage diabetes self-care activities, as may environmental and psychosocial factors, such as peer pressure to engage in certain "forbidden" activities, disruptive interpersonal conflicts, and the normal stresses and strains of everyday life. Overall, an individual's "psychology" may influence, and be influenced by, the process of diabetes management.

According to a systems model of health, there is no simple direct relationship between any single psychological variable and glycemic control [92]. Rather, health outcomes are determined by a system of reciprocal relationships amongst multiple psychological, behavioral, and physiologic variables. Figure 56.1 shows one such model of this process. Psychological *traits* are relatively enduring characteristics that include personality, temperament, and coping style. These may have an indirect impact on glycemic control, via their impact on self-care behaviors and emotional state. Psychological *states*, such as stress, are more transitory, reflecting emotions at a given point in time. These may influence glycemic control directly via the autonomic nervous system or, indirectly, by affecting the individual's self-care behaviors. Both family interactions and self-care behaviors may affect, and be affected by, the individual's mood or level of stress. Family functioning, including conflicts and degree of family cohesiveness, can

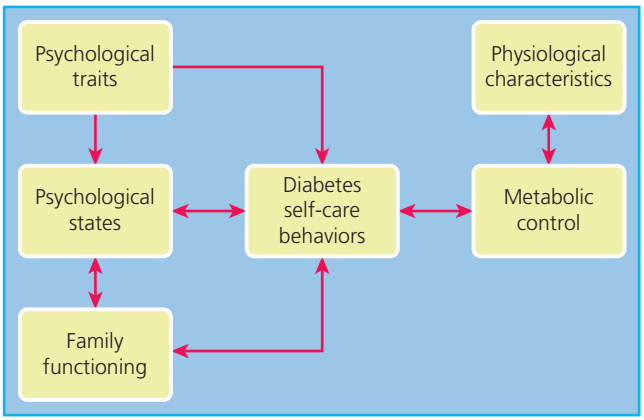

Figure 56.1 A systems model of the relationships between psychological, social, behavioral, and glycemic factors.

affect psychological state (and vice versa), but can also influence self-care behaviors. Self-care behaviors include medication use, diet, exercise and monitoring, and these behaviors serve as the primary final common pathway to glycemic control.

Psychological traits and glycemia

Early psychological research in diabetes focused on the influence of personality traits, and found that glycemic control is more likely to be optimal in individuals with certain personality characteristics such as a strong need for achievement and a high level of responsivity to social demands [93]. By contrast, glycemic control tends to be worse in those who are opportunistic and alienated [94], or who have poor impulse control, a propensity for self-destructive behaviors, and difficulty maintaining interpersonal relationships [95]. Recent work demonstrates that, in adults with T2DM, higher neuroticism levels are associated with better glycemic control, suggesting that moderate levels of worry may be needed to motivate these older adults to manage their diabetes [96]. Furthermore, adults with T2DM and type D personality—defined as high negative affect coupled with high social inhibition—report more barriers to medication use and are less likely to eat healthily or to consult health professionals when problems with diabetes management occur [97].

Locus of control is another psychological trait that may affect glycemic state. Individuals who have an "internal" locus of control believe that they are responsible for their health, whereas those who have an "external" locus believe that their outcomes are due more to chance, or some other outside force (e.g. significant others or health professionals) [98]. One of the most important studies in this area was an early study of insulin pump therapy in the 1980s [99]. Those choosing insulin pumps rather than insulin injections reported higher levels of "medical" control, that is, they believed that their health professionals and treatment regimen were responsible for their diabetes outcomes. Furthermore, among those using pumps at the end of the study, those with worse glycemic control (and those who experienced DKA) held highest beliefs in "medical" control, indicating that they placed undue faith in the newly developed technology to manage their diabetes. This and other studies (e.g. [100]) indicate that individuals with an internal locus generally have better glycemic control, although that is not invariably the case [101], and few studies demonstrate a strong link between locus of control and self-care [100].

Reconciliation of these discrepancies may require a reconceptualization of the locus of control construct. Multidimensional measures that examine different aspects of sense of control as well as different modes of and motivation for control may ultimately provide investigators with deeper insights into the complex interrelationships between perception of control and optimal diabetes management [102]. The complexity of these interactions has been underscored in a study that measured locus of control, self-efficacy and outcome expectancy, and used this information to predict HbA_{1c} among people with T2DM from a predominantly disadvantaged background [103]. Those with an internal locus of control who reported low self-efficacy and low outcome expectancy tended to have better glycemic control, whereas those with an internal locus of control who also expressed low self-efficacy and high outcome expectancy tended to have suboptimal glycemic control [104]. Having an internal locus of control may be particularly beneficial to those with little confidence in their ability to follow their physicians' recommendations (i.e. low self-efficacy), as well as little confidence that following those recommendations will actually improve their health (low outcome expectancies).

