We dedicate this book to all people living with diabetes and the healthcare professionals who look after them. We would also like to dedicate this book to our families without whose support and encouragement the book would never have been finished.

Textbook of Diabetes

EDITED BY

RICHARD I.G. HOLT MA, MB BChir, PhD, FRCP, FHEA
Professor in Diabetes & Endocrinology
Human Development and Health Academic Unit
University of Southampton Faculty of Medicine
Southampton, UK

CLIVE S. COCKRAM MBBS, BSc, MD (Lond), FRCP, FRACP, FHKAM (Med)
Emeritus Professor of Medicine
Chinese University of Hong Kong
Hong Kong SAR
People's Republic of China

ALLAN FLYVBJERG MD, DMSc
CEO at Steno Diabetes Center Copenhagen (SDCC)
The Capital Region of Denmark
Professor of Clinical Endocrinology
Faculty of Health and Medical Sciences
University of Copenhagen, Copenhagen, Denmark

BARRY J. GOLDSTEIN MD, PhD, FACP, FACE
Vice President and Global Therapeutic Area Head
Cardiovascular, Metabolic, Endocrine and Renal
Medical and Scientific Affairs
Covance
Clinical Development Services
Princeton, NJ, USA

FIFTH EDITION

WILEY Blackwell

List of Contributors

Ahmed H. Abdelhafiz MSc, MD, FRCP
Consultant Physician and Honorary Senior Clinical Lecturer, Department of Elderly Medicine, Rotherham General Hospital, Rotherham, UK

Mohammed K. Ali MBChB, MSc, MBA
Emory Global Diabetes Research Center, Associate Professor, Hubert Department of Global Health, and Department of Epidemiology, Rollins School of Public Health, Emory University, Atlanta, GA, USA

Colum F. Amory MD, MPH
Albany Medical College, Albany, NY, USA

Shehab Alshiekh MD
Clinical Research Center (CRC), Lund University; Department of Clinical Sciences/Paediatric Endocrinology, Skåne University Hospital, Malmö, Sweden

Robert C. Andrews MBChB, PhD, FRCP
Associate Professor of Diabetes and Endocrinology, University of Exeter Medical School, Medical Research, Exeter; Department of Diabetes and Endocrinology, Taunton and Somerset NHS Foundation Trust, Musgrove Park Hospital, Taunton, Somerset, UK

Ana María Arbeláez MD
Associate Professor of Pediatrics, Washington University School of Medicine in St. Louis, St. Louis, MO, USA

Angelo Avogaro MD, PhD
Professor of Endocrinology and Metabolism, Department of Medicine, University of Padova, Padova, Italy

Ellena Badrick
Institute of Cancer Sciences, University of Manchester; Health eResearch Centre, Farr Institute, Manchester Academic Health Science Centre, University of Manchester, Manchester, UK

Clifford J. Bailey PhD, FRCP(Edin), FRCPath
Professor in Clinical Science and Head of Diabetes Research, School of Life and Health Sciences, Aston University, Birmingham, UK

Anita Banerjee BSc, MBBS, MRCP
Obstetric Physician, Diabetes and Endocrinology, Princess Royal University Hospital, London, UK

Katharine D. Barnard PhD, MSc, BSc(Hons) CPsychol AFBPsS
Health Psychologist and Visiting Professor, Faculty of Health and Social Sciences, Bournemouth University, Bournemouth, UK

Toke Bek MD, DMSc
Professor of Clinical Ophthalmology, Chair, Department of Ophthalmology, Aarhus University Hospital, and Department of Clinical Medicine, Faculty of Health, Aarhus University, Aarhus, Denmark

Adil E. Bharucha MD
Professor of Medicine, Mayo Clinic College of Medicine; Clinical Enteric Neuroscience Translational and Epidemiological Research Program, Mayo Clinic, Rochester, MN, USA

Cristina Bianchi MD, PhD
Assistant Professor, Department of Medical Specialties, Azienda_Ospedaliero Universitaria Pisana, Pisa, Italy

Fatima Bosch, PhD
Center of Animal Biotechnology and Gene Therapy and Department of Biochemistry and Molecular Biology, School of Veterinary Medicine, Universitat Autònoma de Barcelona, Bellaterra; Centro de Investigación Biomédica en Red de Diabetes y Enfermedades Metabólicas Asociadas (CIBERDEM), Spain

Andrew J.M. Boulton MD, DSc (Hon), FRCP
Professor of Medicine, University of Manchester and Manchester Royal Infirmary, Manchester, UK; Miller School of Medicine, University of Miami, Miami, FL, USA

Michael Camilleri MD
Professor of Medicine, Pharmacology, and Physiology, Mayo Clinic College of Medicine; Clinical Enteric Neuroscience Translational and Epidemiological Research Program, Division of Gastroenterology and Hepatology, Mayo Clinic, Rochester, MN, USA

Riccardo Candido MD, PhD
Diabetes Centre District 3 Azienda Sanitaria Universitaria Integrata di Trieste, Trieste, Italy

Ian D. Caterson MD, PhD
Boden Institute of Obesity, Nutrition, Exercise and Eating Disorders, University of Sydney, Camperdown, NSW, Australia

Eda Cengiz MD, MHS, FAAP
Assistant Professor of Pediatrics (Endocrinology), Department of Pediatrics, Yale University School of Medicine, New Haven, CT, USA

Christine M. Chan MD
Barbara Davis Center for Childhood Diabetes, School of Medicine, University of Colorado Denver, Aurora, CO, USA

Juliana C.N. Chan MBChB, MD, FRCP
Professor of Medicine and Therapeutics, Director, Hong Kong Institute of Diabetes and Obesity, and The Chinese University of Hong Kong, The Prince of Wales Hospital, Hong Kong SAR, China

Mimi Z. Chen MBChB, PhD, MRCP
Diabetes & Metabolism, School of Clinical Sciences, Faculty of Health Sciences, University of Bristol, Learning and Research, Southmead Hospital, Bristol; Consultant in Diabetes and Endocrinology, Department of Diabetes and Endocrinology, Royal United Hospitals Bath NHS Foundation Trust, Bath, UK

Bernard M.Y. Cheung MD, PhD
Chair of Clinical Pharmacology and Therapeutics, Department of Clinical Pharmacology, University of Birmingham, Birmingham, UK

Shivakumar Chitturi MD, FRACP, MRCP (UK)
Associate Professor of Medicine, Australian National University Medical School; Staff Specialist, Gastroenterology and Hepatology Unit, The Canberra Hospital, Woden 2606, Australia

Elaine Y.K. Chow MBChB
Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Hong Kong SAR, China

Mikkel Christensen MD
Center for Diabetes Research, Gentofte Hospital, University of Copenhagen, Copenhagen, Denmark

Leslie Citrome
Department of Psychiatry and Behavioral Sciences, New York Medical College, Valhalla, NY, USA

Clive S. Cockram MB BS, BSc, MD (Lond), FRCP, FRACP, FHKAM (Med)
Emeritus Professor of Medicine, Chinese University of Hong Kong, Hong Kong

Mark E. Cooper MB BS, PhD, FRACP, FAHMS
Chief Scientific Officer, Baker IDI Heart & Diabetes Institute, Melbourne, Australia; Director, JDRF Centre for Diabetes Complications, Melbourne, Australia; Professor of Medicine (Adjunct), Monash University and University of Melbourne, Melbourne, Australia

Amanda J. Cox PhD
Menzies Health Institute Queensland; Postdoctoral Research Fellow, School of Medical Sciences, Griffith University, Southport, Queensland, Australia

Allan W. Cripps PhD, AO
Menzies Health Institute Queensland; Professor, School of Medicine, Griffith University, Southport, Queensland, Australia

Philip E. Cryer MD
Professor of Medicine Emeritus, Washington University in St. Louis, St. Louis, MO, USA

Tim Cundy MD
Professor, Medical, Department of Medicine, Faculty of Medical and Health Sciences, University of Auckland, Auckland, New Zealand

Nicola Dalbeth MD, FRACP
Department of Medicine, University of Auckland, Auckland, New Zealand

David D'Alessio MD
Department of Medicine, Division of Endocrinology, Duke University, Durham VA Medical Center, Durham, NC, USA

Devra K. Dang, PharmD, BCPS, CDE, FNAP
Associate Clinical Professor, University of Connecticut School of Pharmacy, Storrs, CT, USA

Guiseppe Daniele MD, PhD
Assistant Professor, Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy

Melanie J. Davies MBChB, MD, FRCP, FRCGP
Professor of Diabetes Medicine, NIHR Senior Investigator, Leicester Diabetes Centre, University of Leicester, Leicester General Hospital, Leicester, UK

Stefano Del Prato MD
Professor of Endocrinology, School of Medicine, Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy

Ketan Dhatariya MBBS, MSc, MD, MS, FRCP
Consultant, Norfolk and Norwich University Hospitals NHS Foundation Trust, Norwich, UK

Elyse Di Marco PhD
Baker IDI Heart and Diabetes Institute; Department of Medicine, Monash University, Melbourne, Australia

Heinz Drexel MD, FESC
Prim. o.Univ.-Prof. Dr. Dr.h.c., Department of Medicine and Cardiology, Academic Teaching Hospital Feldkirch, Feldkirch, Austria; Vorarlberg Institute for Vascular Investigation and Treatment, Academic Teaching Hospital Feldkirch, Feldkirch, Austria; Private University of the Principality of Liechtenstein, Triesen, Liechtenstein; Drexel University College of Medicine, Philadelphia, PA, USA

Gian Paolo Fadini MD, PhD
Associate Professor of Endocrinology, Department of Medicine, University of Padova, Padova, Italy

Andrew J. Farmer DM, FRCGP
Professor of General Practice, Nuffield Department of Primary Care Health Sciences, University of Oxford, Oxford, UK

Geoffrey C. Farrell MD, FRACP
Professor of Hepatic Medicine, Australian National University Medical School; Senior Staff Hepatologist, The Canberra Hospital, Woden ACT 2606, Australia

Allan Flyvbjerg MD, DMSc
CEO at Steno Diabetes Center Copenhagen (SDCC), The Capital Region of Denmark and Professor of Clinical Endocrinology, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark

Brian M. Frier BSc(Hons), MD, FRCP(Edin), FRCP(Glas)
BHF Centre for Cardiovascular Science, The Queen's Medical Research Institute, University of Edinburgh, Edinburgh, Scotland, UK

Robert A. Gabbay MD, PhD
Chief Medical Officer, Joslin Diabetes Center, Boston, MA; Associate Professor of Medicine, Harvard Medical School, Boston, MA, USA

Karla I. Galaviz PhD, MSc
Emory Global Diabetes Research Center and Hubert Department of Global Health, Rollins School of Public Health, Emory University, Atlanta, GA, USA

Stephen Gough
Professor of Diabetes, Oxford Centre for Diabetes Endocrinology and Metabolism, University of Oxford, and Consultant Physician, Churchill Hospital, Oxford, UK

Stephen P. Gray PhD
Senior Research Officer, Baker IDI Heart and Diabetes Institute, Danielle Alberti JDRF Center

for Diabetes Complications; Department of Medicine, Monash University, Melbourne, Australia

Andrew Grey MD
Department of Medicine, University of Auckland, Auckland, New Zealand

Robert Gregory BA, MBBS, DM, FRCP
Consultant in Diabetes and Endocrinology, University Hospitals of Leicester NHS Trust, Leicester, UK

Leif Groop MD, PhD
Lund University Diabetes Centre, Department of Clinical Sciences, Diabetes and Endocrinology, Lund University, CRC, Skåne University Hospital SUS, Malmö, Sweden; Finnish Institute of Molecular Medicine (FIMM), Helsinki University, Helsinki, Finland

Nicola Guess
Diabetes and Nutritional Sciences Division, Kings College London; Nutrition and Dietetics Research Group, Department of Medicine, Imperial College London, UK

Neil A. Hanley MBChB, PhD
Professor of Medicine, Centre for Endocrinology and Diabetes, University of Manchester, Manchester, UK

Andrew T. Hattersley MD
Professor of Molecular Medicine, Institute of Biomedical and Clinical Science, University of Exeter Medical School, Exeter, Devon, UK

Hans Hauner MD
Professor of Medicine and director of Else Kröner-Fresenius-Center for Nutritional Medicine, Klinikum rechts der Isar, Technical University of Munich, Munich, Germany

Virginia Haurigot PhD
Center of Animal Biotechnology and Gene Therapy and Department of Biochemistry and Molecular Biology, School of Veterinary Medicine, Universitat Autònoma de Barcelona, Bellaterra; Centro de Investigación Biomédica en Red de Diabetes y Enfermedades Metabólicas Asociadas (CIBERDEM), Spain

Richard IG Holt MA, MB, BChir, PhD, FRCP, FHEA
Human Development and Health Academic Unit, Faculty of Medicine, University of Southampton and University Hospital Southampton NHS Foundation Trust, Southampton, UK

David L. Horwitz MD, PhD, FACP
Clinical Professor of Medicine University of Illinois (Retired); Former Chief Medical Officer, Johnson & Johnson Diabetes Institute, Wayne, PA, USA

Silvio E. Inzucchi MD
Professor of Medicine, Clinical Chief, Endocrinology, Yale School of Medicine; Medical Director, Yale Diabetes Center, Yale – New Haven Hospital, New Haven, CT, USA

Sten-A. Ivarsson MD, PhD
Clinical Research Center (CRC), Lund University; Department of Clinical Sciences/Paediatric Endocrinology, Skåne University Hospital, Malmö, Sweden

June James MSc, BA (Hons) Dip Nursing, NP RGN
Consultant Nurse in Diabetes, University Hospitals of Leicester NHS Trust; Honorary Senior Lecturer, University of Leicester, Leicester, UK

Karin A.M. Jandeleit-Dahm MD, PhD, FRACP
Head of Basic Research Domain; Co-Head, Danielle Alberti JDRF Center for Diabetes Complications, Baker IDI Heart and Diabetes Institute; Professor of Medicine (Adjunct), Monash University, Melbourne and University of Hannover, Germany

Rachel E. Jennings MBChB, PhD
Centre for Endocrinology and Diabetes, University of Manchester, Manchester, UK

Veronica Jimenez, PhD
Center of Animal Biotechnology and Gene Therapy and Department of Biochemistry and Molecular Biology, School of Veterinary Medicine, Universitat Autònoma de Barcelona, Bellaterra; Centro de Investigación Biomédica en Red de Diabetes y Enfermedades Metabólicas Asociadas (CIBERDEM), Spain

Isabelle Johansson MD
PhD Fellow, Cardiology Unit, Department of Medicine K2, Karolinska Institutet, Karolinska University Hospital in Solna, Stockholm, Sweden

Peter M. Jones PhD
Professor of Endocrine Biology, Diabetes Research Group, King's College London, London, UK

Tina Jorsal MD
Center for Diabetes Research, Gentofte Hospital, University of Copenhagen, Copenhagen, Denmark

Supriya Joshi MSc, MRCP
Specialist Registrar, Lister Hospital, Stevenage, UK

Kamlesh Khunti MBChB, PhD, MD, FRCGP, DCH, DRCOG
Professor of Primary Care Diabetes and Vascular Medicine, NIHR, Senior Investigator, Leicester Diabetes Centre, University of Leicester, Leicester General Hospital, Leicester, UK

David C. Klonoff MD, FACP, FRCP (Edin), Fellow AIMBE
Medical Director, Diabetes Research Institute, Mills-Peninsula Health Services, San Mateo, CA, USA

Angela Koh
Clinical Islet Transplant Program, University of Alberta, Edmonton Alberta, Canada

Filip K. Knop MD, PhD
Director, Center for Diabetes Research, Gentofte Hospital, University of Copenhagen, Copenhagen, Denmark

Alice P.S. Kong MBChB, MRCP (UK), FRCP (Glasg)
Associate Professor, Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Hong Kong SAR, China

Andrew J. Krentz MD, FRCP
Professor of Endocrinology and Metabolism, Director of the Buckingham Institute for Translational Medicine, Clore Laboratory, University of Buckingham, Buckingham, UK

Lori M.B. Laffel MD, MPH
Pediatric, Adolescent and Young Adult Section, Clinical, Behavioral and Outcomes Research Section, Joslin Diabetes Center, Boston, MA; Professor of Pediatrics, Harvard Medical School, Boston, MA, USA

Helena Elding Larsson MD, PhD
Clinical Research Center (CRC), Lund University; Department of Clinical Sciences/Paediatric Endocrinology, Skåne University Hospital, Malmö, Sweden

Åke Lernmark PhD
Professor of Experimental Diabetes, Clinical Research Center (CRC), Lund University; Department of Clinical Sciences/Paediatric Endocrinology, Skåne University Hospital, Malmö, Sweden

Naomi S. Levitt MBChB, MD, FCP(SA)
Professor and Head of Division of Diabetic Medicine and Endocrinology, Department of Medicine, University of Cape Town and Groote Schuur Hospital, Cape Town, South Africa

Ee Lin Lim MRCP
Consultant Physician University Hospital Southampton NHS Foundation Trust, Southampton, UK

Ronald C.W. Ma MB BChir, FRCP (Edin, Lond)
Professor, Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Shatin, Hong Kong SAR, China and Hong Kong Institute of Diabetes and Obesity, The Chinese University of Hong Kong, Hong Kong SAR, China

Jean MacLeod MBChB, FRCP
Consultant Physician, University Hospitals of North Tees and Hartlepool, Stockton-on-Tees, Cleveland, UK

Ranjit Unnikrishnan MD, FRCP
Director and Consultant Diabetologist, Dr. Mohan's Diabetes Specialities Centre, WHO Collaborating Centre for Non Communicable Diseases Prevention and Control; Madras Diabetes Research Foundation, Gopalapuram, Chennai, India

Michael Vallis PhD, R Psych
Lead, Behaviour Change Institute, Nova Scotia Health Authority; Associate Professor, Family Medicine and Psychiatry, and Adjunct Professor, Psychology and Health & Human Performance, Dalhousie University, Halifax, Canada

Michelle A. Van Name MD
Associate Research Scientist in Pediatrics (Endocrinology), Department of Pediatrics, Yale University School of Medicine, New Haven, CT, USA

Kourosh Vathie MD
Department of Medicine and Cardiology, Department of Interventional Cardiology and Angiology, MedClin Heart Center Coswig, Coswig, Germany

Adrian Vella MD, FRCP(Edin)
Professor of Medicine, Division of Endocrinology, Diabetes, Metabolism and Nutrition, Mayo Clinic, Rochester, MN, USA

Adie Viljoen MBBS, FRCPath
Consultant Chemical Pathologist, Lister Hospital, Stevenage, UK

Tina Vilsbøll MD, DMSc
Klinisk Professor, Center for Diabetes Research, Gentofte Hospital, University of Copenhagen, Copenhagen, Denmark

Mary Beth Weber MPH, PhD
Emory Global Diabetes Research Center, Hubert Department of Global Health, and Nutrition and Health Sciences Program, Rollins School of Public Health, Emory University, Atlanta, GA, USA

Jesse Weinberger MD
Department of Neurology, Mount Sinai School of Medicine, New York, NY, USA

Stuart A. Weinzimer MD
Professor of Pediatrics, Department of Pediatrics, Yale University School of Medicine, New Haven, CT, USA

Nicholas P. West PhD
Menzies Health Institute Queensland; Research Manager, School of Medical Sciences, Griffith University, Southport, Queensland, Australia

Morris F. White PhD
Professor of Pediatrics, Division of Endocrinology, Boston Children's Hospital and Harvard Medical School, Boston, MA, USA

Anthony S. Wierzbicki DM, DPhil, FRCPath, FAHA
Consultant Metabolic Physician and Chemical Pathologist, Guy's and St Thomas' Hospitals, London, UK

Ingrid Willaing RN, DS, MPH
Research Manager, Principal Investigator, Diabetes Management Research, Health Promotion Research, Steno Diabetes Center A/S, Gentofte, Denmark

Bonnie C.K. Wong
Specialist in Infectious Diseases and Hon. Clinical Assistant Professor, The Chinese University of Hong Kong, Hong Kong SAR, China

Paul D. Yesudian MB, MD, MRCP
Consultant Dermatologist, Department of Dermatology, Glan Clwyd Hospital, Bodelwyddan, UK

Hannele Yki-Järvinen MD, FRCP
Professor of Medicine, Department of Medicine, Division of Diabetes, University of Helsinki, Helsinki, Finland

Dan Ziegler MD, FRCPE
Professor of Internal Medicine, Institute for Clinical Diabetology, German Diabetes Center at Heinrich Heine University, Leibniz Center for Diabetes Research; and Department of Endocrinology and Diabetology, Medical Faculty, Heinrich Heine University, Düsseldorf, Germany

Preface to the Fifth Edition

It is seven years since the last edition of the *Textbook of Diabetes* was published and despite many advances in the understanding of diabetes and its treatment over that time, the management of diabetes still remains a major global burden for people with diabetes, their families, and the wider society in which they live. Whereas the global prevalence of diabetes according to the International Diabetes Federation affected 246 million people in 2010, the current estimate is 415 million and is projected to rise further. One in 10 of the world's population has diabetes and one person dies because of diabetes every 6 seconds. Twelve percent of global health expenditure is spent on diabetes. The challenge to people with diabetes and their healthcare professionals has never been greater.

Despite the ever-increasing numbers, better management is starting to pay dividends. The outlook for those with diabetes appears to be improving, at least in high income countries where an individual's risk of developing complications and losing years to diabetes is falling. If the variation between the best and worst care could be obliterated, much morbidity and mortality would be prevented.

Ironically, as the volume of information and the vast numbers of resources available in this digital age have increased, many are finding it overwhelming to keep abreast of the new advances. It is particularly challenging to determine the validity of many source materials. In this textbook, we aim to bring together a series of *up-to-date* chapters from an international group of leading diabetes specialists who provide accurate and clinically relevant information to both academic and practicing diabetes healthcare professionals. Having the key information in one volume still has its merits, and this is further enhanced by *online* access and searchability.

The editors have retained the structure from the previous edition, with a similar length and number of chapters. We begin with a history of diabetes that provides many valuable insights from the past. The book then takes us through the epidemiology of diabetes, the physiology and pathogenesis of diabetes before moving onto management. We have taken a broad view in these sections recognizing that diabetes management encompasses so much more than drug therapy alone. A discussion of the microvascular and macrovascular complications then follows before a new section on the psychosocial aspects of diabetes. Different models of care as well as the management of diabetes in special groups are included before the final section looks into the future. There are new chapters on the biology of glucagon, the microbiome and diabetes, cancer, non-alcoholic fatty liver disease, and end-of-life care. These additions reflect the advances in our understanding of diabetes, its management, and have implications for a variety of related disorders.

As editors, we are only too aware of the hard work that goes into the production of a comprehensive and up-to-date book such as this. Our thanks go to each and every chapter author, who, despite busy academic and professional lives, were prepared to devote the time, energy, and expertise to provide their essential contributions to the text. Thank you for your forbearance of our nagging e-mails!

We are also grateful for the immense help we have received from our publisher, Wiley-Blackwell. Our commissioning editor, Priyanka Gibbons, who took over from Oliver Walter, during the book's development, has provided guidance, encouragement, and support. Our thanks also go to Gill Whitley who kept the momentum going when Rob Blundell left, and to the rest of the production team. The book looks even better than the last edition!

We hope you enjoy reading the book, whether it be dipping in or reading from cover to cover, as much as we did editing it. We have all taken away useful novel information that will aid our daily professional lives and we hope that this book will help you to support those with diabetes in the widest sense of this meaning.

CAPD	continuous ambulatory peritoneal dialysis
CBG	capillary blood glucose
CBT	cognitive–behavioral therapy
CCM	corneal confocal microscopy
CDA	Canadian Diabetes Association
CDC	cardiosphere-derived stem cell
CDC	Centers for Disease Control and Prevention
CDE	Certified Diabetes Educator
CEMACH	Confidential Enquiry into Maternal and Child Health
CETP	cholesteryl ester transfer protein
CGM	continuous glucose monitoring
CI	confidence interval
CKD	chronic kidney disease
CML	carboxymethyllysine
CNS	central nervous system
COC	combination oral contraceptive
COX	cyclooxygenase
CPC	cardiac progenitor cell
CRP	C-reactive protein
CSII	continuous subcutaneous insulin infusion
CT	computed tomography
CV	coefficient of variation
CVD	cardiovascular disease
DAWN	Diabetes Attitudes, Wishes, and Needs study
DCCT	Diabetes Control and Complications Trial
DKA	diabetic ketoacidosis
DPP	dipeptidyl peptidase
DSN	diabetes specialist nurse
DVLA	Driver and Vehicle Licensing Agency
EASD	European Association for the Study of Diabetes
ECG	electrocardiography/electrocardiogram
eGFR	estimated glomerular filtration rate
EMA	European Medicines Agency
ER	endoplasmic reticulum
ERCP	endoscopic retrograde cholangiopancreatography
ERK	extracellular signal-regulated kinase
ERM	ezrin–radixin–moesin
ESC	embryonic stem cell
ESRD	end-stage renal disease
ESRF	end-stage renal failure

FDA	Food and Drug Administration (USA)
FDC	fixed-dose combination
FDKP	fumaryldiketopiperazine
FFA	free fatty acid
FGF	fibroblast growth factor
FHWA	Federal Highways Administration
FMD	flow-mediated endothelium-dependent arterial dilation
FOXO	forkhead box O
FXR	farnesoid-X receptor
G6P	glucose-6-phosphatase
G-6-P	glucose-6-phosphate
G6PD	glucose-6-phosphate dehydrogenase
GAD	glutamine acid decarboxylase
GCGR	glucagon receptor
GCK	glucokinase
G-CSF	granulocyte colony-stimulating factor
GDF	growth differentiation factor
GDM	gestational diabetes mellitus
CF	cystic fibrosis
GI	gastrointestinal
GLO	glyoxalase
GLP-1RA	GLP-1 receptor agonist
GLUT	glucose transporter
GPR	G-protein-coupled receptor
GRPP	glicentin-related pancreatic polypeptide
GWA	genome-wide association
GWAS	genome-wide association studies
HAPO	Hyperglycemia and Adverse Pregnancy Outcomes
HbA_{1c}	hemoglobin A_{1c}
HBV	hepatitis B virus
HCV	hepatitis C virus
HDL	high-density lipoprotein
HGF	hepatocyte growth factor
hGH	human recombinant growth hormone
HHS	hyperosmolar non-ketotic hyperglycemic state
HR	hazard ratio
HRT	hormone replacement therapy
HRV	heart rate variability
HSC	hematopoietic stem cell
hsCRP	high-sensitivity C-reactive protein
IADPSG	International Association of Diabetes Pregnancy Study Groups
IAsp	insulin aspart
IAUC	incremental area under the blood glucose curve
ICA	islet cell antibody
ICU	intensive care unit
i.d.	intradermal
IDDM	insulin-dependent diabetes mellitus
IDeg	insulin degludec
IDF	International Diabetes Federation
IDL	intermediate-density lipoprotein
IDRS	Indian Diabetes Risk Score
IgG	immunoglobulin G
IGR	impaired glucose regulation
IGT	impaired glucose tolerance
IKKβ	inhibitor κB kinase-β
IL	interleukin
IMT	intima-media thickness
InsR	insulin receptor
IRMA	intraretinal microvascular abnormality
ISPAD	International Society for Pediatric and Adolescent Diabetes
IT	information technology
IVUS	intravascular ultrasound
IWGDF	International Working Group on the Diabetic Foot
JBDS	Joint British Diabetes Societies
KDIGO	Kidney Disease: Improving Global Outcomes
K_M	Michaelis constant
LADA	latent autoimmune diabetes in adults
LDL	low-density lipoprotein
LDL-C	low-density lipoprotein cholesterol
LDLR	low-density lipoprotein receptor
LGA	large-for-gestational age
LIRKO	liver-specific InsR knockout
LPS	lipopolysaccharide
Lst	limostatin
LV	left ventricular
LVEF	left ventricular ejection fraction
MAOI	monoamine oxidase inhibitor
MDI	multiple daily injection
MDRD	Modification of Diet in Renal Disease
MG53	mitsugumin 53
mGDP	mitochondrial glycerolphosphate dehydrogenase
MGO	methylglyoxal
MI	myocardial infarction
MIBG	*m*-iodobenzylguanidine
MIRKO	muscle-specific InsR knockout
MODY	maturity-onset diabetes of the young
MPGF	major proglucagon fragment
MPO	myeloperoxidase
MRI	magnetic resonance imaging
MSC	mesenchymal stem cell
MS	mass spectrometry
mTOR	mammalian or mechanistic target of rapamycin
mTORC1	mechanistic target of rapamycin complex 1
MTPI	microsomal transfer protein inhibitor
NAD	nicotinamide adenine dinucleotide
NaDIA	National Diabetes Inpatient Audit
NAFLD	non-alcoholic fatty liver disease
NANC	non-adrenergic, non-cholinergic
NCV	nerve conduction velocity
NEFA	non-esterified fatty acid

MFMU	Maternal–Fetal Medicine Units Network
NEP	neutral endopeptidase
NFκB	nuclear factor κB
Ngn3	neurogenin 3
NHANES	National Health and Nutrition Examination Survey
NHS	National Health Service
NICE	National Institute for Health and Care Excellence
NIDDM	non-insulin-dependent diabetes mellitus
NIH	National Institutes of Health
NMU	neuromedin U
Nox	NAD(P)H oxidase
NOD	non-obese diabetic
NPH	neutral protamine Hagedorn
NRTI	nucleoside reverse-transcriptase inhibitor
NSAID	non-steroidal anti-inflammatory drug
NT-3	neurotrophin-3
NT-proBNP	N-terminal pro-brain-type natriuretic peptide
OCP	oral contraceptive pill
OGIS	oral glucose insulin sensitivity
OGTT	oral glucose tolerance test(ing)
OR	odds ratio
oxLDL	oxidation of low-density lipoprotein
PAS	periodic acid–Schiff
PBA	phenylboronic acid
PC	prohormone convertase
PCB	polychlorinated biphenyl
PCI	percutaneous coronary intervention
PCR	polymerase chain reaction
PCSK-9	proprotein convertase subtilisin kexin type 9
PDH	pyruvate dehydrogenase
Pdx1	pancreatic duodenal homeobox 1
PGF	placental growth factor
PI	protease inhibitor
PI3K	phosphatidylinositol 3-kinase
PID	proportional integral derivative
P/KX	combined pancreas/kidney transplantation
PNDM	permanent neonatal diabetes mellitus
PPAR	peroxisome proliferator-activated receptor
PROactive	Prospective Pioglitazone Clinical Trial in Macrovascular Events
PTDM	post-transplantation diabetes mellitus
PTP1B	protein tyrosine phosphatase 1B
PYY	polypeptide YY
QoL	quality of life
RA	receptor agonist
RAMP	receptor activity-modifying protein
RCT	randomized controlled trial
RDN	renal denervation
RECORD	Rosiglitazone Evaluated for Cardiac Outcomes and Regulation of Glycemia in Diabetes
REMS	Risk Evaluation and Mitigation Strategy
rHuPH20	recombinant human hyaluronidase
RMR	resting metabolic rate
ROS	reactive oxygen species
RR	relative risk
RR	risk ratio
RT-PCR	reverse transcriptase polymerase chain reaction
SCFA	short-chain fatty acid
s.c.	subcutaneous
sdHDL	small, dense high-density lipoprotein
sdLDL	small, dense low-density lipoprotein
SDS-PAGE	sodium dodecyl sulfate polyacrylamide gel electrophoresis
SGA	second-generation antipsychotics
SHP	short heterodimer protein
SMBG	self-monitoring of blood glucose
SMI	severe mental illness
SNP	sub-basal nerve plexus
SSRI	selective serotonin reuptake inhibitor
T1DM	type 1 diabetes mellitus
T2DM	type 2 diabetes mellitus
TAG	triacylglyceride
TB	tuberculosis
TCF7L2	transcription factor 7 like 2
TE	transient elastography
TIND	treatment-induced neuropathy in diabetes
TLR	toll-like receptor
TNDM	transient neonatal diabetes mellitus
TNFα	tumor necrosis factor alpha
Treg	regulatory T cell
TSH	thyroid-stimulating hormone
TZD	thiazolidinedione
UKPDS	UK Prospective Diabetes Study
US	ultrasound
UT	University of Texas
VEGF	vascular endothelial growth factor
VLCD	very low calorie diet
VLDL	very low-density lipoprotein
VRIII	variable-rate intravenous insulin infusion
WGS	whole-genome sequencing
WHO	World Health Organization
XO	xanthine oxidase
YY1	Yin Yang 1

About the Companion Website and Companion Digital Edition

COMPANION WEBSITE

This book is accompanied by a companion website:

www.wiley.com/go/textbookofdiabetes

The website includes:

- Interactive Multiple-Choice Questions for each chapter
- Reference lists with external links
- Figures from the book for downloading

COMPANION DIGITAL EDITION

This book is also accompanied by a companion digital edition.

Simply find your unique companion digital edition redemption code on the inside front cover of this book by carefully scratching away the top coating on the label. Then visit http://www.vitalsource.com/software/bookshelf/downloads to get started.

For more detailed instructions, go to the companion website. Full support is also available at http://support.vitalsource.com

If you purchased this title as an e-book, Wiley Customer Care will provide your access code for the companion digital edition. Visit http://support.wiley.com to request via the "Live Chat" or "Ask a Question" tabs, within 90 days of purchase, and please have your receipt for verification.

Please note that the book cannot be returned once the label is scratched off, and the unique PIN cannot be shared. The site is for individual use by purchasers only and cannot be networked.

1 Diabetes in its Historical and Social Context

1 The History of Diabetes Mellitus

Robert B. Tattersall[1]
University of Nottingham, Nottingham, UK

Key points

- Polyuric diseases have been described for over 3500 years. The name "diabetes" comes from the Greek word for a syphon; the sweet taste of diabetic urine was recognized at the beginning of the first millennium, but the adjective "mellitus" (honeyed) was only added by Rollo in the late 18th century.
- The sugar in diabetic urine was identified as glucose by Chevreul in 1815. In the 1840s, Bernard showed that glucose was normally present in blood, and showed that it was stored in the liver (as glycogen) for secretion into the bloodstream during fasting.
- In 1889, Minkowski and von Mering reported that pancreatectomy caused severe diabetes in the dog. In 1893, Laguesse suggested that the pancreatic "islets" described by Langerhans in 1869 produced an internal secretion that regulated glucose metabolism.
- Insulin was discovered in 1921 by Banting, Best, Macleod, and Collip in acid-ethanol extracts of pancreas. It was first used for treatment in January 1922.
- Diabetes was subdivided on clinical grounds into *diabète maigre* (lean subjects) and *diabète gras* (obese) by Lancereaux in 1880, and during the 1930s by Falta and Himsworth into insulin-sensitive and insulin-insensitive types. These classifications were the forerunners of the etiological classification into type 1 (insulin-dependent) and type 2 (non-insulin-dependent) diabetes.
- Insulin resistance and β-cell failure, the fundamental defects of type 2 diabetes, have been investigated by many researchers. The "insulin clamp" method devised by Andres and DeFronzo was the first accurate technique for measuring insulin action. Maturity-onset diabetes of the young was described as a distinct variant of type 2 diabetes by Tattersall in 1974.
- Lymphocytic infiltration of the islets (insulitis) was described as early as 1901 and highlighted in 1965 by Gepts who suggested that it might be a marker of autoimmunity. Islet cell antibodies were discovered by Doniach and Bottazzo in 1979.
- The primary sequence of insulin was reported in 1955 by Sanger and the three-dimensional structure by Hodgkin in 1969. Proinsulin was discovered by Steiner in 1967, and the sequence of the human insulin gene by Bell in 1980. Yalow and Berson invented the radioimmunoassay for insulin in 1956. The presence of insulin receptors was deduced in 1971 by Freychet, and the receptor protein was isolated in 1972 by Cuatrecasas.
- The various types of diabetic retinopathy were described in the second half of the 19th century as were the symptoms of neuropathy. Albuminuria was noted as a common abnormality in people with diabetes in the 19th century and a unique type of kidney disease was described in 1936 by Kimmelstiel and Wilson. The concept of a specific diabetic angiopathy was developed by Lundbæk in the early 1950s.
- Milestones in insulin pharmacology have included the invention of delayed-action preparations in the 1930s and 1940s; synthetic human insulin in 1979; and in the 1990s novel insulin analogs by recombinant DNA technology.
- The first sulfonylurea carbutamide was introduced in 1955, followed by tolbutamide in 1957 and chlorpropamide in 1960. The biguanide phenformin became available in 1959 and metformin in 1960.
- That improved glucose control in both type 1 and type 2 diabetes was beneficial was proved by the Diabetes Control and Complications Trial (1993) and the UK Prospective Diabetes Study (1998).
- Landmarks in the treatment of complications include photocoagulation for retinopathy first described by Meyer-Schwickerath; the importance of blood pressure control to slow the progression of nephropathy (demonstrated by Mogensen and Parving); the introduction of low-dose insulin in the treatment of diabetic ketoacidosis in the 1970s; and improvements in the care of pregnant women with diabetes pioneered by White and Pedersen.

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

Ancient times

Diseases with the cardinal features of diabetes mellitus were recognized in antiquity (Table 1.1). A polyuric state was described in an Egyptian papyrus dating from *ca* 1550 BC, discovered by Georg Ebers (Figure 1.1), and a clearly recognizable description of what would now be called type 1 diabetes was given by Aretaeus of Cappadocia in the 2nd century AD (Figure 1.2a). Aretaeus was the first to use the term "diabetes," from the Greek word for a syphon, "because the fluid does not remain in the body, but uses the man's body as a channel whereby to leave it." His graphic account of the disease highlighted the incessant flow of urine, unquenchable thirst, the "melting down of the flesh and limbs into urine" and short survival.

Table 1.1 Milestones in the clinical descriptions of diabetes and its complications.

Clinical features of diabetes	
Ebers papyrus (Egypt, 1500 BC)	Polyuric state
Sushrut and Charak (India, 5th century BC)	Sugary urine; thin and obese patients distinguished
Aretaeus (Cappadocia, 2nd century AD)	Polyuric state named "diabetes"
Chen Chuan (China, 7th century)	Sugary urine
Avicenna (Arabia, 10th century AD)	Sugary urine; gangrene and impotence as complications
Diabetic ketoacidosis	
William Prout (England, 1810–1820)	Diabetic coma
Adolf Kussmaul (Germany, 1874)	Acidotic breathing
Hyperlipidemia

The Hindu physicians, Charak and Sushrut, who wrote between 400 and 500 BC, were probably the first to recognize the sweetness of diabetic urine (Figure 1.2b). Indeed, the diagnosis was made by tasting the urine or noting that ants congregated round it. Charak and Sushrut noted that the disease was most prevalent in those who were indolent, overweight, and gluttonous, and who indulged in sweet and fatty foods. Physical exercise and liberal quantities of vegetables were the mainstays of treatment in the obese, while lean people, in whom the disease was regarded as more serious, were given a nourishing diet. The crucial fact that diabetic urine tasted sweet was also emphasized by Arabic medical texts from the 9–11th centuries AD, notably in the medical encyclopedia written by Avicenna (980–1037).

The 17th and 18th centuries

In Europe, diabetes was neglected until Thomas Willis (1621–1675) wrote *Diabetes, or the Pissing Evil* [1]. According to him, "diabetes was a disease so rare among the ancients that many famous physicians made no mention of it … but in our age, given to good fellowship and guzzling down of unallayed wine, we meet with examples and instances enough, I may say daily, of this disease." He described the urine as being "wonderfully sweet like sugar or honey" but did not consider that this might be because it contained sugar.

The first description of hyperglycemia was in a paper published in 1776 by Matthew Dobson (1735–1784) of Liverpool (Figure 1.3 and Table 1.2) [2]. He found that the serum as well as the urine of his patient Peter Dickonson (who passed 28 pints of urine a day) tasted sweet. Moreover, he evaporated the urine

(a)

Diabetes is a dreadful affliction, not very frequent among men, being a melting down of the flesh and limbs into urine. The patients never stop making water and the flow is incessant, like the opening of aqueducts. Life is short, unpleasant and painful, thirst unquenchable, drinking excessive, and disproportionate to the large quantity of urine, for yet more urine is passed. One cannot stop them either from drinking or making water. If for a while they abstain from drinking, their mouths become parched and their bodies dry; the viscera seem scorched up, the patients are affected by nausea, restlessness and a burning thirst, and within a short time, they expire.

XXVII. *Experiments and Obſervations on the Urine in a* Diabetes, *by* Matthew Dobſon, *M. D. of* Liverpool; *communicated by Dr.* Fothergill.

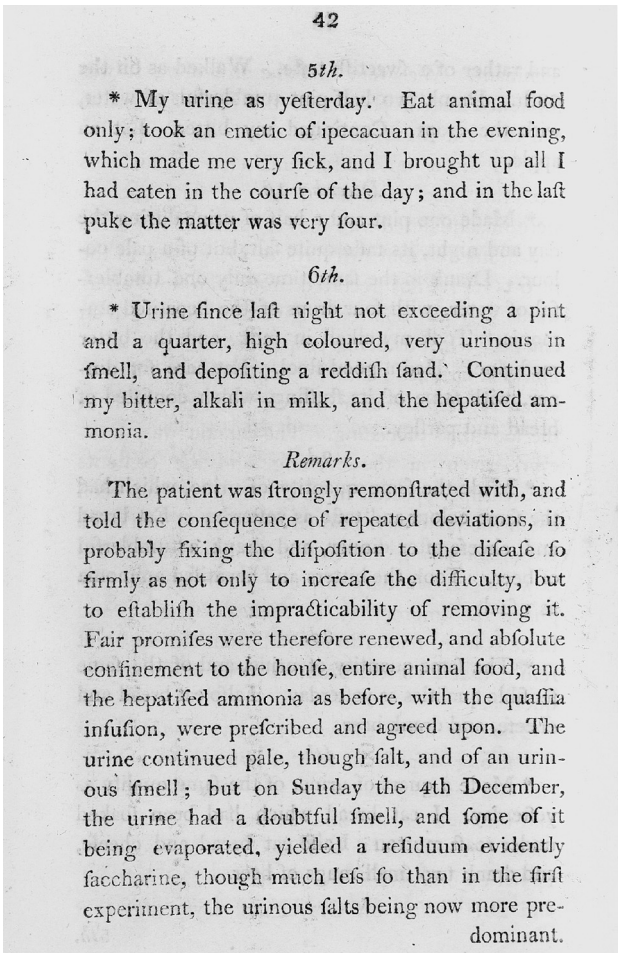
SOME authors, eſpecially the Engliſh, have remarked, that the urine in the diabetes is ſweet. Others, on the contrary, deny the exiſtence of this quality, and conſequently exclude it from being a characteriſtic of the diſeaſe. So far as my own experience has extended, and I have met with nine perſons who were afflicted with the diabetes, the urine has always been ſweet in a greater or leſs degree, and particularly ſo in the caſe of the following patient.

Peter Dickonſon, thirty-three years of age, was admitted into the public hoſpital in Liverpool, October 22, 1772. His diſeaſe was a confirmed diabetes; and he paſſed twenty-eight pints of urine every 24 hours. He had formerly enjoyed a good ſtate of health; nor did it appear what had been the remote cauſes of this indiſpo-

Figure 1.3 Frontispiece and opening page of the paper by Matthew Dobson (1776), in which he described the sweet taste of both urine and serum from a person with diabetes [2].

to "a white cake [which] smelled sweet like brown sugar, neither could it by the taste be distinguished from sugar." Dobson concluded that the kidneys excreted sugar and that it was not "formed in the secretory organ but previously existed in the serum of the blood."

The Edinburgh-trained surgeon, John Rollo (*d.* 1809) was the first to apply the adjective "mellitus" (from the Latin word meaning "honey"). He also achieved fame with his "animal diet," which became the standard treatment for most of the 19th century. Rollo thought that sugar was formed in the stomach from vegetables, and concluded that the obvious solution was a diet of animal food. Thus, the regimen described in his 1797 book, *An Account of Two Cases of the Diabetes Mellitus* [3], allowed his patient Captain Meredith to have for dinner "Game or old meats which have been long kept; and as far as the stomach may bear, fat and rancid old meats, as pork." Rollo was probably the first to note the difficulty that some people with diabetes find in adhering to treatment—a difficulty he blamed for the death of his second patient (Figure 1.4).



42

5*th*.

* My urine as yeſterday. Eat animal food only; took an emetic of ipecacuan in the evening, which made me very ſick, and I brought up all I had eaten in the courſe of the day; and in the laſt puke the matter was very ſour.

6*th*.

* Urine ſince laſt night not exceeding a pint and a quarter, high coloured, very urinous in ſmell, and depoſiting a reddiſh ſand. Continued my bitter, alkali in milk, and the hepatiſed ammonia.

Remarks.

The patient was ſtrongly remonſtrated with, and told the conſequence of repeated deviations, in probably fixing the diſpoſition to the diſeaſe ſo firmly as not only to increaſe the difficulty, but to eſtabliſh the impracticability of removing it. Fair promiſes were therefore renewed, and abſolute confinement to the houſe, entire animal food, and the hepatiſed ammonia as before, with the quaſſia infuſion, were preſcribed and agreed upon. The urine continued pale, though ſalt, and of an urinous ſmell; but on Sunday the 4th December, the urine had a doubtful ſmell, and ſome of it being evaporated, yielded a reſiduum evidently ſaccharine, though much leſs ſo than in the firſt experiment, the urinous ſalts being now more predominant.

Figure 1.4 Extract from John Rollo's account of two cases of diabetes (1797). Rollo was well aware of the problem of non-adherence. Note that "the patient was strongly remonstrated with, and told of the consequences of repeated deviations." Source: Courtesy of the Wellcome Library, London.

The 19th century

In 1815, the French chemist Michel Chevreul (1786–1889) proved that the sugar in diabetic urine was glucose [4]. In the middle of the century, tasting the urine to make the diagnosis was superseded by chemical tests for reducing agents such as glucose as introduced by Trommer in 1841, Moore in 1844 and—the best known—Fehling in 1848. Measurement of blood glucose could only be done by skilled chemists but needed so much blood that it was rarely used in either clinical care or research. It only became practicable with the introduction in 1913 of a micromethod by the Norwegian-born physician Ivar Christian Bang (1869–1918) and it was the ability to measure glucose repeatedly which led to development of the glucose tolerance test between 1913 and 1915.

Glucose metabolism was clarified by the work of Claude Bernard (1813–1878) [5], the Frenchman whose numerous discoveries have given him a special place in the history of physiology (Figure 1.5). When Bernard began work in 1843, the prevailing theory was that sugar could only be synthesized by plants, and that animal metabolism broke down substances originally made in plants. It was also thought that the blood only

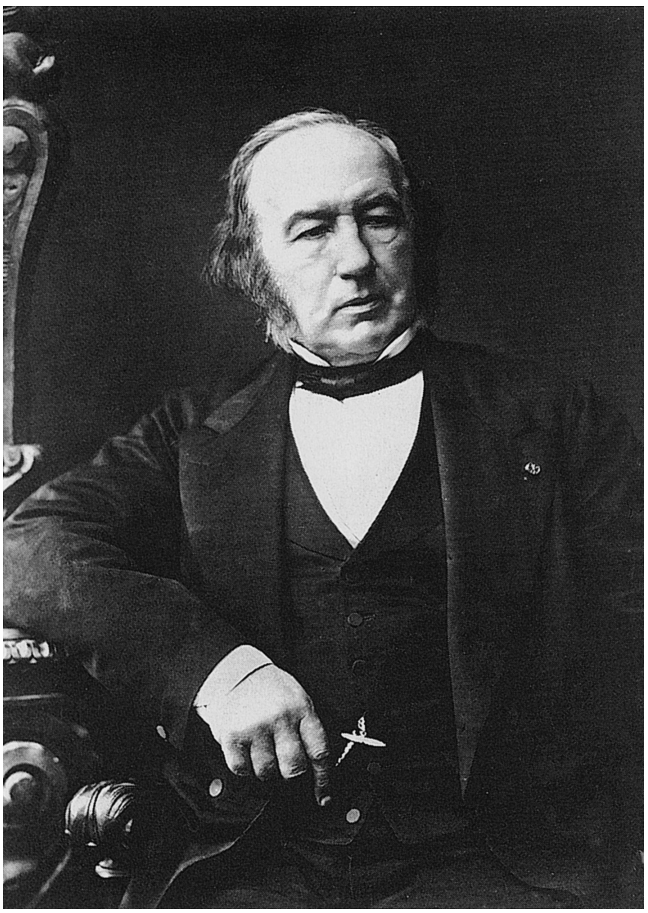


Figure 1.5 Claude Bernard (1813–1878). Source: Courtesy of the Wellcome Library, London.

contained sugar after meals, or in pathologic states such as diabetes. Between 1846 and 1848, Bernard reported that glucose was present in the blood of normal animals, even when starved. He also found higher concentrations of glucose in the hepatic than in the portal vein, and "enormous quantities" of a starch-like substance in the liver which could be readily converted into sugar. He called this "glycogen" (i.e. sugar-forming) and regarded it as analogous to starch in plants. His hypothesis—the "glycogenic" theory—was that sugar absorbed from the intestine was converted in the liver into glycogen and then constantly released into the blood during fasting.

Another discovery by Bernard made a great impression in an era when the nervous control of bodily functions was a scientifically fashionable concept. He found that a lesion in the floor of the fourth ventricle produced temporary hyperglycemia (*piqûre* diabetes) [6]. This finding spawned a long period in which nervous influences were thought to be important causes of diabetes; indeed, one piece of "evidence"—cited by J.J.R. Macleod as late as 1914—was that diabetes was more common among engine drivers than other railway workers because of the mental strain involved [7].

In the first part of the 19th century the cause of diabetes was a mystery, because autopsy usually did not show any specific lesions. A breakthrough came in 1889 when Oskar Minkowski (Figure 1.6) and Josef von Mering (1849–1908) reported that pancreatectomy in the dog caused severe diabetes [8]. This was serendipitous, because they were investigating fat metabolism; it is said that the laboratory technician mentioned to Minkowski that the dog, previously house-trained, was now incontinent of urine. Minkowski realized the significance of the polyuria, and tested the dog's urine (Table 1.3).

Possible explanations for the role of the pancreas were that it removed a diabetogenic toxin, or produced an internal secretion that controlled carbohydrate metabolism. The concept of "internal secretions" had been publicized in June 1889, by the well-known physiologist Charles-Édouard Brown-Séquard (1817–1894), who claimed to have rejuvenated himself by injections of testicular extract [9]. It was given further credence in 1891, when Murray reported that myxedema could be cured by sheep thyroid extract by injection or orally.

In 1893, Gustave Laguesse suggested that the putative internal secretion of the pancreas was produced by the "islands" of cells scattered through the gland's parenchyma [10], which had been discovered in 1869 by the 22-year-old Paul Langerhans (1847–1888) (Figure 1.7). Langerhans had described these clusters of cells, having teased them out from the general pancreatic tissue, but had not speculated about their possible function [11]; it was Laguesse who named them the "islets of Langerhans." At this time, the glucose-lowering internal secretion of the islets was still hypothetical, but in 1909 the Belgian Jean de Meyer named it *insuline* (from the Latin for "island") [12].

It would be wrong to give the impression that Minkowski's experiments immediately established the pancreatic origin of diabetes. In fact, during the next two decades, it was widely agreed that diabetes was a heterogeneous disorder with various subtypes,

Figure 1.6 Oskar Minkowski (1858–1931).

Figure 1.7 Paul Langerhans (1847–1888). Source: Courtesy of the Wellcome Library, London.

and that its pathogenesis involved at least three organs: the brain, pancreas, and liver [13]. The discovery by Blum in 1901 that injection of an adrenal extract caused glycosuria implicated other glands, and led to the "polyglandular theory" of Carl von Noorden (Vienna), who proposed that the thyroid, pancreas, adrenals, and parathyroids controlled carbohydrate metabolism.

Clinical diabetes in the 19th century

Doctors in the 19th century were therapeutically impotent; their main role was as taxonomists who described symptom complexes and the natural history of disease. As a result, most of the major complications of diabetes were well described before 1900.

Eduard von Jaeger (1818–1884) is credited with the first description of diabetic retinopathy, in his beautiful *Atlas of Diseases of the Ocular Fundus*, published in 1869 [14]. In fact, the features illustrated (Figure 1.8), from a 22-year-old man, look more like hypertensive retinopathy. In 1879, Stephen Mackenzie (1844–1909) and Sir Edward Nettleship (1845–1913) found microaneurysms in flat preparations of the retina and, in 1888, Nettleship described new vessels and the beaded appearance of retinal veins [15]. The full picture of diabetic retinopathy was described in 1890 by Julius Hirschberg (1843–1925) who was the first to claim that it was specific to diabetes [16].

Neuropathic symptoms in people with diabetes had been mentioned by Rollo at the end of the 18th century, and in 1864 Charles Marchal de Calvi (1815–1873) concluded that nerve damage was a specific complication of diabetes. In 1885, the Guy's Hospital physician, Frederick Pavy (1829–1911), gave a description of neuropathic symptoms which would grace any modern textbook [17]:

> *The usual account given by these patients of their condition is that they cannot feel properly in their legs, that their feet are numb, that*

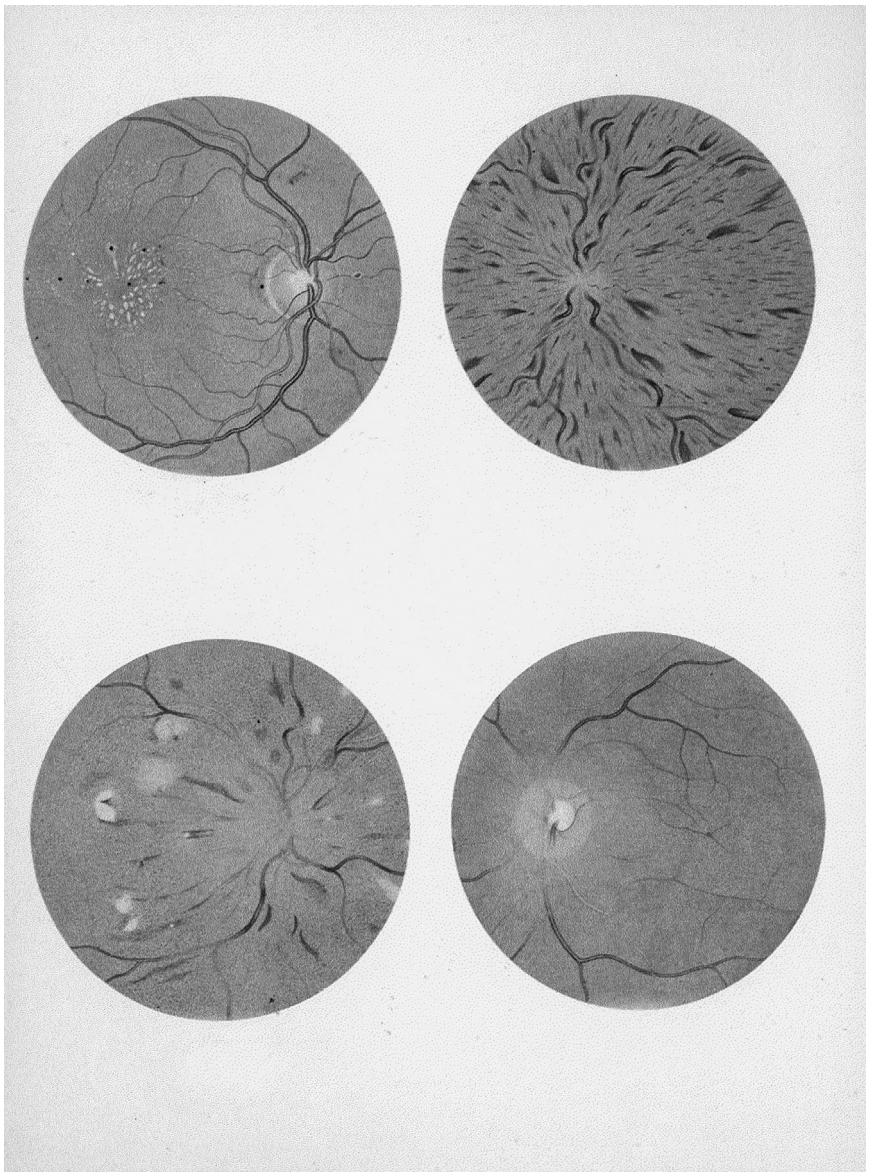

Figure 1.8 Pictures from *Jaeger's Atlas of the Optic Fundus*, 1869 [14]. Top left: Bright's disease. Top right: Jaeger's retinitis hemorrhagica is now recognized as central retinal vein occlusion. Bottom left: A 22-year-old man with suspected diabetes. Bottom right: Central retinal artery occlusion. Source: Courtesy of W.B. Saunders.

their legs seem too heavy—as one patient expressed it, "as if he had 20 lb weights on his legs and a feeling as if his boots were great deal too large for his feet." Darting or "lightning" pains are often complained of. Or there may be hyperaesthesia, so that a mere pinching of the skin gives rise to great pain; or it may be the patient is unable to bear the contact of the seam of the dress against the skin on account of the suffering it causes. Not infrequently there is deep-seated pain located, as the patient describes it, in the marrow of the bones which are tender on being grasped, and I have noticed that these pains are generally worse at night.

Pavy also recorded unusual presentations, including a 67-year-old who complained of "lightning pains on the right side of the waist" and cases in which the third nerve was affected with "dropped lid and external squint" [18].

Kidney disease was known to be relatively common in diabetes. In 1859, Wilhelm Griesinger (1817–1868) reported 64 autopsies in adults, half of whom had renal changes which he attributed to hypertension and atherosclerosis [19]; however, the histologic features of diabetic kidney disease and the importance of renal complications were not reported until the 1930s.

In the latter part of the 19th century it was becoming apparent that there were at least two clinically distinct forms of diabetes. In 1880, the French physician Etienne Lancereaux (1829–1910) identified lean and obese patients as having *diabète maigre* and *diabète gras* [20], and this observation laid the foundations for subsequent etiologic classifications of the disease.

The 20th century

Murray's cure of myxedema in 1891 led to a belief that pancreatic extract would soon result in a cure for diabetes, but, in the face of repeated failures over the next 30 years, even believers in an antidiabetes internal secretion were depressed about the likelihood of isolating it, and diverted their attention to diet as a treatment for the disease.

Best known was the starvation regimen of Frederick Madison Allen (1876–1964), which Joslin (Figure 1.9) described in 1915 as the greatest advance since Rollo's time [21]. This approach was an extreme application of one that had been proposed as early as 1875 by Apollinaire Bouchardat (1806–1886), who

advocated intensive exercise and "*manger le moins possible*." Starvation treatment did work in a limited sense, in that some people could survive for many months or even years, instead of a few weeks or months with untreated type 1 diabetes. The quality of life, however, was very poor, and some died of malnutrition rather than diabetes. In 1921, Carl von Noorden (1858–1944)—proponent of the "oatmeal cure"—turned away in disapproval when he saw Joslin's prize patient, 17-year-old Ruth A, who at just over 1.52 m in height weighed only 24.5 kg (a body mass index of 10.6 kg/m^2).

Discovery of insulin

Many attempts were made between 1889 and 1921 to isolate the elusive internal secretion of the pancreas. These largely failed

Experimentelle Untersuchungen über den Diabetes.[1])

Kurze Mitteilung.[2])

Von

G. Zuelzer.

F. Blum hat vor einigen Jahren gezeigt, dass subkutane oder intravenöse Injektion von Nebennierensaft bei den verschiedensten Tieren Glykosurie hervorruft, die 48 bis 74 Stunden anhalten kann. Ich, und kurze Zeit darauf Metzger wiesen nach, dass gleichzeitig eine Hyperglykämie besteht, dass es sich beim Nebennierendiabetes also nicht etwa um ein Analogon des Phloridzindiabetes, um einen sogenannten Nierendiabetes handeln könne. Während ich mich dahin aussprach, dass dieser Diabetes seiner ganzen Natur nach dem richtigen Diabetes ähnele, nur durch die Dauer seines Bestehens von ihm unterschieden sei und naturgemäss auch keine Tendenz zum Fortschreiten zeigen, i. e. niemals das Endstadium des gewöhnlichen schweren menschlichen Diabetes darbieten könne, wurde die in Frage stehende Glykosurie von den meisten anderen Autoren als eine ziemlich belanglose toxische Glykosurie aufgefasst.

Es schien mir nicht sehr wahrscheinlich, dass ein Körper, der anscheinend unverändert, wie er normalerweise produziert und dauernd[3]) dem Säftestrom des Organismus zugeführt wird, dass ein solcher, quasi physiologischer Körper eine vollkommen unphysiologische Wirkung sollte hervorbringen können. Ich habe also versucht, den Ort des Angriffs des Nebennierensaftes[4]), sowie die Ursachen seiner toxischen Wirkung näher zu erforschen. Ich folgte dabei, wie gesagt, stets dem Gedanken, in dem Nebennierendiabetes ein, wenn auch nur flüchtiges Bild gewisser menschlicher Diabetesformen zu finden.

So untersuchte ich zuerst, welchen Einfluss hat der Nebennierensaft auf die Leber als dasjenige Organ, welches, allgemein ansgedrückt, mit der Zuckerregulierung im Körper in erster

1) Die Untersuchungen wurden zum Teil mit Unterstützung der Gräfin Bose-Stiftung im physiologischen Institut der Berliner Universität, und zwar noch unter Mithilfe der verstorbenen Proff. I. Munk und Paul Schultz ausgeführt.

2) Diese kurze Mitteilung wurde der Redaktion bereits vor ca. 3 Jahren eingereicht. Die Drucklegung unterblieb auf Wunsch des Verf. in der bisher nicht erfüllten Erwartung, dass es gelingen würde, aus den theoretischen Untersuchungen praktisch-therapeutische Resultate zu erzielen.

3) Durch Versuche von Ehrmann, Archiv f. experim. Pathol. u. Pharmakol., Bd. 55, ist inzwischen der Nachweis erbracht worden, dass die Adrenalinsekretion konstant vor sich geht.

4) In meinen ersten Versuchen bediente ich mich des von mir selbst hergestellten Nebennierensaftes. In den zahlreichen späteren Versuchen habe ich inzwischen genau die gleichen Wirkungen mit den verschiedenartig hergestellten käuflichen Adrenalinpräparaten feststellen können.

Figure 1.11 The discoverers of insulin. Clockwise from top left: Frederick G. Banting (1891–1941); James B. Collip (1892–1965); J.J.R. Macleod (1876–1935); and Charles H. Best (1899–1978). Source: Courtesy of the Fisher Rare Book Library, University of Toronto.

because the extracts were inactive or had unacceptable side effects; some preparations may have had limited biologic activity, but this was not recognized, either because hypoglycemia was misinterpreted as a toxic reaction or because blood glucose was not measured. Those who came closest were the Berlin physician, Georg Zuelzer (1840–1949) in 1907 [23], Ernest Scott (1877–1966) in Chicago in 1911 [24], and Nicolas Paulesco (1869–1931) in Romania in 1920–1921 [25] (Figure 1.10).

The story of how insulin was discovered in Toronto in 1921 is well known, at least superficially (Figure 1.11). A young orthopedic surgeon, Frederick Banting, inspired after reading an article by the pathologist Moses Barron (1884–1975), wondered whether the antidiabetes pancreatic principle was digested by trypsin during extraction, and decided to prevent this loss by ligating the pancreatic duct, thus causing the exocrine tissue to degenerate. He approached the Professor of Physiology in Toronto, J.J.R. Macleod, an authority on carbohydrate metabolism, who poured scorn on the idea and suggested that the only likely outcome would be "a negative result of great physiological importance."

Eventually, Macleod relented and installed Banting in a rundown laboratory, later leaving for Scotland and a fishing holiday. A student, Charles Best, was chosen by the toss of a coin to help Banting. Within 6 months of this unpromising start, Banting and Best (referred to in Toronto academic circles as B^2) had discovered the most important new therapy since the antisyphilitic agent Salvarsan. These events are described in detail in the excellent book by Michael Bliss [26].

Their approach began with the injection of extracts of atrophied pancreas (prepared according to Macleod's suggestions) into dogs rendered diabetic by pancreatectomy. Subsequently, they discovered that active extracts could be obtained from beef pancreas which Best obtained from the abattoir. The extraction procedure (using ice-cold acid-ethanol) was greatly refined by James B. (Bert) Collip, a biochemist who was visiting Toronto on sabbatical leave.

The first clinical trial of insulin (using an extract made by Best) took place on January 11, 1922, on 14-year-old Leonard Thompson, who had been on the Allen starvation regimen since 1919 and weighed only 30 kg (Figure 1.12). After the first injection, his blood glucose level fell slightly, but his symptoms were unchanged and he developed a sterile abscess. On January 23, he was given another extract prepared by Collip, and this normalized his blood glucose by the next morning; further injections over the next 10 days led to marked clinical improvement and complete elimination of glycosuria and ketonuria. Initial clinical results in seven cases were published in the March 1922 issue of the *Canadian*

Figure 1.12 Leonard Thompson, the first person to receive insulin, in January 1922. Source: Courtesy of the Fisher Rare Book Library, University of Toronto.

Medical Association Journal [27], which concluded dramatically that:

1 Blood sugar can be markedly reduced, even to normal values;
2 Glycosuria can be abolished;
3 The acetone bodies can be made to disappear from the urine;
4 The respiratory quotient shows evidence of increased utilization of carbohydrates;
5 A definite improvement is observed in the general condition of these patients and, in addition, the patients themselves report a subjective sense of well-being and increased vigor for a period following the administration of these preparations.

The term "insulin" was coined by Macleod, who was unaware of de Meyer's earlier suggestion of *insuline*. News of its miraculous effects spread astonishingly rapidly [28]. In 1922, there were only 19 references in the world literature to "insulin" or equivalent terms such as "pancreatic extract"; by the end of 1923, there were 320 new reports, and a further 317 were published during the first 6 months of 1924.

By October 1923, insulin was available widely throughout North America and Europe. International recognition followed rapidly for its discoverers, and the 1923 Nobel Prize for Physiology or Medicine was awarded jointly to Banting and Macleod. Banting was angered by the decision, and announced publicly that he would share his prize with Best, whereupon Macleod decided to do the same with Collip.

The postinsulin era

It was confidently anticipated that insulin would do for diabetes in the young what thyroid extract had done for myxedema, but it soon became obvious that insulin was a very different type of treatment. Thyroid was given once a day by mouth and at a fixed dosage. Insulin had to be injected in measured amounts which varied from day to day, and carried the ever-present danger of hypoglycemia. One often reads that insulin "revolutionized" the treatment of diabetes; it did so in the sense that it saved the lives of many who would otherwise have died, but its unforeseen effect was to transform an acute, rapidly fatal illness into a chronic disease with serious long-term complications. For example, only 2% of deaths among Joslin's young patients with diabetes before 1937 were caused by kidney disease, while over 50% dying between 1944 and 1950 had advanced renal failure. Strategies to avoid and prevent the chronic complications of diabetes remain important scientific and clinical priorities today.

The rest of this chapter highlights some developments that can be regarded as landmarks in the understanding and management of the disease: to some extent, this is a personal choice, and it is obvious from the other chapters in this book that the "history" of diabetes is being rewritten all the time.

Causes and natural history of diabetes

The recognition that diabetes was not a single disease was important in initiating research that has helped to unravel the causes of hyperglycemia.

The broad etiologic subdivision into type 1 (juvenile-onset, or insulin-dependent) and type 2 diabetes (maturity-onset, or non-insulin-dependent) stemmed ultimately from Lancereaux's *diabète maigre* and *diabète gras* distinction, as well as observations soon after the discovery of insulin that some individuals did not react "normally" to insulin. In the 1930s, Wilhelm Falta (1875–1950) in Vienna [29] and Harold Himsworth (1905–1993) in London [30] proposed that some individuals with diabetes were more sensitive to the glucose-lowering effects of insulin, whereas others were insulin-insensitive, or insulin-resistant. The former were usually thin and required insulin to prevent ketoacidosis, while the latter were older, obese, and ketosis-resistant.

The "insulin clamp" technique developed in the 1970s by Ralph DeFronzo *et al.* [31] in the USA was the first to measure rigorously the hypoglycemic action of insulin, and has led to countless studies of insulin resistance and its relationship to type 2 diabetes and vascular disease. Various groups, including DeFronzo's, have helped to clarify the role of β-cell failure in type 2 diabetes, and how it relates to insulin resistance. Maturity-onset diabetes of the young (MODY) was recognized in 1974 by Robert Tattersall (*b.* 1943) as a distinct, dominantly inherited subset of type 2 diabetes [32]; since 1993 a variety of different molecular defects have been identified in this condition.

The causes of the profound β-cell loss that led to the severe insulin deficiency of type 1 diabetes remained a mystery for a long time. "Insulitis", predominantly lymphocytic infiltration of the islets, was noted as early as 1901 by Eugene L. Opie (1873–1971) and colleagues [33], but because it was apparently very rare,

found in only six of 189 cases studied by Anton Weichselbaum (1845–1920) in 1910, its importance was not appreciated. The possible role of insulitis in β-cell destruction was not suggested until 1965, by the Belgian Willy Gepts (1922–1991) [34]. The theory that type 1 diabetes results from autoimmune destruction of the β cells was first made in 1979 by Deborah Doniach (1912–2004) and GianFranco Bottazzo (*b.* 1946) [35]. Unlike other autoimmune endocrine diseases where the autoantibody persists, islet cell antibodies turned out to be transient and disappeared within a year of the onset of diabetes. An unexpected finding from the Barts–Windsor prospective study of the epidemiology of diabetes in childhood started by Andrew Cudworth (1939–1982) was that islet cell antibodies could be detected in siblings of young people with diabetes up to 10 years before they developed apparently acute-onset diabetes. This long lead-in period raised the possibility of an intervention to prevent continuing β-cell destruction. Cyclosporine in people with newly diagnosed type 1 diabetes prolonged the honeymoon period but without permanent benefit once the drug was stopped [36]. Nicotinamide and small doses of insulin (together with many other interventions) prevented diabetes in the non-obese diabetic (NOD) mouse but were without effect in relatives of people with type 1 diabetes with high titers of islet cell antibodies [37,38].

From 1967, when Paul Lacy (1924–2005) showed that it was possible to "cure" diabetes in inbred rats with an islet cell transplant, it always seemed that the problem of islet cell transplantation in humans was about to be solved. Hope was rekindled in 2000 by a team in Edmonton, Canada. After 5 years 80% of those who had received a transplant were producing some endogenous insulin but only 10% could manage without any injected insulin [39].

Chronic diabetic complications

It had been assumed that arteriosclerosis caused chronic diabetic complications, but this notion was challenged by two papers published in the mid-1930s, which pointed to specific associations of diabetes with retinal and renal disease (Table 1.2). In 1934, Henry Wagener (1890–1961) and Russell Wilder (1885–1959) from the Mayo Clinic reported people who had retinal hemorrhages but no other clinical evidence of vascular disease [40], and concluded that "The very existence of retinitis in cases in which patients have no other signs of vascular disease must mean that diabetes alone does something to injure the finer arterioles or venules of the retina, probably the latter."

In 1936, Paul Kimmelstiel (1900–1970) and Clifford Wilson (1906–1997) described the striking histologic finding of "intercapillary glomerulosclerosis"—large hyaline nodules in the glomeruli—in the kidneys of eight people at autopsy (Figure 1.13) [41]. Seven of the eight individuals had a known history of diabetes, and Kimmelstiel and Wilson noted the common features of hypertension, heavy albuminuria with "edema of the nephrotic type," and renal failure. In fact, this paper led to considerable confusion during the next 15 years: according to one writer, the "Kimmelstiel–Wilson syndrome" came to mean all things to all men [42]. Nonetheless, it was significant because it drew attention to a specific diabetic renal disease.

Acceptance of the concept that diabetic angiopathy was specific to the disease owed much to the work of Knud Lundbæk of Aarhus in Denmark (Figure 1.14), who published his findings in a book in 1953–1954 and a paper in the *Lancet* in 1954 [43,44]. His key arguments were that long-standing diabetic vascular disease differed fundamentally from atherosclerosis, in that both sexes were equally affected and that microaneurysms, ocular phlebopathy, and Kimmelstiel–Wilson nodules were unique to diabetes and usually occurred together.

The molecular and cellular mechanisms underlying diabetic tissue damage remain controversial after decades of intensive research. One of the early landmarks in this field was the work of

Figure 1.13 Nodular glomerulosclerosis. Figure from the paper by Kimmelstiel and Wilson, 1936 [41]. Source: Courtesy of the British Medical Association Library.

J.H. Kinoshita (*b.* 1922) during the early 1970s, which pointed to the involvement of the polyol pathway in the formation of diabetic cataracts [45].

Physiology

In 1907, M.A. Lane, a student of Robert Bensley (1867–1956), Professor of Anatomy in Chicago, used conventional histologic techniques to distinguish two different cell types in the islet of Langerhans, which he termed A and B [46]. The hormones secreted by these respective cell types were not identified until much later (Table 1.2). Frank Young (1908–1988) and colleagues reported in 1938 that injections of anterior pituitary extract could induce permanent diabetes in the dog, and that this was accompanied by selective degranulation and loss of the β cells [47]; it was surmised that these cells produced insulin, and this was finally confirmed using immuno-histochemistry by Paul Lacy in 1959 [48]. Glucagon was similarly localized to the α cells in 1962 by John Baum and colleagues [49].

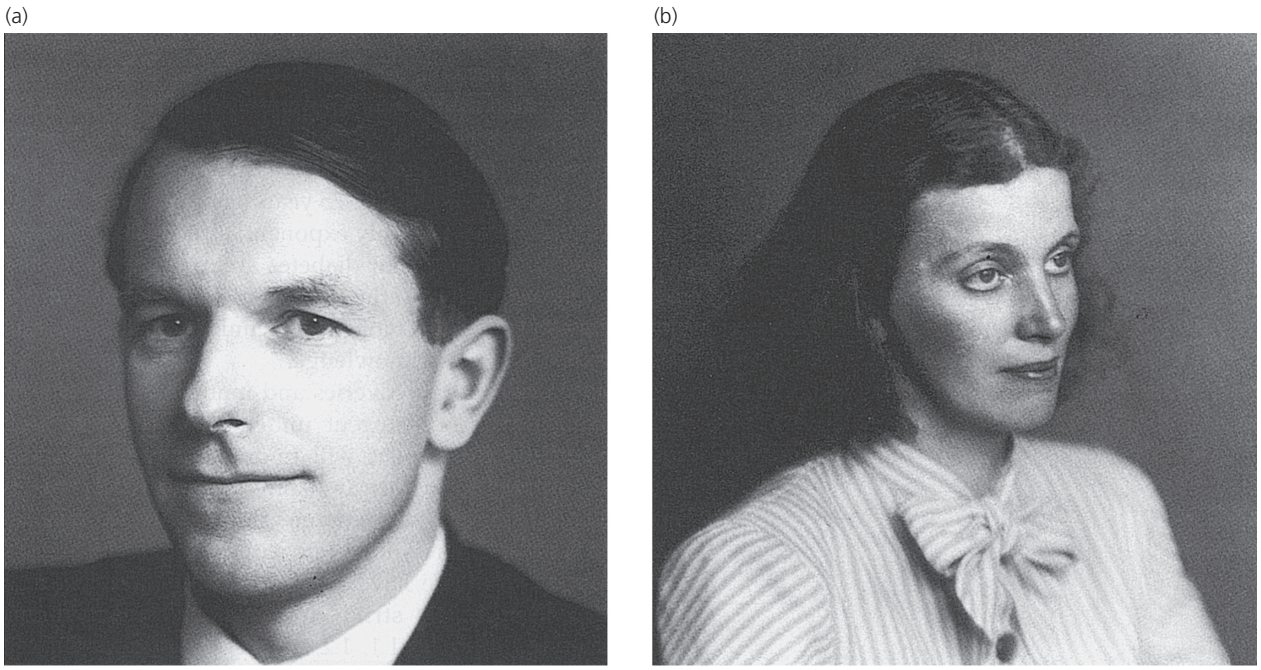

Figure 1.15 Frederick Sanger (1918–2013) and Dorothy Hodgkin, née Crowfoot (1910–1994). Source: Courtesy of Godfrey Argent Studio, London.

The amino acid sequence of insulin was reported in 1955 by Frederick Sanger in Cambridge, UK [50], and the three-dimensional structure of the molecule in 1969 by Dorothy Hodgkin, in Oxford [51]; both discoveries were recognized by the award of Nobel Prizes (Figure 1.15). The complete insulin molecule was synthesized from amino acids by Wang Ying-lai (1908–2001) and colleagues in Shanghai in 1965 [52]. The insulin precursor, proinsulin, was described in 1967 by Donald Steiner (1930–2014) in Chicago [53]. The first bioassay for insulin, based on the hormone's ability to lower blood glucose in the alloxan-diabetic rat, was reported in 1950 by the Australian Joseph Bornstein (1918–1994), working in London with Robin D. Lawrence (see Figure 1.20) [54]. This method was superseded in 1956 by Rosalyn Yalow and Solomon Berson in the USA, who discovered that insulin was antigenic; they exploited the binding of the hormone to anti-insulin antibodies to develop the first radioimmunoassay [55]. This assay method revolutionized endocrinology—and indeed, many areas of physiology and medicine—and was also rewarded with a Nobel Prize (Figure 1.16).

The sequence of rat insulin genes was described in 1977 by Axel Ullrich (*b.* 1945) and colleagues [56], and the human sequence by Graham Bell (*b.* 1948) and his group in 1980 [57]. The existence of insulin receptors was inferred from the insulin-binding characteristics of liver-cell membranes by Pierre Freychet (*b.* 1935) and colleagues in 1971 [58], and the receptor protein was isolated by Pedro Cuatrecasas (*b.* 1936) in the following year [59]. The gene encoding the insulin receptor was cloned and sequenced in 1985 by two groups [60, 61]. In recent years, numerous advances have helped to clarify how insulin exerts its biologic actions. Among these was the discovery in 1985 of the first of the glucose transporter (GLUT) proteins by Mueckler and colleagues in the USA [62].

Management of diabetes

An objective observer surveying clinical diabetes during the half-century after the discovery of insulin and the "resurrection" (a word used by Joslin) of young people with diabetes would have been dismayed by what he saw (Table 1.4). In particular, young people were dying of complications that had previously been assumed to be the preserve of the elderly. Two particularly depressing papers were published in 1947 and 1950. First,

Diabetes Control and Complications Trial (USA, 1993)	Proved that improved glycemic control prevents and slows progression of microvascular complication in type 1 diabetes
UK Prospective Diabetes Study (UK, 1998)	Proved that improved glycemic and blood-pressure control improve microvascular and macrovascular outcomes in type 2 diabetes
Management of complications	
Gerd Meyer-Schwickerath (Germany, 1964)	Use of xenon arc lamp to treat diabetic retinopathy
University of Minnesota Team (USA, 1966)	First combined kidney–pancreas transplants
Carl-Erik Mogensen and Hans-Henrik Parving (Denmark, 1980s)	Strict blood pressure controls slows progression of diabetic neuropathy

Henry Dolger (1909–1997) in New York described 20 people who fulfilled the then-accepted criteria for excellent diabetic control, but who all developed severe retinopathy after 6–22 years [63]; among these was the first person ever to receive insulin at Mount Sinai Hospital, New York, who also had heavy albuminuria and hypertension by the age of 32. Second, Ruth Reuting reported a cohort of 50 young patients originally identified in 1929 [64]. By 1949, one-third had died (mostly from cardiovascular and renal disease) at an average age of 25 years, after only 18 years of diabetes, and the survivors showed "ominous signs of hypertension, azotemia, and proteinuria in significant numbers." This had occurred despite the introduction of more versatile insulin preparations (see below); the situation was so hopeless that it inaugurated 20 years of treatment with "heroic" measures such as adrenalectomy and hypophysectomy.

These and other studies raised questions about whether lowering blood glucose levels to normal could prevent diabetic complications or reverse them once they had appeared. The hypothesis remained untestable for four more decades, until the means to achieve tight glycemic control and measure it had been devised.

Figure 1.17 Hans Christian Hagedorn (1888–1971) from the Hagedorn Medal. Source: Courtesy of C. Binder, Steno Institute, Hvidovre, Denmark.

Insulin

For the first decade after its discovery, insulin was available only in its soluble (regular) formulation, whose short-action profile required multiple daily injections. The first delayed-action preparation, protamine insulinate, was introduced in 1936 by Hans Christian Hagedorn in Denmark (Figure 1.17) [65]. This was followed by protamine zinc insulin later the same year, then globin insulin in 1939, NPH (neutral protamine Hagedorn, or isophane) in 1946, and the lente series in 1952. Long-acting insulins were welcomed by diabetes specialists and people with diabetes, but their use as a single daily injection probably produced worse glycemic control than three or four injections of soluble insulin. Indeed, delayed-action preparations were initially condemned by some diabetes specialists, such as Russell Wilder of the Mayo Clinic, because the patient could slip without apparent warning into hypoglycemia.

The number and variety of insulin preparations proliferated, but the main advances were in methods to produce highly purified preparations from porcine or bovine pancreas, which remained the source for therapeutic insulin until the early 1980s. Insulin was the first therapeutic protein to be produced by recombinant DNA technology, initially by David Goeddel (*b.* 1951), who expressed synthetic genes encoding the A- and B-chains separately in *Escherichia coli* and then combined these chemically to produce human-sequence insulin [66]. From there, genetic engineering has been used to produce "designer" insulins such as the fast-acting insulin analogs lispro and aspart and the "peakless" basal insulins such as glargine, detemir, and degludec. These insulins are more expensive than NPH but the evidence suggests that there is less clinical hypoglycemia with their use [67].

Most people with diabetes still inject insulin subcutaneously. From a patient's viewpoint, major milestones were the replacement of glass and steel syringes by disposable plastic syringes with fine-gauge needles, and then by "pen" injection devices invented by John Ireland (1933–1988) in Glasgow, Scotland, in 1981 [68]. Portable insulin infusion pumps were developed by John Pickup (*b.* 1947) and colleagues in London during the late 1970s [69], and have become progressively smaller and more sophisticated. Both people with diabetes and manufacturers hope that there will eventually be an insulin that can be given without injection. The first inhaled insulin was marketed in 2006 but withdrawn a year later because of lack of demand and concerns about safety [70], but other products have more recently reached the market.

Oral antidiabetes agents

The first orally active glucose-lowering drug, synthalin, a guanidine derivative, was developed by Frank and colleagues in Breslau in 1926 [71], but had to be withdrawn because of toxicity (a recurrent problem for oral antidiabetes drugs). The sulfonylureas originated from the work of Auguste Loubatières (1912–1977) in France during the early 1940s on the glucose-lowering action of a sulfonamide derivative, 2254RP. Loubatières made the crucial observations that proved that these drugs act as insulin secretagogues and that they were effective in intact, but not in pancreatectomized, animals [72]. In 1955 carbutamide was the first sulfonylurea to enter clinical practice and tolbutamide followed in 1957. Phenformin, the first biguanide, was introduced in 1959 following research into the metabolic effects of guanidine derivatives which had built on Frank's initial studies [73]. Metformin appeared on the European market in 1960 but was not marketed in the USA until 1994. Troglitazone, the first of a class of antidiabetes drugs—the glitazones—was also marketed in 1994 but withdrawn because of liver damage. It was followed by rosiglitazone and pioglitazone. Another class of drugs, acting on the incretin system, were introduced in 2005. These are either glucagon-like peptide 1 (GLP-1) receptor agonists (such as exenatide) or inhibitors of the enzyme dipeptidylpeptidase-4 (DPP-4) which breaks down GLP-1 (gliptins).

In 2010 another class of agents, the SGLT2 inhibitors—the gliflozins—became widely available with action blocking the renal sodium-glucose co-transporters and thereby causing glycosuria—with effects on lowering plasma glucose, reducing blood pressure, and causing weight loss. A landmark trial using empagliflozin in high-risk people with existing cardiovascular disease showed a marked reduction in mortality [74].

Tolbutamide, phenformin, and insulin were compared in the treatment of "maturity-onset" diabetes in the first randomized controlled trial, the University Group Diabetes Program [75–77]. This much-criticized study concluded that the death rate was higher for both oral agents than for placebo, and that insulin (whether given in a fixed or variable dose) was no better than placebo [77]. These findings were interpreted by some as suggesting that treatment of maturity-onset diabetes was a waste of time—a myth that was only laid finally to rest by the UK Prospective Diabetes Study [78].

Glucose control and treatment targets

During the 1920s, opinion leaders advocated normalizing blood glucose in young people with diabetes, the rationale being to "rest"

the pancreas, in the hope that it might regenerate. The only way of monitoring diabetic control was by testing the urine for glucose, and attempts to keep the urine free from sugar inevitably resulted in severe hypoglycemia and often psychologic damage. This led to the so-called "free diet" movement—linked particularly with Adolf Lichtenstein (Stockholm) and Edward Tolstoi (New York)—which encouraged people with diabetes to eat whatever they liked and not to worry about glycosuria, however heavy. Tolstoi's view [79] was that a life saved by insulin should be worth living, and that people with diabetes should be able to forget that they had diabetes after each morning's injection; it seems likely that many physicians followed this policy for the next 40 years.

Adult physicians were similarly ambivalent about the importance of good glycemic control. Only one-third of diabetes physicians questioned in England in 1953 thought that normoglycemia would prevent diabetic complications, and only one-half advised urine testing at home [80].

Practical monitoring of diabetic control became feasible in the late 1970s with the introduction into clinical practice of test strips for measuring blood glucose in a fingerprick sample and the demonstration that most people with diabetes could use them at home [81, 82]. The discovery of hemoglobin A_{1c} by Samuel Rahbar (1929–2012) paved the way for glycated hemoglobin (HbA_{1c}) assays which gave an objective measure of overall glucose control [83]. These methods in turn made possible the North American Diabetes Control and Complications Trial, which in 1993 finally established that good control prevents and delays the progression of microvascular complications in type 1 diabetes [84]. For type 2 diabetes, the importance of good glycemic control was definitively proved by another landmark study, the UK Prospective Diabetes Study (UKPDS), masterminded in Oxford, UK, by Robert Turner (Figure 1.18). The UKPDS reported in 1998, and not only showed a beneficial effect of improved glycemic control on microvascular complications [78], but also established the importance of treating hypertension [85]. By the late 1990s it was clear that reducing glucose levels, high blood pressure, or cholesterol separately would reduce the frequency of heart disease and death and it was natural to wonder whether tackling them simultaneously (multiple risk factor intervention) would be even better. The Steno 2 study, which began in Denmark in 1992, enrolled people with type 2 diabetes with microalbuminuria and after 13 years of follow-up showed that multiple risk factor intervention reduced the risk of death by 20% and the risk of developing nephropathy, retinopathy, and neuropathy by 50% [86].

Diabetic complications

Apart from the general benefits of controlling blood glucose, some specific treatments have emerged for certain chronic complications. Well-conducted clinical trials during the late 1970s showed the effectiveness of laser photocoagulation in preventing visual loss from both maculopathy and proliferative retinopathy [87]. This technique was derived from the xenon arc lamp originally described in the late 1950s by Gerd Meyer-Schwickerath (1921–1992) of Essen, Germany [88].

Figure 1.18 Robert Turner (1939–1999), instigator of the UKPDS, the first study to show that good control of blood glucose and blood pressure was beneficial in type 2 diabetes. Source: Courtesy of the British Diabetic Association.

The importance of blood pressure control in preventing the progression of nephropathy is now fully recognized, and blockade of the renin-angiotensin system may be particularly beneficial; that blood pressure control slowed the progression of nephropathy was shown in studies by Carl-Erik Mogensen (*b.* 1938) and Hans-Henrik Parving (*b.* 1943) published in the early 1980s [89]. The detection of very low albumin concentrations in urine (microalbuminuria), now used throughout the world to screen for and monitor the course of diabetic nephropathy, is derived from a radioimmunoassay developed in 1969 by Harry Keen and Costas Chlouverakis, at Guy's Hospital in London [90].

Diabetic ketoacidosis

The introduction of insulin was only one aspect of the management of this acute and previously fatal complication of diabetes. Of the first 33 cases treated by Joslin and his colleagues between January 1, 1923 and April 1, 1925, 31 survived—an excellent

outcome, even by modern standards, which Joslin [91] attributed to: "Promptly applied medical care, rest in bed, special nursing attendance, warmth, evacuation of the bowels by enema, the introduction of liquids into the body, lavage of the stomach, cardiac stimulants, and above all the exclusion of alkalis."

Sadly, other centers did not pay so much attention to detail. In 1933, the death rate from ketoacidosis in Boston was only 5%, but elsewhere in North America and Europe it averaged 30% and could be as high as 75%. An important advance in management was the acceptance of relatively low-dose insulin replacement, following the example of Ruth Menzel and colleagues in Karlsburg, Germany [92]. This broke with the tradition of high-dose regimens such as that proposed by Howard Root in the USA, which had recommended an average of 1200 units of insulin during the first 24 hours of treatment [93]. Another step forward was the recognition by Jacob Holler in 1946 of the danger of hypokalemia [94]. Holler's observation helped to establish the need for monitoring plasma potassium levels, which became feasible with the introduction of the flame photometer, and replacing potassium accordingly.

Diabetic pregnancy

As late as 1950, the outcome of pregnancy in women with diabetes was still very poor in most units, with perinatal fetal losses of 45–65%, some 10 times higher than in the general population. Exceptions to this depressing rule were the units run by Priscilla White at the Joslin Clinic in Boston, who had published excellent results as early as 1935 [95], and by Jørgen Pedersen in Copenhagen (Figure 1.19). Pedersen identified the common features underpinning success as good diabetic control and care provided by an experienced and dedicated team consisting of a physician, obstetrician, and pediatrician [96]. Pedersen's target of a fetal mortality rate of 6% was not achieved in most European or US units until the 1980s.