Coping styles, broadly categorized as emotion-focused and problem-focused [105], serve to modulate the individual's response to stressful situations. Emotion-focused or cognitive coping attempts to reduce threats from the environment by reinterpreting or reappraising the situation ("Stay calm, it really can't hurt you"). Problem-focused coping, in contrast, seeks to change the environment and thereby eliminate the threat. Within each of these categories, specific behavioral strategies may be differentially effective. Some may actually exacerbate stress (e.g. emotion-arousing strategies that include anger, impatience, or anxiety), while others (e.g. stoicism) may reduce or "buffer" the effects of stress [104]. In adolescents with T1DM, an emotion-focused coping style (e.g. behavioral and mental disengagement; aggressive coping) is associated with suboptimal glycemic control and reduced diabetes-specific quality of life, whereas active coping strategies (directed at approaching and making a direct effort to change the situation causing psychological distress) are linked to better glycemic control [106]. A meta-analysis of 21 studies has shown that the use of approach coping is associated with both better overall psychological adjustment and with somewhat better glycemic control [107].

If traits truly reflect enduring personality characteristics, they ought to predict long-term self-care behaviors, as shown in a longitudinal study of children and adolescents [101]. Coping style assessed soon after diabetes onset predicted adherence behaviors 4 years later. Those children who used more mature defense mechanisms and showed greater adaptive capacity, such as higher stress tolerance or greater persistence shortly after diagnosis, were most likely to manage their diabetes satisfactorily in the long term. Two recent reviews indicate that positive psychological characteristics (e.g. optimism, self-efficacy, and resilience) from childhood through to adulthood are consistently associated with optimal glycemic control, fewer diabetes-related complications, and reduced mortality rates [108, 109]. The mechanisms mediating these associations may include behavioral factors (e.g. medication-taking, healthy eating) as well as reduced inflammation, and improved neuroendocrine and autonomic functioning.

Psychological states and glycemia

Another psychological state worthy of consideration is emotional stress. Stress stimulates the release of several stress hormones to mobilize energy to enable the "fight or flight" response. However, in people with little or no endogenous insulin production, stress-induced increases in blood glucose cannot be metabolized properly. Thus, environmental stress and the individual's emotional reaction impact the management of glycemic levels. An

early review [110] demonstrated that the relationship between stress and glycemia is complex and idiosyncratic, causing hyperglycemia, hypoglycemia, or having no effect at all on glucose levels, and often dependent on the initial glycemic state.

The complexities of demonstrating the relationship between stress and glycemia are exacerbated by the many variables that influence the generalizability of findings [111, 112]. Studies have been conducted in children, adolescents and adults with T1DM or T2DM. Stressful experiences have been documented in self-report studies using simple checklists, validated questionnaires, in-depth interviews, or in experimental studies with exposure to an array of stressors (mathematical problems, video games). The duration of exposure may be influential and the major limitation of such studies is that they do not necessarily reflect real-life stressors. Real-world stress can be caused by trauma, threat, major life events (e.g. bereavement or losing a job), chronic stressors (e.g. long-term unemployment or carer responsibilities), or other day-to-day "hassles" (e.g. work, finances, relationships, exams, noise, illness/surgery). Furthermore, individuals perceive stressors in different ways, either as negative (e.g. death, financial problems) or positive (e.g. birth of a child, marriage). Exactly how stress affects glycemia remains controversial and few empirical studies have been conducted in recent years [111, 112]. A relatively recent 5-year prospective study of 132 adolescents, using longitudinal growth curve modelling, found that stressful life events (reported annually) predicted greater psychological distress, and suboptimal self-care and glycemic control [113]. The effect was stronger in older adolescents and that the effect of stress on glycemic control was likely mediated by self-care behaviors.

Family characteristics, interactions, and glycemia

Diabetes can dramatically disrupt the entire family, particularly when the individual with diabetes is a child or adolescent [114]. Children, especially younger ones, are more likely to have optimal glycemic control when their parents take an active role in managing their diabetes, whereas for adolescents, shared management responsibilities with parents typically results in more favorable outcomes [115–117]. Within the family, low levels of conflict are associated with better control [118], as is a higher level of social support from family and friends [119]. Conversely, suboptimal glycemic control in children and adolescents is predicted by higher maternal trait anxiety levels [120], lower parental intelligence [121], greater levels of family stress, more family conflict and less family cohesion [122], and sociodemographic variables (e.g. single-parent households) [123]. In adults with diabetes, better marital satisfaction is associated with better diabetes-related quality of life [90, 124], less diabetes-specific distress [90], and a non-significant trend towards better glycemic control [90].

The relationship between family characteristics and glycemic control in children is most likely mediated via a behavioral pathway whereby family conflicts disrupt planning and performance of diabetes management activities; this pattern has been supported by a large prospective study [122]. New, web-based interventions that aim to decrease parenting stress in parents with a child who has diabetes are currently being tested [125].