Delivery of care for people with diabetes

From the earliest days of insulin injection and urine testing, it was apparent that people with diabetes needed knowledge and practical skills to manage their disease effectively. Lip-service was often paid to the importance of diabetes education, but most patients were badly informed. In 1952, Samuel Beaser (1910–2005) questioned 128 people with diabetes attending the Boston Diabetes Fair, and found that "all were distinctly deficient in knowledge of their disease" [97]; he felt that responsibility lay with both doctors and administrators. Further studies during the 1960s by Donnell Etzwiler (1927–2003) in Minneapolis showed that many doctors and nurses were also ignorant about managing diabetes. Since the 1980s, diabetes specialist nurses and nurse educators have been appointed in increasingly large numbers—thus fulfilling a suggestion originally made by Joslin in 1916.

National and international diabetes associations have also played an important part by supporting scientific and clinical research, providing practical and moral help for people with diabetes, and lobbying governments on their behalf. The first of these organizations was the Portuguese Association for the Protection of Poor Diabetics, founded in 1926 by Ernesto Roma of Lisbon after an inspiring visit to Joslin's clinic in Boston (Figure 1.20). The Association's aim was to provide free insulin and education for people with diabetes and their families. In the UK, the Diabetic Association (later the British Diabetic Association, and now Diabetes UK) was established in 1934 by Robin Lawrence of King's College Hospital, London, helped by the novelist H.G. Wells (Figure 1.20). Similar organizations were later founded in France (1938), the USA (1940), and Belgium (1942), and now exist in most countries.

On a wider scale, the International Diabetes Federation was established in 1950 and the European Association for the Study of Diabetes (EASD) in 1964. These organizations are devoted to the practice of diabetes care as well as the basic and clinical science of the disease, and have been valuable in coordinating treatment targets and strategies at international level; an important example was the St. Vincent Declaration, issued jointly in 1990 by the EASD and the World Health Organization [98].

2 Classification and Diagnosis of Diabetes

Ambady Ramachandran, Chamukuttan Snehalatha, and Arun Nanditha
Dr. A. Ramachandran's Diabetes Hospitals and India Diabetes Research Foundation, Chennai, India

Key points

- Diabetes is a group of metabolic diseases characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both.
- There is a general agreement that there are three main types of diabetes and the fourth type includes the less common specific types of varied etiology.
- Although blood glucose remains the main stay for diagnosis of diabetes, HbA_{1c} is now approved as an alternative diagnostic test for hyperglycemia.
- Diagnostic criteria for gestational diabetes (GDM) are modified.
- Impaired glucose tolerance (IGT) is a predictor for subsequent development of type 2 diabetes and is also a cardiovascular risk factor.

Introduction

Diabetes is one of the most common metabolic diseases with a complex, multifactorial etiology and has varied clinical and biochemical manifestations. Multiple therapeutic approaches are required for glycemic management of its different groups. The main cause of the disease is inadequate secretion and/or impaired action of insulin on the target tissues. Severity of the resultant hyperglycemia and the symptoms and signs vary widely. The vascular damage resulting in microvascular and macrovascular complications depends largely on the degree and duration of hyperglycemia.

Diabetes mellitus has been known since ancient times. The term "diabetes" was probably first used by Apollonius of Memphis around 250 BC, which literally meant "to go through" or siphon as the disease drained more fluid than a person could consume. The Latin word "mellitus" was added later as the urine of people with diabetes was sweet (Chapter 1) [1].

In 1500 BC, Hindu scholars described "a mysterious disease causing thirst, enormous urine output, and wasting away of the body with flies and ants attracted to the urine of people" [2]. At the same period, an Egyptian physician, Hesy-ra and the Greek physician Arateus also documented similar symptoms of a mysterious disease which also caused emaciation. If urine tasted sweet diabetes was diagnosed. It was only in the 1800s that chemical tests were developed to detect the presence of sugar in the urine. The early descriptions were probably related to severe forms of the disease, either type 1 diabetes (T1DM) or late type 2 diabetes (T2DM) [3].

In the late 19th century, two categories were recognized, one category was described as occurring in young people with a short time course before ketoacidosis occurred and the second one was described as common in older and obese people. In 1936, Himsworth showed that diabetes could be divided into insulin-resistant and insulin-sensitive types and the former was more common among the maturity-onset variety [4].

Definition

Diabetes is a group of metabolic diseases characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both. The chronic hyperglycemia of diabetes is associated with long-term damage, dysfunction, and failure of different organs, especially the eyes, blood vessels, heart, nerves, and kidneys [5,6].

Diabetes is characterized by disturbances in carbohydrates, fat, and protein metabolism. The clinical symptoms include polyuria, polydipsia, polyphagia, weight loss, and blurring of vision which usually occur when prolonged hyperglycemia is severe. It exacerbates to uncontrolled diabetes namely ketoacidosis or hyperosmolar non-ketotic coma. Often symptoms are mild or absent among people with T2DM for many years especially when hyperglycemia is mild. The disease may remain undetected, but tissue damage may develop and therefore vascular complications may be present at the time of diagnosis [6]. Chronic hyperglycemia may cause impairment of growth and increase the susceptibility to certain infections in some people with diabetes. In addition to the classic symptoms, people with diabetes may present with vague

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

symptoms such as unexplained weight loss, fatigue, restlessness, and body pain. A few persons in the early stages of hyperglycemia present with symptoms of reactive hypoglycemia.

Long-term complications of diabetes are mainly of two types: (1) microvascular complications which include retinopathy with potential loss of vision, nephropathy leading to renal failure, peripheral neuropathy with risk of foot ulcers, amputations, and Charcot joints; and (2) autonomic neuropathy causing gastrointestinal, genitourinary, and cardiovascular symptoms, and sexual dysfunction [5, 6]. The macrovascular complications include cardiovascular diseases with increased incidence of atherosclerotic cardiovascular, peripheral arterial, and cerebrovascular diseases. Hypertension and dyslipidemia often coexist in people with diabetes.

Classification of diabetes

Diabetes has been known for many centuries and the variations in the severity of diabetes was also described. However, a clear distinction between two types of diabetes emerged only in the 20th century. The first real attempt to classify diabetes was by the World Health Organization (WHO) Expert Committee on Diabetes Mellitus which classified diabetes based on the age of onset of the disease, mainly juvenile-onset diabetes and maturity-onset diabetes [7]. Although at that time other phenotypes such as the brittle, gestational, pancreatic, endocrine, insulin-resistant, and iatrogenic varieties were described, there was no clear understanding of etiology [3].

Glucose measurements in blood became common but no standard criteria for diagnosis were used. Diagnosis was usually made if there were clinical symptoms with high blood glucose and glycosuria. In juvenile-onset diabetes ketonuria was noted to be common. Later on with the availability of insulin measurement using radioimmunoassay, insulin deficiency or lack of insulin secretion in juvenile-onset diabetes and apparently normal or raised levels in maturity-onset diabetes could be demonstrated. This was a major breakthrough in the history of diabetes.

The WHO has published several guidelines for diagnosis of diabetes since 1965 [6–9]. The second report of the WHO published in 1980 [8] marked the beginning of the modern classification which was a revision of the criteria published by the National Diabetes Data Group (NDDG) [10]. For the first time the four major groups were defined: (i) insulin-dependent diabetes mellitus (IDDM, type 1); (ii) non-insulin-dependent diabetes mellitus (NIDDM, type 2); (iii) the "other types"; and (iv) gestational diabetes mellitus (GDM). Two risk classes: previous abnormality of glucose intolerance, and potential abnormality of glucose tolerance were also suggested in place of the terms "prediabetes" or "potential" diabetes. Both diagnosis and classification were reviewed in 1985 [9] and 1999 [6]. At the same time the American Diabetes Association (ADA) also published a report of an expert committee on the diagnosis and classification of diabetes [11]. Both the classifications attempted to encompass both etiology and clinical stages of the disease based on the suggestions of Kuzuya and Matsuda [12]. It was recognized that diabetes may progress through several clinical stages from normoglycemia to ketoacidosis. With the discovery of human leucocyte antigen (HLA) genotypes and also the islet cell antibodies, it was clear that juvenile-onset diabetes or the younger people with diabetes who were insulin-dependent had an autoimmune etiology. Maturity-onset diabetes was considered to be a milder form of the disease.

It was also recognized that people with T2DM can move from one to another stage of varying severity of hyperglycemia, from an insulin requiring stage to non-pharmacological intervention with modification of lifestyle. The etiological classification of glycemia was described by WHO [6] and also approved by ADA [13]. Table 2.1 shows the classification as recently described by ADA [5].

The classification of T2DM is largely characterized by exclusion. As new causes are discovered they are included as "other specific types" such as the maturity-onset diabetes of the young (MODY) [3]. WHO revisited the classification in 2006 [14] and 2010 and no major modifications were made. Impaired glucose tolerance (IGT) was removed from the formal classification of T2DM but was retained as a risk state. A new category of risk status, impaired fasting glucose (IFG), was introduced.

Methods and criteria for diagnosing diabetes [5, 6]

An HbA_{1c} of ≥6.5% (≥48 mmol/L) is recommended as the cut point for diagnosing diabetes [15]. A value less than 6.5% (<48 mmol/mol) does not exclude diabetes diagnosed using glucose tests. The expert group concluded that currently there is insufficient evidence to make any formal recommendation on the interpretation of HbA_{1c} levels below 6.5%. The diagnostic criteria currently recommended by WHO, the International Diabetes Federation (IDF), and also by ADA (with minor variations) are shown in Table 2.2.

Fasting glucose may not be as accurate and equivalent to the use of an OGTT in identifying persons with diabetes. Studies in Asian populations [16] and the European DECODE study [17] showed that if only a fasting blood glucose was used, nearly one-third of cases with diabetes might be missed and vice versa at the point of diagnosis. However, with time, the three groups of people identified by the different tests coalesce so that those diagnosed by only one method will be identified by the other tests in due course.

Glycated hemoglobin (HbA_{1c}) for diagnosis of diabetes

Blood glucose measurement has been the mainstay for diagnosis and monitoring glycemic control in diabetes for many decades. Use of OGTT is a comparatively inexpensive, sensitive index of hyperglycemia including impaired glucose homeostasis. However, several disadvantages such as wide biological variability, poor

Table 2.1 Classification of diabetes (adapted from ADA).

I. Type 1
(β-cell destruction, absolute insulin)
- **A. Immune-mediated**
- **B. Idiopathic**

II. Type 2 diabetes
(Predominantly insulin resistance with relative insulin deficiency to a predominantly secretory defect with insulin resistance)

III. Other specific types
- **A. Genetic defects**
  - MODY 3 (Chromosome 12, HNF-1α)
  - MODY 1 (Chromosome 20, HNF-4α)
  - MODY 2 (Chromosome 7, glucokinase)
  - Other very rare forms of MODY (e.g. MODY 4: Chromosome 13, insulin promoter factor-1; MODY 6: Chromosome 2, NeuroDl MODY 7: Chromosome 9, carboxyl ester lipase)
  - Transient neonatal diabetes (most commonly ZAC/HYAMI imprinting defect on 6q24)
  - Permanent neonatal diabetes (most commonly KCNJ11 gene encoding Kir6.2 subunit of (β-cell KATP channel)
  - Mitochondrial DNA
  - Others
- **B. Genetic defects in insulin action**
  Type A insulin resistance, Leprechaunism, Rabson–Mendenhall syndrome
  Lipoatrophic diabetes and others
- **C. Diseases of the exocrine pancreas**
  Pancreatitis, Trauma/pancreatectomy, Neoplasia, Cystic fibrosis, Hemochromatosis, Fibrocalculous pancreatopathy, and others
- **D. Endocrinopathies**
  Acromegaly, Cushing's syndrome, Glucagonoma, Pheochromocytoma, Hyperthyroidism, Somatostatinoma, Aldosteronoma, and others
- **E. Drug- or chemical-induced**
  Vacor, Pentamidine, Nicotinic acid, Glucocorticoids
  Thyroid hormone, Diazoxide, β-Adrenergic agonists, Thiazides
  Dilantin, γ-Interferon, and others
- **F. Infections**
  Congenital rubella, Cytomegalovirus, and others
- **G. Uncommon forms of immune-mediated diabetes**
  Stiff-man syndrome, Anti-insulin receptor antibodies, and others
- **H. Other genetic syndromes sometimes associated with diabetes**
  Down syndrome, Klinefelter syndrome, Turner syndrome, Wolfram syndrome, Friedreich ataxia, Huntington chorea, Laurence–Moon–Biedl syndrome, Myotonic dystrophy, Porphyria, Prader–Willi syndrome, and others

IV. Gestational diabetes mellitus

reproducibility, influenced by acute factors such as stress, food, and exercise, and also by some medications, are the main disadvantages of using blood glucose [18].

Glycated hemoglobin (HbA_{1c}) initially identified as an index of chronic hyperglycemia has now evolved as a valuable tool to monitor glycemic control, for screening and diagnosis of diabetes and prediabetes and as a predictor of micro- and macrovascular complications [18, 19]. Assays of HbA_{1c} have multiple advantages over that of blood glucose including its preanalytical and analytical stability, its independence of the prandial status, and the assays are well standardized with high precision and accuracy. Presently the results are traceable to the Diabetes Control and

Table 2.2 Criteria for the diagnosis of diabetes (adapted from ADA).

Test	Description	Diagnostic cut-off
HbA_{1c}	The test should be performed in a laboratory using a method that is NGSP certified and standardized to the DCCT assay*	≥6.5% (48 mmol/mol)
OR		
Fasting plasma glucose	Fasting is defined as no caloric intake for at least 8 h*	≥126 mg/dL (7.0 mmol/L)
OR		
Two-hour plasma glucose during an oral glucose tolerance testing (OGTT)	The test should be performed as described by the World Health Organization, using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water*	≥200 mg/dL (11.1 mmol/L)
OR		
Random plasma glucose	The test is advised for people with classic symptoms of hyperglycemia or hyperglycemic crisis	≥200 mg/dL (11.1 mmol/L)

*In the absence of unequivocal hyperglycemia, criteria 1–3 should be confirmed by repeat testing.

Complications Trial (DCCT) assay values (measured as %) [20] and can also be compared to the highly accurate International Federation of Clinical Chemistry (IFCC)-standardized values (mmol/mol) [18]. High cost of the assay and its instrumentation, lack of awareness regarding its utility among the medical practitioners and the assay interferences (hematological abnormalities, hemoglobinopathies, factors influencing erythropoiesis), limit its application in many countries. Healthcare professionals using the test should be aware of these limitations and use their discretion in interpreting the results. Several lacunae still exist in the understanding of the relationship between HbA_{1c} and glycemia [18]. These include the relationship in children and the elderly, in pregnancy, in chronic liver and renal disease, the effect of HIV, the understanding of the genetic influences on HbA_{1c} variance, and ethnic influences [21].

Type 1 diabetes (T1DM) [5, 6]

Formerly known as insulin-dependent diabetes mellitus or juvenile-onset diabetes, TIDM occurs due to cellular-mediated autoimmune destruction of pancreatic β cells, causing an absolute deficiency of endogenous insulin. Persons with T1DM are dependent on exogenous insulin for survival and are ketosis-prone. Markers of the immune destruction of the β cell include islet cell autoantibodies, autoantibodies to insulin, autoantibodies to glutamic acid decarboxylase (GAD-GAD65), and autoantibodies to the tyrosine phosphatases IA-2 and IA-2β. One or more of these autoantibodies are present in 85–90% of individuals when fasting hyperglycemia is initially detected. The disease also has strong HLA associations, with linkage to the DQA and DQB genes, and is influenced by the DRB genes.

The rate of destruction of β cells is rapid mainly in infants, young children, and adolescents and they may present with ketoacidosis at the time of first presentation. Some persons with T1DM, mostly adults, may have slow deterioration of β cells and show detectable levels of plasma C-peptide for many years. Some people with T1DM are also prone to other autoimmune disorders such as Graves' disease, Hashimoto's thyroiditis, Addison's disease, vitiligo, celiac-sprue, autoimmune hepatitis, myasthenia gravis, and pernicious anemia.

About 2–12% of persons diagnosed with diabetes show phenotype characteristics of T2DM and have good glycemic control with oral antidiabetes agents, but rapidly progress to requiring insulin. They also show the presence of autoimmune markers of β-cell destruction, such as GADA-65. This subgroup is termed "latent autoimmune diabetes of adults" (LADA) [22].

A few people with T1DM may have no evidence of autoimmunity, but are prone to episodic ketoacidosis and may exhibit varying degrees of insulin deficiency and insulin dependency during those periods. This form, termed "idiopathic diabetes" is commonly seen in persons of African and Asian ethnicity and is strongly familial.

Type 2 Diabetes (T2DM)

T2DM, previously known as non-insulin-dependent diabetes, constitutes more than 95% of the total population with diabetes. Its prevalence is increasing globally but the most striking changes are now seen in the low- and middle-income countries. T2DM remains asymptomatic for many years and therefore remains undetected in nearly 50% of persons affected by the disease [5, 6,23]. T2DM is commonly diagnosed incidentally when a medical checkup is done for other reasons. Individuals with T2DM have a relative insulin deficiency; they secrete insulin but not enough to overcome insulin resistance. Though most of them require only lifestyle changes and oral antidiabetes agents to maintain glycemic control, many of them become insulin-requiring over a period of time. Chronic exhaustion of β-cell function is a major cause of this.

Although research studies have focused on the molecular mechanisms underlying T2DM, only modest success has been achieved in unraveling the genetic abnormalities. In the past two decades

T2DM in children and adolescents has become common in Asian populations which could be partly attributed to the rising rates of obesity in children. A study from Taiwan has reported T2DM to be the commonest form of diabetes in children aged 6–18 years. Signs associated with insulin resistance are also common among these children [24].

Other specific types

These forms of diabetes are relatively less common. The underlying defects of the disease processes can be identified in these forms, such as those listed below. Some of these defects are remediable and types of glycemia can also be cured [5, 6].

- Genetic defects in β cells such as MODY.
- Genetic defects in insulin action, such as Leprechaunism.
- Diseases of the exocrine pancreas, such as cancer of the pancreas, cystic fibrosis, and fibrocalculous pancreatopathy (a form of diabetes, which was formerly classified as one type of malnutrition-related diabetes mellitus).
- Endocrinopathies, such as Cushing syndrome, acromegaly, and pheochromocytoma.
- Drug-induced, such as steroid and thiazides.
- Infections, such as rubella, cytomegalovirus; immune-mediated diabetes such as seen in cases with insulin-receptor antibodies; a number of genetic syndromes as shown in Table 2.1 are associated with diabetes.

Gestational diabetes (GDM)

GDM is a state of carbohydrate intolerance resulting in hyperglycemia of variable severity, with onset or first recognition during pregnancy. It does not exclude the possibility that the glucose intolerance may antedate pregnancy but has previously gone unrecognized. The definition applies irrespective of whether or not insulin is used for treatment or whether the condition persists after pregnancy [5, 6].

Women who have diabetes and subsequently become pregnant are termed as having "diabetes mellitus and pregnancy" and should be treated accordingly during and after the pregnancy. GDM may develop at any stage of pregnancy. Hyperglycemia may resolve after the delivery. However, 5–10% of women may continue to have diabetes, often T2DM and will require treatment with lifestyle changes and appropriate hypoglycemic agents.

Women with GDM should be screened for diabetes 6–12 weeks postpartum, using non-pregnant OGTT criteria. Diagnosis using HbA_{1c} at the postpartum screening is not recommended but may be considered beyond 12 weeks postpartum. Women who show impaired glucose regulation at this stage should be treated with lifestyle interventions and in some circumstances metformin.

Women with any of the following risk factors should be screened with an appropriate blood test as shown in Table 2.3, during the first prenatal visit; if the result is found to be normal, they should be tested again between 24 and 28 weeks of pregnancy [5, 6]. The risk factors for GDM include older age, obesity, history of elevated blood glucose levels or GDM during previous pregnancy, women who had large-for-gestational age babies, strong family history of diabetes, and women from high-risk ethnic groups such as Asians.

The criteria used for diagnosis of GDM are shown in Table 2.3.

Different criteria are now used to diagnose GDM. Establishing a uniform approach to diagnosis will have extensive benefits for patients, caregivers, and policy makers [5].

Table 2.3 Screening for and diagnosis of GDM (adapted from ADA).

Test	Cut-off values	Diagnosis
"One-step" (IADPSG consensus) The test is performed at 24–48 weeks of gestation in women with no history of overt diabetes. 75-g Oral glucose tolerance test (fasting for minimum 8 hours)	Fasting: >92 mg/dL (5.1 mmol/L) 1 h: >180 mg/dL (10.0 mmol/L) 2 h: >153 mg/dL (8.5 mmol/L)	Diagnosis of GDM is made when any of the plasma glucose value exceeds the cut-off values
"Two-Step" (NIH consensus) The test is performed at 24–48 weeks of gestation in women with no history of overt diabetes. **Step 1:** 50-g Oral glucose tolerance test (non-fasting) **Step 2:** 100-g Oral glucose tolerance test (fasting for minimum 8 hours)	1 h post glucose: ≥140 mg/dL* (7.8 mmol/L) 3 h post glucose: ≥140 mg/dL (7.8 mmol/L)	If plasma glucose measured 1 h post load is ≥140 mg/dL* (7.8 mmol/L) proceed to Step 2. Diagnosis of GDM is made when plasma glucose measured 3 h after the test is ≥140 mg/dL (7.8 mmol/L)

*The American College of Obstetricians and Gynecologists (ACOG) recommend a lower threshold of 135 mg/dL in high-risk ethnic minorities with higher prevalence of GDM.

Intermediate hyperglycemia or impaired glucose regulation (prediabetes)

Prediabetes is typically defined as blood glucose levels above normal, but below diabetes thresholds and is a risk state that increases the chance of developing diabetes. About one-third of persons with IGT develop T2DM; the annual incidence rate ranges between 2% to 10% per year depending on the population and presence of risk factors [14].

T2DM goes through several subclinical stages of abnormalities before its clinical manifestations occur. IGT is a postprandial abnormality of glucose tolerance where the 2-hour plasma glucose value after 75 gm glucose intake is between 7.8–11.1 mmol/L (140–199 mg/dL). Nearly 20–30% of people with IGT will also have IFG. The values for IFG are a fasting plasma glucose concentration of ≥6.1 mmol/L (110 mg/dL), but <7.0 mmol/L (126 mg/dL). IFG can also exist as an isolated condition [14]. The ADA applies the same threshold for IGT, but uses a lower cut-off value for IFG, that is, fasting plasma glucose of 5.6–6.9 mmol/L (100–125 mg/dL) [5]. The ADA has also introduced the use of HbA_{1c} levels of 5.7–6.4% (38.8–46.4 mmol/mol) as a new category of high diabetes risk. It is possible to prevent the development of diabetes in these people by lifestyle modification.

Use of the term prediabetes has been criticized on the basis that not all people with this condition progress to T2DM and the term "intermediate hyperglycemia" is preferred.

Conclusion

Over the past two decades significant clarity has been achieved in both the classification of diabetes mellitus, and in the diagnostic criteria. This has helped to establish some uniformity in data collection and has also allowed comparison of the international profile of the disease.

However, consensus is still lacking in many areas, for example the diagnostic criteria for GDM. Moreover, sufficient importance is not being given to identifying prediabetes states, which are the strongest predictors of incident T2DM. Conversion of prediabetes to T2DM can be prevented or delayed in a large proportion of individuals by healthy lifestyle modification.

The classification of diabetes continues to evolve as underlying genetic, and other, factors become identified with increasing precision.

Keypoints

- Type 1 diabetes mellitus (T1DM) develops in genetically susceptible individuals after a preclinical phase of variable length usually with immune-mediated destruction of pancreatic β cells, and requires lifelong treatment with insulin.
- The disease can occur at any age, but the incidence peaks around puberty. Classification of T1DM versus type 2 diabetes mellitus (T2DM) becomes increasingly difficult with age.
- In childhood, the incidence is similar in females and males, but there is a 1.3–2.0-fold male excess in incidence after about 15 years of age in most populations.
- The incidence in childhood varies enormously between countries. Some Asian and South American populations have low incidences (~0.1–8 per 100,000/year), whereas Finland (>40 per 100,000/year), Sardinia (~38 per 100,000/year), and Sweden (~30 per 100,000/year) have high incidences. North America (15–25 per 100,000/year) and Australia (~15 per 100,000/year) have moderate to high incidences, while eastern countries in Europe have low to moderate incidences (4–10 per 100,000/year).
- About 10–20% of newly diagnosed childhood cases of T1DM have an affected first-degree relative. Those with an affected sibling or parent have a cumulative risk of 3–7% up to about 20 years of age, compared with cumulative risks of 0.2–0.8% in the respective general populations. The cumulative incidence among monozygotic co-twins of persons with T1DM is less than 50%, even after >30 years' follow-up.
- Some of the geographic differences and familial aggregation may be explained by human leukocyte antigen haplotypes.
- The incidence of childhood-onset T1DM has increased by 3–4% per year, and there is a tendency towards younger average age at onset over time, which cannot be explained by genetic factors. The causes of this increasing trend are not known.
- Virus infections and nutritional factors have been implicated, but no specific environmental factor has been established as a risk factor.
- Even though insulin replacement therapy and other advances in the management of T1DM have improved the prognosis of persons with T1DM, their mortality is still at least two times (~2–8-fold) higher than in the background population. This is because of both acute and chronic complications of the disease, including cardiovascular disease, after about 30 years of age.

Introduction

Type 1 diabetes mellitus (T1DM) requires lifelong treatment with insulin, and in the majority of cases results from a cell-mediated autoimmune destruction of the β cells in susceptible individuals. This occurs after a preclinical period of months to years when islet autoantibodies to insulin, glutamic acid decarboxylase (GAD), and insulinoma-associated antigen 2 (IA-2) and other autoantigens can be detected [1]. Autoantibodies are not thought to cause the disease, but are markers of ongoing β-cell destruction. Persistent positivity for two or more islet autoantibodies in early life is associated with a high probability of developing T1DM within the following months to years in genetically susceptible individuals—a more than 60% cumulative incidence after 10 years [2].

Genetic factors influence the susceptibility to T1DM, particularly human leukocyte antigen (HLA) genes [3, 4]. The combination of HLA class II haplotypes DR3-DQ2 and DR4-DQ8 confers a very high risk of T1DM, whereas those who carry only one of the two risk haplotypes have moderately increased risk. Several other alleles, including those in class I loci, further influence the genetic risk. More details on the role of genetic factors and the pathological process are covered elsewhere in this volume. Diagnosis of T1DM among children is considered relatively simple, typically

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

with very high glucose levels and clear dependence upon insulin, but classification and early detection become increasingly difficult with increasing age.

Occurrence of T1DM by age, sex, place, and time

The World Health Organization (WHO) DIAMOND Study (Multinational Project for Childhood Diabetes) [5] and the EURODIAB ACE Study [6] have collected standardized incidence data for T1DM among children aged under 15 years, based on notification by the diagnosing physician and date of diagnosis, defined as the date of first insulin injection. In both projects, the degree of undercounting of cases has been estimated using a second source of information.

Incidence rates are calculated as the number of new cases per 100,000 person-years. Person-years are typically estimated by the mean population size in each calendar year, sex, and age group. The proportion of the population expected to develop the disease by a certain age, the cumulative incidence, can be approximated by multiplying the average incidence rate in an age group by the number of years covered by the age group. For instance, if the average incidence rate among 0–14-year-olds is 20 per 100,000 person-years, then ([20/100,000] × 15 = 0.003) 0.3% of children in that population will develop disease before they reach 15 years of age. Note that this corresponds closely to the prevalence at age 15 years (assuming no mortality), while the prevalence in the age group 0–14 years will be substantially lower.

Most of the incidence data available today come from studies of children in European countries. Incidence data from Africa are still sparse, but increased information on the incidence of T1DM among Asian and South American populations has changed the understanding of the global patterns in variation in incidence.

Occurrence of T1DM by age

In principle, T1DM may occur at any age, but it is very rare in the first year of life and becomes increasingly difficult to distinguish from other types of diabetes after about 30 years of age. Essentially all populations display a steady increase in incidence rate with age up to around 10–15 years [5], but more recent data from Finland indicate an incidence in 0–4-year-olds that is nearly as high as that in 10–14-year-olds [7]. The incidence rate increases from birth to peak at around puberty (Figure 3.1) and in most populations is lower among 15–29-year-olds than among 0–14-year-olds [8–12]. In some populations there seems to be a second rise in incidence after the age of about 25–30 years [13–15].

In the Swedish nationwide prospective incidence study of 15–34-year-olds, 78% of the newly diagnosed participants were classified as having T1DM and 15% as having type 2 diabetes mellitus (T2DM) at the time of the diagnosis [16]. The follow-up showed that 92% of participants diagnosed before 30 years of age were treated with insulin at a later date [17]. These findings are consistent with incidence data from Finland among 15–39-year-olds [18, 19]. In these studies, the incidence of T2DM exceeded that of T1DM by the age of about 30 years. By contrast, in Turin, Italy, which has a much lower incidence of T1DM, the incidence of T2DM is about three times higher than that of T1DM at the age of 30 years [13]. Although beyond the scope of this chapter, it is important to consider the possible clinical heterogeneity and increasing difficulty of classification of diabetes with increasing age, and also potential monogenic diabetes among those with very early onset [20]. A proportion of the apparent heterogeneity may represent extremes within a continuum.

There is a lack of population-based incidence data for age groups above 35 years of age. The only published population-based incidence studies covering the incidence of T1DM over the whole age span is one from Rochester, Minnesota, 1945–1969 [21]

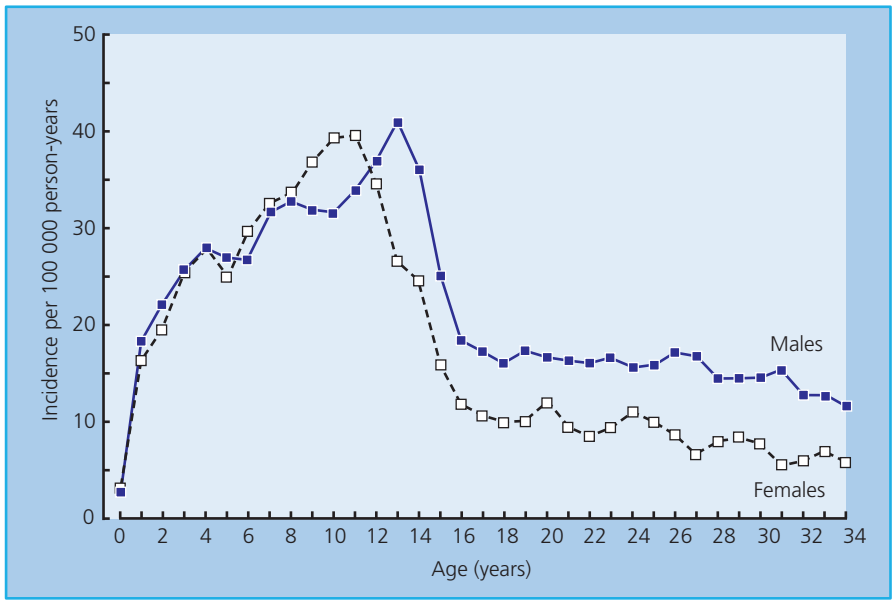

Figure 3.1 Incidence rate of type 1 diabetes per 100,000/year in Swedish males and females by age during 1983–1998. Source: Pundziute-Lyckå et al. 2002 [11]. Reproduced with permission of Springer.

and from Denmark, 1973–1977 [22]. The latter study indicated that the cumulative probability of developing T1DM before age 80 years is in the range 1–1.5%.

Incidence by sex

The peak in incidence rate among children occurs slightly earlier in girls than boys (Figure 3.1), suggesting an influence of puberty. During the 1970s, there was a male excess of T1DM in children in populations of European origin and a female excess in populations of African and Asian origin [23]; however, during the early 1990s, the sex-specific pattern in incidence among children changed towards more modest differences. Of 112 centers with data during 1990–1999, only six showed a significant excess of females (Beijing, Hong Kong, and Zunyi in China, New South Wales in Australia, Puerto Rico, and the African American ethnic group in the United States) and six centers showed a significant male excess (West Bulgaria, Finland, and Attica in Greece, Switzerland, Oxford in the United Kingdom, and the Dominican Republic), and all differences were generally of modest magnitude [5]. The general impression is still that it is the high-incidence countries that tend to have a slight male excess, whereas the opposite is seen in low-incidence countries. Many studies have shown a male excess in the incidence of T1DM among young adults. Whereas the male : female ratio among children in most populations is 0.9–1.1 [5], the male : female ratio among young adults ranges from about 1.3 up to 2.0 in many populations [12, 24].

Incidence by country

The incidence rate of T1DM among childhood populations shows a vast geographic variation worldwide (Figure 3.2) [5, 25–27]. Over the period 1990–1999, the age-adjusted incidence rate of T1DM ranged globally from 0.1 in Zunyi (China) and Caracas (Venezuela) to 37.8 in Sardinia and 40.9 per 100,000/year in Finland [5]. The most recent data from Finland indicate an incidence rate of nearly 60 per 100,000 in 2006 [7], the highest incidence ever recorded.

European countries are well represented with registries, and there is an ~10-fold difference between highest and lowest incidence countries in Europe [26], with the apparently lowest rate of 3.6 per 100,000/year in Macedonia during 1989–1994. Sweden has a high incidence rate (30 per 100,000/year). Centers in France and mainland Italy, for instance, report intermediate incidence rates of ~10 per 100,000/year, whereas some other European countries have intermediate to high incidence rates [5]. In general, the incidence rates are low in Eastern European countries, although the most recent EURODIAB data show that for several countries where the incidence rate previously was below 10 per 100,000/year, during 1999–2003 it increased to 10 per 100,000/year or more, for example, in Lithuania, Bucharest in Romania, and in Katowice in Poland [27].

Standardized data for the age group 15–29 years from European centers (in Belgium, Lithuania, Romania, Sardinia, Slovakia, Spain, Sweden and the UK) during 1996–1997 showed incidence rates between 5 and 12 per 100,000/year [12]. Incidence rates among 15–29-year-olds within this range have also been reported, albeit from earlier time periods, in other European centers, such as 5.5 per 100,000/year in Rzeszow, Poland, in 1980–1992 [28], ~7 per 100,000/year in Turin, Italy, in 1984–1991 [13, 29], and ~13 per 100,000/year in two regions of Denmark in 1970–1976 [8].

Although Sweden and Sardinia had higher incidence rates among children, the incidence rate among young adults was not much higher there than in the other centers in the multicenter study [12]. Older data from Norway (1978–1982) [10] indicated a higher incidence rate of 17 per 100,000/year and more recent data from Finland (1992–2001) [18] indicated 8 per 100,000/year among 15–29-year-olds. Recent data on new users of insulin (and no other hypoglycemic agents) indicated stable incidences over 30 per 100,000/year among 15–29-year-olds in Norway during 2006–2010 [30]. In addition to problems with correct classification of type of diabetes in adults mentioned above, incomplete ascertainment may also be a greater problem for young adults than among children [31], whereas incomplete ascertainment is not a likely problem with the insulin use data. Differences between countries in the incidence among young adults should be interpreted with caution until more data are collected using comparable methodology.

The USA is represented with the data collected during the 1990s from Allegheny County in Pennsylvania, Chicago in Illinois, and Jefferson County in Alabama, with incidence rates in the range 11–18 per 100,000/year among children. Alberta and Calgary in Canada had slightly higher rates (~23 per 100,000/year; Figure 3.2) [5], while the data from the Avalon Peninsula, Newfoundland, indicated a higher incidence rate of 35.9 per 100,000/year [32].

In South America, children in centers in Venezuela, Paraguay, and Colombia had incidence rates of <1 per 100,000/year, Chile (Santiago) had ~4 per 100,000/year, and Argentina and Brazil had an average of ~8 per 100,000/year. Many centers in Central America and the West Indies (except Puerto Rico and St. Thomas) generally had low to intermediate incidence rates, with indications of decreasing time trends [5].

Data from New Zealand and parts of Australia show moderate to high incidence rates (15–25 per 100,000/year) among children [5]. Data from other Pacific Island countries are lacking, and would be difficult to interpret because the populations in most island countries are small. In Asia, the mean incidence rate among the 23 centers in China during the early 1990s was 0.8 per 100,000/years. Japan had a slightly higher average incidence rate of 1.7 per 100,000/year among three centers, and Kuwait stood out with a high incidence rate of 22 per 100,000/year.

There is limited information on the incidence rate of T1DM from sub-Saharan Africa [33]. The five DIAMOND centers are all in North Africa (Algeria, Libya, Sudan, and Tunisia) or Mauritius, an island off the coast of Madagascar. Incidence rates reported from these centers range from low to intermediate, but these countries cannot be said to be representative of Africa.

Additional incidence data from other regions are discussed in sections below.

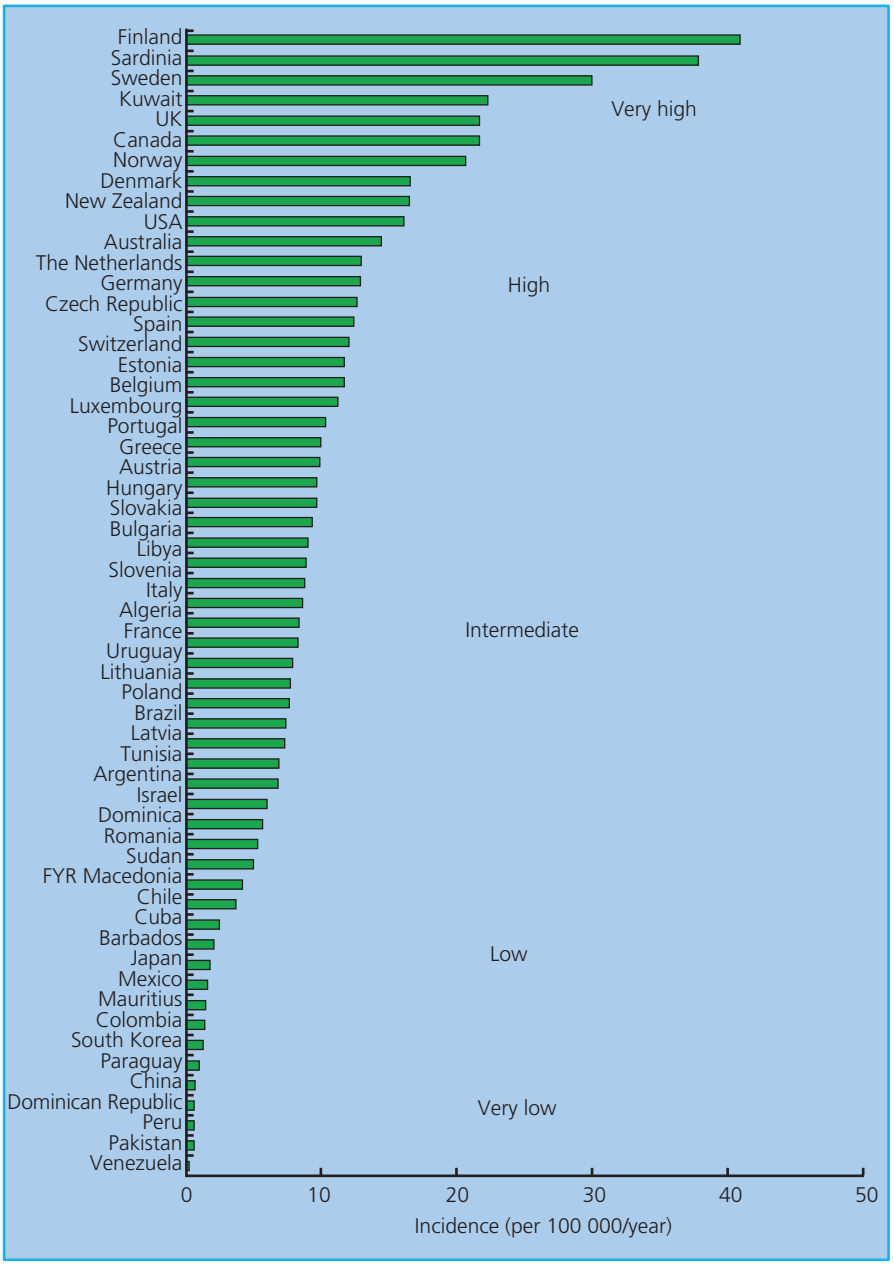

Figure 3.2 Geographic variation in childhood onset type 1 diabetes incidence rates, 1990–1999. Note that most registries were not nationwide and that several countries display within-country variation. Source: The DIAMOND Project Group 2006 [5]. Reproduced with permission of John Wiley & Sons.

Trends in incidence over time

The methodology for population-based incidence registries was not standardized until the late 1980s, but a number of older data sources have been reviewed to assess possible time trends. There is a general impression that the incidence of T1DM increased strongly after the middle of the 20th century [34, 35], although in Denmark the incidence among 0–29-year-olds seemed stable from 1924 to the 1970s [8]. An analysis of incidence trends of more standardized registry data from 1960 to 1996 in 37 populations worldwide showed a significant increase in incidence rate over time in the majority of populations, with a steeper relative increase in low-incidence than in high-incidence populations [36].

In the 103 centers participating in the WHO DIAMOND project for at least 3 years during 1990–1999, the overall relative increase in incidence rate was 2.8% per year [5]. By continent, overall increasing trends per year were estimated at 5.3% in North America, 3.2% in Europe and 4.0% in Asia [5]. The only regions with an overall decreasing trend were Central America and the West Indies [5].

In general, the increasing trend appeared to be strongest in the centers with high and very high incidence rates during the 1990s. In the centers with low and very low incidence rates, there were no significant increases in incidence rates over time. However, the 15-year (1989–2003) time trends in Europe reported to EURODIAB indicated an overall mean increase in incidence

rate of 3.9% per year, with a tendency towards stronger relative increases in the countries with the lowest average incidence rates during the first 5 years (1989–1994) [27].

Overall, the relative increase over time during the 1990s among the DIAMOND centers was most pronounced in the younger age group: 4.0% among 0–4-year-olds, 3.0% in 5–9-year-olds and 2.1% in 10–14-year-olds, and was similar for boys and girls in most centers. The pattern of a steeper relative increase among the youngest was seen in Europe and Oceania, but not in Asia and North America [5]. A smaller relative increase in incidence rate over time among older individuals than among younger ones has also been seen in European studies covering wider age ranges [11, 14, 15, 37, 38]. This latter observation is in line with a model where a certain pool of genetically susceptible individuals contract the disease at younger ages [11, 14, 39]. The few available data, however, are not entirely consistent with this idea. An increasing incidence rate has been seen also among older age groups in some populations [15, 19, 29], but the lack of standardized incidence data covering the whole age range makes it difficult to draw firm conclusions. Note that despite the time trends indicated in Sweden with decreasing average age of onset, the peak incidence rate remained around the age of puberty [11].

In Finland, the incidence rate increased linearly from the mid-1960s to the mid-1990s [40] and thereafter even more steeply, reaching almost 60 per 100,000/year in 2006. After a peak in 2006, the incidence among children in Finland seems to have plateaued [41]. However, when considering the year-to-year variation in long-term data from Finland and other Nordic countries, this may well be only temporary (Figure 3.3). Whereas data from the Swedish Childhood Diabetes Register suggested a possible plateau in the incidence in Sweden in 2006 [42], other register data from Sweden showed a continuing increase up to 2009 [43]. Furthermore, data from Germany [44], Israel [45], USA [46], Yorkshire, UK [47], and Shanghai, China [48] show these to be examples of countries or regions with continuing rises in incidence up to recent years. Data from Western Australia suggest a continuing increase over the long term, but that the incidence varies in cycles of ~5 years [49]. Similar patterns have been observed elsewhere, but it does not seem to be a general pattern (Figure 3.3). On the other hand, a plateau in incidence in Norway is strongly suggested from about 2004 to 2012 [50]. Also, in the Czech Republic, the incidence among children seems to have leveled off [51]. We are not aware of countries where consistent and significant decreases in incidence have been observed during the past 2–3 decades. When stratified by sex and age groups, the year-to-year variation in most studies becomes very large and trends should be interpreted with caution. It should be clear from the observed long-term trends (Figure 3.3) that predictions about future trends in incidence rates are more or less futile.

Variation in incidence within countries, including by ethnic group

In several countries, marked within-country variations in the incidence rate of T1DM have been reported, even in relatively homogeneous populations. Marked ethnic variations have also been observed, generally in line with differences in countries or regions discussed above, and some geographic differences may be due in part to differences in the distribution of ethnic groups. Potential methodological problems should be considered when making inferences based on epidemiological studies of different ethnic groups and immigrants. These include differential ascertainment and definition of ethnic group, underestimation of the base population in some ethnic groups, genetic admixture, and possible heterogeneity in clinical presentation [20, 52]. Among childhood-onset cases, however, it seems that the large majority, even in Japan [53], have classic autoimmune T1DM.

Historically, the incidence of T1DM has been higher in populations of European origin, particularly those living in Europe, than that among populations of non-European origin [52, 54]. The incidence rates of T1DM in most South American studies with standardized registries seem to be much lower than those among Latino people in the USA and lower than those among Spaniards living in Spain [52]. Data from the SEARCH study in the USA showed clear ethnic differences in the prevalence of T1DM in 2009 [55]. The highest prevalence was among non-Hispanic white

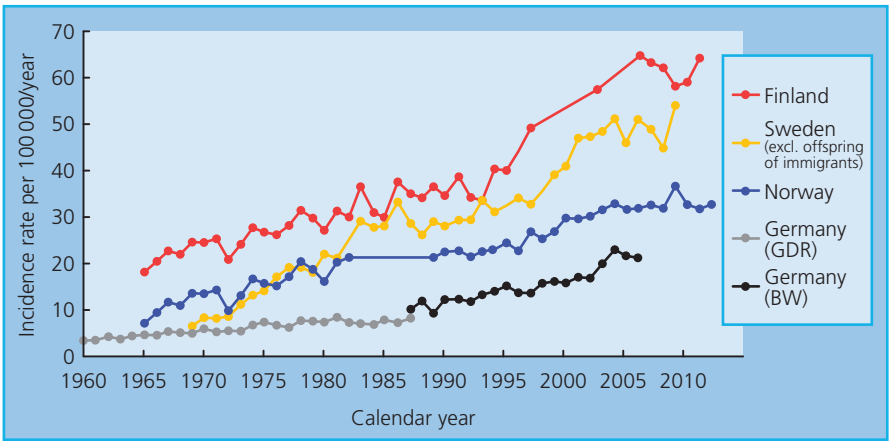

Figure 3.3 Long-term time trends in incidence rate of type 1 diabetes diagnosed before 15 years of age in Finland, Sweden, Norway, and Germany. Source: Data from Tuomilehto et al. 1999 [40], Harjutsalo et al. 2008 [7], Harjutsalo et al. 2013 [41], Hussen et al. 2013 [43], Joner & Søvik 1989 [163], Skrivarhaug 2014 [50], and Ehehalt et al. 2012 [44]. Finish data 1965–1996 are for age group 1–14 years, and thereafter 0–14 years (and data from 1997 to 2005 are averages for three calendar years); all other data are observed incidence per calendar year without smoothing of curves. Nordic data are from nation-wide registries and German data are from former Eastern Germany (GDR) and the Baden-Württemberg registry 1987–2006.

youth, while African American and Hispanic youth had approximately half, Asian Pacific Islanders approximately one-quarter, and American Indian youth approximately one-seventh of the prevalence compared with non-Hispanic white youth. Other studies have indicated that the differences in incidence among ethnic groups in the USA are less dramatic, at least for some groups in some regions of the USA [5, 54]. It is worth noting that many ethnic groups in the USA have considerable admixture with people of European ancestry, which may dilute any potential effect of ethnicity on T1DM risk.

Up to 1.5-fold differences have been described among counties or regions within Finland, Sweden, and Norway [56–58]. In Italy during 1990–2003, the incidence rate among children varied from ~40 per 100,000/year in the island Sardinia, from 11 to 19 per 100,000/year in regions of northern mainland Italy, and from 8 to 12 per 100,000/year in the central-southern part of Italy [59]. Sardinia's population history is different from that for mainland Italy. Children born in families who moved to mainland Italy from Sardinia kept their high T1DM incidence [60]. In New Zealand, the 1.5-fold higher incidence among children in the South Island compared with that in the North Island was largely explained by the 4.5 times higher incidence among children of European origin compared with that among Māoris [61]. In China, there was a 12-fold geographic variation (0.13–1.61 per 100,000/year), generally with higher incidence in the north and east. In addition, there was a sixfold difference between the Mongol (1.82 per 100,000/year) and the Zhuang (0.32 per 100,000/year) ethnic groups [62]. Considering immigrants as a single group, the time trends in incidence differed significantly from "ethnic Swedes" from the late 1980s and onwards [43] (Figure 3.4). In Israel, there was a parallel increase over time, but a consistently lower incidence in childhood-onset T1DM among non-Jews (mainly Palestinians) than among Jews during 1997–2010 [45]. There also seemed to be a systematically lower incidence among South Asian than among non-South Asian children in Yorkshire [47] (Figure 3.4).

The incidence of T1DM among children of immigrant parents in Germany, Sweden, and mainland Italy has been shown to correlate with the incidence in the country or region of origin of their parents, whether the incidence in the country of origin is higher or lower [60, 63, 64]; however, the incidence among immigrants from Pakistan to the UK (or their children) is similar to that among native Britons [65, 66], despite the very much lower incidence recorded in Karachi, Pakistan [5].

In summary, although there are clear ethnic differences in incidence rate of T1DM and strong evidence for a role of genetic factors, some of the above-mentioned studies also suggest a possible role for as yet unidentified environmental factors.

Seasonal variation in diagnosis of T1DM

Several studies have reported a peak in the number of cases diagnosed in the autumn (fall) and winter, and a smaller proportion of cases diagnosed in the spring or summer, consistent in both the northern and southern hemispheres [9, 26]. Although reasonably consistent, there is some variation in exact peak and nadir between countries, age groups, sexes, and periods. Generally, the degree of seasonal variation is stronger among those diagnosed at age 10–14 years than in younger children (Figure 3.5) [26]. Different methods have been used in the analysis of seasonal variations, and often with data covering relatively short periods of time and a limited number of cases; the results are therefore not necessarily comparable. Interpretation of seasonal variation must be carried out in light of the long and variable preclinical period in T1DM, and it is speculated that viral or other periodic factors have a role in the timing of the precipitation or onset of the disease in susceptible individuals who would develop it sooner or later.

Familial clustering and twin studies

In addition to providing clues regarding the relative importance of genetic and non-genetic factors in the etiology of disease, data on risk of T1DM among people with affected relatives may also

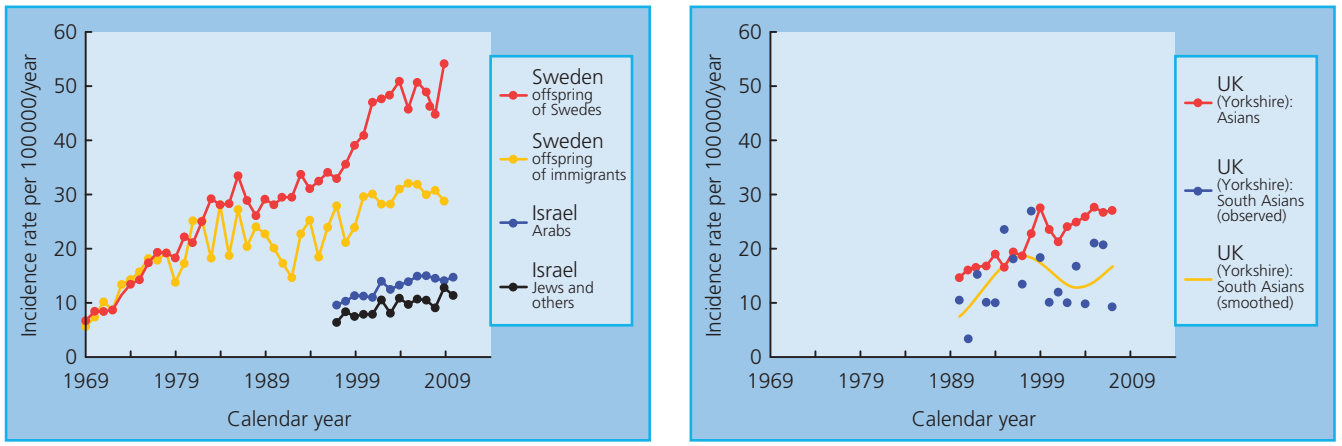

Figure 3.4 Incidence trends in type 1 diabetes among ethnic groups in Sweden and Israel (left panel) and Yorkshire, UK (right panel). Source: Data from Hussen et al. 2013 [43] and Harron et al. 2011 [47]. Note that the data from Israel shown here are for ages below 15 years, as for the Swedish and UK data. R.C. Parslow and O. Blumenfeld kindly provided raw data for UK and Israel, respectively.

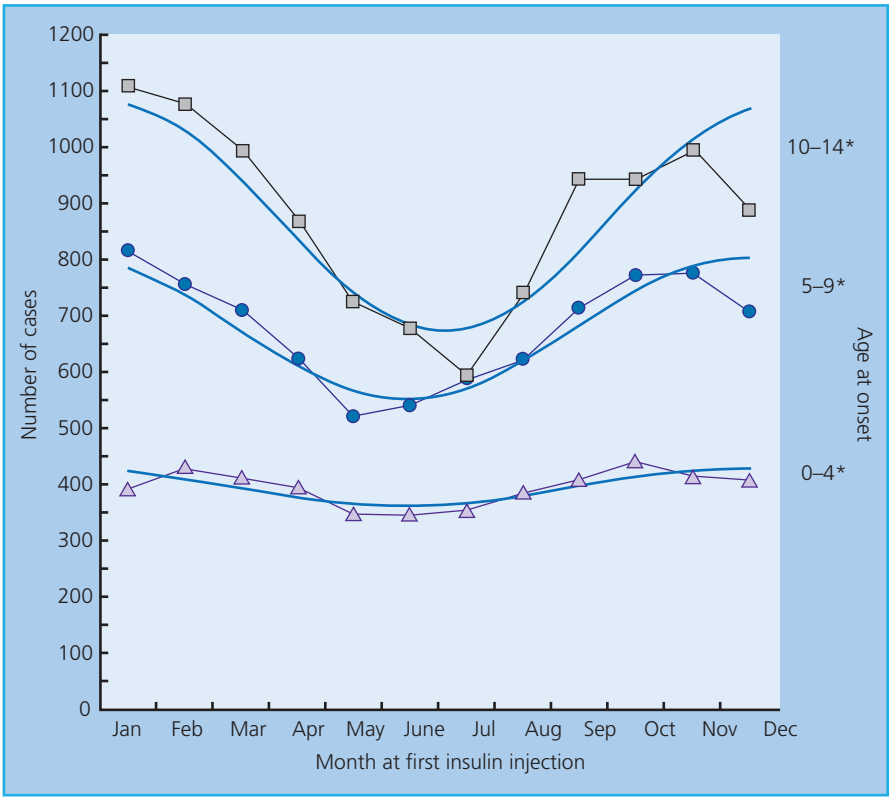

Figure 3.5 Seasonal variation in diagnosis of type 1 diabetes among >22,000 children diagnosed 1989–1998 in European centers, by age at onset. *Age (years) at first insulin injection. Source: Green and Patterson 2001 [26]. Reproduced with permission of Springer.

aid the clinician in counseling family members of newly diagnosed individuals. Around 80–90% of people with newly diagnosed T1DM do not have any affected siblings or parents, but first-degree relatives of a person with T1DM are at increased risk. By the age of 20 years, ~4–6% of siblings of T1DM probands have been reported to develop T1DM in populations of European origin [67–69], compared with around 0.2–1.0% in the corresponding background populations. The offspring of affected fathers have a 1.5–3-fold increased risk of T1DM compared with the offspring of affected mothers [70, 71]. By 20 years of age, 5–8% of the offspring of men with diabetes, but only 2–5% of the offspring of women with diabetes, have been found to be affected. There is currently no accepted explanation for this phenomenon.

Given the well-established effect of genetic factors, it is no surprise that the concordance rate for T1DM in monozygotic (MZ) twins is much higher than that in dizygotic (DZ) twins [72, 73]. In one study from North America, the estimated cumulative risk 10 years after onset in the proband (diagnosed before age 40 years) was about 25% in MZ twins and about 11% in DZ twins [74]. Corresponding 10-year cumulative risks from Finland were estimated as 32% for MZ twins and 3.2% for DZ twins [73]. Comparable estimates were also found in the Danish twin registry, although the exact age at onset was not known in this study [72]. In general, the risk for the co-twins was higher and the discordance time shorter the earlier the onset in the proband [73–75]. In a long-term follow-up of discordant MZ twins from the USA and the UK, more than 50% of MZ pairs remained discordant for T1DM (Figure 3.6) [75]. Because MZ twins share 100% of their genomic DNA, this suggests that genetic susceptibility is in most cases not sufficient for the development of disease.

Despite the relatively high proportion of MZ twins being discordant for clinical T1DM, many of the non-diabetic co-twins of persons with T1DM develop islet autoimmunity [76]. Together with the limited variation in prevalence of positivity for islet autoantibodies between countries [39] and animal studies suggesting a two-stage disease process [77], this supports the idea that environmental factors may have an important role in the progression from islet autoimmunity to overt disease.

Environmental risk factors for T1DM: clues from epidemiological studies

The time trends described above must be ascribed to some change in the environment, even in the event that the increase is brought about by a change in the age distribution. Some of the variation in incidence rate between European countries can be explained by differences in the frequency of HLA susceptibility genotypes [78], but clearly not all [79]. It has been suggested that the proportion of persons with newly diagnosed T1DM who carry the highest risk genotype (DR3-DQ2/DR4-DQ8) has decreased over time (reviewed in [80]). It may be speculated that increased exposure to some risk factor or decreased exposure to some protective factor have caused more individuals with moderate risk

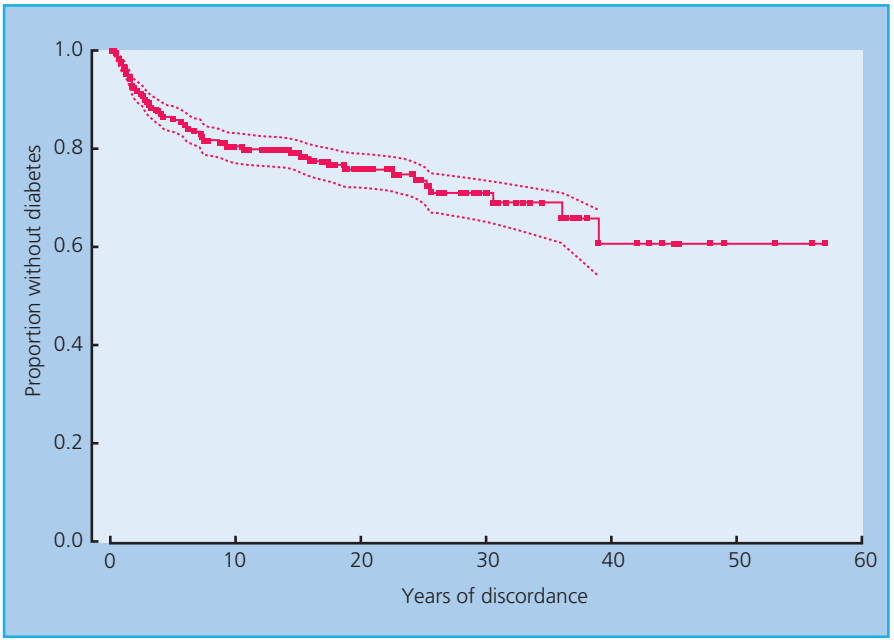

Figure 3.6 Diabetes-free survival in non-diabetic monozygotic twins whose co-twin had type 1 diabetes, after several years of follow-up. Dotted lines represent 95% confidence intervals. Source: Redondo et al. 2001 [75]. Reproduced with permission of Springer.

("permissive") genotypes (e.g. either DR3-DQ2 or DR4-DQ8, but not both) to develop T1DM in recent years. Although there is overwhelming evidence for an essential role of genetic factors in the etiology of T1DM, available evidence strongly suggests that one or more non-genetic factors are also involved; however, the nature of these putative factors is not well known.

In general, environmental factors may be envisioned to have a role in the following:

1 initiating of the autoimmune disease process;

2 modulating the progression from islet autoimmunity to clinical T1DM; or

3 "precipitating" disease in individuals with advanced preclinical disease.

Little is known about the initiation of autoimmunity in humans [81], but some form of immune-mediated mechanism leading to the breakdown of self-tolerance is likely to be involved. An incidence peak in islet autoimmunity in the second year of life and instances of very early seroconversion for islet autoantibodies among children who develop T1DM suggests that potential environmental factors influencing step 1 are likely to operate very early in life [82]. Limited geographic variation in the prevalence of islet autoimmunity despite the large differences in incidence of T1DM between countries suggests a major importance of environmental factors in the progression from islet autoimmunity to T1DM [39], although the hypothesis that there are environmental triggers of autoimmunity cannot be discarded [83]. Responsible factors may operate by modulating the immune system and metabolism. *In vitro* experiments have suggested that actively insulin-secreting β cells hyperexpress islet autoantigens such as GAD, and are more susceptible to toxic effects of the cytokine interleukin-1β [84]. It may be speculated that factors that increase the stress on β cells may contribute non-specifically to the precipitation of clinical disease [84]. This includes insulin resistance or other mechanisms implied in infections, puberty, and growth spurts. Insulin resistance is not easy to measure reliably in humans, but several studies have found measures of insulin resistance relative to first-phase insulin response to an intravenous glucose tolerance test to be predictive of progression to T1DM (reviewed in [85]). Below, some of the most frequently studied non-genetic factors with a potential role in the etiology of human T1DM are discussed.

Specific putative environmental factors

Viral infections

There is a large body of literature linking infections and T1DM [86], but the link has not been established as causal in humans. Studies vary in design, ranging from *in vitro* studies [87], experiments with various animal models [88], studies of people with disease including of pancreatic tissue [87, 89–92], and epidemiological case–control and cohort studies [9, 93–95]. Congenital rubella syndrome has been associated with a several-fold increase in the incidence of T1DM [96]. Although not contributing to the incidence of T1DM in most countries today, this observation has been cited as a proof of principle that intrauterine factors and viral infections in general can influence the risk of T1DM in humans. It probably remains the best example of a non-genetic factor contributing to increased risk of T1DM in humans, but the consistency of the available evidence and the absolute risk associated with congenital rubella syndrome may have been overstated [97, 98].

Several early studies based on assays for antibodies to enteroviruses in cases with T1DM and controls initially seemed promising, but systematic review of the data showed too much

heterogeneity in the methodology and results to be able to draw any conclusion [93]. Prospective study design and detection of enterovirus RNA represent important contributions to the methodology of such studies in recent years, but a careful review of available data revealed only limited consistency across studies with similar design [95].

Increased risk of childhood-onset T1DM has been associated with evidence of maternal enterovirus infections during pregnancy in some studies, but not in all [95, 99]. Using both serum enterovirus antibodies and RNA as indications of postnatal infection, independent prospective studies from Finland have found enterovirus to be associated with increased risk of islet autoimmunity and T1DM [83], whereas other similar studies did not find any significant association [95]. It seems that the presence of viral particles in the blood is more strongly correlated to T1DM than mere presence in the stool, although still larger studies are needed [94, 95, 100]. An immunohistochemical study of stored sections of pancreatic biopsies obtained post-mortem in young individuals with recent-onset T1DM found that the β cells of multiple islets stained positive for enterovirus capsid protein VP1 in 44 of 72 cases. Very few of the controls in that study stained positive [91]. This study substantiated previous evidence based on one or a few participants [89, 90] and indicated problems with the methods used in a previous study of a similar material where no such evidence was found [101]. Based on early data [89], the Coxsackie B4 serotype of human enterovirus has been suspected to be particularly diabetogenic. Technical difficulties with the detection and interpretation of small quantities of viral particles remain, but a recent study found signs of enterovirus by multiple techniques and in different laboratories in fresh pancreatic tissue obtained from six newly diagnosed young adults with T1DM [92]. Nevertheless, the serotype or other characteristics of the enterovirus could not be determined in this study. Recently, application of serotype-specific neutralizing antibody tests to the prospective DIPP study suggested a novel association between the Coxsackie B1 serotype, and rather a possible protective association with Coxsackie B4, but this needs to be replicated [83].

Enterovirus infections are common and there is evidence that the frequency of infection has decreased with improved hygiene in recent decades, opposite to the trend seen for T1DM. It has been postulated that the increasing incidence of T1DM in children may be explained in part by decreased protection from maternal enterovirus antibodies [102]. A more direct test of this hypothesis is still lacking.

The so-called "hygiene hypothesis" comes in different versions but essentially proposes that the decline in microbial exposure in many populations over the past few decades has caused a concomitant increase in incidence of immune-mediated diseases, including T1DM [103]. Some infections and microbial agents reduce the incidence of autoimmune diabetes in experimental animals [104]. Epidemiological studies have investigated non-specific infections and infectious symptoms, but the results have been inconsistent. Daycare attendance is usually associated with increased exposure to microbial agents, and a meta-analysis concluded that there is some evidence for a lower risk of T1DM among children who attended daycare centers early in life, but the results were not sufficiently homogeneous to allow a strong conclusion [105].

There are many promising observations supporting a possible role of viral infections in the etiology of T1DM, but the current evidence that infections have an important and causal role in human T1DM is not conclusive. Although the problem of identifying the potential strain of enterovirus that might be diabetogenic would pose an additional problem, early work on vaccine development towards such a strain is in progress. Others have suggested that it may be possible to develop a vaccine that can reproduce the potential beneficial effects of viral infections (cf. "hygiene hypothesis") regardless of the existence or identification of one or a few diabetogenic viral serotypes [104]. However, it is currently unknown whether such vaccines will be efficacious and feasible for the prevention of T1DM.

Toxins

A number of other environmental chemicals may influence the immune system and potentially the risk of T1DM [106]. The rodenticide Vacor has been associated with T1DM in humans after ingestion of large doses [107]. There are structural and mechanistic similarities between Vacor and streptozotocin and alloxan [107], which are specifically toxic to β cells, and used to induce diabetes in experimental animals [107, 108]. Some epidemiological studies have assessed the intake of nitrates and nitrites, which may be converted to related *N*-nitroso compounds, but most studies have used ecological study designs and assessed levels in community drinking water, which is probably a poor indicator of total exposure. A potential diabetogenic role of *in utero* exposure to bafilomycin, a toxin produced by bacteria growing on the skin of root vegetables such as potatoes, has been suggested based on experiments with rodents and *in vitro* studies [109]. In a prospective study, there was no support for the idea that frequent potato consumption during pregnancy could increase the risk of islet autoimmunity in the offspring, but it is unknown whether frequency of potato intake really is a marker for bafilomycin exposure [110]. In a case–control study nested within a cohort of pregnant women, persistent organochlorine pollutants in stored sera were not associated with later risk of T1DM in the offspring [111]. If anything, there was a tendency towards inverse associations. In conclusion, few high-quality studies are available on the potential influence of environmental chemicals on T1DM incidence in the population, and there is currently little direct evidence for an important involvement of such factors in human T1DM.

Nutritional factors

Several possible plausible mechanisms have been proposed to link dietary factors to T1DM, including "molecular mimicry" and a detrimental effect of bovine insulin in cow's milk (reviewed in [112]). A reduced risk conferred by prolonged breastfeeding and/or delayed introduction of cow's milk has been suggested in

many case–control studies, but most of these studies were susceptible to recall bias and the issue is controversial [113]. Prospective studies of genetically susceptible children have found mixed results. In the DIPP study, neither multiple islet autoantibodies nor T1DM were associated with duration of exclusive or total breastfeeding [114], whereas the DAISY study found an association between early or late introduction of solid foods and increased risk of T1DM [115]. In MIDIA, there was an inverse association between long duration of any breastfeeding and risk of T1DM, but no association with duration of full breastfeeding, age at introduction of solid foods, or breastfeeding when introducing solid foods [116]. Duration of breastfeeding was not associated with self-reported T1DM up to age 30 years in a prospective population-based study including 61 cases [117]. It is difficult to differentiate the role of breastfeeding versus introduction of weaning foods, but the hypothesis that delaying the introduction of intact cow's milk proteins (regardless of breastfeeding duration) is tested in a large randomized trial called the TRIGR. While results for the primary endpoint (T1DM at age 10 years) are expected in 2017, the intervention showed no significant reduction in positivity for multiple islet autoantibodies [118].

The immunomodulatory effects of vitamin D and the preventive effect of pharmacological (hypercalcemic) doses of 1,25-dihydroxyvitamin D on diabetes development in experimental animals have been documented in several studies [119]. Systemic concentration of 1,25-dihydroxyvitamin D is tightly controlled by hydroxylation of 25-hydroxyvitamin D, and this must be taken into account when evaluating experimental results from animal models. Vitamin D is also produced in the skin upon exposure to ultraviolet light, and no prospective study has yet been published of serum 25-hydroxyvitamin D, which is an established marker of vitamin D status, and risk of T1DM. A multicenter case–control study found a significantly lower risk of T1DM associated with reported use of vitamin D supplement in early life [120], although recall and selection bias may have affected these findings; however, this was also supported by a prospective Finnish study [121]. In the DAISY study of genetically predisposed children followed longitudinally, there was no significant association between 25-hydroxyvitamin D in serum from toddlers and risk of islet autoimmunity or progression from islet autoimmunity to T1DM [122]. The German BABYDIAB study similarly found no significant association between circulating 25-hydroxyvitamin D and progression from islet autoimmunity to T1DM [123]. Prospective studies of maternal intake of vitamin D via food during pregnancy and risk of islet autoimmunity in children have not produced convincing evidence for any relation [124]. However, a study in Norway found a significant association between low 25-hydroxyvitamin D in late pregnancy and higher risk of T1DM in the offspring [125]. A study of serum 25-hydroxyvitamin D in pregnant women collected during the first trimester of index pregnancies did not find any significant association with risk of childhood-onset T1DM in the offspring [126].

A case–control study in Norway found an association between the use of cod liver oil in the first year of life and lower risk of T1DM [127]. Cod liver oil, which is commonly used in Norway, is an important source of both vitamin D and long-chain n-3 fatty acids docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) in this population. The lack of association with other vitamin D supplements in these studies supports a role of n-3 fatty acids rather than vitamin D. Recall bias cannot be ruled out entirely from the latter study. Although support for the hypothesis that intake of dietary n-3 fatty acids may prevent islet autoimmunity and/or T1DM came from a prospective study including both dietary assessment and analysis of fatty acid composition of red-cell membranes, which is a biomarker of n-3 fatty acid status [128], a later follow-up of this study did not find any association with progression from islet autoimmunity to T1DM [129].

Despite previous indications from two prospective studies that serum α-tocopherol (vitamin E) could be associated with lower risk of T1DM, there was no association with advanced islet autoimmunity or T1DM in early life in the DIPP study [130]. In conclusion, the role of nutritional factors in T1DM remains uncertain.

Perinatal factors and postnatal growth

Offspring of mothers without diabetes aged 35 years or more when giving birth have a ∼20–30% increased risk compared with offspring of mothers who are aged 25 years or less [131, 132]. Results for birth order and for paternal age have been less consistent [131, 133, 134]. Birth by cesarean section has been associated with a ∼20% increased risk of T1DM in children according to a meta-analysis of 20 published studies [135]. Although there is some potential for selection bias in the case–control studies included, and the mechanism is unknown, it was speculated that delayed colonization of the infant's intestine associated with cesarean section may be involved. On the other hand, a recent study of discordant sibships did not find any association between cesarean section and T1DM [136].

Increased birth weight has been associated with a relatively weak but significant increase in risk of childhood-onset T1DM in large cohort studies based on linkage of population registries, independent of maternal diabetes and other potential confounders [137]. There have also been studies reporting no significant association, but these were generally smaller case–control studies. Birth weight is certainly only a marker of some other phenomenon and the mechanisms involved remain to be defined.

Associated factors such as postnatal growth or excess body weight might be of relevance. A number of studies have indicated that children developing T1DM are taller, heavier, or gain more weight or height prior to diagnosis compared with their peers [138, 139]. However, there was substantial heterogeneity between studies in methodology and results, such as age at measurement of body size, which body size or growth measurement was associated with T1DM, and how data were analyzed statistically. Many of the published studies were case–control studies, which are prone to selection bias. However, two recent large-scale cohort studies found that for each standard deviation (approximately 1 kg) increase in weight or weight gain up to age 12 months, the risk of

T1DM [140] or multiple islet autoantibodies [141], increased by approximately 20%.

In summary, environmental factors may influence individuals very differently, depending on the genetic background, although direct evidence for specific gene–environment interactions from humans is scarce. No specific single factor has been identified thus far. Taking into account the multifactorial nature of T1DM, specific environmental risk factors with sufficiently large impact to be of clinical importance and detectable in epidemiological studies may not exist; however, identification of potential environmental risk factors and their role in the disease process is important in the potential prevention of T1DM in the future, and lack of consistent findings may reflect lack of properly conducted prospective studies. Given the enormous amount of resources necessary for conducting preventive intervention trials, and the negative results of completed trials, it may be wise to initiate future trials based on consistent findings from properly conducted prospective observational studies.

Mortality

Before the discovery of insulin in 1922, T1DM meant an almost certain death soon after its onset. After the initiation of insulin replacement therapy, a dramatic improvement in survival occurred. Another major improvement in survival occurred in people with diabetes diagnosed in the 1950s [142]; however, even today T1DM is associated with a ~2–8-fold excess risk of premature mortality [143] (Figure 3.7). A large variation in relative mortality has been reported from different countries. For instance, the standardized mortality ratio (SMR) for people with T1DM in Finland was lower than that in Lithuania, Estonia, and Japan [144, 145]. A higher mortality in African American compared with white individuals with T1DM in the USA has been reported, and this difference seems to be attributable to acute complications [146].

Data from Europe showed that the short-term mortality was two times higher in people followed from diagnosis of T1DM in childhood than the respective general populations, with variation in the SMR from about 1.1 to 4.7 in different countries [147]. In a nationwide cohort of individuals with T1DM in Norway followed from onset before 15 years of age and up to 40 years' duration (mean 17 years), the SMR was 3.6 [148]. In a UK cohort of more than 7000 prevalent cases of T1DM with a mean age of 33 years at baseline, the SMR after up to 7 years of follow-up (mean 4.5 years) was 3.7 [149]. Many studies have reported that the SMR varies with age and with diabetes duration, or both, but the results are not consistent among studies.

Ascertainment of cause of death is difficult, but around one-third of the early deaths in the European multicenter study were clearly attributable to diabetic ketoacidosis (DKA), and about half of the relatively few deaths among young people with T1DM seem to be unrelated to diabetes [147, 150]. This was consistent also in a recent study where a clinical committee evaluated

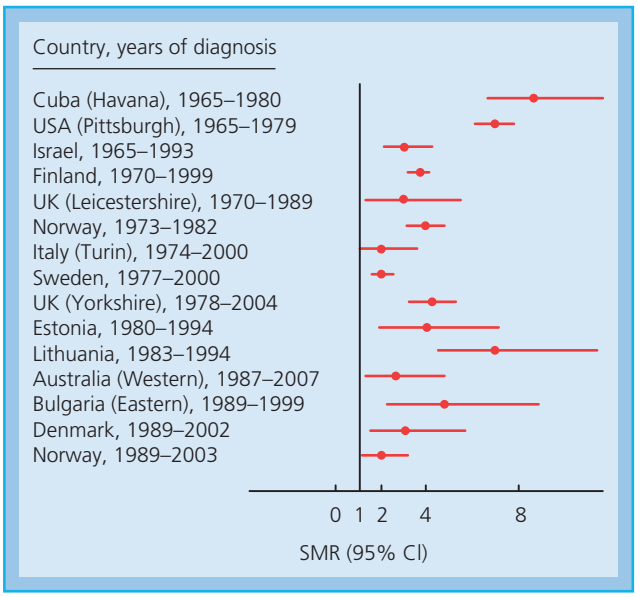

Figure 3.7 Standardized mortality ratios (SMRs) for people followed from diagnosis of childhood-onset type 1 diabetes. Data are from different studies, summarized by Morgan et al. 2015 [143]. Only studies with at least 10 observed deaths are shown. An SMR of 1.0 means a mortality rate among people with type 1 diabetes that is equal to that in the background population for the same age, sex, and calendar period. Studies were sorted by the earliest year of diagnosis of type 1 diabetes, and secondarily by SMR. Note that there were differences in duration of follow-up and other minor methodological differences between studies.

all available death certificates, medical records, autopsy reports, and police reports to adjudicate the cause of death [151]. Hypoglycemia as a cause of death is currently rare compared with DKA, but potentially increasing because of the more vigorous glycemic control suggested for the prevention of long-term complications [152]. After ~10–15 years of diabetes duration, microvascular and macrovascular chronic diabetes complications start to make an impact, and after about 30 years of age cardiovascular causes become increasingly important [153]. The relative mortality from cardiovascular causes is at least as high for women as for men. SMRs for cardiovascular causes of death of 8–40 have been reported in people with T1DM, and the SMR depends strongly on nephropathy [154]. There are some data suggesting that people with T1DM who remain free of nephropathy do not have higher mortality than that in the background population [153, 155], but this has not been confirmed in other studies [156, 157].

There is growing evidence that better glycemic control and improved risk factor control such as lowering of blood pressure and lipids are associated with reduced risk of late complications and improved survival [154]. Long-term follow-up in the DCCT/EDIC showed that multiple daily insulin injections (today's standard mode of treatment) compared with less intensive insulin treatment for 1–15 years resulted in a significant reduction in total mortality [158]. Nevertheless, a large proportion of individuals with T1DM have suboptimal HbA_{1c} levels. Despite the relationship between increased HbA_{1c} and increased mortality,

a Swedish study found that even those with low HbA_{1c} seem to have a significantly higher mortality than people without diabetes [155]. In line with the impression that treatment is gradually improving, people diagnosed with T1DM in more recent years seem to have lower short-term mortality than those diagnosed in earlier time periods [159–161]. Nevertheless, a major gap in mortality compared to the general population remains in recent large-scale studies [162]. A continuing challenge is the deaths of individuals with undiagnosed T1DM and people without access to care in the developing world.

Conclusions

T1DM is one of the most common chronic diseases diagnosed in childhood, but the disease can occur at any age. Its incidence varies drastically between populations and even within populations. T1DM has a strong genetic component and familial clustering, but the majority of cases have no affected siblings or parents. Only a minority of carriers of the susceptibility genes develop T1DM. The incidence of T1DM is increasing in most studied populations at an average rate of ~3–4% per year. The causes of this increase are not known. It is believed that some environmental factors may have contributed to it, but no definite causal environmental factor for autoimmune T1DM has yet been identified.

T1DM was a fatal disease before the insulin era. Although mortality in people with diabetes has decreased drastically, both acute and late complications lead to increased morbidity and premature mortality in T1DM. Primary prevention of T1DM would be the only solution to these problems, but unfortunately no practical preventive measures are currently available.

Acknowledgments

We would like to apologize to the authors of the many original papers that we were unable to cite because of space limitations. L.C. Stene were supported in part by the Research Council of Norway (grant 221909/F20). We thank Torild Skrivarhaug and Geir Joner (Oslo), Roger C. Parslow (Leeds) and Orit Blumenfeld (Ramat Gan) for kindly providing raw incidence data for Figures 3.3 and 3.4.

4 Epidemiology of Type 2 Diabetes

Ronald C.W. Ma and Peter C.Y. Tong
Division of Endocrinology and Diabetes, Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Prince of Wales Hospital, Shatin, Hong Kong SAR, China

Key points

- The prevalence of type 2 diabetes mellitus (T2DM) is increasing worldwide.
- Approximately 415 million people worldwide had diabetes in 2015, making it one of the most common non-communicable diseases globally.
- The largest increase is observed in regions with rapidly developing economies and urbanization.
- The aging population, with an increase in the proportion of people aged >65 years in most countries, has contributed significantly to this increase in prevalence.
- The age of onset of diabetes is also decreasing in many countries, giving rise to an increasing proportion of young people of working age being affected by the disease.
- Several risk factors are known to be associated with increased risk of T2DM. Many of these risk factors are associated with a Westernized lifestyle and increase with urbanization, although novel environmental risk factors have emerged.
- Areas with a high ratio of impaired glucose tolerance (IGT) to diabetes are at an earlier stage of the diabetes epidemic, and thus may be a particular target for preventive strategies.
- The regions with the highest diabetes prevalence rate at present are in the Pacific Islands and Middle East.
- The largest increase in diabetes prevalence is predicted to occur in China and India.
- Diabetes is associated with approximately twofold increased mortality in most populations, with the excess risk decreasing with increasing age.
- The increase in diabetes prevalence, particularly among young adults, along with the increased morbidity and mortality associated with microvascular and macrovascular complications, is likely to lead to an escalation of healthcare costs and loss of economic growth.
- Prevention efforts require widespread public education and coordinated multisectoral efforts to encourage physical activity and a healthy diet.
- Maternal health and the intrauterine environment have also emerged as an important window of opportunity for primordial prevention.

Introduction

Type 2 diabetes mellitus (T2DM) is one of the commonest forms of chronic disease globally and few societies or ethnic groups are spared. It accounts for about 85% of cases of diabetes in white Europeans and virtually all other ethnic groups. In 2015, the International Diabetes Federation (IDF) estimated that 415 million people worldwide had diabetes, of whom 75% live in low- and middle-income countries. Among those aged 20–79 years, about 8.8% had diabetes globally, of whom an estimated 46.5% remain undiagnosed. The highest number of people with diabetes was in the Western Pacific region, with 153.2 million, and the region with the highest prevalence rate, at 12.9%, was North America and the Caribbean [1].

The number of people with diabetes is expected to reach 642 million by 2040, an increase of 55% [1]. The largest increases will be in countries with rapidly growing economies, such as India and China. With the increasing consumption of high-energy food, increasing adoption of sedentary lifestyles and urbanization, increasing numbers of individuals are developing T2DM, and the age at which individuals are diagnosed is decreasing. Individuals exposed to longer periods of hyperglycemia will undoubtedly have increased risks of developing vascular complications related to diabetes. The potential healthcare costs and burden of diabetes in these regions will have a significant impact on the economic growth of these regions, as discussed further in Chapter 5.

The epidemiology and prevalence of diabetes are partly determined by the diagnostic criteria used to diagnose diabetes, and these have been modified on a number of occasions. The diagnostic criteria for diabetes and impaired glucose tolerance are based on epidemiological evidence relating microvascular complications to specific degrees of hyperglycemia, and the fasting glucose cut-off has been modified as new data emerged. These changes have major implications for the interpretations of current and future epidemiological studies on diabetes. In 1999, the diagnostic threshold of fasting glucose was lowered from 7.8 mmol/L (140 mg/dL) to 7.0 mmol/L (126 mg/dL). A fasting glucose level

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

between 6.1 and 6.9 mmol/L (111–125 mg/dL) was considered to be prediabetic and the term "impaired fasting glucose" was used. Subsequent lowering of the "normal" fasting glucose level to 5.6 mmol/L (100 mg/dL) further increases the number of people with "prediabetes." Impaired glucose tolerance (IGT), on the other hand, is another prediabetic state, which is only identified by oral glucose tolerance testing, with a post-load glucose level of 7.8–11.0 mmol/L (140–199 mg/dL). It is estimated that about 318 million people or 6.7% in the 20–79 years age group have IGT [1].

Risk factors for T2DM

Several risk factors are known to be associated with increased risk of T2DM, including increasing age, obesity (especially central obesity), dietary excess, dietary factors such as increased intake of animal fats and sugar-sweetened beverages, sedentary lifestyle, a positive family history, history of gestational diabetes, polycystic ovary syndrome, presence of hypertension, hyperlipidemia, or other cardiometabolic risk factors (Figure 4.1) (see Part 8). Many of these risk factors are associated with a Westernized lifestyle and increase with increasing urbanization and mechanization. The recognition of the role of these factors in the pathogenesis of T2DM has led to recommendations for selective screening for T2DM in people with these risk factors [2, 3].

Several large studies, including the Nurses Health Study in the United States and the InterACT Study in Europe, have contributed to improved understanding of the role of dietary factors and the risk of incident T2DM. Dietary factors that increase the risk for T2DM include the following [4, 5]:

- increased fat intake;
- increased intake of red and processed meat;
- consumption of fried food;
- increased intake of white rice;
- sugar-sweetened beverages.

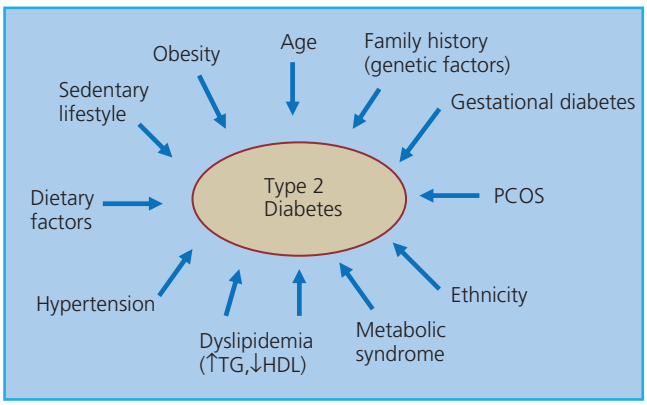

Figure 4.1 Risk factors in the development of T2DM. HDL, high-density lipoprotein cholesterol; PCOS, polycystic ovarian syndrome; TG, triglycerides.

Dietary factors that decrease the risk for T2DM include the following [4, 5]:

- increased fruit and vegetable intake;
- a Mediterranean diet pattern;
- fermented dairy products;
- intake of oily fish;
- tea.

Obesity accounts for 80–85% of the overall risk of developing T2DM, and underlies the current global spread of the disease [6]. The risk of T2DM increases as the body mass index (BMI) increases above 24 kg/m^2, although the risk appears to be present with lower BMI in Asians [7, 8]. Although central obesity is a particularly strong factor, it can impart further risk regardless of the overall level of general obesity. This obesity-related risk is marked in certain ethnic populations such as Pima Indians, black Africans, South Asians, Chinese, and other Asian populations [9–13], and may be related to increased visceral adiposity. Obesity, particularly central adiposity, is associated with insulin resistance, and also β-cell dysfunction, partly through increased free fatty acids and lipotoxicity (see Chapter 16). Obesity is also associated with other metabolic abnormalities such as dyslipidemia and hypertension.

The clustering of some of the risk factors, namely hypertension, elevated blood glucose, elevated triglyceride, low high-density lipoprotein (HDL) cholesterol, and abdominal obesity, is termed the metabolic syndrome. Presence of the metabolic syndrome, according to the definition, is associated with a 2–5-fold increased risk of developing diabetes in most populations [14].

A positive family history is an important risk factor for T2DM. In the InterAct case–cohort study, a family history of T2DM was associated with a 2.7-fold risk of incident diabetes [15]. There have been advances in our understanding of the genetic basis of T2DM over the last few years, with more than 80 genetic variants so far identified as being associated with T2DM (see Chapter 14) [16]. Nevertheless, the identified genetic variants explain <10% of the heritability of T2DM. In the InterAct study, a genetic risk score composed of known genetic variants for T2DM explained only 2% of the family history-associated risk of T2DM, suggesting that there are still unexplained factors that contribute to the association between family history and T2DM, including yet-to-be identified genetic factors, shared environment and behavior, epigenetic factors, and possibly other factors [15]. Most of the known genetic variants for T2DM were identified in European populations. Although several T2DM-associated genetic variants have been identified in other populations including, East Asians and South Asians, our current knowledge of genetic variants associated with T2DM cannot explain the marked geographical and ethnic variations in diabetes prevalence [13, 17].

Traditional risk factors such as increasing age, adiposity, physical inactivity, dietary factors, positive family history, and presence of other cardiometabolic risk factors are well-recognized factors for diabetes and many are considered to be on the causal pathway. Current approaches to diabetes prevention are mostly focused on addressing these risk factors for diabetes, in particular unhealthy

diet and physical inactivity. In the prospective Whitehall II study, it was estimated that traditional modifiable risk factors such as health behavior and obesity, when measured repeatedly over time, explain approximately half of the social inequalities in incidence of T2DM [18].

Recent emerging risk factors

Sugar-sweetened beverages

Consumption of sugar-sweetened beverages is now recognized as an important contributor to the recent rapid escalation in obesity and diabetes [19, 20]. Sugar-sweetened beverages include carbonated soft drinks, fruit juices, iced tea, and energy and vitamin water beverages, and are similar in having high sugar content, low satiety, and low nutritional value. The intake of such beverages has increased markedly over recent decades, and consumption trends often mirror those of obesity and diabetes prevalence in different parts of the world [21]. Sugar-sweetened beverages contain added sugars in the form of fructose, chronic exposure to which can lead to hepatic steatosis, insulin resistance, central obesity, and metabolic abnormalities [22].

Decreased sleep

In addition to changes in diet and physical activity, it has recently been recognized that there is a U-shaped relationship between sleep duration and diabetes risk, with short sleep duration, another facet of our modern lifestyle, being an important contributor to the increasing prevalence of T2DM. Early seminal work highlighted the detrimental effects of sleep deprivation on glucose tolerance and insulin sensitivity [23]. Subsequent cross-sectional studies have suggested an association between short sleep duration and diabetes [24] and obesity [25]. In a prospective study of more than 70,000 women in the Nurses Health Study, short sleep duration was associated with a ~57% increase in diabetes risk over the 10-year study period [26]. Similar data were obtained from the First National Health and Nutrition Examination Survey (NHANES I), which noted that people with a sleep duration of ≤5 h had a 47% increase in incident diabetes over a 10-year period [27]. The exact mechanism whereby sleep restriction increases diabetes risk is unclear, although it may be related to activation of the sympathetic nervous system, decrease in cerebral glucose utilization, changes in the hypothalamic–pituitary–adrenal axis, and other neuroendocrine dysregulation [27]. In addition to short duration, other sleep disturbances, and also altered circadian rhythm, for example during shift work, are associated with increased risk of diabetes [28].