The impact of behavioral factors ("adherence") on diabetes management

Historically, the terms "concordance," "adherence," and "compliance" have been used interchangeably to refer to the extent to which an individual simply follows their diabetes management regimen or plan, so-called "doctor's orders." This model is now referred to as the "acute care model." In recent years, there has been a shift from the acute care model to chronic care models [126], and in terminology, from "adherence" to "engagement" in self-care. Chronic care models acknowledge that:

- Most of the diabetes care activities are self-care activities by the person with diabetes.
- Diabetes self-care management is behaviorally complex.
  - It can be helpful to consider diabetes management (e.g. taking medications, self-monitoring of blood glucose (SMBG), eating healthily, counting carbohydrates (if relevant), and physical activity) as a series of balls that need to be juggled, while balancing on a beam (that represents life and all its competing demands (e.g. work, family, social life).
  - If, from time to time, one or more balls are dropped, it is not something to be criticized or viewed as a character flaw but rather it is because juggling all day every day is challenging, tedious and, ultimately, exhausting.
- Clinicians can offer advice but optimal outcomes are less likely to be achieved unless the person is fully engaged in adopting and sustaining the self-care behaviors and only the person themselves is in a position to know what self-care activities are appropriate, possible, and sustainable in their unique living situation [127].
- The degree, to which one *follows* a diabetes regimen, cannot be determined easily because there is no standard against which the person's actual behavior can be compared. For example:
  - Few clinicians provide a written management plan that specifies all aspects of diabetes care.
  - Recommendations often differ between clinicians, and the extent to which the clinician has communicated clearly in the consultation or the extent to which the person agrees with the regimen discussed is often unclear.
  - As it is the person with diabetes, and not the healthcare professional, who is responsible for nearly all diabetes care, increasingly, these outdated terms and gross over-simplifications of the realities of managing diabetes are being replaced with the question of the extent to which a person with diabetes *engages* in various self-care behaviors [128, 129].
- Not all self-care activities are equal in value in terms of their relative effectiveness for optimizing glycemic control. Furthermore, certain self-care behaviors are far more likely to be maintained than others.
  - The international DAWN2 study demonstrated that taking medications as recommended and having a healthy diet are

more common than self-monitoring of blood glucose (SMBG) and physical activity, and that engagement in these activities varies across countries [48].

- Specific self-care behaviors are sometimes [130], but not invariably [131], related to glycemic control.

Behavioral factors: the example of self-monitoring of blood glucose (SMBG)

Self-monitoring of blood glucose ought to be a particularly salient self-care activity. A large medical registry study of 24,312 adults with diabetes found that those with T1DM who self-monitored three or more times daily subsequently had HbA_{1c} values that were 1% (11 mmol/mol) lower than those who monitored less frequently. For adults with T2DM using oral medication or insulin, monitoring at least daily also resulted in a statistically and clinically significant reduction in HbA_{1c} (0.6%, 7 mmol/mol). For adults with T2DM not using medications (for whom there was no clear recommendation regarding SMBG frequency), there was a statistically significant HbA_{1c} reduction (0.4%, 4 mmol/mol) compared with those not using SMBG at all [132]. Other studies have provided less positive results. For example, a clinical trial comparing continuous glucose monitoring (CGM) with SMBG found a small different in HbA_{1c} (0.5%, 6 mmol/mol) at 26 weeks favoring CGM in adults aged 25 years or older but no difference among those aged 15–24 years or 8–14 years [133]. Use of CGM averaging six or more days per week was 83% in the adult group, 30% in the young adult group, and 50% in the pediatric group. These data indicate that active use of the CGM device is crucial in achieving improved glycemic control and that further work is needed to determine barriers to effective use.

In adults with T2DM not using insulin, the value of SMBG is more controversial. In recent years, a systematic review and a meta-analysis concluded there is little clinical benefit from SMBG in this group [134, 135]. However, these reviews combined studies with considerable variation in trial design and implementation of SMBG (education, frequency, and follow-up action) and it is unsurprising that little benefit was found "on average" [134–137]. These data suggest that simply monitoring blood glucose values, and not using that information to adjust insulin or oral medications frequently and systematically, has little meaningful impact on long-term glycemic control; however, they also suggest that there is considerable benefit to be derived by individuals who are motivated to monitor [136, 137].

It is noteworthy that SMBG has no dose-response and is not an active agent (i.e. the mere act of checking blood glucose levels cannot reduce HbA_{1c}). Indeed, while SMBG is often considered as a single self-care activity among many others, it is actually just one aspect of a complex intervention with multiple facets including:

- agreement on glucose targets between the person and their health professional;
- timing and frequency of SMBG;
- a supportive health professional trained in interpretation of SMBG patterns;
- appropriate training and feedback for the person with T2DM;
- collaborative review of SMBG patterns to identify areas for improvement and what may have contributed to the readings;
- a plan for how to change diet, physical activity levels, or medication;
- behavioral change (i.e. modifying diet, increasing physical activity, or changing medication regimen).

A more recent clinical trial demonstrated that a structured approach to monitoring (incorporating these steps) indicates SMBG offers both clinical benefits (i.e. reduced HbA_{1c}, particularly in those following the protocol as intended) [138], as well as improved emotional well-being and confidence in diabetes self-care [138, 139].

Methodological issues in self-care assessment

The generally weak relationship between self-care behaviors and glycemic control remains problematic for any model purporting to predict successful diabetes management. This could reflect the possibility that HbA_{1c} is not the most appropriate measure of glycemic control but it is more likely that the unexplained variance in glycemic control reflects unspecified physiologic or situational characteristics, as well as difficulties inherent in measuring various self-care behaviors [140]. A review of 23 studies found that greater medication adherence was associated with better HbA_{1c} and this was a stronger relationship when adherence was characterized in terms of prescription refills (78%; 7 of 9 studies) than when self-report (subjective) measures were used [141]. As self-care is typically assessed by asking people to describe their behavior, rather than by direct observation, it is possible that self-reports may exaggerate or otherwise misrepresent the extent to which person with diabetes performed a particular self-care behavior [140]. Furthermore, self-care questionnaires typically ask the person to report on their average behavior over the past week (or few weeks), whereas HbA_{1c} reflected average blood glucose over the past 8–12 weeks. Thus, "average" behaviors may be too crude and the two time periods are likely incompatible with a strong relationship. Finally, other factors such as stress, dietary behaviors, physical activity levels, hormonal changes, and other medications can affect blood glucose such that they may have an (unmeasured) influence on HbA_{1c}.

Interventions to reduce psychological distress and improve quality of life, self-care, and glycemic control

Reducing depression and diabetes distress

The treatment of depression among people with diabetes is both necessary and effective. A systematic review and meta-analysis of 14 randomized controlled trials (involving 1724 adults with T1DM or T2DM) demonstrated that treatment (psychotherapy, pharmacotherapy, or collaborative care) is effective in reducing depressive symptoms [142]; of the various treatment options available, the effect was greatest for psychotherapeutic interventions (Cohen's $d = -0.58$). Cognitive-behavioral therapy (CBT) appears

to be particularly promising in reducing the severity of depressive symptomatology. CBT trains individuals to use problem-solving strategies to reduce stressful situations and trains them to use cognitive techniques to "think away" their distorted beliefs, and replace them with more accurate and adaptive thoughts. Van Bastelaar et al. tested a web-based, diabetes-specific treatment of depression that was based on the principles of CBT, showing that this intervention reduced both depression and diabetes-specific distress [143].

Another effective treatment approach is mindfulness-based cognitive therapy (MBCT). MBCT is an 8-week protocolized therapy program that can be delivered in groups or individually. MBCT combines meditation exercises with elements of cognitive therapy. The main goal of this intervention is the cultivation of mindfulness, which is the self-regulation of one's attention focusing on direct experience, while adopting an open, curious, and accepting attitude toward these experiences, especially one's psychological processes, such as thoughts and feelings. Mindfulness-based interventions appear to be effective in people with diabetes who report elevated levels of depression and/or anxiety [144, 145]. Few studies have focused specifically on reducing diabetes-specific distress, though many intervention trials have included diabetes distress as a secondary outcome [143]. Recently, a systematic review of 41 such trials (involving 6650 adults with T1DM or T2DM) demonstrated no overall effect of intervention on diabetes distress [146]. Where diabetes distress was reduced, this was most likely to occur when the intervention was psychoeducational in nature, involving at least six sessions, over at least 3 months' duration, and delivered by a generalist rather than a mental health professional [146]. Further intervention studies focused specifically on the reduction of diabetes-specific distress are needed.

Empowerment-based approaches to improve outcomes

The "empowerment" approach encourages clinicians to understand what living with diabetes is like from the individual's perspective and to enable people with diabetes to take personal responsibility for their health, making self-selected choices about self-management [127, 147]. Embracing empowerment requires a paradigm shift on the part of clinicians to a position where they acknowledge that the person with diabetes is in control of, responsible for, and ultimately lives with the consequences of, their own diabetes care. Knowledge is the cornerstone of empowerment. Empowerment programs also aim to improve the persons' ability to identify and set realistic goals, apply problem-solving strategies to overcome barriers to those goals, develop more effective coping strategies in general, manage stress more effectively, increase social support and improve self-motivation. Empowerment occurs when the health professional's objective is to enable the person with diabetes to make autonomous, informed decisions, and when the person with diabetes is doing so [147].