Depression and treatment of depression

There is a bidirectional relationship between depression and diabetes/IGT (see Chapter 57). The incident rate of T2DM is modestly higher among those with baseline depressive symptoms. Once T2DM was diagnosed, there was a positive association with depressive symptoms, illustrating the emotional burden of having diabetes [29]. The use of second-generation antipsychotic agents, commonly referred to as "atypical antipsychotics," has been linked with hyperglycemia and diabetes [30]. A complex association exists between mental illness, use of psychiatric medications, and diabetes [31].

Drug-induced metabolic changes

There is increasing recognition that some commonly used medications may be associated with adverse metabolic effects and increased risk of diabetes (see Chapter 19) [32]. High-dose thiazide diuretics worsen insulin resistance and β-blockers can impair insulin secretion. The increasing use of highly active antiretroviral therapy (HAART) has dramatically reduced the mortality of people with HIV infection. However, protease inhibitors and, to a lesser extent, nucleoside reverse transcriptase inhibitors are associated with insulin resistance, deranged glucose and lipid metabolism, and an increased risk for T2DM. The increasing use of such agents will likely have a significant impact on the epidemiology of diabetes in areas where HIV/AIDS is endemic, such as Africa [33].

Environmental toxins

Whereas most studies on the increasing burden of diabetes with Westernized lifestyle have focused on changes in dietary patterns and the increasingly sedentary lifestyles, some studies suggest that environmental pollutants may represent a previously unrecognized link between urbanization and diabetes [34, 35]. For example, there is strong cross-sectional association between serum concentrations of chlorinated persistent organic pollutants with diabetes [36] and also components of the metabolic syndrome [37]. Brominated flame retardants, bisphenol A, and perfluorinated compounds have emerged as other classes of organic pollutants that are associated with diabetes [38, 39]. These environmental toxins may accumulate in adipose tissue and act as endocrine disruptors, leading to dysregulation of glucose and lipid metabolism.

Low birthweight and fetal malnutrition

There is a relationship between intrauterine environment, fetal malnutrition, and the risk of diabetes and cardiovascular disease later in life [40, 41]. Maternal undernutrition and low infant birthweight, along with rapid postnatal growth, are associated with increased risk of diabetes in the offspring. This "mismatch" of a metabolic phenotype programmed during intrauterine development and the nutritionally rich postnatal environment may be most important in regions that are undergoing rapid economic development, and may be an important factor contributing to the rapid rise in diabetes in Asia and the Pacific region [42].

Maternal obesity, maternal hyperglycemia, and other factors in early development

In addition, offspring of obese women or women with diabetes have an increased risk of diabetes and cardiometabolic abnormalities [43, 44]. This is partly caused by the effects of maternal

overnutrition and effects of intrauterine hyperglycemia on fetal growth, although it may also involve epigenetic changes [45]. With increasing numbers of women with obesity or young-onset diabetes, this is likely to exacerbate the epidemic of diabetes further by setting up a vicious cycle of "diabetes begetting diabetes" [41, 46, 47].

Despite the increasing recognition of these novel risk factors, the main risk factors associated with diabetes remain the traditional ones such as increasing age, adiposity, physical inactivity, dietary factors, positive family history, and presence of other cardiometabolic risk factors, as outlined in Figure 4.1.

Methodological issues in the epidemiology of T2DM

In comparing epidemiological data in T2DM, one must be aware of the importance of the study methodology. Survey methods must be robust, to allow comparison and standardization. A large, truly random sample of a community, with a good response rate, is best; workplace samples may demonstrate "healthy worker" effects, whereas selective samples (e.g. volunteers or people with another disease) are the least useful because of inbuilt recruitment bias. The age distribution of sample populations is crucial in studying T2DM, whose prevalence rises with age; study populations must be age stratified and any comparisons age adjusted, either within the data set or standardized against a reference population. Finally, ascertainment methods are important, for example, whether participants undergo an oral glucose tolerance test, with or without preliminary blood glucose screening. Although reference is often made to the global and national estimates of diabetes prevalence in the *IDF Diabetes Atlas*, one has to be aware of several important limitations of these estimates. For countries in which prevalence studies are available, the data are presented in the *Atlas*. However, for many countries for which no updated prevalence studies are available, the estimates are based on modeled data from nearby countries matched in terms of percentage urbanization, ethnicity, and income group [48]. Owing to these methodological issues, prevalence figures for countries where estimates are based on modeling are not necessarily accurate, and not directly comparable with those from countries in which nationwide epidemiology surveys have been conducted.

As will be discussed later, studies conducted in different regions of the world have highlighted an increase in the prevalence of T2DM. Although few would argue that this translates into increasing burden associated with diabetes, it is important to recognize the factors that have contributed to this increased prevalence. Several factors directly affect the prevalence of diabetes, and may partly account for the increasing prevalence (Figure 4.2). These include:

- changes in the ratio of diagnosed to undiagnosed cases of diabetes;
- population demographic changes with an aging population;
- earlier age at onset of diabetes;

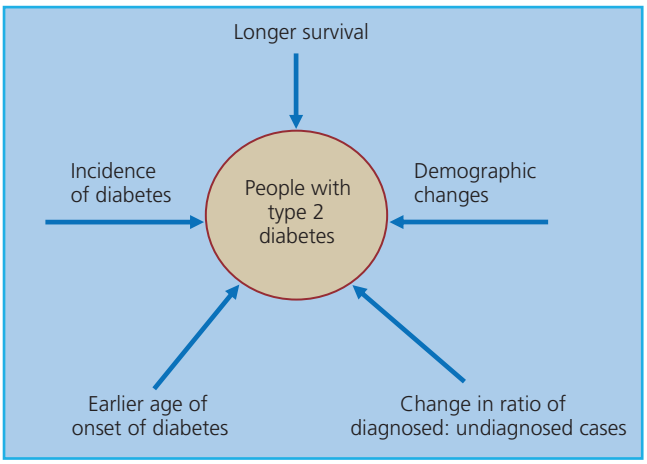

Figure 4.2 Diabetes epidemiological model. Factors directly affecting the prevalence of diabetes included in the present analysis. Source: Adapted from Colagiuri et al. 2005 [49]

- longer survival in people with diabetes;
- increasing incidence of diabetes [49].

The different factors may have different contributions depending on the population being studied, although most if not all are of some importance in most populations. The differences in the contributions of different factors to the prevalence of diabetes is illustrated by the fact that, for example, in Europe the incidence of diabetes has stabilized but longevity and increased case finding now explains the increased numbers, whereas in Africa and parts of Asia there is still a marked increase in incidence [1, 50, 51].

Effects of changes in the definition of diabetes

Although it has long been established that diabetes is a condition associated with hyperglycemia, there was no widespread accepted definition until the 1980s, when the World Health Organization (WHO) Expert Committee on Diabetes Mellitus defined diabetes as a state of chronic hyperglycemia that may result from many environmental and genetic factors often acting together [52]. The precise degree of hyperglycemia that defines diabetes has evolved with time, and relies on epidemiological studies regarding the distribution of glucose levels within various populations.

There are several consequences of the changes in the definition of diabetes with time on the epidemiology of diabetes. First, the American Diabetes Association (ADA) and 1999 WHO classification lowered the diagnostic threshold of fasting glucose from 7.8 to 7.0 mmol/L, thereby increasing the number of individuals in any given population that fulfilled a diagnosis of diabetes mellitus.

It is important to appreciate whether the diagnosis was based on elevated fasting glucose or post-load values during an oral glucose tolerance test. Although the lower fasting glucose level of 7 mmol/L was chosen to resemble the diagnostic significance of the 2-h post-load concentration more closely, numerous studies

Table 4.1 Comparison of WHO and ADA recommendations for the diagnostic criteria for diabetes and intermediate hyperglycemia.

	WHO (2006/2011)	ADA (2003/2010)
Diabetes		
Fasting plasma glucose	≥7.0 mmol/L (126 mg/dL)	≥7.0 mmol/L (126 mg/dL)
	or	
2-h plasma glucose[a]	≥11.1 mmol/L (200 mg/dL)	
HbA_{1c}	(Since 2011)	(Since 2010)
	≥6.5% (48 mmol/mol) (if assay standardized and accurately measured)	≥6.5% (48 mmol/mol) (if assay standardized and accurately measured)
Impaired glucose tolerance (IGT)		
Fasting plasma glucose	<7.0 mmol/L (126 mg/dL)	
	and	
2-h plasma glucose[a]	≥7.8 and <11.1 mmol/L (140 and 200 mg/dL)	
Impaired fasting glucose (IFG)		
Fasting plasma glucose	6.1–6.9 mmol/L (110–125 mg/dL)	5.6–6.9 mmol/L (100–125 mg/dL)
	and (if measured)	
2-h plasma glucose[a]	<7.8 mmol/L (140 mg/dL)	

[a]Venous plasma glucose 2 h after ingestion of 75 g oral glucose load.

have demonstrated that the fasting glucose and post-load criteria identify slightly different people in most populations [53–55]. The use of fasting glucose alone will reduce the overall prevalence of diabetes compared with that identified by 2-h post-load glucose values [56]. Furthermore, there is an increasing number of epidemiological studies that utilize the measurement of HbA_{1c} as an indicator of dysglycemia [57], and several professional organizations, including the ADA in 2010 and the WHO in 2011, have now included HbA_{1c} for the diagnosis of diabetes [58, 59], though this remains an area of debate [60, 61].

The WHO and ADA recommendations for the diagnostic criteria for diabetes and intermediate hyperglycemia are summarized in Table 4.1. Although the lower ADA threshold for diagnosing impaired fasting glucose will result in more people being diagnosed with intermediate hyperglycemia compared with the WHO recommendation, increased diagnostic activity, for example through the use of the oral glucose tolerance test, will increase the ratio of diagnosed to undiagnosed diabetes, and may impact on the prevalence rate reported in epidemiological studies. In a study utilizing 96 population-based cohorts to compare the different diagnostic criteria on population prevalence of diabetes, the prevalence based on HbA_{1c} was in general slightly lower than that based on fasting blood glucose. Furthermore, diabetes diagnosed on HbA_{1c} ≥6.5% had a pooled sensitivity of around 53% (95% confidence interval [CI]: 51.3–54.3%) compared with a definition of fasting glucose of ≥7.0 mmol/L for diagnosing individuals without a previous known history of diabetes [62].

In an earlier comprehensive report on the global prevalence of diabetes [63], it was noted that the most important demographic change to diabetes prevalence across the world was the increase in the proportion of people aged >65 years. Another major factor that has affected the prevalence of diabetes is the increasing age-specific prevalence, especially in the younger age groups [63]. This suggests an earlier age of onset of diabetes, which may be of particular importance in developing countries. It is noteworthy that the tendency is for the prevalence of IGT to decline as that of diabetes rises, suggesting that areas with a high ratio of IGT to diabetes are at an earlier stage of the diabetes epidemic and thus may be a particular target for preventive strategies. Changes and variations in the ratio of IGT to diabetes prevalence, the so-called "epidemicity index," may provide a useful marker for the scale of the epidemic in that particular region [64].

Regional and ethnic patterns of T2DM worldwide

This section considers the geographical distribution and secular changes in the prevalence of T2DM and intermediate hyperglycemia in the major regions of the world. Whenever possible, the most representative recent prevalence studies are presented. In addition, data from the *IDF Diabetes Atlas*, which utilized age- and sex-specific estimates for diabetes prevalence from available epidemiological surveys to extrapolate prevalence in related countries using a combination of criteria including geographical proximity, ethnic, and socioeconomic similarities, are also presented when necessary owing to lack of recent prevalence studies.

Current estimates of the total number of people with diabetes in each region of the world and in those countries with the highest overall numbers are shown in Figure. 4.3. Table 4.2 shows the

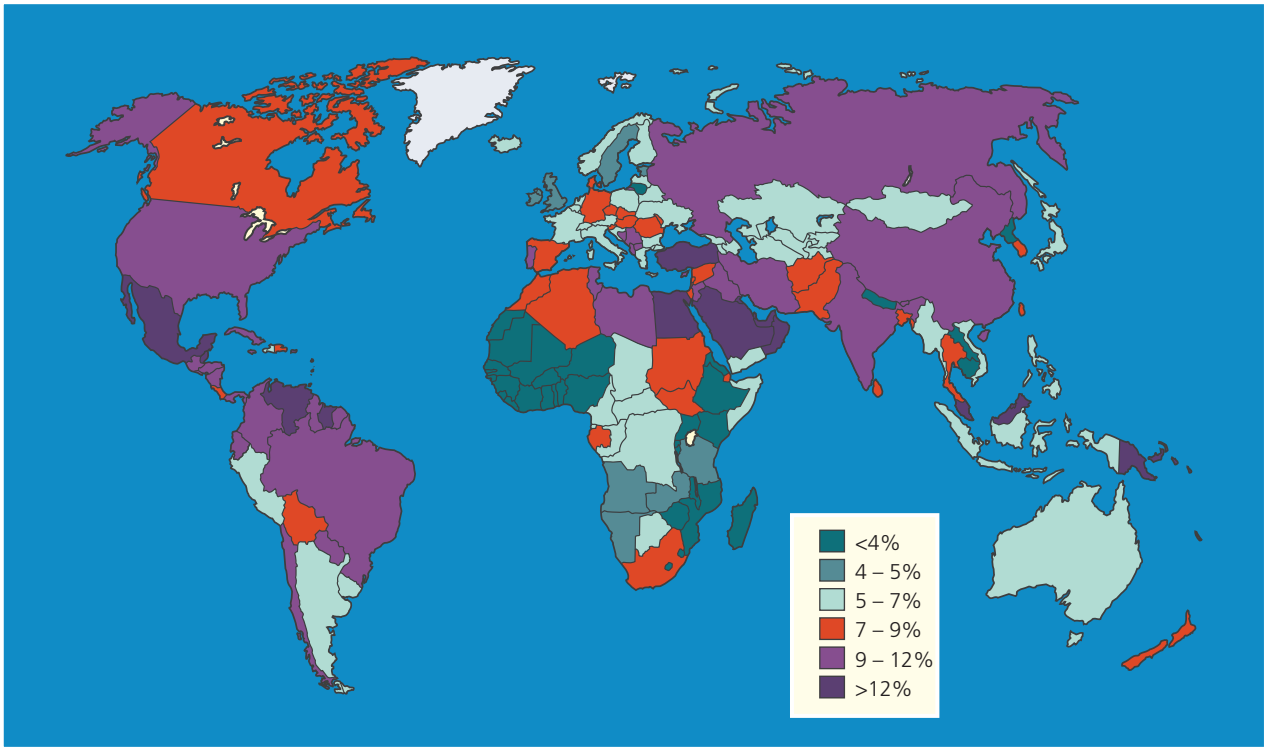

Figure 4.3 Global prevalence of diabetes. Source: Adapted from *IDF Diabetes Atlas*, International Diabetes Federation 2015 [1], Chapter 3, Map 3.1.

countries with the highest prevalence and projected prevalence, and Table 4.3 lists the countries with the greatest number of people with diabetes. These estimates are based on modeling of data available from countries in which prevalence data were obtained from epidemiological surveys, and hence are only estimates that must be treated with caution [48].

Africa

T2DM in the African continent provides contrasting pictures between more urbanized and more rural regions. Whereas poverty and malnutrition are still a major problem affecting sub-Saharan Africa, a region where diabetes is comparatively rare, urbanized areas such as North Africa are reporting increasing prevalence rates [65]. The IDF estimated that overall, ~3.2% of the adult population in the African region are currently affected by diabetes, and is projected to increase to 3.7% by 2040 [1]. Other important epidemiological issues in the region include a low incidence of type 1 diabetes mellitus (T1DM), which is complicated by the occurrence of atypical "ketosis-prone"

Table 4.2 List of countries with the highest prevalence of diabetes (age group 20–79 years, age-adjusted for comparative prevalence) in 2015.

Rank	Country	Prevalence (%)
1	Tokelau	30.0
2	Nauru	24.1
3	Mauritius	22.3
4	Cook Islands	21.5
5	Marshall Islands	21.3
6	Palau	20.9
7	Saudi Arabia	20.0
8	Kuwait	20.0
9	Qatar	20.0
10	United Arab Emirates	19.3

diabetes. This initially presents as T1DM with severe hyperglycemia and ketosis, but subsequently has long-term remission with a clinical course more compatible with T2DM [66]. In addition, there is also a form of early-onset diabetes termed malnutrition-related diabetes mellitus that is associated with past or present malnutrition and sometimes accompanied by pancreatic calcification [33]. Although infective diseases such as HIV infection and tuberculosis are currently the main causes of mortality in sub-Saharan Africa, the increasing prevalence of diabetes and other non-communicable diseases is likely to overtake infections as major causes of mortality. In sub-Saharan Africa, only a small proportion of the population reaches ages at which T2DM becomes a major health problem. Although greater access to HAART has led to markedly reduced mortality, the improvement in life expectancy, coupled with the adverse metabolic effects of HAART, is likely to contribute to further increases in the prevalence of T2DM within the region [33, 67].

Sub-Saharan Africa

There is a paucity of prevalence data from sub-Saharan Africa, with most of the studies coming from Ghana, Cameroon, Nigeria, Tanzania, and South Africa [65, 68]. In a systematic review of prevalence data from Ghanaians and Nigerians, diabetes was rare at 0.2% in urban Ghana in 1963 and 1.65% in urban Nigeria in 1985. The prevalence of diabetes had risen to 6.8% in Nigeria in 2000 (for adults aged ≥40 years) and 6.3% in Ghana in 1998 (for adults aged ≥25 years) [69, 70]. In Cameroon (West Africa), adults aged 24–74 years had an overall diabetes prevalence of 1.1%, with an IGT rate of 2.7%. Prevalence rates in the capital of Cameroon (Yaounde) were 1.3% for diabetes and 1.8% for IGT, compared with rural prevalences of 0.8% for diabetes and 3.9% for IGT [71]. Undiagnosed cases accounted for the majority of cases in these studies, again reflecting a region at the early stages of a looming diabetes epidemic.

In South Africa, both diabetes and IGT are commoner in both urban and rural communities. In Cape Town, age-adjusted prevalences were 8% for diabetes and 7% for IGT [72]. A study conducted in a rural South African community based on a 75-g oral glucose tolerance test and the 1998 WHO criteria reported overall age-adjusted prevalences of diabetes of 3.9%, IGT 4.8%, and IFG 1.5%. Notably, 85% of the cases with diabetes were uncovered by the survey [73].

In addition to exposure to an urban environment, other factors that determine the risk of T2DM in African populations include positive family history, ethnic origin, central adiposity, and physical inactivity [65]. Possible ethnic differences have been examined in several studies. In both Tanzania and South Africa, migrant Asians have higher diabetes prevalence rates than indigenous Africans [74], but this could reflect lifestyle differences. In Tanzania, the difference was particularly marked (1.1% in Africans vs. 9.1% in Asians), which again emphasizes the low prevalence in urban East Africans.

The emerging epidemic of T2DM is further compounded by the various problems hampering the delivery of effective diabetes care within this region. This has resulted in poor glycemic control among most people with diabetes, and also a high frequency of chronic microvascular complications. The rising prevalence of diabetes may also hamper tuberculosis control efforts by increasing the number of susceptible individuals in endemic areas [75]. Better access to healthcare and treatment, improvements in infrastructure to support services (for example, by aligning diabetes care with screening and healthcare delivery for infectious diseases such as HIV and tuberculosis) and healthcare information systems, and also primary prevention measures are urgently needed to reduce the burden of acute and chronic complications of diabetes in the region [33, 65, 67, 76].

North America and the Caribbean

Diabetes and its complications are common and a significant cause of morbidity in North America. The NHANES reported a crude prevalence of total diabetes in 1999–2002 of 9.3%, comprising 6.5% diagnosed and 2.8% undiagnosed [77]. This was significantly increased compared with a crude prevalence of total diabetes in 1988–1994 of 5.1%, mainly through an increase in diagnosed diabetes. There was marked variation in prevalence between ethnic groups, with age- and sex-standardized prevalences of diagnosed diabetes approximately twice as high in non-Hispanic black Americans (11%) and Mexican Americans (10.4%) compared with non-Hispanic white Americans (5.2%). The prevalence of diabetes among the elderly of these minority groups was particularly high, exceeding 30% [77].

The high prevalence rates in US Hispanic people and black Americans are well documented. In 1991, the age-adjusted prevalence of diabetes was 6% in white Americans, 9% in Cubans, 10% in black Americans, 13% in Mexican Americans and 13% in Puerto Ricans [78]. Rates have risen in all groups, but these differences appear to persist. Between 1987 and 1996, the 7–8-year incidence of T2DM approximately tripled in both Mexican Americans and non-Hispanic white Americans, although the absolute rate was twice as high in the Mexican Americans [79]. T2DM is also significantly commoner among older Puerto Ricans (38%) and Dominicans (35%) than among non-Hispanic white Americans (23%) [80]. Economic disadvantage may explain much of the excess prevalence of T2DM among African American women [81].

Other populations in the USA that are particularly at risk of T2DM are the Native American Indian communities, notably the Pima Indians, of whom 50% have diabetes [82]. Reports have highlighted the developing epidemic of T2DM in American Indian youth [83]. Among 15–19-year-olds, diabetes affected 5.1% of Pima Indians (a sixfold increase in prevalence over the previous 20 years) and 0.2% of Canadian Cree and Ojibway Indians. The overall prevalence among all US American Indians of this age is 0.5%. This epidemic of T2DM in young American Indians is supported by secular trends in the incidence rate of T2DM over the previous 40 years in Pima Indians, which showed a more than fivefold increase in incidence rates among Pima Indians aged 5–14 years [84].

A similar situation was seen in Canada, where Aboriginal peoples had more than a twofold increase in prevalence compared with the general population [85]. Other minority groups are also not spared. Among native Hawaiians (Polynesians), the crude (i.e. not age-adjusted) prevalence rates of T2DM and IGT were reported in 1998 to be 20 and 16%, respectively. The age-adjusted rate for T2DM was four times higher than among the US NHANES II study population [86]. In 1991, second-generation Japanese Americans had prevalence rates of 16% (diabetes) and 40% (IGT) [87], and incidence rates remained high at 17.2 per 1000 person-years [88]. This may be due to the increase in visceral adiposity in a population predisposed to impaired β-cell function [89]. Other Asian populations living in the USA that are particularly prone to diabetes include Asian Americans, in whom linguistic difficulties may be a particularly relevant barrier to diabetes education and effective care delivery [90].

It has been estimated that the number of adults in the USA with diagnosed diabetes will rise from 11 million in 2000 (overall prevalence 4.0%) to 29 million in 2050 (overall prevalence 7.2%). The fastest growth is expected to be among black Americans. The projected increase of 18 million is accounted for by approximately similar contributions from changes in demographic composition, population growth, and secular trends [91]. In 2014, it was estimated that 29.1 million people in the USA had diabetes, of whom 8.1 million were undiagnosed. The direct and indirect medical cost attributed to diabetes in the USA in 2012 was $245 billion [92]. Recent data suggest that the percentage of diagnosed people reaching glycemic goals and achieving risk factors control has improved over the last two decades, although only 14% met all three targets regarding glycemic, blood pressure, and lipid control, along with smoking cessation [93]. There has been a substantial reduction in the rates of diabetic complications over the last two decades, especially with regard to myocardial infarction and acute hyperglycemic emergencies [94].

An increasing number of younger people will be affected. In the SEARCH for Diabetes in Youth Study, a multiethnic, population-based study, the incidence of diabetes was 24.3 per 100,000 person-years. The incidence rates of T2DM were highest among American Indians and African American adolescents, varying from 17 to 49.4 per 100,000 person-years, compared with 5.6 per 100 000 person-years in non-Hispanic white Americans [95].

Caribbean

Studies in Jamaica exemplify the secular trend in the West Indies. Rates in the 1960s (underestimated owing to the screening procedure used) [103] were low but rose in the 1970s to 4% in those aged 25–44 years and 8–10% in those aged 45–64 years [104, 105], and to an overall rate of 7.4% in 1996 [106]. A report in 1999 indicated prevalence rates of 16% in women and 10% in men (13% overall). As elsewhere, this exceeds the rate of rise among European-origin populations and parallels the spread of obesity [107].

Central and South America

Data from this region are scarce. In the Mapuche natives in rural Chile, the prevalence of T2DM estimated in 2001 was 3% in men and 5% in women [96], which represents a substantial rise above the very low prevalence of <1% reported in 1985 [97]. Diabetes is clearly much more common in urban communities, for example, 14% in Mexico City in 1994 [98], compared with a 5–10% prevalence nationwide [99]. Surveys in Brazil and Colombia in the early 1990s indicated age-adjusted prevalence rates of ~7% [100, 101]. A recent study in Brazil revealed a rate of self-reported diabetes of 10.1% [102]. A high prevalence of abdominal obesity was noted in these populations, affecting more than 80% of women [99].

Europe

This region contains a diverse mix of countries that have marked differences in affluence, and includes some of the most developed countries in the world. Nevertheless, updated nationwide survey data are only available in some countries. In the *IDF Diabetes Atlas*, only a minority of the 56 European countries had recent published data on national prevalence of diabetes, which ranged from 4.7% in the United Kingdom to 12.8% in Turkey [1, 51] (Table 4.4).

Table 4.4 National estimates of diabetes in Europe in 2015.

	Prevalence of diabetes (%)	
Country	**National population[a]**	**Comparative population[b]**
Albania	12.0	10.3
Austria	9.5	6.9
Belgium	6.7	5.1
Cyprus	10.4	9.6
Denmark	9.9	7.2
Finland	9.0	6.0
France	7.4	5.3
Germany	10.6	7.4
Greece	7.5	5.2
Iceland	7.6	6.1
Ireland	5.3	4.4
Israel	8.5	7.5
Italy	7.9	5.1
Malta	13.9	9.9
The Netherlands	7.9	5.5
Norway	7.8	6.0
Poland	7.6	6.2
Spain	10.4	7.7
Sweden	6.3	4.7
Turkey	12.5	12.8
UK	6.2	4.7

United Kingdom

T2DM imposes particular burdens in inner cities with multiethnic populations, as those originating from the Indian subcontinent have a high diabetes prevalence. In typical studies [108, 109], the age-adjusted prevalence rates were 3% and 5% in white European men and women, respectively, compared with 12% and 11% in their Asian counterparts in the UK. Asians also show a higher prevalence of IGT, a male preponderance, a younger age at diagnosis, and a lower proportion of undiagnosed diabetes [109].

Poverty and social deprivation apparently contribute to the increasing prevalence of T2DM among inner-city residents; for example, in all ethnic groups in inner-city Manchester there was a surprisingly high age-standardized prevalence, including a rate of 20% among white Europeans [110]. Social deprivation, obesity, physical inactivity, and smoking tend to co-segregate, which may explain this phenomenon. The importance of dietary factors was highlighted by two studies, which demonstrated an association between high dietary energy density or unhealthy dietary patterns characterized by a high intake of sugar-sweetened beverages, burgers, and sausages and snacks with incident T2DM [111, 112]. In the Ely Study, a population-based longitudinal study, the 10-year cumulative incidence of diabetes was 7.3 per 1000 person-years [113].

Scandinavia and Nordic countries

Here, the more homogeneous population may indicate more accurately the true prevalence of T2DM among white Europeans. A survey in northern Sweden revealed a prevalence of diabetes of 8.1% in 2002 [114]. Similar data were obtained in a study in Finland, with age-standardized prevalence of diabetes in 45–64-year-olds being 10.2% for men and 7.4% for women [115]. Lower prevalence data were noted for Iceland [116].

In the early 1990s, T2DM was rare in northern Finland but the prevalence of IGT was 29% in men and 27% in women [117], comparable to that in a homogeneous white female Swedish population aged 55–57 years (28%) [118]. In Denmark, around 15% of the population had IGT in 2003 [119]. The high prevalence of IGT in Finland prompted the Finnish Diabetes Prevention Study [120], which examined whether lifestyle changes could prevent the development of T2DM. Strikingly, nutritional advice and increased physical activity reduced the risk of developing diabetes by 58% in people with IGT, and the effect was sustained over subsequent follow-up [120]. A more recent study in three regions in Finland noted prevalence of IGT of 10.5 and 9.2% in men and women, respectively, which were substantially lower than previously reported figures from northern Finland. It is unclear whether this difference is due to regional differences or to changes in the diabetes to IGT ratio [115].

Using a register of people with diabetes, the calculated incidence rate of diabetes in Denmark was 1.8 per 100,000 at age 40 years and 10 per 100,000 at age 70 years. The incidence rate increased by 5% per year before 2004 but then stabilized. The lifetime risk of diabetes was estimated at 30% [121]. Another study in Finland noted an alarming increase in the incidence of T2DM among young adults, with the age-adjusted incidence of T2DM among 15–39-year-olds being 11.8 per 100,000 per year. The incidence rate increased by 7.9% per year. Interestingly, despite having the highest incidence of childhood T1DM in the world, the incidence of T2DM among young adults in Finland is approaching that of T1DM among the 15–39-year-old age group (age-adjusted incidence of T1DM 15.9 per 100,000 per year) [122].

Continental Europe

A population-based survey in Verona, Italy, revealed an overall prevalence of T2DM of 2.5%, which increased significantly after the age of 35 years [123]. In northern Italy, the age-adjusted prevalence of T2DM was 9% in men and 8% in women over the age of 44 years [124]. In a study that compared the prevalence of diabetes in Casale Monferrato in northwest Italy in 1988 and 2000, the age- and sex-adjusted prevalence of diabetes had increased from 2.1% in 1988 to 3.1% in 2000, with higher age-specific prevalence rates of diabetes in every age group in the later survey, including a twofold increase in the risk for those aged ≥80 years [125].

In France, the MONICA study estimated the adjusted prevalence of T2DM to be 7% in men and 5% in women aged 35–65 years and the adjusted prevalence of impaired fasting glucose to be 12% in men and 5% in women [126]. The prevalence of diabetes increased to 19% in men and 9% in women aged over 60 years [127]. In the more recent French Nutrition and Health Survey conducted between 2006 and 2007, the prevalence of diabetes according to elevated fasting plasma glucose or HbA_{1c} ≥6.5% was 5.6%, with undiagnosed diabetes contributing to fewer than 20% of all cases of diabetes [128].

In The Netherlands, T2DM affects 8% of elderly white Dutch [129]; 65% of those with impaired fasting and post-load glucose levels went on to develop diabetes within 6 years [130]. In a prospective population-based study between 1998 and 2000, the age- and sex-adjusted prevalence of diagnosed diabetes was 2.2% at baseline and 2.9% after 2 years of follow-up, with the elderly aged ≥70 years accounting for 50% of the population with T2DM [131].

In Greece, the prevalence of diabetes increased from 2.4% in 1974 to 3.1% in 1990 [132], as the population aged and became more obese [133, 134]. The prevalence of T2DM was 7.6% in men and 5.9% in women in a survey conducted between 2001 and 2002 [135]. In a follow-up study on those free of cardiovascular disease at baseline, the incidence rate of diabetes within a 5-year period was 5.5% [136]. In Turkey, the overall prevalence rates of T2DM and IGT were 6 and 9%, respectively. Low levels of occupational activity, family history, and obesity were all associated risk factors [137, 138]. Adherence to a Mediterranean diet may have protective effects against diabetes [139].

Prevalence data from Eastern Europe are comparatively sparse. The age-adjusted prevalence of T2DM for men and women in Fergana, Uzbekistan, was estimated to be 8% in both urban men and women, with IGT affecting 5% of men and 6% of women.

Lower prevalence rates for both T2DM and IGT were reported for semirural inhabitants [140]. A survey in the rural area in the Sirdaria province of Uzbekistan confirmed similar age-adjusted prevalence rates of diabetes for men (10%) and women (7.5%). However, prevalence rates of IGT in Sirdaria women (14%) and in men (11%) were higher than for semiurban or urban inhabitants in Fergana [141]. In Russia, the estimated prevalence was 6% in men and 7% in women for diabetes and 6%, and 13%, respectively, for IGT; clustering of hyperlipidemia, obesity, hypertension and low 10-year survival was observed among those with diabetes [142]. A survey conducted in Moscow found a low incidence of reported diagnoses of diabetes (2%) [143], which was supported by another study based on self-reported doctor diagnoses [144]. In addition to underdiagnosis, undertreatment and infrequent insulin use are also likely to contribute to the burden of morbidity [144]. Much of the estimated prevalence data in other East European countries have been extrapolated from data from Poland, where the prevalence of T2DM increased from 3.7 to 10.8% between 1986 and 2000, with a similar increase in prevalence of IGT from 2.9 to 14.5% [145].

Southeast Asia

India

India is the second most populous country in the world and in terms of the number of people with diabetes, with an estimated 69.2 million affected in 2015, a figure that is projected to rise to 123.5 million by 2040 [1]. Sequential surveys in India [146–149] indicate that the prevalence of diabetes has risen steadily since the 1970s, although methodological differences hamper direct comparisons between prevalence studies.

The National Urban Diabetes Survey, carried out in six cities in 2001, found age-standardized prevalence rates of 12% for diabetes (with a slight male preponderance) and 14% for IGT; people ≤40 years old had prevalences of 5% (diabetes) and 13% (IGT) [149]. Diabetes was positively and independently associated with increasing age, BMI, and waist/hip ratio, and a family history of diabetes, a higher monthly income, and physical inactivity. IGT showed associations with age, BMI, and family history of diabetes. Subsequent studies showed an increasing prevalence, with a prevalence rate of 14.3% reported in the Chennai Urban Rural Epidemiology Study (CURES-17) [150], and 18.6% in the city of Chennai in another study [151]. In the large Indian Council of Medical Research-INdiaDIABetes (ICMR-INDIAB) study involving more than 13,000 adults across 188 urban and 175 rural sites in four different regions, the prevalence of diabetes was 10.4% in Tamilnadu, 8.4% in Maharashtra, 5.3% in Jharkhand, and 13.6% in Chandigarh [152]. This gave rise to estimates of 62.4 million people with diabetes and 77.2 million people with prediabetes in India in 2011 [152]. In addition to the increasing prevalence of diabetes, there appears to be a decreasing prevalence of IGT [150]. Another secular trend is the shift towards younger onset of diabetes, especially in urban areas, where up to 36% of those with diabetes are aged ≤44 years [150, 151].

Urban—rural differences in the prevalence of diabetes have been consistently reported in different studies in India. A study in Chennai noted a progressive increase in prevalence rate with increasing urbanization: 2.4% in rural areas, 5.9% in semiurban areas, and up to 11.6% in urban areas [148, 153]. Likewise, more recent data revealed a prevalence of 18.6% in the city of Chennai compared with 16.4% in a town, and 9.2% in periurban villages [151]. In a study of 77 centers in India (40 urban and 37 rural), the standardized prevalence rates for diabetes in the total Indian, urban, and rural populations were 4.3, 5.9, and 2.7%, respectively. Although the prevalence rates of diabetes and IGT are significantly higher in urban than rural areas, it appears that the rural–urban gradient is becoming increasingly attenuated [154].

The Chennai Population Study (CUPS) in 2008 reported alarming rates of incident diabetes (20.2 cases per 1000 person-years) [155]. This has been confirmed by a recent study, which reported an incidence of 22.2 per 1000 person-years, where 59% of those with prediabetes progressed to diabetes during mean follow-up of 9.1 years [156]. Identification of those at high risk and increasing the awareness of the population are much needed. A risk score specific for the Indian population, the Indian Diabetes Risk Score (IDRS), has been developed. It utilizes four clinical variables: age, family history, regular exercise, and waist circumference. A score of >21 identifies those with diabetes with a sensitivity and specificity of close to 60% [157]. This will help target high-risk individuals to early intervention, since lifestyle modification is effective in reducing progression from IGT to diabetes in the Indian population [158]. The pilot phase of a National Program on Diabetes, Cardiovascular Disease, and Stroke (NPCDS) was launched by the Ministry of Health and Family Welfare in January 2008, with the aims of improving awareness of lifestyle-related diseases, disease prevention through screening and targeted intervention, and to coordinating the multisectoral effort that is urgently needed to address the epidemic of obesity and diabetes in India [159].

Pakistan, Bangladesh, and Sri Lanka

The situation in these countries largely mirrors that in India. Diabetes is particularly common (16% of men, 12% of women) in the rural Sindh Province in northern Pakistan [160]. A more recent study in Pakistan indicated similar prevalence rates of 10–11% in urban and rural men and urban women, although lower rates were seen in rural women (5%). However, IGT rates in women were twice those in men [161]. Combining the data from the four provinces of Pakistan, the prevalence of diabetes in the urban areas was 6.0% in men and 3.5% in women, with a total of 22% of the urban population estimated to have some degree of glucose intolerance [162]. In rural Bangladesh, diabetes prevalence was reported in an older study to be 2.1% compared with an IGT prevalence of 13% despite a mean BMI of only 20.4 kg/m^2 [163]. A recent study based on fasting glucose criteria alone that included more than 7000 adults reported a prevalence of 9.7% [164].

In addition to urbanization, the main factor for the high prevalence of diabetes and metabolic abnormalities among Asians is the tendency for central obesity and insulin resistance [148, 165–168].

Despite being born smaller, with lower birth weight, Indian babies have more body fat, which persists into adulthood, thus putting them at increased risk of cardiometabolic complications [169]. Interestingly, one study showed that maternal nutrition and, in particular, low maternal vitamin B_{12} and high folate might be associated with increased adiposity and risk of T2DM in the offspring [170], suggesting that in addition to increased intake of fat and calorie-rich foodstuffs, other dietary factors may play a contributory role.

Mauritius

The high prevalence of diabetes and cardiovascular disease on the island of Mauritius, in the Indian Ocean, has been intensively studied. Here, diabetes is common in an urbanized setting; across several ethnic groups (Asian Indian, Chinese, and Creole), in 1990 the prevalence rates were 10–13%, rising to 20–30% in those aged 45–74 years [171]. A repeat survey in 1998 revealed a rise in prevalence of T2DM to 17.9%. In both studies, the highest prevalence was seen in Asian Indians [171, 172]. The age-standardized prevalence of diabetes was 22.3% in 2009 among men and 20.2% among women, representing an increase of over 60% compared with figures from 1987 [173].

The Middle East and North Africa

Marked socioeconomic changes in many countries in the region, especially among the affluent oil-producing countries, have led to dramatic changes in lifestyle, with changes in nutritional intake, decreased physical activity, and increased obesity and smoking. This, coupled with increasing urbanization and improved life expectancy, has led to a marked increase in the prevalence of diabetes and IGT (Table 4.5). A recent review of prevalence of diabetes in the Middle East highlighted the paucity of data and large differences in prevalence rates among different countries. Obesity and age appeared to be the main driver for high prevalence [174]. Saudi Arabia, Kuwait, and Qatar are among the countries with the highest prevalence rates of diabetes, and Egypt is among the top 10 countries with the highest burden of people with diabetes [1], highlighting this region as one that requires concerted public health action to reduce the potential impact of diabetes [175].

North Africa

Prevalence rates are relatively high (3–8%) in Sudan and Tunisia in addition to Egypt. An Egyptian study of adults aged >20 years showed an IGT prevalence rate of 10% [176]. Urban–rural differences were demonstrated; in Cairo city, diabetes was more common (prevalence 14–20%, depending upon socioeconomic status), whereas the IGT prevalence was lower (6–9%). The converse applied in a rural setting, with a diabetes prevalence of only 5% but a higher IGT prevalence of 13%. As suggested earlier, this may reflect the diabetes epidemic being at an earlier stage in rural populations. In the Tunisian National Nutrition Survey, the prevalence of diabetes was 9.9%, giving an age-adjusted prevalence of 8.5%, with marked urban–rural differences [177].

Table 4.5 Prevalence of diabetes from reported epidemiology studies in selected countries in the Middle East. IGT: Impaired glucose tolerance; IFG: Impaired fasting glycaemia.

		Prevalence (%)	
Year	Country [ref.]	T2DM	IGT
1998	Lebanon [274]	13.2	6.0
2006	Oman [275]		
	Males	11.8	
	Females	11.3	
2000	Oman [276]		
	Males	11.8	7.1 (IFG)
	Females	11.6	5.1 (IFG)
1995	Oman [277]		
	Males	9.7	8.1
	Females	9.8	12.9
2011	Saudi Arabia [278]		
	Males	34.7	
	Females	28.6	
2000	Saudi Arabia [279]		
	Males	26.2	14.4
	Females	21.5	13.9
1995	Saudi Arabia [280]		
	Males	11.8	10.0
	Females	12.8	9.0
1992	Iran [281]		
	Urban males	7.1	8.9
	Urban females	7.6	14.9
	Rural	7.3	7.2
2004	Jordan [282]	17.1	7.8
2009	Qatar [283]	16.7	
	Males	15.2	
	Females	18.1	

Western Pacific region

Australia

The first report of the AusDiab Study [178], published in 2000, provides information about diabetes in a developed country. The overall prevalence of diabetes in Australians aged ≥25 years was 7.5% (8% for men and 7% for women), rising from 2.5% in those aged 25–44 years to 24% among those aged ≥75 years; the prevalence more than doubled since 1981 [179, 180]. About 50% of cases discovered in this survey were previously undiagnosed. The combined prevalence of impaired fasting glucose (IFG) and IGT was 16% (men 17%, women 15%); hence almost 25% of Australians aged ≥25 years have abnormal glucose metabolism. In Australia, T2DM accounts for over 85% of cases and T1DM for 10%. Using data from the AusDiab study, it has been estimated that the prevalence of diabetes is likely to rise from 7.6% in 2000 to 11.4% by 2025 [181]. In the 2012 AusDiab Study Report, the annual incidence of diabetes was reported to be 0.8% per year for men and 0.6% per year for women [182].

T2DM is commoner in native Australian populations, for example, 16–30% of adults in the Aborigine and Torres Strait Islander communities [183]. In this population, diabetes was associated with higher rates of hypertension (69% vs. 21%), obesity (44% vs. 16%), elevated triglyceride, and lower HDL-cholesterol concentrations compared with those who have normal glucose tolerance.

New Zealand

In New Zealand, T2DM is consistently commoner among Polynesians (Māoris and Pacific Islanders) than in white New Zealanders; it accounts for 89% of diabetes in white New Zealanders and 95% in Polynesians. Polynesians are also diagnosed, on average, 5–10 years younger than white New Zealanders and have a 4–8-fold higher prevalence of diabetic nephropathy. Strikingly high prevalence rates of 37–75% were reported for unemployed men, emphasizing again the role of socioeconomic status [184]. In the 2006–2007 New Zealand Health Survey, prevalence rates reported for adults aged >30 years were 4.3% for white New Zealanders, 5.8% for Māoris, 6.5% for Asians, and 10.0% for Pacific Islanders, respectively [185, 186].

Pacific Island countries

The Melanesian, Micronesian, and Polynesian populations of the Pacific Islands show great variations in diabetes prevalence, largely attributable to differences in economic development and lifestyle. Some of the highest prevalence rates worldwide come from this region, notably from Nauru and Papua New Guinea. The Micronesian population of Nauru, made wealthy by bauxite mining and with a longer history of Westernization than other Pacific Island Countries, currently have an age-standardized prevalence rate of 40%. High prevalence rates in Nauru have been maintained since the late 1970s, but now appear to have stabilized as bauxite mining is exhausted [50, 187].

Fiji has a largely bi-ethnic population consisting of native Fijians of Melanesian ancestry together with migrants from India. Recent surveys from Fiji are lacking, but a survey conducted over 30 years ago showed that diabetes prevalence rates were already higher among Indian migrants than in Melanesians. In adults above 20 years of age, crude prevalence rates were 13% among the Indian migrants (with no significant urban–rural gradient), but 7% and 1.7% among urban and rural Melanesians, respectively [188]. At the time, these results were thought to indicate a difference in ethnic (genetic) predisposition, but this conclusion has since been tempered by the finding of high prevalence rates in urbanized Melanesians in Papua New Guinea.

The situation in Papua New Guinea provides an excellent example of the damage inflicted by rapid urbanization: diabetes is virtually non-existent in highland populations [189], in stark contrast to the age-standardized prevalence rate of over 40% among urbanized Koki people (Melanesians) in Port Moresby [190]. Intermediate rates are reported in Austronesians of coastal ancestry.

High prevalence rates of diabetes have been reported in Polynesian populations, conspicuously associated with obesity, both of which are particularly common in Polynesian women. In Western Samoa, diabetes prevalence was reported in 1991 to be 7–9% in two rural communities and 16% in Apia; the prevalence had doubled since 1978 [191]. In the Kingdom of Tonga, situated south of Samoa, the age-standardized prevalence of diabetes was 15.1%, of which 80% was undiagnosed [192].