The theoretical argument is compelling and a review of qualitative studies describes positive experiences in using the empowerment approach [148]. However, surprisingly few trials have been conducted. Results from an early randomized controlled trial demonstrated that following a 6-week empowerment program, adults with diabetes showed a significant decline in HbA_{1c} as well as increased ability to set goals, manage stress, obtain external support and make decisions about diabetes management [149]. The limitations of this study include the short-term follow-up (6 weeks post intervention) and small sample ($n = 64$), which was highly educated (77% college education, 84% diabetes education). Other trials of person-centered consultation approaches have had less positive outcomes overall. For example, in a randomized trial involving 250 adults with newly-diagnosed T2DM, in which clinicians in the intervention arm received 1.5 days theoretical and practical training in person-centered consulting skills, the intervention group reported significantly better communication with the doctor, greater treatment satisfaction and better psychological well-being than the control group [150]. However, there was no impact on glycemic control and cardiovascular risk increased, prompting the authors to urge caution: "Professionals committed to achieving the benefits of patient-centered consulting should take care not to lose focus on disease while paying attention to the unique experience of illness of each patient" [150: 1208].

Structured training/education to improve outcomes

The education of people with diabetes has evolved from didactic information-giving ("obedience training to follow dietary prescriptions" [151:1724]) one-to-one or in large groups, to theoretically driven, evidence-based structured training in small groups, in which people with diabetes are able to talk with diabetes educators (nurses/dieticians) and their peers about their diabetes, and problems with self-care, and learn the knowledge and skills they need for a life with diabetes (Chapter 24). In modern times, this approach began in Germany in the 1980s, with the structured diabetes teaching and treatment program developed by Michael Berger and Ingrid Mühlhauser, where several trials demonstrated the effectiveness of flexible, intensive insulin therapy for improving glycemic control in people with T1DM without increasing severe hypoglycemia [151] (unlike the intensive treatment approach adopted in the DCCT [34]). In the UK, this approach was adopted as the "Dose Adjustment For Normal Eating" (DAFNE) program, where an RCT demonstrated, for the first time, the unique combination of benefits for both biomedical and psychological outcomes [82]. Several studies have demonstrated sustainability of outcomes over the long term [152], and successful implementation in the real-world [153, 154], while qualitative research has highlighted where the program can be improved [155], and this is now the focus of further research (DAFNE*plus*) in the UK. The DESMOND program offers a range of structured training sessions for people with newly diagnosed or ongoing T2DM, with RCT findings demonstrating greater improvements in weight loss, smoking cessation, and beliefs about illness, although no benefit for glycemic control up to 12 months after diagnosis [156]. Three years later, HbA_{1c} had improved in both groups, but no differences were observed between those receiving DESMOND or control intervention in any biomedical or psychological outcomes [157]. Importantly, improvements in four out of

five health beliefs were sustained [157], and these were found to be predictive of psychological distress at 3 years, indicating the importance of early formative experiences around diagnosis, and in terms of education provision and health provider support [158].

Programs have also been developed that teach those using insulin to recognize and anticipate blood glucose fluctuations to enable them to prevent extreme high and low levels, and reduce their fear of hypoglycemia. A review demonstrated that the benefits of the face-to-face "Blood Glucose Awareness Training" (BGAT) program, developed in the USA, can be substantial. There was a 57–92% reduction in severe hypoglycemic events, 65–86% reduction in driving mishaps, 10–51% improvement in hypoglycemia awareness, and a 6–21% reduction in fear of hypoglycemia [159]. Several studies have been limited by small sample sizes, and by a focus on skills acquisition (estimation of blood glucose) rather than clinically important outcomes, such as severe hypoglycemia. The German, face-to-face program "HyPOS" has also demonstrated improved awareness of hypoglycemia and reduced frequency of severe hypoglycemia in a fully powered RCT [160].

Technological approaches to improve outcomes

Advanced technologies for insulin delivery (e.g. predictive low glucose suspend pumps) and real-time continuous glucose monitoring (RT-CGM) have improved dramatically in recent years, and have the potential to reduce HbA_{1c} and fear of hypoglycemia, and to improve quality of life [161]. In the first large-scale trial of sensor-augmented pump therapy in 485 adults and children with T1DM, over a 12-month follow-up, sensor-augmented pump therapy offered significant advantages in terms of reducing fear of hypoglycemia in adults and parents of children, as well as improving treatment satisfaction in adults, children and parents [162]. However, such devices are expensive and require uninterrupted use (which many users find too burdensome). A 12-month observational study of sensor-augmented pump therapy in 15 countries in Europe and Israel found that improvement in HbA_{1c} was associated with more frequent sensor use [163]; average sensor use over 12 months was 30% (range: 0–94%) and sensor use decreased with time (37% over first 3 months, 27% over final 3 months). For those with recurrent severe hypoglycemia and its debilitating impact on quality of life, the adoption of technology into everyday management seems an obvious option. However, a recent trial demonstrated that insulin pumps and RT-CGM offered no added benefit over multiple daily injections and standard finger-prick SMBG for reducing severe hypoglycemia, time spent in hypoglycemia, or fear of hypoglycemia—with the insulin pumps offering an advantage in terms of greater treatment satisfaction [164].

Most recently, the personal impact of "closed loop" (artificial pancreas) technology has been investigated overnight in the home setting. Semi-structured interviews with 15 adolescents with T1DM using the technology and 13 parents have demonstrated several perceived benefits (e.g. reassurance/peace of mind, confidence, "time off" from diabetes demands, safety, and improved glycemic control) as well as disadvantages (e.g. difficulties with calibration, alarms, and size of the devices, and mixed effects were found on fear of hypoglycemia) [165]. Semi-structured interviews with 24 adults using the technology have demonstrated similar positive and negative themes [166].

Cognitive-behavioral approaches to improve outcomes

Individual or group psychotherapy or supportive counselling is effective in children or adults with diabetes [167]. Many recommendations have been made for such interventions, while several recent meta-analyses have generally found them to have modest effects in reducing psychological distress and improving glycemic control [168–170]. Traditional individualized and group therapy provides emotional support for both children and adults with diabetes, and may be particularly beneficial for those who are confronting the development of complications. When a time-limited problem-oriented individualized treatment was compared with standard insulin treatment counselling in adults with T1DM, those receiving psychotherapy showed greater reductions in both problem severity and HbA_{1c} [171].

Coping skills training programs are effective in improving the diabetes management skills of adolescents treated with intensive insulin therapy [172]. Based on a cognitive–behavioral skills-building model, coping skills training presents participants with a series of social situations that are particularly problematic for adolescents, and asks them to demonstrate how they would resolve that situation (e.g. manage food choices with friends). As implemented by Grey et al. [172], groups of two to three adolescents role-play each scenario with a highly trained group leader who provides correction and models appropriate coping behavior. Six weekly sessions lasting 60–90 minutes followed by monthly visits are typical for a training program. Over a 12-month follow-up period, adolescents randomized to coping skills training plus intensive diabetes management had significantly lower HbA_{1c} (7.5% vs. 8.5%; 58 vs. 69 mmol/mol) and reported better self-efficacy as well as less difficulty in coping with diabetes and less depression when compared with adolescents who received intensive diabetes management alone [116].

Peyrot and Rubin [173] discuss the utility of including both problem-focused and emotion-focused interventions as part of an integrated behavior change support program. According to their model, interventions must occur in a particular sequence of five steps:

1 Specify the person's problem;
2 Translate the person's intentions to change into concrete, attainable goals;
3 Collaborate with the person to identify barriers to reach those goals and formulate effective strategies;
4 Establish a "contract" with the person to meet, or approach, those goals; and
5 Provide continuing support.

This framework makes much sense from a clinical perspective. The extent to which such an approach is successful in initiating lasting clinically significant changes in mood, behavior, and glycemic control is likely to be dependent on the problem, the

person, and the relationship with health professionals, but it is certainly an approach worth evaluating in formal clinical trials. Arguably, this was the basis of the HypoCOMPaSS study, which demonstrated prevention of severe hypoglycemia and reduced fear of hypoglycemia in a 6-month RCT [164] as well as in an, as yet, unpublished 2-year follow-up study. The new DAFNE*plus* program will incorporate concrete goal-setting into the structured training and provide ongoing proactive health professional support, both of which will then be evaluated in a RCT.

More traditional psychotherapeutic approaches

Several behavioral and psychological interventions have been developed to improve engagement in self-care among people with diabetes [173, 174]. These differ from more traditional group therapy programs in so far as they use several sessions to target one or more self-care behaviors and the psychological factors that may interfere with optimal self-care. A typical self-management program may meet once or twice monthly for seven or more sessions, discuss specific self-care strategies (e.g. SMBG, physical activity), role-play appropriate behaviors, use homework assignments to practice what has been learned and resolve problems or barriers encountered during diabetes management. Variations on this basic theme include the use of 6 or 12 monthly "booster" sessions after the end of the program, which are designed to review and reinforce previously learned material. Interventions developed initially for people without diabetes with high levels of psychological distress are increasingly being applied to persons with diabetes, and both CBT and "motivational interviewing" [175, 176] or "motivational enhancement therapy" [154] programs have led to modest improvements in HbA_{1c} and in self-reported quality of life.

Family-focused behavioral interventions are particularly successful in improving diabetes management in children. In one of the largest studies of its kind, Wysocki et al. [177] randomized 119 families of adolescents to either 10 sessions of behavioral family systems group therapy, 10 sessions of an education and support group, or standard diabetes therapy (with minimal psychological support). Behavioral family systems therapy included four modules:

- problem-solving training, which focused on conflict resolution;
- communication skills training;
- cognitive restructuring to identify and change those attitudes and beliefs that impede effective communication;
- specialized family therapy interventions.

In the 12 months following treatment, adolescents who participated in behavioral family systems therapy showed long-term improvement in relationships with their parents compared with adolescents in the other two treatment groups, and also manifested improved adherence to their diabetes management regimen, although these behavioral and psychological changes were not associated with improvements in metabolic control [178]. Similar interventional approaches have also been applied to older adults with T2DM and, as is the case with children and adults with T1DM, there are reductions in psychological distress and occasionally, but not invariably, small improvements in long-term glycemic control [179].