Diabetes remains undiagnosed in most Pacific Island people with the disease—perhaps 80–100% in some communities, compared with around 25–50% in high-income countries [180]. This is likely to contribute to high rates of complications and frequent presentation with diabetes-related problems, such as foot sepsis [193].

Japan

T2DM has become commoner in Japan since the 1960s, and data from rural parts of Japan suggested a prevalence of 9.1% in men and 10.8% in women, with corresponding IGT prevalences of 12 and 16.5% for Japanese men and women, respectively [194]. A National Diabetes Survey conducted in 2002 estimated a prevalence of 9% [195]. In the National Health and Nutrition Survey in 2007, it was estimated (using HbA_{1c}) that the prevalence of diabetes was 15.3% in men and 7.3% in women [196]. The emerging problem of T2DM among Japanese children is now recognized as a critical problem in that country. T2DM cases outnumber T1DM in children and adolescents by a ratio of 4 :1 [197], and the incidence rate of T2DM for 1981–1990 was 4.1 per 100,000 person-years, approximately twice the incidence rate of T1DM [198]. Nutritional factors are believed to play an important part, with the prevalence of diabetes among Japanese Americans approximately twice that among Japanese in Japan [199].

The causes of death in people with T2DM have also shifted, possibly because of Westernization of diet and increased fat and total calorie intake; higher death rates from renal disease than in white European populations are now being supplanted by rising deaths from coronary artery disease [200]. In order to reduce the burden of diabetes, the Japanese government has launched a large national strategic research project named J-DOIT to reduce diabetes, improve adherence to follow-up, and reduce complications of diabetes [201].

Korea

In the Korean National Health and Nutrition Survey conducted in 2001, the age-adjusted prevalence of diabetes was reported to be 7.6%. The prevalence of impaired fasting glucose was an alarming 23.9% [202], suggesting a future epidemic of diabetes in the Korean population, similar to that in the other Asian countries [203]. In the Korean National Health and Nutrition Survey conducted in 2010–2012, prevalence of diabetes was reported to be 10.1% [204].

China and Chinese populations

The rapid increase in the prevalence of T2DM in China provides one of the most striking examples of the impact of urbanization

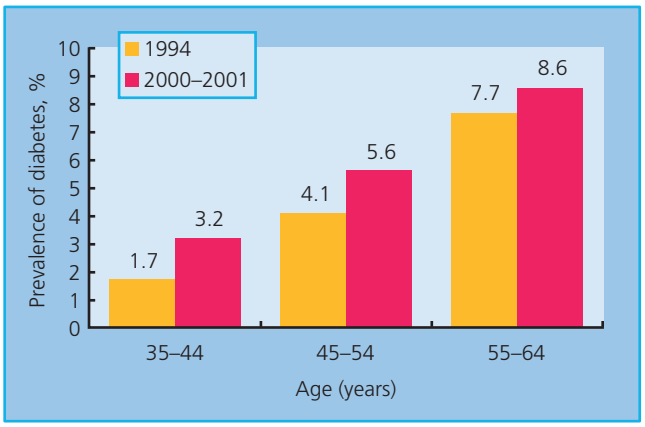

Figure 4.4 Changes in prevalence of diabetes among Chinese adults aged 35–64 years. Source: Data from the 1994 Chinese National Survey and the 2000–2001 InterASIA study (Gu et al. 2003 [209]).

on increasing diabetes prevalence. China, with its current population of nearly 1.4 billion, is the world's most populous country. Diabetes used to be rare: prevalence rates reported between 1980 and 1990 were consistently ≤1.5% even in urban areas such as Shanghai [205], and as low as 0.3% in rural Guangdong Province. Recently, however, the prevalence has risen rapidly, a trend first demonstrated by studies conducted in the Da Qing area of northeastern China. There, the prevalence in 1986 was 1.0%, but by 1994 it had increased over threefold to 3.5% [206, 207]. The 1994 survey of 200,000 people aged 25–64 years in 19 provinces that included Da Qing found overall prevalence rates of 2.3% for diabetes and 2.1% for IGT. A community-based survey of 40,000 people aged 20–74 years in China between 1995 and 1997 confirmed this rising trend and also demonstrated urban–rural gradients in prevalence rates. Age-standardized prevalence rates were 3.2% for diabetes, and 4.8% for IGT, with the highest prevalence in provincial cities and the lowest in rural areas [208]. The International Collaborative Study of Cardiovascular Disease in Asia, conducted in 2000–2001, revealed a further increase in the prevalence of diabetes (undiagnosed and diagnosed) to 5.5%, with another 7.3% affected by IGT [209] (Figure 4.4). Furthermore, amongst the 20 million Chinese people estimated to have diabetes based on fasting blood glucose, only 30% were previously diagnosed [209]. The large proportion of those with IGT is particularly alarming. In the community-based Shanghai Diabetes Study, people with IGT and/or IFG had an 11.7-fold increased risk of diabetes compared with those with normal glucose tolerance over a 3-year follow-up period [210].

Chinese populations in affluent societies such as Hong Kong SAR, Singapore, Taiwan, and Mauritius all show higher prevalence rates compared with mainland China. In Hong Kong, the prevalence of diabetes increased from 8 to 10% between 1990 and 1995 [211, 212]. Studies in Taiwan indicate prevalence rates of 9–11%, although methodological discrepancies make direct comparisons difficult [205]. The annual *incidence* rate in Taiwan was reported in 1997 to be 1.8% [213]. In a review summarizing the findings from prevalence studies conducted in Chinese populations in 1995–2003, it was noted that Chinese people in Hong Kong and Taiwan have a 1.5–2.0-fold increased risk of diabetes adjusted for age and diagnostic criteria compared with their mainland counterparts [214].

The rapid increase in diabetes prevalence in China is likely to have been driven by the increase in obesity, particularly among children and adolescents [168, 215]. Analysis of data from the 2002 National Nutrition and Health Survey noted prevalences of overweight of 4.1%, among children aged 7–12 years and 5.6% among those aged 12–18 years, with obesity prevalences of 2.5 and 1.6%, respectively [216]. In Hong Kong, a community-based study involving more than 2000 adolescents aged 11–18 years found alarming rates of obesity, with 8–10% of those aged 12–13 years fulfilling criteria for obesity [217]. In a national screening program among schoolchildren in Taiwan between 1992 and 1999, the rate of newly identified diabetes was 9.0 per 100,000 for boys and 15.3 per 100,000 for girls. Obesity was found to be the major risk factor for the development of T2DM, where children with BMI in the 95th percentile or higher had an ~19-fold increase in risk of T2DM compared with those with BMI in the <50th percentile [218].

Such alarming data for Chinese populations highlight the potential for further rises within China itself. Unless effective measures can be implemented, given the huge population of China, the consequences could be devastating. Indeed, two recent large nationwide epidemiological studies, involving more than 46,000 and 98,000 adults, respectively, reported diabetes prevalences of 9.7% in 2008 [219] and (if including elevated HbA_{1c} as a diagnostic criterion) 11.6% in 2010 [220]. This translates to a staggering estimate of 92.4 million individuals with diabetes and 148.2 million adults with prediabetes in China in 2008 [219].

South-East Asian peninsula

There is considerable economic diversity within this region, although the recent emerging data showed that despite the relatively traditional lifestyle in many of the countries, diabetes is increasingly common within the region. A survey performed in two villages in Cambodia in 2004 revealed a diabetes prevalence rate of 5% in the rural community in Siem Reap but up to 11% in a semi-urban community [221]. A study conducted in adults in Ho Chi Minh City in southern Vietnam indicated that the prevalence of diabetes increased substantially from 2.5% in 1993 to 3.8% in 2001 [222]. A more recent study using data from 2013 reported an age-standardized prevalence of 6.0% [223]. Similar increases have been reported in Indonesia [224] and the Philippines [225]. Prevalence rates in Thailand appear to be approaching those reported in Malaysia and Singapore, with prevalence of diabetes and IGT in a 2004 national survey reported to be 6.7 and 12.5%, respectively [226].

In Singapore, serial studies since 1975 showed a rising prevalence of diabetes from 2% in 1975 to 4.7% in 1984, 8.6% in 1992, and 9% in 1998. Two more recent surveys indicate that the rate of rise may have stabilized. Ethnic Indians and Malays (especially

Malay women) have the highest rates of diabetes (16.7–14.3%) and also the highest rates of obesity. A further 15% of the adult population have IGT. In a survey conducted in 2004 by the Ministry of Health, Singapore, the prevalence of diabetes among the adult population was estimated to be 8.2% [227]. A more recent survey conducted by the Ministry of Health in 2010 noted a diabetes prevalence of 11.3% [228]. Obesity and adoption of a Westernized diet and lifestyle are again closely associated. T2DM in childhood is also highlighted as an emerging problem. The prevalence of diabetes increased by more than twofold over 20 years in Malaysia, with the most recent nationwide survey reporting a prevalence of 22.6%, compared with a prevalence of 11.6% in 2006 [229].

Impact of diabetes

The epidemic of diabetes has major impact on both personal and societal aspects. The major burden of diabetes stems from the treatment cost of its complications, such as stroke, blindness, coronary artery disease, renal failure, amputation, and infection. In 2015, about 5 million people died of diabetes and its related diseases [1, 230]. Most people die from cardiovascular disease (particularly coronary artery disease and stroke) and end-stage renal disease. In a recent study on the trends in the incidence of diabetes-related complications in the USA, the rates of lower extremity amputations, end-stage renal disease, acute myocardial infarction, stroke, and death from hyperglycemic crisis declined from 1990 to 2010, although there remains a substantial healthcare burden due to the rising diabetes prevalence [94].

There are geographic differences in both the magnitude of these problems and their relative contributions to overall morbidity and mortality [231]. In white European and American populations, macrovascular complications, such as coronary artery disease and amputation, are major causes of disability. In contrast, end-stage renal disease and stroke are more prevalent among Chinese and Asian ethnic groups [13].

It is well established that the occurrence of vascular complications of diabetes is related to the duration of hyperglycemia. With the earlier onset of T2DM, most people will have an increased risk of developing these complications. Despite the high prevalence of complications of diabetes and, hence, the high costs of management, simple, inexpensive measures are effective in preventing the development of diabetes and its vascular complications. Rather than merely focusing on the control of hyperglycemia, global risk reduction with attention on cardiovascular risk factors has been found to be the most effective way of reducing the burden of diabetes. The challenge is to provide a platform whereby effective care can be delivered at an affordable cost.

Mortality and morbidity

Diabetes is associated with approximately twofold increased mortality in most populations, with the excess risk decreasing with increasing age [232–234]. Although initial data suggest that the excess mortality associated with diabetes may be higher in Asian populations, this is probably related to differences in death certificate coding practices [235–237]. It was recently estimated that diabetes accounted for 14.5% of global all-cause mortality among people aged 20–79 years, with close to half of deaths due to diabetes being in people under the age of 60 years [1].

The most systematic comparative data, using standardized methodology, originate from the WHO Multinational Study of Vascular Disease in Diabetes, which has drawn from 14 centers in 13 countries since the 1980s. A follow-up report from 10 of these centers [238] shows that coronary heart disease and limb amputation rates varied 10–20-fold among different centers; there was also marked variation in prevalence of clinical proteinuria and renal failure, but less variation in retinopathy and severe visual impairment. Striking features include the relative rarity of ischemic heart disease and lower extremity amputation in Hong Kong and Tokyo, contrasting with a high incidence of stroke, especially in Hong Kong. A high incidence of stroke was also found in Arizona and Oklahoma, the two Native American Indian centers. The highest rates of ischemic heart disease were seen in the European centers, notably among women in Warsaw. Myocardial infarction was also common in Native American Indians, especially among men, while renal failure and proteinuria rates were highest among Native American Indians and in Hong Kong.

Other issues include the apparent vulnerability of Pacific Island populations to diabetic foot problems associated with neuropathy and of South Asians to coronary heart disease [42]. Importantly, the risk of coronary heart disease is already increased twofold at the stage of IGT [239].

Another cause of morbidity and mortality that is increasingly recognized is the increased risk of cancer in people with diabetes. Various epidemiological studies in different populations have suggested a link between diabetes and increased risk of pancreatic, hepatocellular, endometrial, breast, and colorectal carcinoma [240–242]. Although some of this may be due to presence of common risk factors such as obesity and dietary factors, it has been shown in a large prospective study that cancer risk increases with increasing fasting glucose at baseline [243]. In a large population-based study in Australia, both T1DM and T2DM were found to be associated with increased risk of incidence and mortality for overall and a number of site-specific cancers [244].

Intensive multifactorial interventions to reduce cardiovascular risk factors are effective in reducing cardiovascular mortality in diabetes [245, 246]. Although intensive blood glucose control does not lower cardiovascular mortality in the short term [247, 248], it may have beneficial effects in reducing cardiovascular and total mortality in the longer term, as suggested by long-term follow-up data from UKPDS [249]. It appears that the relative mortality of diabetes is decreasing in some countries [250, 251], and this may be related to the increased utilization of drugs to control hyperlipidemia, hyperglycemia, and hypertension [252].

Healthcare burden and economic costs

The increase in the prevalence of diabetes, particularly among young adults, along with the increased morbidity and mortality

associated with microvascular and macrovascular complications, is likely to lead to an escalation of healthcare costs and reduced economic growth. The IDF estimated that in 2015, diabetes-related health expenditure would reach 320 billion International Dollars (ID) in the USA, 90 billion ID in China, 33 billion ID in Germany, 38 billion ID in Japan, and 29 billion ID in Brazil [1]. The global health expenditure for diabetes in 2015 was estimated to be US$673 billion, of which half would have been spent in North America (around $348 billion), and one-quarter in Europe ($156 billion). In the USA, the estimated total costs (direct and indirect) of diabetes increased from $23 billion in 1969 to $132 billion in 2002 [253, 254]. The cost of diabetes in the USA in 2007 was estimated by the American Diabetes Association to be $174 billion, which includes $116 billion in excess medical expenditures and $58 billion in reduced national productivity [255]. These estimates were revised in 2012 to a total estimated cost of diagnosed diabetes of $245 billion, including $176 billion in direct medical costs and $69 billion in reduced productivity [92]. The largest components of medical expenditures attributed to diabetes are hospital inpatient care, accounting for 43% of total costs, and medications to treat complications of diabetes (18%) and antidiabetes medications and diabetes supplies (12%) [92]. However, the actual burden is likely to be even greater, since other nonmonetary effects such as changes in quality of life, disability and suffering, care provided by unpaid caregivers, and other factors cannot be included in such analyses. The burden of diabetes affects all sectors of society, including higher insurance premiums paid by employees and employers, reduced earnings through productivity loss, and reduced overall quality of life for people with diabetes and their families and friends. The cost of medical care for diabetes varies greatly among the different regions (Table 4.6). Although diabetes is a very costly disease, interventions used to prevent or control diabetes differ greatly in their cost-effectiveness [256]. The cost-effectiveness and feasibility of diabetes interventions in developing countries, as assessed by the World Bank, are listed in Table 4.7. Cost-effective interventions that are technically and culturally feasible should be implemented with the highest priority [257].

Table 4.6 Estimated direct medical costs of diabetes by region, 2003.

Region	Direct medical costs ($ millions)

Prevention of T2DM

"There are entirely too many diabetic patients in the country. Statistics for the last thirty years show so great an increase in the number that, unless this were in part explained by a better recognition of the disease, the outlook for the future would be startling. Therefore, it is proper at the present time to devote attention not alone to treatment, but still more, as in the campaign against the typhoid fever, to prevention. The results may not be quite so striking or as immediate, but they are sure to come and to be important."

[Elliot Joslin, 1921]

Given the cost of diabetes, it is essential to prevent or delay the onset of diabetes and its associated complications. With improved understanding of the natural history of the development of T2DM and the role of various modifiable risk factors in its pathogenesis, a number of randomized clinical trials have examined the effect of lifestyle intervention to prevent T2DM. A large body of evidence has accumulated from these studies on the effectiveness of lifestyle measures in the prevention of diabetes, as summarized in Table 4.8. Most of these interventions include structured education and exercise programs, reducing fat intake and increasing fiber intake, moderate exercise for at least 30 min per day, and moderate weight reduction of ≥5%. Importantly, in addition to being highly cost-effective, the effect of structured lifestyle intervention on reduction of diabetes risk appears to be maintained over a long duration of follow-up [258, 259]. In a follow-up of the China Da Qing Diabetes Prevention Study, participants who received lifestyle intervention had a 51% lower incidence of diabetes during the 6-year active intervention period and 43% lower incidence of diabetes over 20 years [259]. Furthermore, with follow-up extended to 23 years, those randomized to lifestyle intervention had a 41% reduction in cardiovascular mortality and a 29% reduction in all-cause mortality [260].

In addition to lifestyle intervention, several drugs used in the treatment of T2DM and obesity have been evaluated in clinical trials and are effective in preventing diabetes, including metformin, the thiazolidinedione class of compounds, acarbose, orlistat, and insulin itself, as summarized in Table 4.9. The largest body of evidence for pharmacological prevention of diabetes is with metformin treatment, which was associated with an ~40% reduction in risk of diabetes in a meta-analysis [261]. In addition, several clinical trials indicated that angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers may reduce incident diabetes in high-risk people with hypertension [262–266]. A large randomized clinical trial compared the ACE inhibitor ramipril with placebo in people with IGT or IFG. It did not show a significant reduction in incident diabetes after a

Screening for undiagnosed diabetes	5140	6910	8550	7260	4280	3870	++	3
Annual screening for microalbuminuria	3310	4450	5510	4680	2760	2500	++	3

[a]Feasibility was assessed based on difficulty of reaching the intervention population (the capacity of the healthcare system to deliver an intervention to the targeted population), technical complexity (the level of medical technologies or expertise needed for implementing an intervention), capital intensity (the amount of capital required for an intervention), and cultural acceptability (appropriateness of an intervention in terms of social norms and/or religious beliefs). ++++ indicates feasible for all four aspects, +++ indicates feasible for three of the four, ++ indicates feasible for two of the four, and + indicates feasible for one of the four.
[b]Implementing priority was assessed by combining the cost-effectiveness of an intervention and its implementation feasibility; 1 represents the highest priority and 3 represents the lowest priority.

median follow-up of 3 years, although ramipril was associated with increased regression to normoglycemia [267]. A large number of pharmacological agents are currently in development or undergoing clinical trials for the treatment of T2DM or obesity, which should provide a constant supply of promising agents for evaluation in their effectiveness for preventing T2DM. At present, however, lifestyle intervention remains more cost-effective as a strategy for diabetes prevention. Recent prevention studies have also demonstrated the effectiveness of using mobile phone messaging or other aids to deliver support for lifestyle modification or patient empowerment [268]. Among those who have morbid obesity, bariatric surgery has a significant impact on glycemic control and more than 60% of severely obese individuals with diabetes experience remission after gastric bypass surgery [269]. In the 3-year follow-up of people with severe obesity who underwent bariatric surgery in the USA, incidence of diabetes was 0.9% after Roux-en-Y gastric bypass and 3.2% after laparoscopic gastric banding [270].

Given the increased appreciation of the important role of the intrauterine environment and early development in modifying the risk of non-communicable diseases, it is increasingly recognized that pregnancy represents a critical period that requires optimal maternal nutrition [271], and also has long-term consequences for the health of the offspring. Therefore, diabetes and non-communicable disease prevention efforts now include considerations of primordial prevention, whereby measures

to avoid the establishment of different environmental, social, behavioral, and physical exposures that may impair long-term health start early, including preconception and the pregnancy period [272].

More detailed discussion on epidemiological aspects of diabetes can be found elsewhere [273].

Conclusions

The interaction between genetic predisposition, the popularization of fast food and a sedentary lifestyle, in addition to aging of the general population, plays a major role in the increase in the prevalence of impaired glucose tolerance and T2DM globally. Countries in the Asia–Pacific regions and with a growing economy will bear the major burden in the increase in number of people with diabetes. The significant increase in macro- and microvascular complications of diabetes places a heavy burden on healthcare resources. Studies have confirmed the benefit of intensive multifactorial risk management in reducing all-cause mortality and cardiovascular adverse events. Measures such as weight reduction and exercise are effective in preventing the progression of IGT to diabetes. Hence, despite being one of the commonest chronic diseases, diabetes can be prevented or controlled effectively with interventions that are relatively cost-effective compared with the cost of treating the micro- and macrovascular complications.

Key points

- Diabetes results in a range of distressing symptoms, altered daily functioning (requiring attentive self-care, health monitoring, and treatments), changed family roles, higher healthcare costs, lost productivity, disability, and premature mortality, which are felt by individuals, households, communities, and national economies.
- The prevalence of diabetes has grown worldwide, with no country or region spared. With time, the availability of data regarding diabetes burdens has improved; importantly, the prevalence and absolute number estimates for diabetes have consistently outpaced each previous projection. There are still major gaps in data, particularly for incidence, prevalence in some parts of the world, and rate and absolute numbers of people experiencing diabetes complications and mortality in several countries.
- Diabetes is a leading cause of death in the world (5.1 million deaths annually), outnumbering global deaths due to HIV/AIDS, and 75% of this mortality occurs in low- and middle-income countries, disproportionately affecting the young and economically-active populations.
- Cost appraisal methods require epidemiological, clinical, and economic data, and utilize different approaches to calculate the direct medical costs (of treatment, self-management and monitoring, outpatient follow-up, inpatient stays, diagnostic tests, and procedures), indirect costs (of lost outputs due to disability and premature death), and intangible losses (psychosocial burdens) attributable to diabetes.
- Even though there are large variations in methods of cost appraisal, cost items incorporated, and purchasing power, and also accessibility to and patterns of clinical care, together resulting in widely varied between-country per capita expenditures, it is clear that the presence of diabetes results in excess consumption of resources worldwide.
- Progressive severity of diabetes complications, long duration of disease, comorbidities, and complexity of therapy all increase the monetary, infrastructural, and human resource costs of care.
- Individuals in vulnerable subpopulations are at an elevated risk of developing diabetes and progression towards significantly harmful outcomes, and a large proportion of resources is devoted to their therapies and diabetes care; confronting the increased susceptibility and burdens will require addressing the underlying political, socioeconomic, biological, and behavioral factors that perpetuate disparities.

Introduction

Diabetes has emerged as a major health problem worldwide, with serious health-related and socioeconomic impacts on individuals and populations alike. Pandemic growth of diabetes is being spurred on by transitioning demographic (e.g. population aging), socioeconomic, migratory (e.g. between or within countries; urbanization), nutritional and lifestyle patterns, and an affiliated proliferation of overweight and obese adults and children [1–3]. The International Diabetes Federation estimates that there were 415 million people with diabetes worldwide in 2015, and projects that the absolute number will reach 642 million by 2040 [1]. The overwhelming majority of this escalation will be attributable to growth of type 2 diabetes (T2DM). Rapid socioeconomic transformations globally will also result in a parallel growth of diabetes precursors (impaired fasting glucose [IFG] and impaired glucose tolerance [IGT]) and ensuing health consequences [4–6].

Current estimates suggest that three-quarters of those affected by diabetes live in low- and middle-income countries (LMICs) [1, 7]. This challenges traditional paradigms that segregated chronic non-communicable diseases (NCDs) as problems of affluent countries alone. Although this burden of greater absolute numbers may be partially explained by larger population size, the incidence rates for NCDs in rapidly transitioning LMICs are

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

much steeper than those in more affluent high-income counties (HICs) [8]. For example, it was previously estimated that by 2025, the number of diabetes cases will increase by 170% in LMICs, compared with a 41% increase in HICs [9].

Thus far, the attention on health burdens in LMICs has justifiably focused on the persistence of infectious diseases, reproductive health problems, and nutritional deficiencies. However, these same countries must also contend with 80% of the global mortality associated with chronic diseases [10, 11]. Projections suggest that this already overwhelming "double-burden" will be exacerbated by the growth of NCDs such as diabetes. Altogether, projected increases in diabetes in all corners of the globe will result in a corresponding escalation of burdens in the form of serious morbidity, disability, diminished life expectancy, reduction in quality of life, loss of human and social capital, and individual and national income losses. This chapter describes these burdens in a global context, and systematically introduces data regarding regional patterns and associated themes.

Distribution

Epidemiological evidence quantifies the impacts and predictors of disease, identifies vulnerable populations and their needs, and facilitates the formulation of appropriate disease prevention and control strategies. However, there is still limited representative epidemiological data, and very few prospective studies, originating from a great many LMICs – the parts of the world that together contribute to the greatest diabetes burdens. Moreover, the utility of currently available estimates is hampered by methodological deficiencies (inconsistent diagnostic criteria, poor standardization of methods) and limited coverage (regional sampling with a predominance of urban studies even though most of the populations in question are rural inhabitants) [12, 13]. To address these barriers, the International Diabetes Federation and World Health Organization use sophisticated modeling approaches to provide global estimates, by country, for diabetes prevalence. Despite many intra-region differences, there are notable patterns for different income-group regions, which are described here.

In Africa:

- There is a general lack of awareness about chronic diseases and their risk factors [12]. For example, three out of five people with diabetes in Africa remain undiagnosed [1], and a mere 25–35% of people with hypertension were aware of their elevated blood pressure status [13].
- There are limited data originating from a few localized centers in certain parts (western, eastern, and southern) of the continent, and prevalence estimates vary widely, between 0–3% in rural areas and 6–10% in urban environments [12, 14]. Since prevalence estimates are largely based on fasting blood glucose levels, diabetes defined by post-prandial hyperglycemia is largely being missed.
- Although urbanization, socioeconomic development, epidemiological transition, and increases in overweight and obesity are cited as factors leading to growth of diabetes [15], data on population-level dietary and physical activity patterns are severely lacking in African countries; also, the prevalence of overweight and obesity is highest among peri-urban low socioeconomic status dwellers, and consequent diabetes risk may also be higher, although again, there are limited data among this population.
- Although HIV/AIDS overshadows NCDs such as diabetes in African countries [14, 16, 17], diabetes and other metabolic factors may be a future concern in this population for various reasons: first, demographic projections alone suggest that the prevalence of diabetes will continue to grow in this region; and second, as HIV mortality declines owing to more widespread use of anti-retroviral therapies, there will be direct (in the form of pancreatic dysfunction associated with therapy) and indirect (increasing longevity of life) impacts that may be associated with increased diabetes prevalence [18]. More data are needed to comprehend fully the relative impacts of HIV infection, anti-retroviral therapy, life expectancy, and contemporary sociodemographic and epidemiological transitions.
- There is variation in risk by ethnicity with higher prevalence of diabetes noted among people of Egyptian and Asian Indian origin than among indigenous African communities [12, 19].

In Europe, the United States, and Canada:

- Available data are derived from population studies, records of insulin and other medication sales, and/or reimbursement claims; estimates still suggest that 30% of people in these HICs have undiagnosed diabetes [1, 4, 20].
- Prevalence of type 1 diabetes (T1DM) is highest in Europe and incidence continues to increase in Europe and North America [21–23].
- Prevalence of T2DM is highest and growing fastest in vulnerable subgroups—lower socioeconomic groups and the elderly [4].
- Life expectancy of people with diabetes, although reduced compared with the general population [24], is markedly higher than in LMICs of the world.
- Therapies are associated with inflated and growing health expenditures [25].

In Central and Latin America:

- The average prevalence of diabetes is 8% [1], although there is variation in diabetes prevalence reflecting the diversity of ethnicities and stage of development between countries [7]. Indigenous populations are estimated to have a high prevalence of metabolic dysfunction and diabetes, as has been noted in Brazil [26], but the patterns and proportions of indigenous peoples in each country are not clearly documented [27].
- The pattern of T1DM incidence seems to correspond to the size of the population of white European ancestry [28, 29].
- Poor accessibility to health services continues to be a problem for many of those affected [28].
- Countries such as Mexico are starkly affected as diabetes has climbed the list of leading causes of mortality over the past three

decades [30], and is now one of the top two causes of death for Mexicans [31].

Asia is emerging as the epicenter of the cardiometabolic pandemic [32, 33] since:

- Populous countries in this region (India and China are estimated to have 66 and 96 million people living with diabetes, respectively) are confronted with diabetes risk being manifest at younger ages and at lower body mass indices compared with populations in other regions [32].
- Patterns of genetic/ethnic propensity and phenotypes are diverse:
  - South Asians have lower BMIs but susceptibility to low β-cell output (low insulin secretion) and also a tendency to deposition of metabolically active visceral adiposity; together, these may explain the greater vulnerability to diabetes in this population [34–36].
  - Peninsular Arabs and Pacific Islanders exhibit a very high prevalence of obesity and diabetes (estimated to be ~20% and ~25–35%, respectively) [1, 37].
  - There are also still rural–urban differences in prevalence of diabetes among Asians, which suggests genetic, environmental, and "thrifty" genotype factors, and their interactions all have a role to play [38].
- More epidemiological data, especially from longitudinal studies, are needed that can inform our understanding of pathophysiology, and also data on best practices and interventions to screen, prevent, and control diabetes cost-effectively.

Diabetes is renowned as a "silent epidemic" [39]. The slow progression and lack of symptoms in the early stages of disease often delays people seeking a glucose test, preventive care, and/or medical attention. As such, self-reported prevalence often reflects an underestimation of the number of cases because it does not account for undiagnosed cases. Almost half of all people with diabetes worldwide (~192 million) remain undiagnosed [1], and the prevalence of undiagnosed diabetes is much higher in low-income than lower- and upper-middle income countries (75% vs. 46%, respectively) [40]. Overall, it is estimated that 84% of all cases of undiagnosed diabetes are in LMICs, with Pacific Island nations showing the highest prevalence [41]. This is particularly concerning because, as the pathophysiology of diabetes sets in, diabetes-related complications such as nerve, eye, kidney, and/or vascular diseases can already manifest before diagnosis occurs [42–44]. Target organ damage of this nature can be life threatening and/or seriously disabling [45].

The traditional socioeconomic gradient associated with chronic diseases may itself be transitioning. As the world's urban population size begins to outnumber those living in rural areas, many LMICs face enormous challenges related to growth of peri-urban slums and squatter settlements, disparities in provision of basic amenities, and poor sanitation and nourishment along with subsequent exposure to contemporary dietary choices, tobacco use, and mechanization of transport with consequent growth in incidence of NCDs. Thus, the paradigm is shifting *globally* towards the inverse relationship found in established market economies where the greatest burdens of NCDs are felt by the least well-off segments of the population [46–51]. In India, for example, it has been demonstrated [52] that although family history and prevalence of glycemic abnormalities in high-income groups were double those of low-income groups, the reverse was true for smoking, alcohol consumption, prevalence of comorbid cardiovascular risks, and occurrence of complications (macrovascular disease, cataracts, proteinuria, and neuropathy). Indeed, since lower and middle socioeconomic classes make up such a large proportion of the populations in South Asia, even though the prevalence is lower, the absolute numbers of people in these classes affected by diabetes and comorbid cardiovascular disease (CVD) risks are much higher than in their wealthier counterparts [53]. Some studies even show greater disease susceptibility in lower socioeconomic groups in India [54, 55], mimicking patterns in wealthier nations [56–59]. As this chapter progresses, it will become evident that the countries suffering the greatest burdens of disease are also those least equipped to manage the growing epidemics.

Major burdens

The burden of any disease, including diabetes, can be described by its health-related impacts, the morbidity and mortality caused, and the social and economic costs to individuals, families, communities, and national economies (Box 5.1).

Acute and chronic disease complications

The patterns of major health-related burdens of diabetes vary with the type of disease. Of the two most common forms, T1DM and T2DM, the latter accounts for 90–95% of all cases worldwide. Both T1DM and T2DM may be associated with acute and chronic metabolic consequences, but the frequency of events varies according to the underlying pathophysiology and level of glycemic and cardiovascular risk factor (i.e. blood pressure, cholesterol, and tobacco) control [60].

Box 5.1 Evaluation of burden.

- Health-related burdens
  - Disease events and/or ill-health
  - Morbidity (physical and psychosocial)
  - Mortality
- Social implications of disease
  - Disability
  - Alteration of social roles or family structure
  - Caregiver burdens
- Economic costs of disease
  - Health-seeking and utilization (frequency and costs)
  - Direct medical expenditure
  - Direct non-medical expenditure (ancillary expenses of health seeking and care)
  - Indirect costs (losses in productivity)

Acute fluctuations in serum glucose may rapidly spiral into emergency situations, with potentially fatal repercussions if untreated. Episodes of severe acute hyperglycemia (e.g. diabetic ketoacidosis [DKA] [61] and hyperosmolar non-ketotic coma) or, conversely, severe hypoglycemia, most often require immediate medical management. Longer term follow-up is then intended to promote better blood glucose regulation and avoidance of precipitants (e.g. infection, non-adherence to treatments, missing meals, alcohol abuse). Apart from atypical variants such as ketosis-prone T2DM in Africans [12, 14], most acute metabolic complications occur in people with T1DM, whereas ~10–12% occur in those with T2DM. When treated properly, the mortality from acute hyperglycemic episodes such as DKA is extremely low (e.g. DKA mortality in Taiwan, the United States, and Denmark were estimated to occur in 0.67–4.0 % of cases) [62, 63]. In contrast, in some African countries, mortality from DKA can be as high as 25–33% [64], although data on the incidence of these complications from LMICs are limited [65]. Individual person (e.g. age, additional comorbidities) and resource (e.g. hospital facilities, experience of staff) characteristics may also modify the outcomes. In under-resourced settings, for example, complex, cumulative, and interconnected barriers (poor accessibility, inadequate therapeutic instruments and medication, and insufficient numbers of trained staff) result in poor glycemic control and higher risk of mortality [66]. Hence early-life mortality in persons with T1DM in low-resource settings is commonplace (e.g. the post-diagnosis life expectancy in some regions of Africa is just 1 year) [67].

Both T1DM and T2DM are associated with damaging effects on tissues, with eventual progression to devastating complications. In a large proportion of people with diabetes, other cardiometabolic risk factors (hypertension, dyslipidemia, proinflammatory, and procoagulant states) often co-occur [28], which further increase the risk of diabetes-related complications [68]. Diabetes-related complications include the following:

- Macrovascular diseases such as coronary heart disease, cerebrovascular disease or "stroke," and peripheral vascular disease). Those with diabetes have a 2–4-fold higher risk of developing coronary disease than people without diabetes [69]. More significantly, however, the age- and sex-adjusted mortality risk in persons with diabetes is roughly equivalent to that of individuals without diabetes who have suffered a previous myocardial infarction [68, 70, 71]. T2DM and CVD have common precursors such as insulin resistance, visceral adiposity, and excess inflammation [72–76], and also a complex mix of mechanistic processes including oxidative stress, enhanced atherogenecity of cholesterol particles, abnormal vascular reactivity, augmented hemostatic activation, and renal dysfunction [77]. Hence simply controlling glucose, at least in the short term, has not been found to reduce CVD events and mortality in large randomized controlled trials [78–80]. The implications, therefore, are that individualized, comprehensive, multifactorial risk management (i.e. treating all risk factors together) has been advocated for people with T2DM [81, 82], adding to the burdens on patients, providers, and health systems.
- Microvascular diseases (retinopathy and nephropathy): together with hypertension, diabetes is a leading risk factor for nephropathy and end-stage renal disease requiring dialysis or transplant [83, 84]. Further, visual impairment, mainly due to cataract development, and retinopathy in diabetes are increasingly common, and diabetes is the leading cause of adult-onset blindness globally [85]. In the case of retinopathy and nephropathy, duration of disease, age, glycemic control, and blood pressure control have all been found to be prominent modifying factors of disease onset, progression, and outcomes.
- Neurovascular diseases (neuropathies): neuropathies are also common consequences of diabetes and can occur in one-third of people affected by this disease. Lower extremity sensory loss and compromised peripheral vascular circulation [86, 87] put these persons at risk of ulceration [88] and subsequent infection. The combination of neuropathy, infection, poor wound healing, and poor distal circulation increases the risk of lower extremity amputation 15–40-fold [84, 89].

As diabetes and chronic diseases grow in LMICs, these countries still face residual burdens of communicable infectious diseases [90, 91]. This challenge is not just one of parallel epidemics, as diabetes predisposes both to higher risk of infections [92] and possibly poorer outcomes for those who contract infections. Indeed, this has been documented in terms of higher risks of pneumonia, urinary tract infections [93], osteomyelitis, and even tuberculosis (TB) [94, 95]. Regarding outcomes, we can use TB as an example: data from observational studies increasingly show that TB disease severity (e.g. sputum smear grade [96, 97], hemoptysis, cavitation [96, 98–100], and drug resistance[100]), treatment failure, TB relapse, and death appear greater among those with TB and diabetes than those with just TB alone.

These complications and the consequences that stem from them (e.g. congestive heart failure, diabetic foot, and death) are associated with considerable morbidity, greater healthcare seeking, reduced quality of life, disability, premature mortality, and high economic costs [42, 43, 101].

Health utilization patterns

Health-seeking and health utilization behaviors are influenced by a number of individual-, provider- and system-level factors. In the case of diabetes, the individual's ill-health and morbidity and desire for preventive care drive more health seeking. In addition, expert guidelines recommend regular follow-up and providers may request that persons with diabetes return more frequently. Hence people with diabetes visit medical care providers more than those without diabetes [25, 102–105]. Increased health seeking and utilization in people with diabetes and associated complications result in greater medical costs being incurred compared with the general population without diabetes [106, 107]. Further discussion of healthcare costs from individual, societal, and national

perspectives will continue in the section "Economic costs of diabetes."

Various studies have shown that having diabetes doubles one's risk of hospitalization and associated costs, compared with not having diabetes, and this risk is amplified by the development of diabetes-related complications [106]. The presence of poor peripheral circulation increases the risk of hospitalization by 70%, and CVD increases this risk by 310% [84, 103]. Although studies from most regions of the world report late-stage macro- or microvascular complications as the leading cause of diabetes-related hospitalizations, lower income settings also confront high proportions of admissions from acute episodes of hyperglycemia [108]. Furthermore, individuals with diabetes utilize an average of 3–4 medications (including all antihypertensives, lipid-lowering and antidepressant medications, and aspirin, in addition to glucose-lowering drugs) [109], hence the cost implications are substantial. The use of oral antidiabetes drugs increases health expenditure by 40% compared with the general population, and regular insulin use incurs a further 2–4-fold greater expense [103, 110].

Healthcare infrastructure and financing have strong impacts on health seeking and utilization. In a number of LMICs such as India, most healthcare costs are borne by individuals and their families from household income [109, 111–113]. Surveys have shown that health expenditures due to diabetes and CVD are associated with financial difficulties as a result of illness [102, 114]. Financial limitations to accessing treatment are not confined to LMICs, as persons with low socioeconomic status living in HICs curtail purchases of diabetes medications due to costs [115, 116].

Disability

Aside from the medical or biological dysfunction caused by diabetes, ill-health affects how an individual interacts with and functions in society. This concept of "disability" signifies that psychosocial illness or physical deviations (from generally accepted norms of anatomical structure or physiological function) may impair one's ability to perform domestic and occupational activities and assume societal roles. As a result, diabetes may inhibit one's general utility and ability to integrate fully in society.

Diabetes can lead to disability in a variety of ways. Excluding the medical aspects of diabetes-related complications that directly restrict bodily function, diabetes may be considered a "hidden" disability, whereby the individual concerned is hampered from partaking in routine activities, but displays no physical manifestation of this illness. For example, children with T1DM may suffer discrimination at school or may not be permitted to engage in physical activities [117]. Adults in the workplace may suffer lower work performance by virtue of any number of symptoms (impaired fine motor skills and concentration, grogginess, urinary frequency) [118], or even a decline in cognitive functioning [119–121]. People with diabetes take more working days off and often report difficulties with completing work tasks [122, 123]. Those requiring insulin may be limited additionally by highly structured activities of daily living (the requirement for meticulous glucose monitoring, insulin administration, timed eating), recurrent hospitalizations, hyper- and hypoglycemic episodes, and regular preventive or therapeutic medical visits. In the DAWN2 study, ~40% of participants reported that their medication interfered with their ability to live a normal life, and 57% reported that they were not working because of their disease [124]. The physical manifestations of diabetes become more significant with the development of complications. Visual impairment, restricted mobility (due to shortness of breath, chest pain, or even amputation), and general ill-health (ranging from increased susceptibility to infection to uremia related to irreversible renal dysfunction) are all considerable impediments to productive work and engagement in socially valuable activities [118, 125].

Depending on the health status of the individual and severity of disease, disability can be temporary or permanent. There are limited country-specific data on the permanent disability resulting from diabetes, although diabetes is the leading cause worldwide of adult-onset blindness, non-traumatic amputations, and irreversible kidney failure [39].

Psychosocial burdens

Less tangible, but no less severe, are the psychological, interpersonal, and social burdens that people with diabetes and their caregivers may experience (Table 5.1). In a study assessing

Table 5.1 The psychosocial burdens of diabetes.

Type	Individual	Family
Physical	Diabetes may lead to temporary or permanent disability: impaired fine motor skills and concentration, grogginess, increased urinary frequency, visual impairment, restricted mobility, non-traumatic amputations, and irreversible kidney failure	–
Mental	Diabetes may lead to mental health problems: decline in cognitive functioning, depression, distress, anxiety, sense of hopelessness, and suicidal ideation	Caring for persons with diabetes may lead to mental health problems: emotional well-being, distress, frustration, and depression
Societal	Diabetes may lead to poor productivity, poor functioning, and societal problems: difficulties with daily life activities, loss of work days, low social integration, discrimination, and stigma	Caring for persons with diabetes may lead to absenteeism, loss of income by family members, affected family and peers relations, and discrimination

the psychosocial burden of diabetes in 8596 adults across 17 countries (the DAWN2 study), 44% reported experiencing high diabetes-related distress, 14% were identified with depressive symptoms, and 12% reported very poor or poor quality of life [124]. Further, diabetes has been found to be a significant risk factor for suicidal ideation [126], hopelessness, and poor quality of life in adults [127] and for suicidal ideation in adolescents with diabetes [128, 129]. Compared with their healthy counterparts, adults with diabetes exhibit higher odds for depression, anxiety and cognitive dysfunction [130, 131] and spend three times more on anxiety medications annually [132]. These mental health issues interfere with optimal self-management and may lead to other diabetes complications and increased risk for all-cause mortality [133, 134]. Family members caring for relatives with diabetes also experience high levels of distress and report that diabetes has a significant negative impact on their well-being [135].

The mental health burdens associated with diabetes may also affect productivity and functioning [136, 137]. Of those suffering from any form of work disability inducing absence and/or poor productivity, over half of them had minor and/or major signs and symptoms of depression [138]. Similarly, family members of persons with diabetes report that their work-related activities are negatively affected by their relative's disease, and some report working part time to help care for the relative with diabetes [135].

Strong social networks and good social support are associated with fewer psychosocial problems and better self-management among people with diabetes [139, 140]. However, some studies have shown that people with diabetes have low levels of social integration (e.g. low contact with family) and support (e.g. living without a partner) [141, 142]. In the DAWN2 study, 20% of surveyed participants reported that diabetes had negatively impacted their family and peer relations [124]. This suggests that diabetes is a shared ailment negatively impacting people's interpersonal relations.

Studies have shown that one in five people with diabetes and their families experience some form of discrimination [124, 135]. The reasons for discrimination are varied; one involves perceiving that persons with diabetes are using up societal resources [143]. As a result, stigma is common among people with diabetes and prevents them from disclosing their disease. For instance, adolescents with T2DM have reported hiding their diagnosis from their peers because they fear their reaction [144], and adults with diabetes have reported that disclosing their disease to their supervisors and colleagues would jeopardize their job [143] or, possibly, their education opportunities or marital prospects [145, 146]. Owing to the stigma attached to T1DM, some parents choose not to disclose the condition of their child to relatives [145]. Use of insulin adds to the stigma, as people with diabetes report feeling mistaken for intravenous drug users [143, 144]. Societal stigma and discrimination are significant barriers to self-management and to improving care and social support for individuals with diabetes.

The individual and societal dysfunction associated with disability is difficult to quantify. Several methods have been used in attempts to quantify diabetes-related disability, but most suffer from at least some imperfection owing to the necessity for making judgments about the value of activities and subjectivity of responses. This is especially difficult where there are cultural and ideological dissimilarities between the evaluator and the population being appraised.

Mortality

Diabetes is associated with a 1.4–6-fold higher risk of mortality, and this varies by age and sex [147]. Diabetes is also associated with premature mortality, shortening life expectancy by ~7–15 years [148, 149]. An estimated 48% of deaths due to diabetes occur under the age of 60 years [1].

The most common causes of death among people with diabetes are CVD, chronic kidney disease, and/or infections (e.g. pneumonias). In HICs, CVDs account for an overwhelming 65–75% of deaths in people with diabetes [150, 151]. In low-resource settings, infections and acute metabolic emergencies are still the prevailing causes of death in people with diabetes [14, 15, 152, 153]. End-stage renal disease also carries inexorably high mortality, due mainly to the inaccessibility (physical and financial) of treatment (dialysis and/or transplant) in most LMICs [14]. Globally, CVD and nephropathy are the most prominent fatal endpoints, and long-standing duration of disease increases the susceptibility to succumbing from these illnesses [43].