Neuropsychological and cognitive consequences of diabetes

Diabetes affects cognition as well as emotion, leading to disruption of mental efficiency and neuropsychological dysfunction. The magnitude of these effects is relatively modest in most individuals, and few people with diabetes manifest "clinically significant" cognitive changes unless they developed diabetes early in life. Until recently, when cognitive dysfunction was found in people with diabetes it was invariably attributed to the adverse effects of severe and recurrent hypoglycemia on the CNS. New research suggests that chronic hyperglycemia, and the metabolic and vascular complications that are associated with it, underlie the development of most structural and functional changes to the CNS, particularly in adults [180]. Although hypoglycemia can never be considered to be entirely benign, it may have a relatively small role in the etiology of neurocognitive changes in younger adults with diabetes [181, 182].

CNS sequelae of diabetes in children and adolescents

Cognitive manifestations

The nature and extent of cognitive dysfunction in children and adolescents differs depending on age of diagnosis. Those diagnosed in the first 5–7 years of life appear to have an elevated risk of manifesting a moderately severe cognitive impairment, which is evident across a range of cognitive domains, including measures of attention, mental flexibility, psychomotor efficiency, learning, memory, problem-solving, and overall intelligence [183–187]. In contrast, those diagnosed after that early "critical period" show very mild cognitive dysfunction that is limited primarily to measures of overall intelligence and to performance on speeded tasks, particularly those having a visuo-perceptual component [184]. Learning, memory and problem-solving skills are largely intact in this "later onset" population, or are inconsistently affected [188, 189]. In some studies, children with diabetes tend to achieve lower scores than their peers without diabetes on measures of academic achievement, regardless of age at diagnosis [190], with this especially pronounced in children with a very early onset of diabetes [191]. In a large and a more recent study [192], 2500 individuals with T1DM selected from the Swedish Childhood Diabetes Register were coupled to national population registers including the Swedish Education Register and were found to be similar to four controls from the general population, matched for year of birth and residence at the time of diagnosis [192]. T1DM had negative effects on mean final grades in compulsory school and theoretical programs in upper secondary school. Children with early-onset diabetes (before age of 4 years) suffered a greater disadvantage in compulsory school. It is unclear whether school performance of young people with T1DM differs between countries

[193]. A recent Australian study, for example, used data on four educational outcome domains from 666 children with T1DM and 3260 school and school-year matched children without diabetes. There were no significant differences between those with T1DM and their peers, across any of the tested domains and school years analyzed [194]. Furthermore, there was no decline over time or following diagnosis. However, children with T1DM had lower school attendance, with 3% fewer days attended per year. Less optimal glycemic control was associated with a lower test score and with poorer attendance. In the same Australian study, a history of severe hypoglycemia, diabetic ketoacidosis, and the age of onset of diabetes were not associated with school test scores. However, a longitudinal study from the DKA Brain Injury group compared young people (aged 6–18 years) with T1DM, who presented at diagnosis with or without DKA [195]. These two groups were compared at four time points: <48 hours, 5 days, 28 days, and 6 months after diagnosis, using data from magnetic resonance imaging (MRI) and spectroscopy with cognitive assessment at each time point. Those with DKA at diagnosis had reductions in white matter volume over 6 months in the frontal, temporal, and parietal lobes. Age at time of presentation and pH level were predictors of the neuroimaging and functional outcomes.

Overall, the magnitude of the cognitive dysfunction seen in children with diabetes is modest, as demonstrated by a formal meta-analysis of 19 pediatric studies encompassing 1393 children with diabetes and 731 healthy comparators [184]. For studies comparing children with later-onset T1DM with children without diabetes, Cohen's *d* values were ≤0.20, indicating small to negligible effects. In contrast, effect sizes were more than twice as large when comparing those with early-onset diabetes and their peers without diabetes [184]. Using clinical rather than statistical criteria, there are similarly marked differences between children with an early, as compared with a later, onset of diabetes. One large study found that 24% of children with early-onset diabetes met criteria for clinically significant impairment, compared with only 6% of children with a later onset of diabetes, and 6% of a comparison group without diabetes [196].

This "age at onset" phenomenon continues in adults diagnosed with diabetes early in life. Young adults who developed diabetes before 7 years of age performed more poorly on measures of information processing speed, and earned lower performance IQ scores than their peers with diabetes diagnosed at or after age 7 [197]. Abnormalities in brain structure are also evident. Magnetic resonance imaging (MRI) scans showed higher rates of mild to moderate ventricular atrophy (61% vs. 20%), as well as somewhat higher rates of small punctate white matter lesions within the hippocampus (14% vs. 2%). Smaller brain volumes were also correlated with poorer cognitive test performance, supporting the view that cognition dysfunction is necessarily linked to changes in CNS morphology.

Neurocognitive abnormalities appear relatively early in the course of diabetes (within 2–3 years of diagnosis). In an older, prospective pediatric study, a representative sample of 90 newly diagnosed youngsters with diabetes and 84 healthy children drawn from the community have been followed over a 12-year period. No between-group differences were evident at study entry [188] but, 2 years later, those children diagnosed before age 4 manifested developmental delays as their scores on both the Wechsler Vocabulary and Block Design subtests improved less over time, relative to either children with a later diabetes onset or to community control children [189]. After 6 years of follow-up, children with diabetes—regardless of age at diagnosis—performed worse than their peers without diabetes on measures of intelligence, attention, processing speed, long-term memory, and executive skills. Children with an early age at onset were particularly affected, and performed significantly worse on measures of attention and executive function than those with a later onset of diabetes [185]. After 12 years of follow-up, these children with diabetes—now young adults—continued to earn lower verbal and full-scale IQ scores, demonstrating that these effects are not a developmental delay, but reflect a true, albeit modest, loss in cognitive efficiency, relative to those without diabetes [198]. Studies have also noted gradual decline in IQ scores as diabetes duration increases [198, 199].

Effects of hypoglycemic episodes on brain function

As young children with diabetes (aged <6 years) are often unable to recognize, describe, and/or manage their hypoglycemic symptoms, special attention needs to be given to hypoglycemia risk in this group. Hypoglycemia may also present more often in children with T1DM because of variable eating patterns and erratic activities. At the same time, use of new therapeutic options, such as new long-acting insulin analogs and continuous glucose monitors and low glucose suspend insulin pumps, may lower the incidence of severe hypoglycemia. Older studies suggest that severe hypoglycemia causes neuropsychological deficits, particularly in children whose diabetes is diagnosed below the age of 6 years [196, 200]. More recent data have confirmed this notion, but effect sizes appear to be small [201, 202]. For example, a meta-analysis based on data from 441 children with recurrent severe hypoglycemia and 560 children without recurrent severe hypoglycemia [201] found that the children with recurrent severe hypoglycemia only had slightly lower performance. This was evident for the cognitive domains: intelligence, verbal fluency/language and particularly in memory and learning, while no impairment was found for motor speed [201]. A working group of the American Diabetes Association and The Endocrine Society reviewed the evidence about the impact of hypoglycemia, concluding that 4–10% of deaths of people with T1DM were caused by hypoglycemia [202]. In the DCCT, participants with and without a history of severe hypoglycemia performed the same on a comprehensive battery of neurocognitive tests at 18 years follow-up [203].

The potential impact of hypoglycemia on brain functioning has also been studied in T2DM. In a population-based study, older adults with T2DM with hypoglycemic episodes that required emergency medical care had a doubled risk of incident dementia [204]. However, it is noteworthy that the study did not use detailed tests of cognitive function at baseline. The ACCORD MIND study also assessed cognitive function in people with T2DM randomly

assigned to the intensive versus the standard therapy arms. No differences in cognitive function were observed between groups at 20-month or 40-month follow-up, despite the fact that the intensive therapy group experienced three times as much hypoglycemia [205].

Brain structure and function in adults with type 1 diabetes

Neurocognitive manifestations

A highly circumscribed pattern of mild cognitive dysfunction characteristic of adults with T1DM has been identified from a systematic meta-analysis of data from 31 studies published in English between 1980 and 2004 that compared the performance of those with and without diabetes on multiple cognitive domains [206]. People with T1DM, aged 18–50 years and in relatively good health, performed significantly worse on measures of intelligence, attention, psychomotor speed, cognitive flexibility, and visual perception, whereas no between-group differences were found on measures of language, learning, and memory. Even when differences were detected, they were modest at best, with effect sizes ranging from 0.3 to 0.8 standard deviation units. Not all cognitive domains were affected; learning and memory skills, which are generally considered to be sensitive to early brain damage [207], were well preserved in this diverse population, despite an average of ≥20 years of T1DM. Moreover, with only one exception ("crystallized intelligence"), virtually all of the cognitive tasks on which people with diabetes performed worse were those that also required a rapid response. Thus, mental slowing appears to be the fundamental deficit associated with T1DM in adulthood [208]. A similar pattern of results was found in older adults (≥60 years) with T1DM [209]. Remarkably, the magnitude of the cognitive differences found in these older adults was similar ($d = 0.3$–0.5) to that reported in their younger counterparts, despite their longer duration of diabetes.

Similarly to children, adults with diabetes also manifest slowed neural processing on measures of brainstem auditory evoked potentials [210], visual evoked potentials [211], and EEG recordings [212]. The magnitude of these effects is greatest in those individuals who have clinically significant microvascular complications [213, 214]. Multiple studies have demonstrated that cerebral blood flow patterns are abnormal in adults with diabetes, with these effects greatest in frontal and frontotemporal brain regions [215]. Changes in cerebral perfusion, measured by SPECT, are common. In one large study, 85% of middle-aged adults with diabetes showed hypoperfusion in one or more region of interest compared to 10% of controls; similarly, 58% of people with diabetes showed hyperperfusion, compared to 20% of controls [216]. Again, these effects were greatest in those with microvascular complications.

Changes in gray and white matter