Ascertaining the global mortality attributable to diabetes is no easy task. Most mortality statistics rely on documented causes of death and do not acknowledge the underlying roles of glucose dysregulation in diseases leading to death. For example, it has been argued that evaluating actual diabetes-related mortality should take into account that diabetes contributes to 21% of coronary heart disease and 13% of stroke mortality worldwide [45]. The International Diabetes Federation takes these aspects into account and approximates that diabetes was responsible for 14.5% of total global mortality (5 million deaths) of adults aged 20–79 years in 2015 [1]. In addition, the mortality attributable to diabetes would be even higher if deaths related to IGT were also included. This diabetes precursor independently increases the risk of mortality, and has a prevalence of 15–40% in adults [6].

There are some important themes regarding diabetes mortality. First, over time, the absolute numbers of deaths due to diabetes have increased, and the proportion of all deaths attributable to diabetes has also increased in every region of the world (Table 5.2) [1, 147, 154]. Second, there is some regional variation in the global distribution of diabetes-related mortality. Although the proportion of deaths in LMICs is lower than in HICs, the absolute numbers of deaths (by virtue of the larger population size) outnumber those in HICs. The highest absolute numbers of deaths due to diabetes were in the most populous countries of the world, i.e. China, India, USA, and Russia [155]. Third, there is a noticeably greater proportion of deaths in younger age groups in LMICs [147], resulting in a greater loss of life-years and affecting the economically active subpopulations in these countries. Fourth, whereas some higher income countries are demonstrating reductions in the incidence of mortality [24], the diabetes mortality has

Table 5.2 Estimated percentage of deaths attributed to diabetes by region and year.

Region	WHO 2005 Male	WHO 2005 Female	WHO 2010 Combined	IDF 2013 Combined
Africa	2.2	2.5	6.0	~8.5
Eastern Mediterranean and Middle East	6.1	8.8	11.5	~13
Europe	6.6	5.1	11.0	~10.5
North America	8.7	8.3	15.7	~13.5
South and Central America	4.0–4.4	6.5–9.4	9.5	~12
South-East Asia	5.4	6.9	14.3	~14
Western Pacific	3.4	4.8	9.7	~16

been increasing in LMIC regions, particularly Africa, the Western Pacific, and the Middle East.

Economic costs of diabetes

The prototypical chronic nature of diabetes requires empowered self- and clinician-guided management for the duration between diagnosis and death. Forestalling complications and premature mortality is the central theme underlying metabolic control and preventive management. Together, the care and serious consequences of diabetes are burdensome and costly. Quantifying the costs of diabetes from the perspectives of people with diabetes and also national resource use and losses is critical towards informing appropriate healthcare planning, resource allocation, and response strategies.

Approaches used to estimate economic costs of disease vary, not only by the perspective taken, but also by the methodology applied, data sources used, year of estimation, and purchasing power and clinical practice patterns in different settings. Needless to say, between-country comparisons are even more problematic when issues emerge regarding uncertainty of incidence and prevalence estimates, and standardization of measures and criteria. General principles and concepts of estimating cost [2, 84, 156, 157] are described in the following.

Types of costs

- *Direct costs ("inputs"):* These include costs of treatment and/or care of the disease, broadly encompassing all outpatient consultations, inpatient care, diagnostic investigations, therapeutic procedures, pharmacotherapy, paramedical care (e.g. home nursing, physiotherapy), and rehabilitation. There are also direct nonmedical costs (e.g. transportation to and from care providers).
- *Indirect costs ("lost output"):* These costs represent the present and future value of economic productivity lost by society on account of temporary or permanent disability, excess morbidity, and premature mortality due to disease. They are typically calculated by estimating foregone income (summing the cumulative impacts of absenteeism and presenteeism based on employment status and income, for both the individual and employer or society).
- *Intangible costs:* These costs are associated with psychosocial impacts (e.g. stress, depression, emotional problems) and altered quality of life due to an illness. They may include diminished family role, informal care, and income foregone by family members. They are typically difficult to estimate owing to a lack of standardized methods.

Cost appraisal methods

- *Cost-of-illness method:* This is the most widely used approach to describe the direct and indirect costs of disease to society, conducted by exploring costs in a group of selected persons either over a defined finite period (e.g. 1 year) or through the natural progression of the disease.
- *Human capital approach:* This is a method of estimating indirect costs of disease, with an emphasis on foregone earnings and employment. It is criticized as a tool owing to a tendency for overestimating future values, accepting wage disparities, and disregarding socially valuable activities such as housekeeping and volunteer work.
- *Friction cost approach:* This is a more conservative measure of indirect costs that considers lost productivity as finite where restoration of productivity (return to work or replacement of worker) occurs within a time-frame and therefore limits production losses. It requires detailed data.
- *"Top-down" approach:* This involves calculating costs from national databases/estimates and partitioning costs of different illnesses according to diagnoses. It requires accurate data entry, especially when indirect costs are being investigated. It avoids the risk of double counting.
- *"Bottom-up" approach:* This involves following the trail of illness-related costs of a defined subpopulation with the illness over a finite period.

Studies that have examined the costs of diabetes vary in their estimates of the excess costs generated through resource consumption. The major drivers of direct healthcare costs include health service utilization (outpatient health practitioner consultations and inpatient care), medication usage, diagnostic tests, self monitoring and therapeutic medical devices, and therapeutic procedures. In HIC settings, auxiliary services such as paramedical care (dieticians, physiotherapists, occupational therapists, and home nursing) and preventive checks (foot care, urine, and eye testing) may contribute to costs.

In 2015, US$1 in every $8 of healthcare expenditures globally was spent on diabetes [1]. The relative contributions of different cost drivers in various regions of the world are shown in Table 5.3.

Table 5.3 Regional and country estimates of costs of diabetes.

Region	Country	Year	Method	Annual total cost per individual	Annual total costs for country/region	Main drivers of cost	Limitations
Europe	France [164]	2010	Cost of illness, prevalence-based study: review of published studies, policy documents, and government reports	€6930 for persons with T1DM; €4890 for persons with T2DM	€17.7 bn	€4.2 bn for treatment of diabetes complications; €3.5 bn due to comorbidities; €3.6 bn due to health expenditure indirectly related to diabetes; €2.5 bn for diabetes treatment and prevention; €7.4 bn due to health expenditure unrelated to diabetes	Excluded indirect and intangible costs; study based on data from health insurance claims
	Germany [160]	2000–2007	Retrospective, bottom-up, cost of illness study: national insurance database (275,000–320,000 individuals)	€5197 in 2000 to €5726 in 2007 (direct); €2400 in 2000 and €2605 in 2007 (incremental)	€27.8 bn in 2000 and €42.0 bn in 2007 (direct); €12.9 bn in 2000 and €19.1 bn in 2007 (incremental)	Direct: 37% for inpatient care, 19% for outpatient medications, 18.5% for other services, 15% for nursing care, and 13% for physician outpatient services Incremental: 31% for inpatient care, 23% for other services, 21% for outpatient medications, 13% for physician outpatient services, and 12% for nursing care 46% for diagnosis and laboratory, 28% for pharmaceuticals, and 56% for physician visits	Retrospective analysis; only included insured persons; excluded indirect and intangible costs; only included the state of Hesse
	Greece [175]	2007	Retrospective study employing patient records, national formulary, and physician survey (102 patients)	€1297: €981 (controlled); €1566 (not controlled)	n/r		Excluded indirect and intangible costs; excluded T1DM; excluded costs of hospitalizations and comorbidities; small patient sample selected from 51 physician practices
	Italy [200]	2012	Top-down and bottom-up approaches; expert interviews and review of published studies and national sources	€2756–2991	€9 bn	Hospital admissions (57%), medications (30%), and outpatient care (13%)	Excluded indirect costs; cost estimates obtained from five different studies employing different methodologies; included only one national study
	Lithuania [201]	2011	Prevalence-based, top-down approach: data from national health insurance database (762 persons)	€955; from €672 (no complications) to €1588 (with complications)	n/r	Inpatient: €1720 for psychiatrics, €1632 for hemodialysis, €1040 for nursing and palliative care, €1004 for vascular surgery Outpatient; €286 for outpatient day care, €43 for GP visits, €38 for rehab specialist	Excluded T1DM; excluded indirect and intangible costs
	The Netherlands [202]	2012	Cost–utility analysis and friction cost approach; prospective pre–post study using patient questionnaires ($n = 407$)	€3489	n/r	Direct: €941 for primary care, €338 for outpatient hospital care, €701 for inpatient hospital care, and €518 for medication Indirect: €174 for travel costs and €216 for loss of productivity	12-month prospective design subject to recall bias; excluded annual direct and indirect costs; only included 4 diabetes management programs in The Netherlands

	Spain [165]	2009	Bottom-up, top-down, cost of illness, and human capital approaches: review of published studies and national data sources (n = 3,007,182)	€1660 (direct); €916 (indirect)	€5.1 bn (direct); €2.8 bn (indirect)	Direct: €757 m for macrovascular complications, €579 m for microvascular complications Indirect: only loss of productivity included	Excluded intangible costs; used human capital approach for estimating indirect costs; excluded non-healthcare direct costs and informal care costs faced by people with diabetes and society as a whole
	UK [203]	2010–2011	Cost of illness, top-down approach: aggregated data sets from national health system, public health, hospital databases, and literature review	n/r	£23.7 bn; £9.8 bn (direct); £13.9 bn (indirect)	Direct: £7.7 bn due to complications, £2 bn for diagnosis Indirect: £4.8 bn for due to mortality, £945 m due to sickness days, £2.9 bn due to presenteeism	Excluded foot care and primary care monitoring costs; obtained data from various sources employing different methodologies; excluded intangible costs
Africa	Africa (46 member states in the WHO African Region) [183]	2000	Cost of illness, prevalence-based study: WHO publications, online resources, and health system sources	INT$3633	INT$25.5 bn; $8.1 bn (direct); $17.4 bn (indirect)	Direct: 32% for insulin treatment, 9% due to diabetes testing Indirect: 38% due to permanent disability, 4% due to premature deaths	Costs of diabetes complications were not included; the use of gross national income per capita might overestimate the economic burden of diabetes; it assumed that people with diabetes received five diagnostic tests; intangible costs were not included
	Algeria [204]	1998, 2010 and 2013	Cost of illness, prevalence-based study: literature review, online resources, and consultations with experts	Treatment costs US$503 DM spending US$313	US$513 m (direct)	US$28,422 for renal transplantation, US$3901 for ambulatory peritoneal dialysis, US$3742 for hemodialysis, and US$2451 for cardiovascular complications	Excluded indirect and intangible costs; cost estimates obtained from different studies employing different methodologies, estimates based on insufficient national data or limited reliability
	Morocco [161]	n /r	Cost of illness, prevalence-based study and human capital approach; review of published studies, Ministry of Health and international federations/organizations documents	US$259–830 (direct) US$1113 (indirect)	US$0.47–1.5 bn (direct); US$2 bn (indirect)	Direct: medications US$90,685,180–$217,363,962; hospitalization US$1,547,594–$326,190,375; testing US$32,619,037–$69,897,937; outpatient visits US$181,921,500–$454,803,750 Indirect: permanent disability US$1,486,940,942; temporary disability US$19,832,628; life years lost US$517,757,550	The cost of disability in young people (0–14 years) and those retired (above 60 years) was ignored; estimates are based on assumptions around the number of people using insulin, oral drugs, glucose meters and those needing outpatient care or inpatient hospitalization; scarcity of reliable data
	Sudan [185]	2001	Cost of illness, bottom-up approach: parent interviews of 147 T1DM children	US$283 per child	n/a	Direct costs: insulin (36%), glucose testing, physician visits Indirect costs: poor school performance, 65% of family expenses were used for care of one T1DM child	Subject to recall bias; sample may not be representative of wider population (private clinics); subjects had ≤5 years' duration of diabetes

(*continued*)

Table 5.3 (*Continued*)

Region	Country	Year	Method	Annual total cost per individual	Annual total costs for country/region	Main drivers of cost	Limitations
	Republic of Seychelles [205]	2004–2005	High-risk strategy to estimate direct medication costs; population-based survey (1255 aged 25–64 years)	US$45.6 in 2004 and US$84.6 in 2005	n/r	Diabetes US$ 21.5 in 2004 and US$ 3.8 in 2005; hypertension US$30.4 in 2004 and US$11.2 in 2005; hypercholesterolemia US$32.7 in 2004 and US$30.6 in 2005; medical visits US$8.2 and laboratory exams US$14.4	Excluded hospitalization, indirect and intangible costs; costs for a treatment strategy provided are likely to correspond to minimal figures; only the public sector was included
Asia	China[a] [206]	2007–2011	Cost of illness, prevalence-based study: national household survey from insurance evaluation (5344 people with DM)	¥8,914; ¥8,582 (direct); ¥331 (indirect)	n/r	¥8289 due to direct medical costs, ¥5519 due to medication costs, ¥1091 due to non-medical costs, ¥3769 out of pocket spending	Costs estimated from an analysis including 5 chronic diseases
	China [207]	2007	Cost of illness study: interviews with 1913 people with DM	¥10,164 (direct)	Direct: ¥6056 (complications); ¥3583 (no complications)	Outpatient: ¥242 for treatment, ¥28 for diagnosis, ¥0.5 for medical supplies Inpatient: ¥10,102 for treatment, ¥3218 for diagnosis, ¥430 for medical supplies, ¥86 for nursing	Excludes T1DM; estimates are based on patient self-report; excluded indirect and intangible costs; cross-sectional study including secondary and tertiary care hospitals from 4 cities
	Indonesia [208]	2005–2010	Review of published studies, national guidelines, policies, and Ministry of Health and insurance data	US$40–800	US$22.4 m	US$7691 m for renal-replacement therapy, US$4900–6500 for hemodialysis, $75 for hypertension and retinopathy complications	Excluded indirect and intangible costs; paucity of data representative at the national level; lack of a clear reference date; lack of data from primary care; lack of data from certain regions of the country
	Iran [209]	2004–2005	Cost of illness, prevalence-based study and human capital approach: interviews with people with DM ($n = 710$)	US$192; US$152 (direct); US$40 (indirect)	US$112 m (direct); US$10 m (indirect); US$50 m (complications)	Direct: 29% due to medications and devices and 29% due to hospitalization Indirect: only lost work days included Complications: 71% due to hospitalizations	Estimates are based on patient self-report; indirect costs were estimated in workers only; study was conducted in Tehran, which is more urbanized than other provinces of Iran; intangible costs were excluded
	India [187]	1999–2012	Bottom-up approach: systematic review of published studies (19 studies including 13,490 persons)	US$6–314 (direct); US$48 (indirect)	US$114–816 (direct); US$91–$393 (indirect)	Direct: 54–62% for medications Indirect: 61% for patient income loss and 39% for carer income loss	Excludes intangible and loss of productivity costs; heterogeneity of study designs and diversity of methods in included studies; provides a fragmented picture

	Pakistan [210]	2004–2005	Bottom-up approach: retrospective study employing case note review of hospital documents (214 patients)	n/r	PKR356 (transtibial or transfemoral amputation); PKR389 (minor amputation)	The cost of medication and of home visits for ulcers grades 2 and 3 constitute ~22–79% of the total cost	Included only one tertiary hospital; excluded indirect and intangible costs; small sample size; study findings are not generalizable
	Pakistan [211]	2006	Cost of illness: questionnaires; human capital approach; $n = 345$ (age 20–60 years) at 6 OPD clinics	PKR11,580 (= US$197)	Direct costs projection = PKR71 bn (= US$1.21 bn) annually	Direct: medication (46%), laboratory investigations (32%); age, complications, and duration of disease	Inclusion restricted to 20–60 years age group; did not include costs of self-monitoring; calculation of lost productivity limited to those employed
	Turkey [212]	2009	Cost of illness, prevalence-based study: literature review, expert interviews, hospital health records, and national databases, (4 million people)	₺.622–2.966 (direct)	₺11.4-12.9 bn (direct)	28% due to cardiovascular complications, 27% due to renal complications, 15% for non-diabetes drugs, 13% for other complications, 12% for diabetes drugs, 5% for complication screening	Excluded indirect and intangible costs; diabetes complications costs were derived from a single center in Turkey; the cost of undiagnosed people was excluded; incidence and prevalence rates were not exclusively derived from Turkey-specific studies
	Thailand [213]	2008	Cost of illness, prevalence-based study and human capital approach: hospital service utilization records, medical records and patient interviews (475 people with diabetes)	US$881.47	US$418,696; 23% direct medical cost, 40% direct non-medical cost, and 37% indirect cost	Direct medical (provider): 11% due to hospital care/inpatient service, 3% drug and outpatient visits Direct non-medical (patient): 28% due to informal care (the care provided by the family members, friends, relatives) Indirect: 19 % due to permanent disability, 17% due to mortality cost	Only one primary care hospital and affiliated health centers were included; persons not requiring treatment were omitted from the cost estimation, which may have inflated the cost per case; indirect cost calculation did not take into account reduced earnings or productive capacity due to disability; ignored intangible costs
Americas	Argentina [159]	2004	Review of published studies and national/provincial official sources	US$1628	n/r	Direct: Hospitalization is the main component of the total direct cost per person of diabetes care Intangible: 1,328,802 DALYs lost; 85% ascribed to disabilities	No annual total cost for country is reported; indirect medical costs are not reported; data were obtained using different methodologies, many of which have changed over time
	Brazil [174]	2007	Bottom-up and human capital approaches: healthcare system, Ministry of Health, and public health system data (1000 people in 2007)	US$2108, 63.3% (direct); 36.7% (indirect)	US$2,108,287; US$1,329,075 (direct); US$773,212 (indirect)	Direct: 48.2% due to medication; US$ 2062 per person for microvascular complications; US$2517 per person for macrovascular complications Indirect: loss of productivity of US$437 per person/year	Data on hospitalization costs was not included; only 8 Brazilian cities were included which are not representative of the whole country; the majority of included persons were women or workers

(*continued*)

Table 5.3 (*Continued*)

Region	Country	Year	Method	Annual total cost per individual	Annual total costs for country/region	Main drivers of cost	Limitations
	Canada [214]	2011	Cost of illness, prevalence-based study: utilizing economic burden of illness documents, medical billing system, and published studies	CAN$2300	CAN$ 2.5 bn; CAN$769.4 million (direct); CAN$1.7 bn (indirect)	Direct: CAN $350.1 m in hospital care, CAN$246.4 m in medication spending, and CAN$172.9 m in physician care costs Indirect: CAN$1.0 bn due to premature death and CAN$671.7 m due to long- and short-term disability	Does not take into account the indirect costs of complications, direct costs focus on the primary management of diabetes only, does not include costs associated with mental health
	Colombia [215]	2007	Cost of illness, incidence-based and human capital study; review of literature, national price lists, national statistics, and Ministry of Health data	US$847: $288 (direct); $559 (indirect)	US$2.7 m; US$921 m (direct); US$1.8 m (indirect)	Direct: 47% for drugs, 24% for cardiac and coronary disease, 15% for stroke, and 9% for amputation Indirect: 52% for cardiac disease, 10% for retinopathy and stroke	Excluded intangible costs and T1DM; the costs of hypoglycemia, diabetic neuropathies, ketoacidosis, infections, and other complications were not considered; cost estimates were based on international guidelines; quality of care variables were excluded
	Mexico [216]	2010	Cost of illness, prevalence-based study and human capital approach: national surveys, instrument developed, and expert panel consensus	n/r	US$778 m; US$343 m (direct); US$435 m (indirect)	Direct: US$133 m for medications, US$110 m for complications, US$60 m for diagnostics/consultations, and US$40 m for hospitalizations Indirect: US$409 m for permanent disability, US$196 m for premature mortality, US$64 m for temporary disability	Excludes T1DM, costs per person and intangible costs; estimates are based on expert reports and probabilistic models
	Mexico [217]	1992–2011	Cost of illness, prevalence-based study: review of published studies	n/r	US$205 bn	Direct: outpatient US$718 m, inpatient US$223 m Complications: retinopathy US$10 m, CVD US$13 m, nephropathy US$82 m, neuropathy US$3 m, peripheral vascular disease US$2 m Indirect: US$177 m	Estimates were obtained from studies conducted in different years using different methodologies; costs are based on probabilistic simulations
	USA [218]	2007	Cost of illness, prevalence-based study: cost of diabetes model utilizing published studies, government statistics, and analysis of national survey and medical claims databases	US$443 for prediabetes; US$2864 for undiagnosed diabetes; US$9677 for T2DM; US$14,856 for T1DM; US$3514 for gestational diabetes	US$218 bn; US$174.4 bn for diagnosed diabetes; US$18 bn for undiagnosed diabetes; US$25 bn for pre-diabetes; US$636 m for gestational diabetes	Direct: US$153 bn in medical costs Indirect: US$65 bn for productivity loss (higher levels of absenteeism, presenteeism, disability, and early mortality)	Estimates do not include intangible costs; calculation of lost productivity limited to those employed; does not estimate productivity loss associated with prediabetes or gestational diabetes

	USA [158]	2012	Cost of illness, prevalence-based study: cost of diabetes model utilizing national surveys and claims database (22.3 million people in 2012)	US$13,700 (US$7900 directly for diabetes care)	US$245 bn; US$176 bn (direct); US$69 bn (indirect)	Direct: 43% in hospital inpatient care, 18% in prescription medications to treat the complications of diabetes, 12% in antidiabetes agents and diabetes supplies, 9% in physician office visits, and 8% in nursing/residential facility stays	Estimates do not include: intangible costs, research, programs and administrative costs, over-the-counter medications, dental and optometry costs, caregiver loss of productivity, and undiagnosed diabetes
	Latin America and Caribbean [102]	2000	Cost of illness, prevalence-based study: cost estimates for groups of countries and human capital approach	US$703 (range: US$442–1219)	US$65.2 bn; US$10.7 bn (direct); US$54.5 bn (indirect)	Direct: drug costs (44%), consultations (24%), complications (23%—especially nephropathy) Indirect: disability and productive life years lost (93%), mortality (7%)	General lack of data forced the use of estimates in heterogeneous countries; diabetes-related deaths undercounted on death certificates; high indirect cost may reflect poor access to medical care
Australia	Australia: DiabCost Study	2003	Cost of illness, bottom-up approach: persons with T2DM; self-reported surveys	A$9625 (no complications); A$15,580 (with complications)	A$3 bn	n/r	Data were self-reported; costs not associated with DM could not be separated out
	Australia – AusDiab Study [132]	2004–2005	Bottom-up approach: data from national insurance, medical, hospital, and pharmaceutical databases; patient (558) questionnaires and examinations	A$3806 (direct); A$5379 (government subsides); A$2003 (non-healthcare)	A$10.6 bn; A$4.4 bn (direct); A$6.2 bn (government subsidies); A$1.3 bn (non-healthcare)	Direct: 35% for hospitalization, 32% for medication, 28% for ambulatory service, and 5% for consumables Non-healthcare: 48.7% for supported accommodation, 35.4% for home service and day center, 13.9% for transport, and 1.9% for purchase of special food	Excluded indirect and intangible costs; heart attack and stroke events were collected via patient self-report; the sample is skewed towards more people being diagnosed with diabetes

[a]Data obtained from article abstract.
T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus; DM, diabetes mellitus; BP, blood pressure; bn, billion; m, million; DALY, disability-adjusted life-year; OPD, outpatient department; GP, general practitioner or primary care doctor; €, euro (European Union); £, British pound sterling; US$, American dollar; CAN$, Canadian dollar; A$, Australian dollar; PKR, Pakistani rupee; , Turkish lira; ¥, Chinese yuan.

Broadly, diabetes results in ~2–5.6-fold greater healthcare expenditure than for the general population, depending on the context and the cost appraisal methodology employed [132, 158–161]. Themes that surface from these studies affirm the high costs of complications and associated hospitalization in HICs, but also point to high costs (relative to their purchasing power) of purchasing medications in LMICs [106, 162, 163]. In addition, it is important to note that the complex interconnections between the underlying pathophysiology of T2DM and associated cardiometabolic comorbidities may alter the scope of costs [106]. Hence, depending on the viewpoint and chosen values, resource use attributable to diabetes alone may in fact underestimate the broader range of costs associated with diabetes-related illnesses as a group. Indeed, from the data in Table 5.3, the supplemental costs of drugs for comorbid CVD risk management were also pronounced [102, 158, 164, 165]. Undiagnosed diabetes may not be described as a contributor to morbidity, mortality, and resource use, suggesting that we may be underestimating the true burden of this disease [41]. This is particularly relevant in regions of the world where there are few or no representative data regarding disease prevalence and causes of death (e.g. most LMICs) [166]. Finally, the value placed on the opportunity cost of diabetes-related ill-health and disability has not been widely quantified or even qualitatively described.

Individual-level cost drivers

Demographic and clinical characteristics can have profound influences on costs. Annual per capita cost increases for managing diabetes are higher for men than women in some countries, and among older age groups compared with their younger counterparts [103, 160]. The types of diabetes have different costs. T1DM accounts for a smaller proportion (~5%) of people with diabetes, but almost double the per capita costs compared with people with T2DM [167]. It has been postulated that more consultations and faster progression to retinopathy and nephropathy are the main drivers of cost and mortality risk in those with T1DM [43, 104]. In T2DM, the coexistence of hypertension and dyslipidemia has a relatively more significant role in mediating outcomes and associated costs [106, 168].

Promoting healthy behaviors, mainly physical activity, healthy eating, and weight loss, can help people with diabetes self-manage their illness and delay the onset of diabetes-related complications [169, 170], and are considered cost-effective from a health systems perspective [171]. Based on this, lifestyle programs have been included in expert guidelines for diabetes prevention and care [172]. However, lifestyle programs and changes adopted by people with diabetes also have a cost attached to them, compared with doing nothing. For instance, engaging in a 3-mile daily walk over 2 years can cost the person up to US$400 when one considers the cost of the individual's time, items needed to exercise (e.g. exercise apparel, footwear), transportation, and health center admissions [173]. Higher physical activity intensity translates into higher costs [173]. Dietary modifications are also costly, equivalent to about 20% of the direct ambulatory care costs incurred by people with diabetes [109]. As an example, in Brazil, people with diabetes spend approximately US$286 on artificial sweeteners and dietary products based on their diagnosis of diabetes [174]. Therefore, adhering to lifestyle changes can contribute to the financial burden that people with diabetes face.

Clinical status also matters with regard to resource utilization. Uncontrolled diabetes is associated with higher healthcare costs; people with uncontrolled diabetes have ~30% higher annual pharmaceutical costs, 70% higher costs for laboratory/diagnostic tests, and 85% higher consultation costs than those with good control [175]. A rudimentary but practical finding is that for every 1% increase in HbA_{1c} over 7%, there is a corresponding 10% increase in costs [168]. As mentioned previously, the presence of diabetes-related complications greatly increases both the magnitude and duration of resource consumption. Complications contribute up to 60% of all direct costs and 80–90% of indirect losses due to absenteeism and lost productivity [176]. Globally, healthcare costs are three times higher for people with macrovascular complications than for those without complications [166]. In particular, CVD and nephropathy are associated with the highest healthcare costs in most regions of the world. Coronary and cerebrovascular events, and heart failure have been found to increase hospital costs significantly, from INT$76 to $1800 (International dollars) in Asia, from INT$156 to $3000 in Eastern Europe, and from INT$296 to $4000 in more Established Market Economy countries [106]. Similarly, early renal dysfunction is the basis for 65% more costs, and the onset of end-stage renal disease signifies a 771% increase in costs [177–179]. Both the presence and the number of complications are associated with increased costs—the costs among persons with both micro- and macrovascular complications are 25–50% higher than for people with only one micro- or microvascular complication [113, 162, 174].

Country-level cost patterns

Globally, health expenditures related to diabetes totaled an estimated US$673–1197 billion in 2015 [1]. There are large differences in healthcare expenditures by region and country income level. By 2030, it is estimated that the world's richest countries will be responsible for more than 90% of the global expenditure on diabetes [180, 181]. The imbalance between resource expenditure and needs is further exemplified by estimates that only 20% of global expenditure occurs in the regions where 80% of people with diabetes live [155], demonstrating that Julian Tudor Hart's [182] "inverse care law" is very relevant to global diabetes burden (it states that "the availability of good medical care tends to vary inversely with the need for it in the population served").

Overall, direct costs were the main drivers of total diabetes-related costs across regions, although indirect costs (costs associated with loss of productivity, temporary or permanent disability, and premature mortality) were the main drivers for some regions of the world. For instance, in Africa, Latin America, and the Caribbean, indirect costs represent 70–80% of total diabetes costs [102, 183]. The main drivers of direct costs in HICs are the costs of hospitalization and patient care, whereas for LMICs, the

costs of medications and drugs predominate. In countries such as Mexico, India, Pakistan, and Sudan, medication spending accounts for 32–60% of total diabetes expenditures [162]. There are sizeable between-country disparities in per capita expenditures on diabetes [184]. These differences in expenditure are partially related to differences in pricing and prescription but are also linked to the high costs of new diagnostic and therapeutic options (e.g. treating a patient with maximal daily doses of metformin is approximately one-twentieth of the cost of using newer medication classes).

Industrialized countries are also advantaged in the organization of healthcare infrastructure, in addition to the financing of the healthcare system (e.g. nationalized insurance and social security schemes in Western Europe cover 80–90% of population costs), which ensure high accessibility to care for citizens [103, 110]. Owing to the inadequate public spending on health in LMICs and the lack of health insurance and other health financing mechanisms, sizeable proportions of household income are spent on healthcare costs. For instance, the healthcare expenses that families bear from their own pockets in LMICs ranges from 40 to 60% [14, 15, 102, 185]. In LMICs, the lowest income groups bear the greatest burdens, paying a larger proportion of their household incomes towards diabetes care [185, 186]. In a study of 35 LMICs, people with diabetes showed a greater risk of incurring catastrophic medical expenses than their counterparts without diabetes (18% vs. 14%), and the risk among persons from LMICs was more pronounced (21% vs. 15%) [163]. Poor access to medications augments the economic burden that low-income persons with diabetes and their families bear, as drug costs represent over half of the total household spending on diabetes [187]. Year-on-year increases in this proportion are greater in impoverished groups and worsen with duration of diabetes, presence of complications, hospitalization, surgical therapy, and glycemic control requiring insulin [113, 186, 188].

Additional considerations with regard to national economic impact concern the distribution of diabetes burden *within* populations. In LMICs, diabetes and its complications disproportionately affect the economically productive age range (15–59 years), whereas in HICs, the disease affects the older (≥65 years), disadvantaged, and minority subpopulations [189]. The implications emanating from these trends are that economic development in transitioning countries may be subdued owing to loss of unrealized productivity, whereas direct health costs for the aging and uninsured populations in HICs will continue to escalate [2].

Furthermore, LMICs contain large and growing populations of people with prediabetes, and also groups of people unaware that they have an asymptomatic metabolic disorder. Prediabetes is independently associated with the development of complications and increased specialist consultations, requiring supplementary expenses per person [190].

Augmented expenditures associated with complications further perpetuate destitution and socioeconomic disadvantage (i.e. opportunity costs of healthcare expenses are often endured by foregoing investments in education of children, etc.). Meanwhile, socioeconomic hardship amplifies vulnerability to disease as healthy foods and behaviors are costly. Studies on diabetes showed that later age at diagnosis of diabetes and occurrence of disabling complications were associated with lack of awareness, being unemployed, and being less educated (e.g. a 7-year difference in age of diagnosis was demonstrated between illiterates and those with college education) [44, 191, 192]. Similar observations substantiate a bidirectional link between poor health and poverty (Figure 5.1).

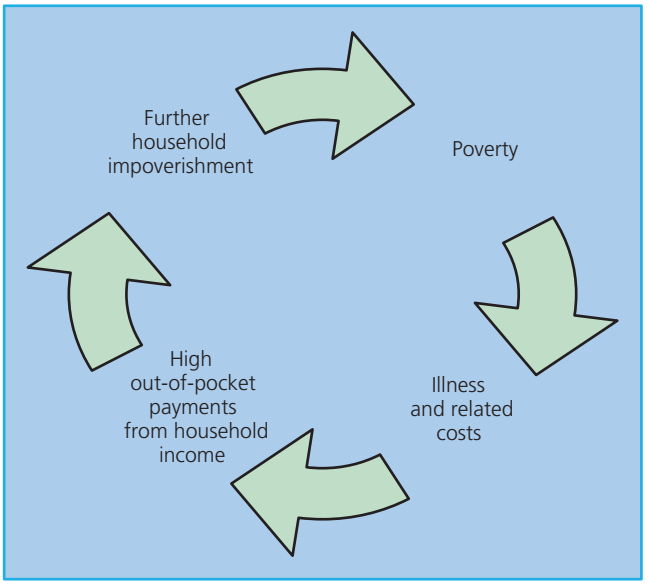

Figure 5.1 Diagram illustrating the cyclical relationship between poverty and ill-health: poverty predisposes one to illness, and costs of illness in a system of fee-for-service care have the potential to impoverish households, further perpetuating poverty.

Changing trends in costs

The global burdens associated with diabetes have been growing rapidly and are projected to escalate even further in the future. The hypothesized explanations for these trends of increasing burdens include, but are not limited to, the rising prevalence of diabetes and prediabetes worldwide, aging and longevity accompanied by costly comorbidities, lowered diagnostic thresholds, more attentive detection of cases, availability of newer, more costly treatment methods on the basis of industry research and development, and changes in clinical management, especially growth in the use of self monitoring and medical devices, new therapeutic drugs, and increasing demand for paramedical services. While it is evident that these latter reasons are more relevant in HICs, the continued epidemiological transitions will no doubt affect LMICs also. It is unfortunate that scarcity of resources and inadequate access in LMIC settings will result in greater disability and mortality, perpetuating the obstacles to socioeconomic development.

Gaps and future directions

Diabetes imposes serious health, social, and economic burdens worldwide. However, we still need more widespread and reliable data regarding burdens, access, and expenditures [193], especially in LMICs where the greatest burdens of diabetes occur. Few longitudinal studies are available in LMICs, thus limiting our understanding of incidence, risk factors, pathophysiology, variations in phenotypes, and natural history in these settings. In addition, studies are needed that include both long-understood and emerging complications of diabetes, such as cognitive function, in the models to create better estimates of diabetes-attributable mortality, morbidity, and cost. Assessing burdens using reliable, consistent methods will aid our comprehension of the complex mix of programmed, predisposing, and modifiable factors associated with diabetes and lays a foundation for policy development and advocacy.

Despite varied estimates of expenditure, the pattern is consistent: people with diabetes experience greater symptoms, morbidity, comorbidities, and mortality than those without diabetes, they suffer diminished functional capacity and psychosocial illness, and they incur greater costs for healthcare, self-care, and losses in earning potential and societal role. Also, although reductions in quality of life and other psychosocial measures of mental wellness are less numerically evident, they are no less distressing. Needless to say, intervening before diabetes onset may hold great benefit in reducing global burdens. However, although there is evidence from large trials demonstrating that prevention can forestall conversion from prediabetes to diabetes [194–197], widespread translation of these findings is hampered by multiple levels of barriers (political, social, cultural, behavioral, and economic factors). Preparation for the increasing diabetes burden requires progress in the wider collection of reliable data, collected in a standardized manner across various countries (especially assuaging the scarcity from LMICs regarding diabetes-related mortality, complications, disability, and costs), and a greater emphasis on cost-effectiveness studies that may inform better resource allocation [198]. On the shoulders of compelling evidence, greater investment and political will are required to overcome low accessibility and awareness, and also to translate the evidence into the practical, real-life implementation of proven and effective prevention strategies [199].

2 Normal Physiology

6 Islet Function and Insulin Secretion

Peter M. Jones and Shanta J. Persaud
Diabetes Research Group, King's College London, London, UK

Key points

- Regulation of fuel homeostasis in mammals is dependent on numerous small endocrine organs known as islets of Langerhans, which are located in the pancreas.
- Islets contain β cells, which are the only source of the polypeptide hormone insulin.
- Islet β cells are equipped to detect changes in circulating nutrients.
- Elevated levels of nutrients initiate an insulin secretory response from β cells that results in the storage of circulating nutrients in liver, muscle, and adipose tissue.
- A wide range of other signals, including hormones, neurotransmitters, and neuropeptides, can modify the insulin secretory response to circulating nutrients.
- Complex interactions between islet cells, the autonomic nervous system, and gastrointestinal incretin hormones allow precise integration between metabolic fuel intake, usage, and storage.

Introduction

The German anatomy student Paul Langerhans first described in 1869 the "islands of clear cells" distributed throughout the pancreas [1] but he did not realize the physiological significance of these cell clusters, which are today known as islets of Langerhans. We now know that islets are the endocrine compartment of the pancreas, comprising ~2–3% of the total pancreatic volume. Islets are approximately spherical (Figure 6.1a), with an average diameter of 100–200 μm, and a healthy human pancreas may contain up to a million individual islets, each having its own complex anatomy, blood supply, and innervation.

Islet structure and function

Islet anatomy

A typical mammalian islet comprises ~1000 endocrine cells including the insulin-expressing β cells (~60% of adult human islet cells), glucagon-expressing α cells (20–30%), somatostatin-expressing δ cells (~10%), and cells expressing pancreatic polypeptide (<5%), ghrelin, and peptide YY (<1%). The anatomical arrangement of islet cells varies between species. In rodents, the majority β-cell population forms a central core surrounded by a mantle of α and δ cells (Figure 6.1a), but human islets show less well-defined organization with α and δ cells also being located throughout the islet (Figure 6.1b) [2].

Islets are highly vascularized, and receive up to 15% of the pancreatic blood supply despite accounting for only 2–3% of the total pancreatic mass. Each islet is served by an arteriolar blood supply that penetrates the mantle to form a capillary bed in the islet core. Earlier studies using vascular casts of rodent islets suggested that the major route of blood flow through an islet was from the inner β cells to the outer α and δ cells [3], but more recent studies using optical imaging of fluorescent markers to follow islet blood flow *in vivo* [4] revealed more complex patterns of both inner-to-outer and top-to-bottom blood flow through the rodent islet.

Islets are well supplied by autonomic nerve fibers and terminals containing the classic neurotransmitters acetylcholine and norepinephrine, along with a variety of biologically active neuropeptides [5]. Vasoactive intestinal polypeptide (VIP) and pituitary adenylate cyclase-activating polypeptide (PACAP) are localized with acetylcholine to parasympathetic nerves, where they may be involved in mediating prandial insulin secretion and the α-cell response to hypoglycemia [6]. Other neuropeptides, such as galanin and neuropeptide Y (NPY), are found with norepinephrine in sympathetic nerves, where they may have a role in the sympathetic inhibition of insulin secretion, although there are marked inter-species differences in the expression of these neuropeptides [5].

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

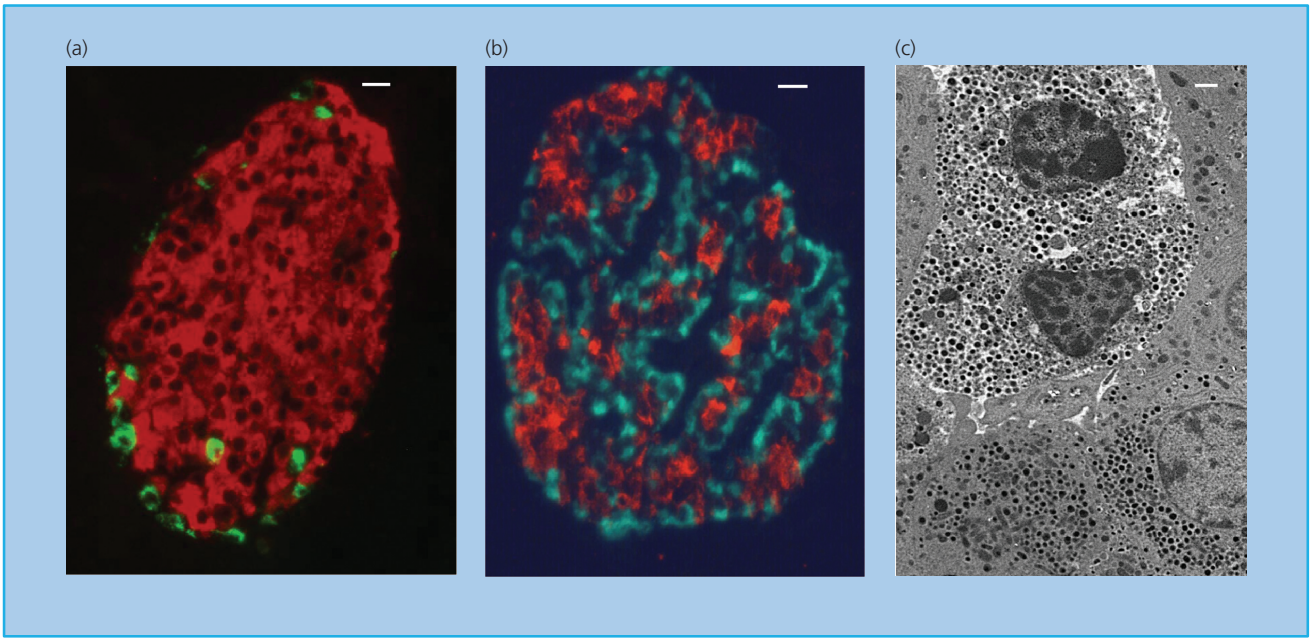

Figure 6.1 Anatomy of the islet of Langerhans. (a) Mouse islet. The image shows a section through a mouse pancreas in which insulin and glucagon are identified by red and green immunofluorescence, respectively, demonstrating the typical β-cell core surrounded by a thin mantle of α cells. In mouse islets, β cells comprise ~80% of the endocrine cell mass. Scale bar is 10 μm. Source: image courtesy of C. Li, King's College London. (b) Human islet. The image shows a section through a human pancreas in which insulin and glucagon are identified by red and green immunofluorescence respectively, demonstrating the less organized structure of the human islet when compared with mouse islets. In human islets, β cells comprise ~50–60% of the endocrine cell mass. Scale bar is 10 μm. Source: image courtesy of V. Foot, King's College London. (c) Transmission electron micrograph of human islet cells. The image shows a transmission electron micrograph of several cells within a human islet. The two cells at the top with the electron-dense secretory granules surrounded by a clear halo are β cells. The cells in the lower part of the micrograph are α cells. Scale bar is 2 μm. Source: authors' unpublished data.

Intra-islet interactions

The anatomical organization of the islet has a profound influence on the ability of the β cells to recognize and respond to physiological signals [7–9]. There are a number of mechanisms through which islet cells can communicate, although the relative importance of the different mechanisms is still uncertain [10]. Islet cells are functionally coupled through a network of gap junctions, and gene deletion studies in mice have highlighted the importance of gap-junctional coupling via connexin 36 in the regulation of insulin secretory responses [11, 12]. Cell–cell contact through cell surface adhesion molecules in localized microdomains offers an alternative communication mechanism [13], and interactions mediated by E-cadherin [13–15] or ephrins [16] have been implicated in the regulation of β-cell function. Components of the intra-islet extracellular matrix, which is predominantly synthesized by islet endothelial cells, influence β-cell proliferation, survival, and function via interactions with integrins on the β-cell surface [17]. A further important level of control is exerted via numerous intra-islet paracrine and autocrine effects in which a biologically active substance released by one islet cell can influence the functional status of a neighboring cell (paracrine), or of itself (autocrine) [18]. Figure 6.2 shows some of the molecules that have been implicated in this type of intra-islet cell–cell communication. Thus, islet cells can interact with each other via the classic islet hormones—insulin, glucagon, and somatostatin [19–22]; via other products secreted by the endocrine cells, including neurotransmitters, peptides such as kisspeptin [23], GLP-1 [24], and urocortin3 (Ucn3) [25], and adenine nucleotides and divalent cations that are co-released with insulin [26–29]; and via other less well-known mechanisms, including the generation of gaseous signals such as nitric oxide and carbon monoxide [30–32]. The wide range of intra-islet interactions presumably reflects the requirement for fine tuning and coordinating secretory responses of many individual islet cells to generate the rate and pattern of hormone secretion appropriate to the prevailing physiological conditions.

Insulin biosynthesis and storage

The ability to release insulin rapidly in response to metabolic demand, coupled with the relatively slow process of producing polypeptide hormones, means that β cells are highly specialized for the production and storage of insulin, to the extent that insulin comprises ~10% (~10 pg/cell) of the total β-cell protein.

Biosynthesis of insulin

In humans, the gene encoding preproinsulin, the precursor of insulin, is located on the short arm of chromosome 11 [33]. It is 1355 base pairs in length and its coding region consists of three exons: the first encodes the signal peptide at the N-terminus of preproinsulin, the second the B chain and part of the C

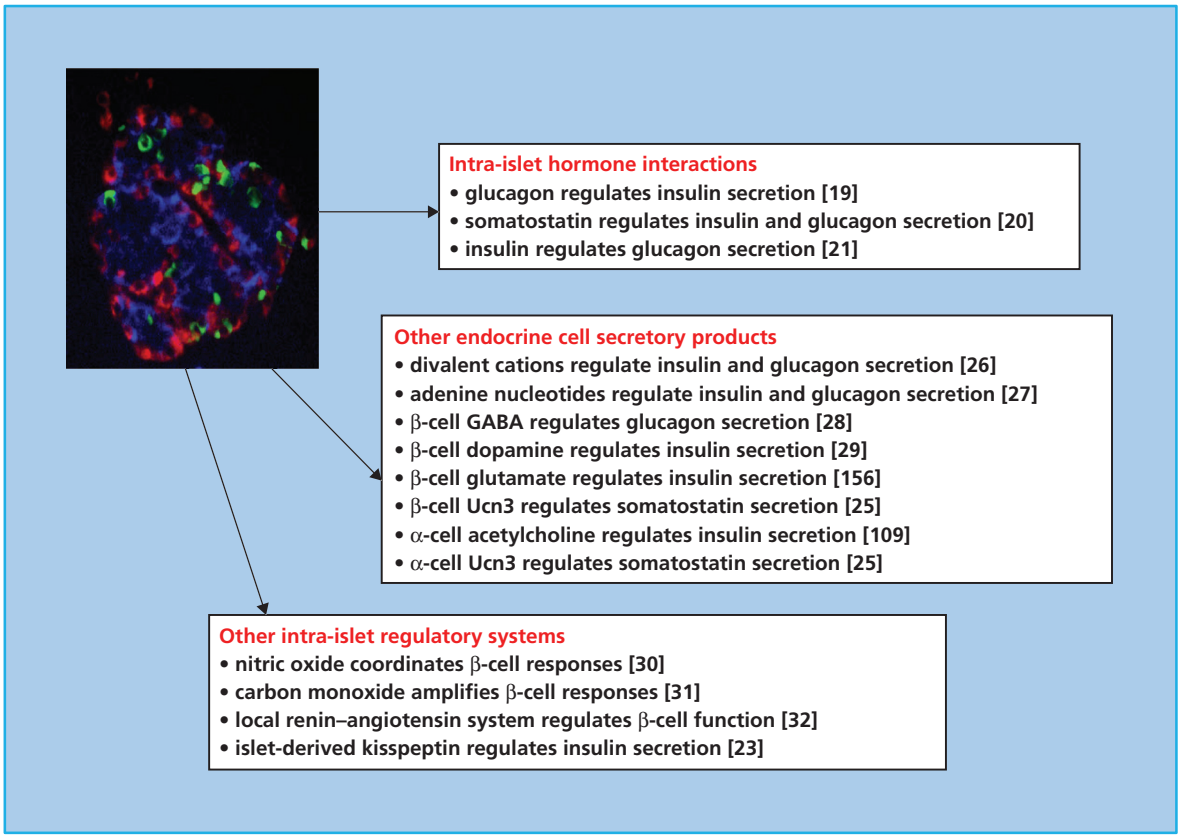

Figure 6.2 Intra-islet autocrine–paracrine interactions. The heterogeneous nature and complex anatomy of the islet permit numerous interactions between islet cells that are mediated by the release of biologically active molecules.

(connecting) peptide, and the third the rest of the C-peptide and the A chain (Figure 6.3). Transcription and splicing to remove the sequences encoded by the introns yields a messenger RNA of 600 nucleotides, translation of which gives rise to preproinsulin, an 11.5-kDa polypeptide. The cellular processes and approximate time-scales involved in insulin biosynthesis, processing, and storage are summarized in Figure 6.4.

Preproinsulin is rapidly (<1 min) discharged into the cisternal space of the rough endoplasmic reticulum, where proteolytic enzymes immediately cleave the signal peptide, generating proinsulin. Proinsulin is a 9-kDa peptide, containing the A and B chains of insulin (21 and 30 amino acid residues, respectively) joined by the C-peptide (30–35 amino acids). The structural conformations of proinsulin and insulin are very similar, and a major function of the C-peptide is to align the disulfide bridges that link the A and B chains so that the molecule is correctly folded for cleavage (Figure 6.5). Proinsulin is transported in microvesicles to the Golgi apparatus, where it is packaged into membrane-bound vesicles known as secretory granules. The conversion of proinsulin to insulin is initiated in the Golgi complex and continues within the maturing secretory granule through the sequential action of two endopeptidases (prohormone convertases 2 and 3) and carboxypeptidase H [34], which remove the C-peptide chain, liberating two cleavage dipeptides and finally yielding insulin (Figure 6.5). Insulin and C-peptide are stored together in the secretory granules and are ultimately released in equimolar amounts by a process of regulated exocytosis. Under normal conditions, >95% of the secreted product is insulin (and C-peptide) and <5% is released as proinsulin. However, the secretion of incompletely processed insulin precursors (proinsulin and its "split" products; Figure 6.5) is increased in some people with type 2 diabetes.

The β cell responds to increases in the circulating concentrations of nutrients by increasing insulin production in addition to increasing insulin secretion, thus maintaining insulin stores [34]. Acute (<2 h) increases in the extracellular concentration of glucose and other nutrients result in a rapid and dramatic increase in the transcription of preproinsulin mRNA and in the rate of proinsulin synthesis [35]. There is a sigmoidal relationship between glucose concentrations and biosynthetic activity, with a threshold glucose level of 2–4 mmol/L. This is slightly lower than the threshold for the stimulation of insulin secretion (~5 mmol/L), which ensures an adequate reserve of insulin within the β cell.

Storage and release of insulin

The insulin secretory granule has a typical appearance in electron micrographs, with a wide space between the crystalline electron-opaque core and its limiting membrane (Figure 6.1c).

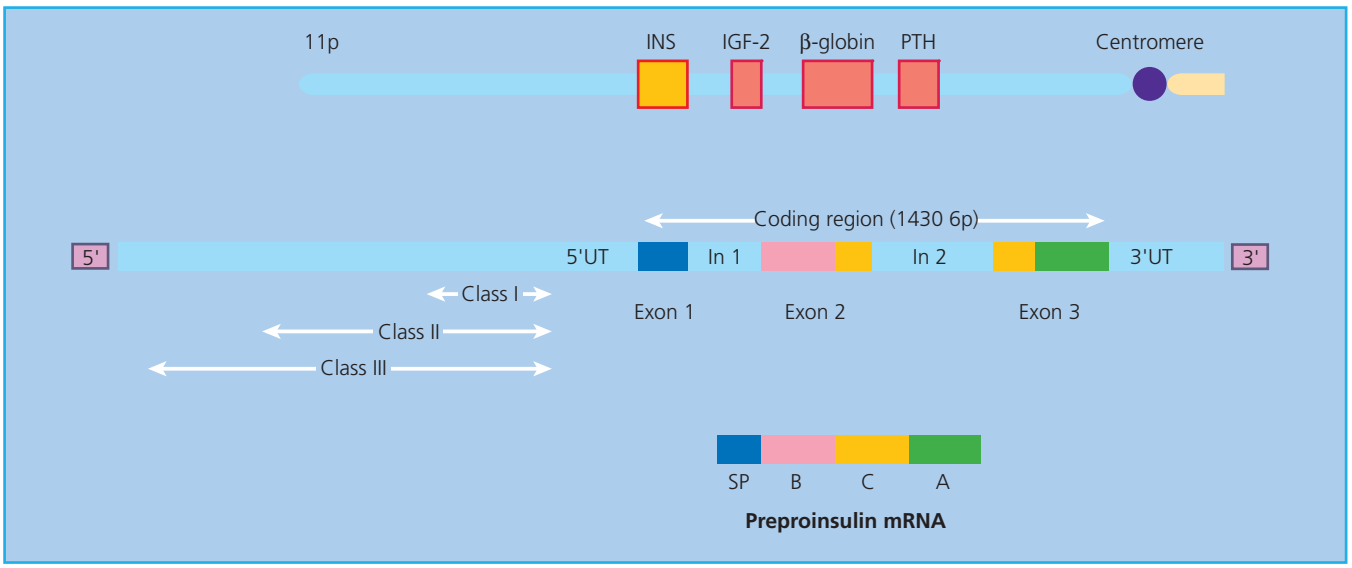

Figure 6.3 Structure of the human insulin gene. The coding region of the human insulin (INS) gene comprises three exons, which encode the signal peptide (SP), B chain, C-peptide, and A chain. The exons are separated by two introns (In1 and In2). Beyond the 5′ untranslated region (5′UT), upstream of the coding sequence, lies a hypervariable region in which three alleles (classes I, II and III) can be distinguished by their size.

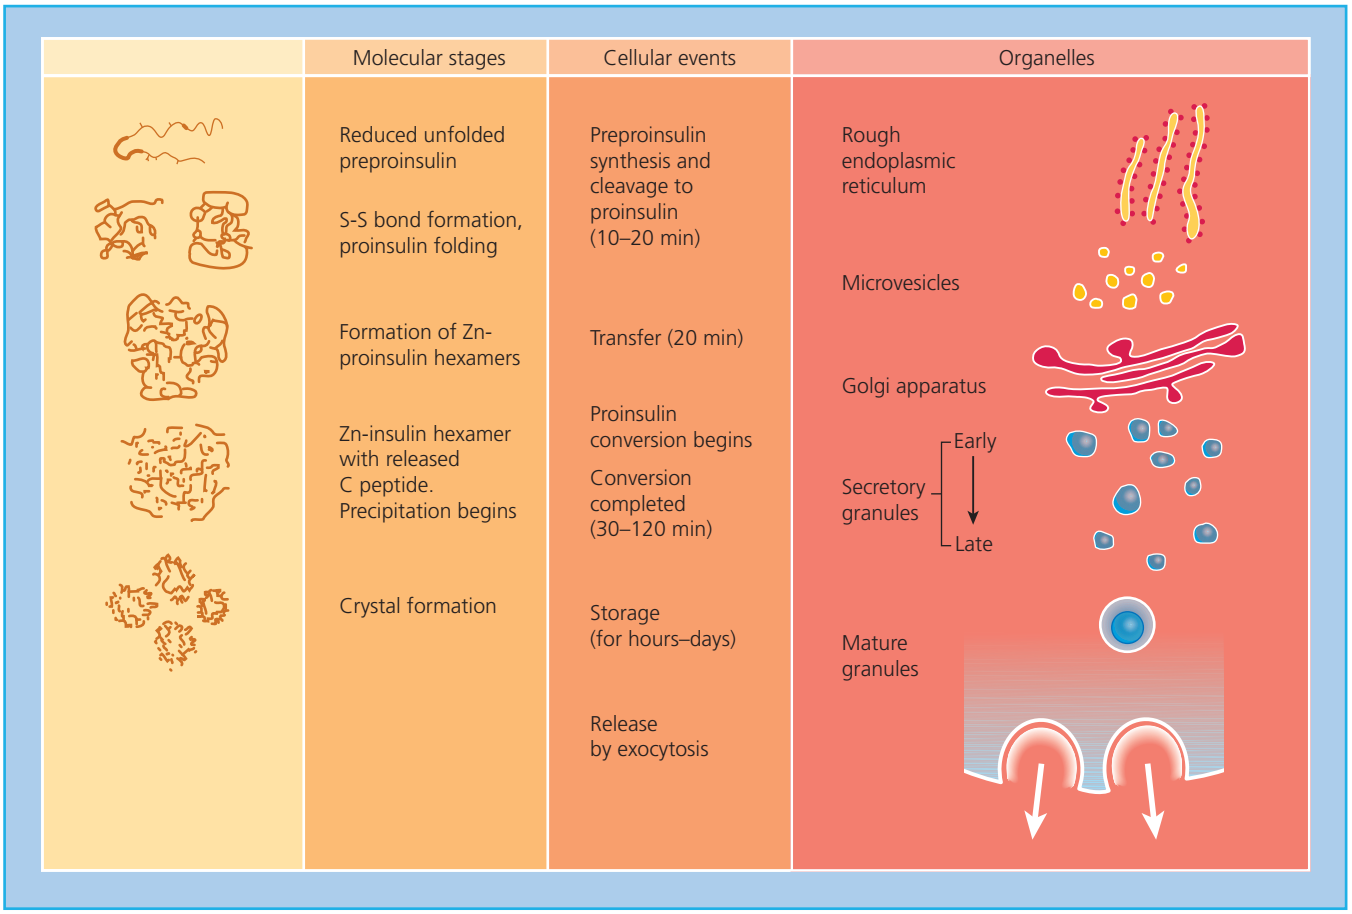

Figure 6.4 The intracellular pathways of (pro)insulin biosynthesis, processing, and storage. The molecular folding of the proinsulin molecule, its conversion to insulin, and the subsequent arrangement of the insulin hexamers into a regular pattern are shown at the left. The time course of the various processes and the organelles involved are also shown.

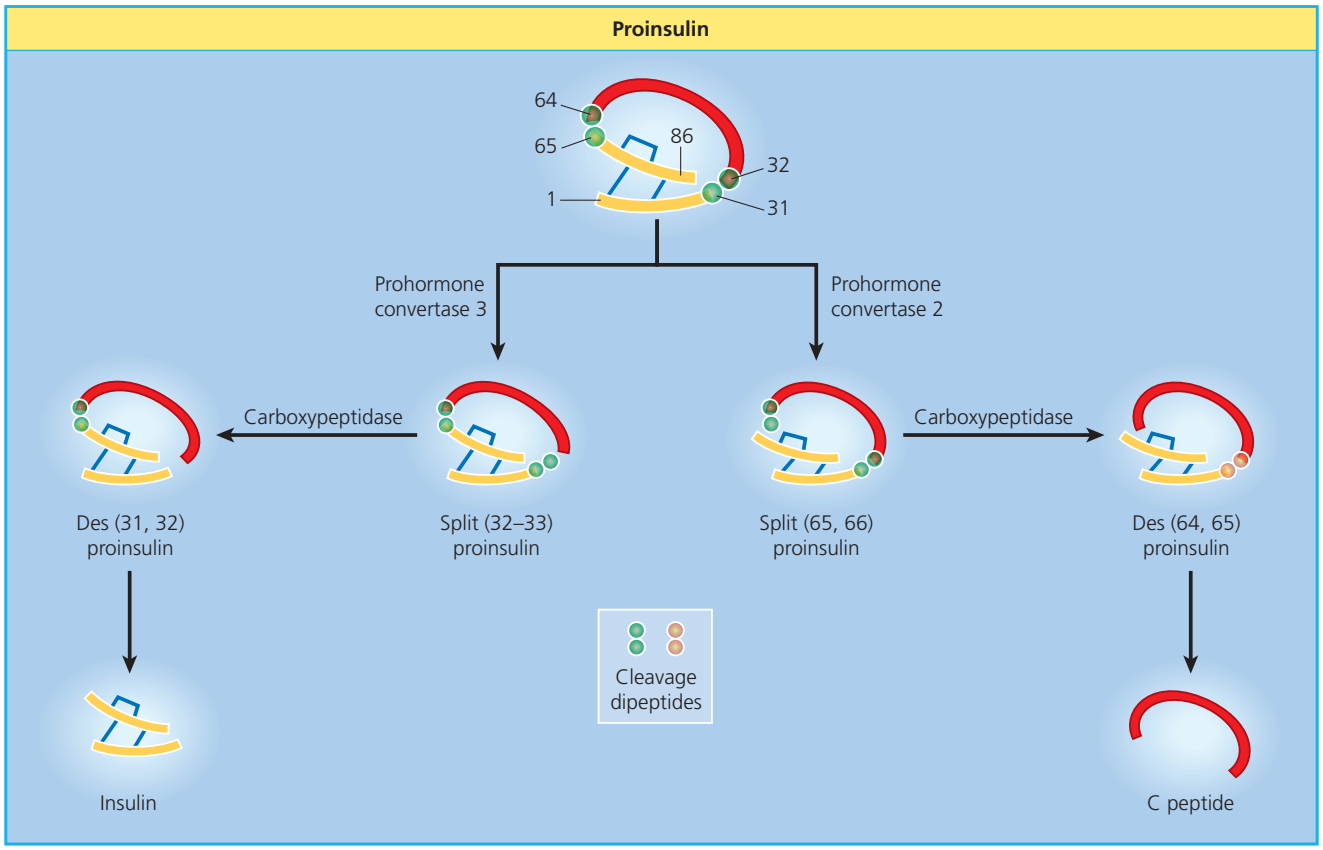

Figure 6.5 Insulin biosynthesis and processing. Proinsulin is cleaved on the C-terminal side of two dipeptides, namely Arg^{31}–Arg^{32} (by prohormone convertase 3) and Lys^{64}–Arg^{65} (prohormone convertase 2). The cleavage dipeptides are liberated, so yielding the "split" proinsulin products and ultimately insulin and C-peptide.

The major protein constituents of the granules are insulin and C-peptide, which account for ~80% of granule protein [36], with numerous minor components including peptidases, peptide hormones, and a variety of (potentially) biologically active peptides of uncertain function [36, 37]. Insulin secretory granules also contain high concentrations of divalent cations, such as zinc (~20 mmol/L), which is important in the crystallization and stabilization of insulin within the granule [38]. Zinc is transported into the insulin secretory granules by the islet specific zinc transporter ZnT8, where it binds to insulin to form a crystalline lattice of insoluble hexamers. Polymorphisms in the SLC30A8 gene encoding ZnT8, in which a single nucleotide polymorphism (SNP) generates a ZnT8 variant with lower Zn^{2+} transporting activity, are associated with increased risk of type 2 diabetes [39]. However, deletion of SLC30A8 in a number of transgenic mouse models produces only modest effects on insulin storage and secretion, and on whole-body glucose homeostasis, so the mechanistic link between SLC30A8 polymorphisms and type 2 diabetes risk remains unclear [39]. The intragranular function(s) of calcium (~120 mmol/L) and magnesium (~70 mmol/L) are uncertain, but they are co-released with insulin on exocytosis of the secretory granule contents so they may have extracellular signaling roles via the cell surface calcium-sensing receptor [26]. Similarly, the adenine nucleotides found in insulin secretory granules (~10 mmol/L) may have a signaling role when they are released into the extracellular space [27].

The generation of physiologically appropriate insulin secretory responses requires complex mechanisms for moving secretory granules from their storage sites within the cell to the specialized sites for exocytosis on the inner surface of the plasma membrane, and the role of cytoskeletal elements, notably microtubules and microfilaments, in the intracellular translocation of insulin storage granules has been studied extensively [40, 41]. Microtubules are formed by the polymerization of tubulin subunits and normally form a network radiating outwards from the perinuclear region [42]. The microtubular network is in a process of continual remodeling and the dynamic turnover of tubulin, rather than the total number of microtubules, is important for the mechanism of secretion. The microtubule framework may provide the pathway for the secretory granules but microtubules do not provide the motive force so other contractile proteins are likely to be involved. Actin is the constituent protein of microfilaments and exists in cells as a globular form of 43 kDa and as a filamentous form (F-actin), which associates to form microfilaments. F-actin remodeling in β cells is regulated by agents that alter rates of insulin secretion, and the pharmacological disruption of microfilament formation inhibits insulin secretion [43]. Myosin light and heavy chains are expressed at high concentrations in

β cells, suggesting that actin and myosin may interact to propel granules along the microtubular network, and a myosin- and Rab-interacting protein (MyRIP) has been implicated in cyclic adenosine monophosphate (cAMP)-dependent insulin secretion through interaction with the motor protein MyoVa [44]. It is likely that other molecular motors, including kinesin and dynein [45–47], are also involved in the movement of secretory granules, and perhaps other organelles, in β cells.

Insulin is released from secretory granules by exocytosis, a process in which the granule membrane and plasma membrane fuse together, releasing the granule contents into the interstitial space. Much of our knowledge of the molecular mechanisms of exocytosis is derived from studies of neurotransmitter release from nerve cells, and similar mechanisms operate in β cells, although some proteins implicated in synaptic vesicle exocytosis are not required for release of β-cell secretory granules [48]. The docking of the granules at the inner surface of the plasma membrane is via the formation of a multimeric complex of proteins known as the SNARE (soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor) complex, which consists of proteins associated with secretory granules and the plasma membrane, and soluble fusion proteins [43, 49, 50]. The docked granules will fuse with the membrane and release their contents only in the presence of elevated levels of intracellular calcium, which is sensed by synaptotagmins, a class of calcium-binding granule proteins [49, 51]. Secretory granules are distributed throughout the β-cell cytoplasm (Figure 6.1c), and it is likely that the transport of granules from distant sites to the plasma membrane is regulated independently from the final secretory process, with a reservoir of pre-docked granules available at the inner surface of the plasma membrane. Fusion of this "readily releasable" pool of granules may account for the rapid first-phase release of insulin in response to glucose stimulation and direct electrophysiological measurements have demonstrated that the β-cell exocytotic response consists of a short-lived first phase with a very rapid rate of granule exocytosis from the readily releasable pool, followed by a sustained second phase with a slower rate of exocytosis, from a reserve pool [52]. A key role for the regulatory protein Munc18c in the β-cell secretory granule fusion complex has recently been identified in experiments where its knockdown in human β cells led to significant reductions in exocytosis of granules of both the readily releasable and reserve pools [53].

Regulation of insulin secretion

To ensure that circulating levels of insulin are appropriate for the prevailing metabolic status, β cells are equipped with mechanisms to detect changes in circulating nutrients, in hormone levels, and in the activity of the autonomic nervous system. Moreover, β cells have fail-safe mechanisms for coordinating this afferent information and responding with an appropriate secretion of insulin. The major physiological determinant of insulin secretion in humans is the circulating concentration of glucose and other nutrients, including amino acids and fatty acids. These nutrients possess the ability to initiate an insulin secretory response, so when nutrients are being absorbed from the gastrointestinal system the β cell detects the changes in circulating nutrients and releases insulin to enable the uptake and metabolism or storage of the nutrients by the target tissues. The consequent decrease in circulating nutrients is detected by the β cells, which switch off insulin secretion to prevent hypoglycemia. The responses of β cells to nutrient initiators of insulin secretion can be modified by a variety of hormones and neurotransmitters which act to amplify, or occasionally inhibit, the nutrient-induced responses (Table 6.1). Under normoglycemic conditions, these agents have little or no effect on insulin secretion, a mechanism that prevents inappropriate secretion of insulin, which would result in potentially harmful hypoglycemia. These agents are often referred to as potentiators of insulin secretion to distinguish them from nutrients that initiate the secretory response. The overall insulin output depends on the relative input from initiators and potentiators at the level of individual β cells, on the synchronization of secretory activity between β cells in individual islets, and on the coordination of secretion between the hundreds of thousands of islets in a human pancreas. This section considers the mechanisms employed by β cells to recognize and respond to nutrient initiators and non-nutrient potentiators of insulin secretion.

Table 6.1 Non-nutrient regulators of insulin secretion.

Stimulators	Inhibitors
Islet products	
Glucagon	SST-14
Adenine nucleotides	Ghrelin
Divalent cations	PYY
Neurotransmitters	
Acetylcholine	Norepinephrine
VIP	Dopamine
PACAP	NPY
GRP	Galanin
Gastrointestinal hormones	
CCK	SST-28
GIP	Ghrelin
GLP-1	
Adipokines	
Adiponectin	Leptin
	Resistin

CCK, cholecystokinin; GIP, glucose-dependent insulinotropic peptide; GLP-1, glucagon-like peptide-1; GRP, gastrin-releasing polypeptide; NPY, neuropeptide Y; PACAP, pituitary adenylate cyclase activating polypeptide; PYY: peptide tyrosine tyrosine; SST; somatostatin; VIP, vasoactive intestinal polypeptide.

Nutrient-induced insulin secretion

Nutrient metabolism

Islet β cells respond to small changes in extracellular glucose concentrations within a narrow physiological range and the

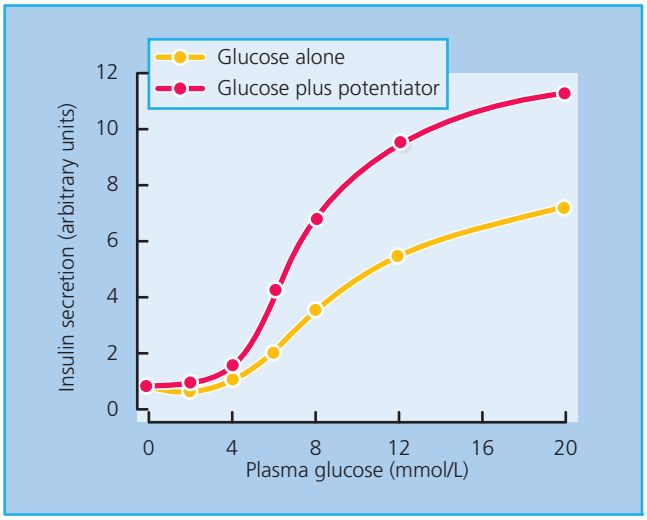

Figure 6.6 Glucose-induced insulin secretion from islets of Langerhans. No stimulation is seen below a threshold value of ~5 mmol/L glucose. Potentiators amplify insulin secretion at stimulatory concentrations of glucose, but are ineffective at subthreshold glucose levels.

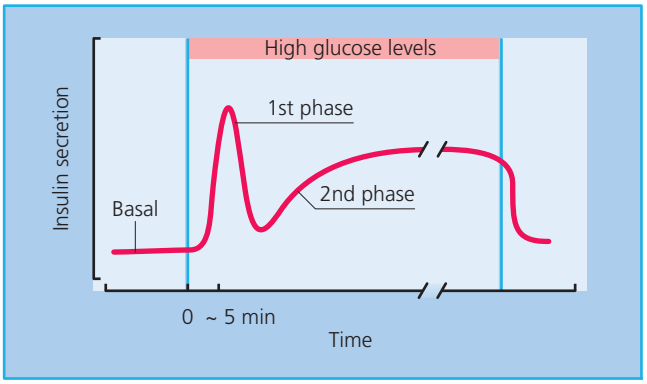

Figure 6.7 Glucose-induced insulin release *in vitro*. The image shows the pattern of glucose-induced insulin secretion from perfused pancreas, in response to an increase in the glucose concentration. An acute first phase, lasting a few minutes, is followed by a sustained second phase of secretion that persists for the duration of the high-glucose stimulus.

mechanisms through which β cells couple changes in nutrient metabolism to regulated exocytosis of insulin are becoming increasingly well understood. Glucose is transported into β cells via high-capacity glucose transporters (GLUT; GLUT-2 in rodents, GLUT-1, -2 and -3 in humans [54, 55]), enabling rapid equilibration of extracellular and intracellular glucose concentrations. Once inside the β cell, glucose is phosphorylated by glucokinase, which acts as the "glucose sensor," coupling insulin secretion to the prevailing glucose level [56]. The dose–response curve of glucose-induced insulin secretion from isolated islets is sigmoidal (Figure 6.6) and is determined primarily by the activity of glucokinase. Concentrations of glucose below 5 mmol/L do not affect rates of insulin release, and the rate of secretion increases progressively at extracellular glucose levels between 5 and ~15 mmol/L, with half-maximal stimulation at ~8 mmol/L. The time course of the insulin secretory response to elevated glucose is characterized by a rapidly rising but transient first phase, followed by a maintained and prolonged second phase, as shown in Figure 6.7. This profile of insulin secretion is obtained whether insulin levels are measured following a glucose load *in vivo*, or whether the secretory output from the perfused pancreas or isolated islets is assessed, suggesting that the characteristic biphasic secretion pattern is an intrinsic property of the islets.

ATP-sensitive potassium channels and membrane depolarization

In the absence of extracellular glucose, the β-cell membrane potential is maintained close to the potassium equilibrium potential by the efflux of potassium ions through inwardly rectifying potassium channels. These channels were called ATP-sensitive potassium (K_{ATP}) channels because application of ATP to the cytosolic surface of β-cell membrane patches resulted in rapid, reversible inhibition of resting membrane permeability to potassium ions [57]. This property of the K_{ATP} channel is pivotal in linking glucose metabolism to insulin secretion. Thus, it is now well established that ATP generation following glucose metabolism, in conjunction with concomitant lowering of ADP levels, leads to closure of β-cell K_{ATP} channels. Channel closure and the subsequent reduction in potassium efflux promote depolarization of the β-cell membrane and influx of calcium ions through voltage-dependent L-type calcium channels. The resultant increase in cytosolic Ca^{2+} triggers the exocytosis of insulin secretory granules, thus initiating the insulin secretory response (Figure 6.8).

At around the time that the K_{ATP} channels were established as the link between the metabolic and electrophysiological effects of glucose, they were also identified as the cellular target for sulfonylureas. The capacity of sulfonylureas to close K_{ATP} channels explains their effectiveness in type 2 diabetes where the β cells no longer respond adequately to glucose, as the usual pathway for coupling glucose metabolism to insulin secretion is bypassed. The β-cell K_{ATP} channel is a hetero-octamer formed from four potassium channel subunits (termed Kir6.2) and four sulfonylurea receptor subunits (SUR1) [58]. The Kir6.2 subunits form the pore through which potassium ions flow and these are surrounded by the SUR1 subunits, which have a regulatory role (Figure 6.8). ATP and sulfonylureas induce channel closure by binding to Kir6.2 and SUR1 subunits, respectively, while ADP activates the channels by binding to a nucleotide-binding domain on the SUR1 subunit. Diazoxide, an inhibitor of insulin secretion, also binds to the SUR1 subunit to open the channels. The central role of K_{ATP} channels in β-cell glucose recognition makes them obvious candidates for β-cell dysfunction in type 2 diabetes. Early studies in people with type 2 diabetes, maturity-onset diabetes of the young (MODY), or gestational diabetes, failed to detect any Kir6.2 gene mutations that compromised channel function [59, 60]. Since then, larger scale studies of variants in genes encoding Kir6.2 and SUR1 have demonstrated polymorphisms associated with increased risk

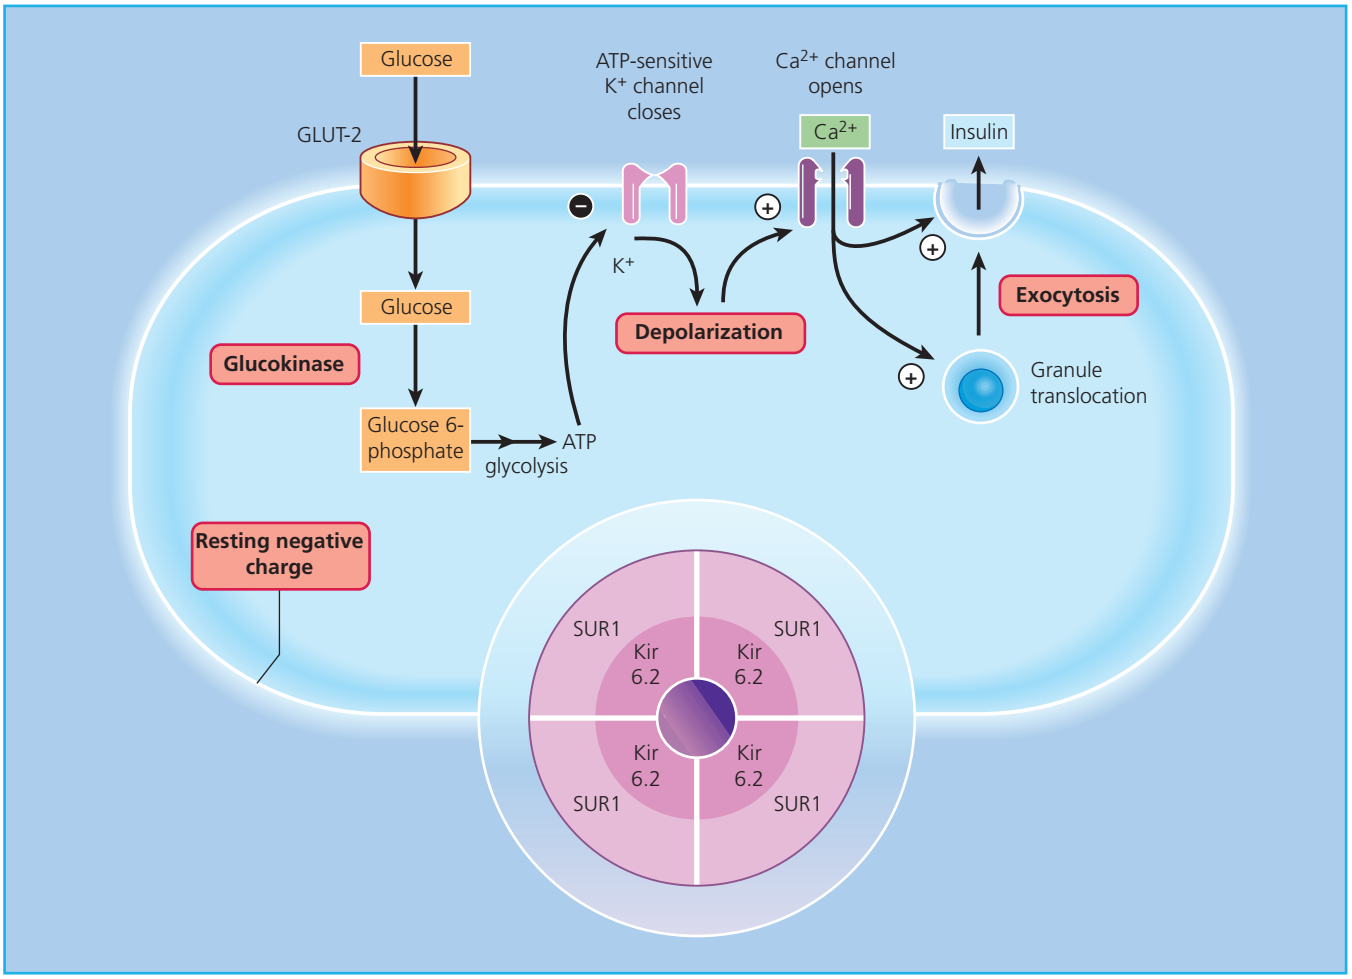

Figure 6.8 Intracellular mechanisms through which glucose stimulates insulin secretion. Glucose is metabolized within the β cell to generate ATP, which closes ATP-sensitive potassium channels in the cell membrane. This prevents potassium ions from leaving the cell, causing membrane depolarization, which in turn opens voltage-gated calcium channels in the membrane and allows calcium ions to enter the cell. The increase in cytosolic calcium initiates granule exocytosis. Sulfonylureas act downstream of glucose metabolism, by binding to the SUR1 component of the K_{ATP} channel (inset). GLUT, glucose transporter.

of type 2 diabetes [61]. Similarly, activating mutations in the Kir6.2 gene are causal for cases of permanent neonatal diabetes (PNDM) [62], which has enabled individuals with insulin-dependent PNDM to achieve glycemic control with sulfonylurea treatment alone. In contrast, loss of β-cell functional K_{ATP} channel activity has been implicated in the pathogenesis of congenital hyperinsulinism [63], a condition characterized by hypersecretion of insulin. Numerous mutations in both the Kir6.2 and SUR1 subunits have been identified in people with congenital hyperinsulinism and these are thought to be responsible for the severe impairment in glucose homeostasis in these individuals [64, 65].

Calcium and other intracellular effectors

Intracellular calcium is a principal effector of the nutrient-induced insulin secretory response, linking depolarization with exocytosis of insulin secretory granules (Figure 6.8). A large electrochemical concentration gradient (~10,000-fold) of calcium is maintained across the β-cell plasma membrane by a combination of membrane-associated calcium extruding systems and active calcium sequestration within intracellular organelles. The major route through which calcium is elevated in β cells is by influx of extracellular calcium through voltage-dependent L-type calcium channels that open in response to β-cell depolarization, and it has been estimated that each β cell contains about 500 L-type channels [66].

Studies with permeabilized β cells have demonstrated that elevations in intracellular calcium are alone sufficient to initiate insulin secretion [67], and conditions that elevate intracellular calcium usually stimulate insulin release. An increase in cytosolic calcium is essential for the initiation of insulin secretion by glucose and other nutrients: preventing calcium influx by removal of extracellular calcium or by pharmacological blockade of voltage-dependent calcium channels abolishes nutrient-induced insulin secretion. Glucose and other nutrients also induce a calcium-dependent activation of β-cell phospholipase C (PLC) [68], leading to the generation of inositol 1,4,5-triphosphate (IP_3)

and diacylglycerol (DAG), both of which serve second-messenger functions in β cells [69]. The generation of IP_3 leads to the rapid mobilization of intracellular calcium, but the significance of this in secretory responses to nutrients is uncertain, and it is likely to have little more than a modulatory role, amplifying the elevations in cytosolic calcium concentration induced by the influx of extracellular calcium.

The elevations in intracellular calcium are transduced into the regulated secretion of insulin by intracellular calcium-sensing systems within β cells. Important among these are the calcium-dependent protein kinases, which include myosin light-chain kinases, the calcium/phospholipid-dependent kinases, and the calcium/calmodulin-dependent kinases (CaMKs). CaMKs are protein kinases that are activated in the presence of calcium and the calcium-binding protein calmodulin, and a number of studies have implicated CaMK II in insulin secretory responses [69]. It has been proposed that CaMK II activation is responsible for the initiation of insulin secretion in response to glucose and other nutrients, and for enhancing nutrient-induced secretion in response to receptor agonists that elevate intracellular calcium [69]. Cytosolic PLA_2 ($cPLA_2$) is another β-cell calcium-sensitive enzyme. It is activated by concentrations of calcium that are achieved in stimulated β cells, and it generates arachidonic acid (AA) by the hydrolysis of membrane phosphatidylcholine. AA is capable of stimulating insulin secretion in a glucose- and calcium-independent manner, and it is further metabolized in islets by the cyclooxygenase (COX) pathways to produce prostaglandins and thromboxanes, and by the lipoxygenase (LOX) pathways to generate hydroperoxyeicosatetraenoic acids (HPETES), hydroxyeicosatetraenoic acids (HETES), and leukotrienes.

The precise roles of AA derivatives in islet function remain uncertain because experimental investigations have relied on COX and LOX inhibitors of poor specificity, and although prostaglandin E_2 is largely inhibitory in rodent islets [70] it has stimulatory effects on insulin secretion from human islets [71]. Calcium sensors are also important at the later stages of the secretory pathway, where the calcium-sensitive synaptotagmin proteins are involved in the formation of the exocytotic SNARE complex, as described above, to confer calcium sensitivity on the initiation and rate of exocytotic release of insulin secretory granules [49].

The elevations in intracellular calcium induced by nutrients activate other effector systems in β cells, including PLC and $cPLA_2$, as discussed above, and calcium-sensitive adenylate cyclase isoforms, which generate cAMP from ATP. Although these signaling systems are of undoubted importance in the regulation of β cells by non-nutrients, their role in nutrient-induced insulin secretion is still uncertain. Thus, DAG generated by glucose-induced PLC activation has the potential to activate some protein kinase C (PKC) isoforms. PKC was first identified as a calcium- and phospholipid-sensitive, DAG-activated protein kinase, but some isoforms of PKC require neither calcium nor DAG for activation. The isoforms are classified into three groups: calcium- and DAG-sensitive (conventional), calcium-independent, DAG-sensitive (novel), and calcium- and DAG-independent (atypical) groups, and β cells contain conventional, atypical, and novel PKC isoforms [69, 72]. The early literature on the role of PKC in nutrient-induced insulin secretion is confusing, but several studies have shown that glucose-induced insulin secretion is maintained under conditions where DAG-sensitive PKC isoforms are depleted, suggesting that conventional and novel PKC isoforms are not required for insulin secretion in response to glucose [69, 73].

The role of cAMP in the insulin secretory response to nutrients is similarly unclear. cAMP has the potential to influence insulin secretion by the activation of cAMP-dependent protein kinase A (PKA), or via the cAMP-regulated guanine nucleotide exchange factors known as exchange proteins activated by cAMP (EPACs) [74]. However, elevations in β-cell cyclic AMP do not stimulate insulin secretion at substimulatory glucose concentrations, and the secretagogue effects of glucose can be maintained in the presence of competitive antagonists of cAMP binding to PKA or EPACs [75]. These observations suggest that cAMP does not act as a primary trigger of nutrient-stimulated β-cell secretory function, but observations linking glucose-induced oscillations in β-cell cAMP to oscillations in insulin secretion [76] suggest that a role for this messenger system in nutrient-induced insulin secretion cannot be ruled out.

K_{ATP} channel-independent pathways

Since the early reports linking K_{ATP} channel closure to the exocytotic release of insulin, it has become apparent that β cells also possess a K_{ATP} channel-independent stimulus–secretion coupling pathway: this is termed the amplifying pathway to distinguish it from the triggering pathway that is activated by K_{ATP} channel closure [77]. Studies in which β-cell calcium is elevated by depolarization and K_{ATP} channels are maintained in the open state by diazoxide have indicated that glucose, at concentrations as low as 1–6 mmol/L, is still capable of stimulating insulin secretion [78]. The triggering and amplifying pathways are both physiologically relevant for the first and second phases of glucose-induced insulin secretion [79], but the mechanisms by which glucose stimulates insulin secretion in a K_{ATP} channel-independent manner have not been established [79, 80]. However, it is clear that glucose must be metabolized and there is convincing evidence that changes in adenine nucleotides are involved [81], and it has been established that activation of PKA and PKC is not required. It has been suggested that the K_{ATP}-independent amplifying pathway is impaired in type 2 diabetes and that identification of novel therapeutic strategies targeted at this pathway may be beneficial in restoring β-cell function in people with type 2 diabetes [77].

Amino acids

Several amino acids stimulate insulin secretion *in vivo* and *in vitro*. Most require glucose, but some, such as leucine, lysine, and arginine, can stimulate insulin secretion in the absence of glucose, and therefore qualify as initiators of secretion. Leucine enters islets by a sodium-independent transport system and stimulates a

biphasic increase in insulin release. The effects of leucine on β-cell membrane potential, ion fluxes, and insulin secretion are similar to, but smaller than, those of glucose [82]. Thus, metabolism of leucine within β cells decreases the potassium permeability, causing depolarization and activation of L-type calcium channels through which calcium enters the β cells and initiates insulin secretion. Leucine is also able to activate the amplifying pathway of insulin secretion in a K_{ATP} channel-independent manner, as described above for glucose. The charged amino acids lysine and arginine cross the β-cell plasma membrane via a transport system specific for cationic amino acids. It is generally believed that the accumulation of these positively charged molecules directly depolarizes the β-cell membrane, leading to calcium influx.

Regulation of insulin secretion by non-nutrients

The complex mechanisms that have evolved to enable changes in extracellular nutrients to initiate an exocytotic secretory response are confined to islet β cells, and perhaps to a subset of hypothalamic neurons [83]. However, the mechanisms that β cells use to recognize and respond to non-nutrient potentiators of secretion are ubiquitous in mammalian cells, and so are covered only briefly in this section, followed by a review of the physiologically relevant non-nutrient regulators of β-cell function.

Most, if not all, non-nutrient modulators of insulin secretion influence the β cell by binding to and activating specific receptors on the extracellular surface. Because of its central role in coordinating whole-body fuel homeostasis, the β cell expresses receptors for a wide range of biologically active peptides, glycoproteins, and neurotransmitters (Table 6.1), and quantitative reverse transcriptase polymerase chain reaction (RT-PCR) analysis has indicated that human islets express 293 different types of G-protein-coupled receptors [84]. However, receptor occupancy generally results in the activation of a limited number of intracellular effector systems, which were introduced in the section Nutrient-induced insulin secretion (Figures 6.9 and 6.10).

Islet hormones

There is convincing evidence for complex intra-islet interactions via molecules released from islet endocrine cells (Figure 6.2). The physiological relevance of some of these interactions is still uncertain, but some of the intra-islet factors that are thought to influence insulin secretion are discussed briefly in this section.

It is now clear that β cells express insulin receptors and the associated intracellular signaling elements, suggesting the existence of autocrine and/or paracrine feedback regulation of β-cell function [22, 85]. Earlier suggestions that secreted insulin regulates insulin secretion [86] have not been confirmed [22, 87], and the physiological rationale of a positive feedback loop for insulin to promote further insulin release is questionable [88]. The main autocrine function of insulin on β cells is to regulate β-cell gene expression [85, 89] and β-cell mass through effects on proliferation and apoptosis [22, 90].

Glucagon is a 29 amino acid peptide secreted by islet α cells. The precursor, proglucagon, undergoes differential post-translational processing in the gut to produce entirely different peptides with different receptors and biological activities. These include glucagon-like peptide 1 (GLP-1) (7–36) amide, an "incretin" hormone that is discussed below, and GLP-2, which promotes growth of the intestinal mucosa. Although glucagon is the major proglucagon product in islet α cells, a subpopulation of human α cells also synthesize and secrete GLP-1, presumably to exert local effects within islets [24]. Glucagon secretion is regulated by nutrients, islet and gastrointestinal hormones, and the autonomic nervous system, with hypoglycemia and sympathetic nervous input being important stimulators of glucagon secretion [91]. Glucagon enhances insulin secretion through the stimulatory G-protein (G_s)-coupled activation of adenylate cyclase and the consequent increase in intracellular cAMP (Figure 6.9).

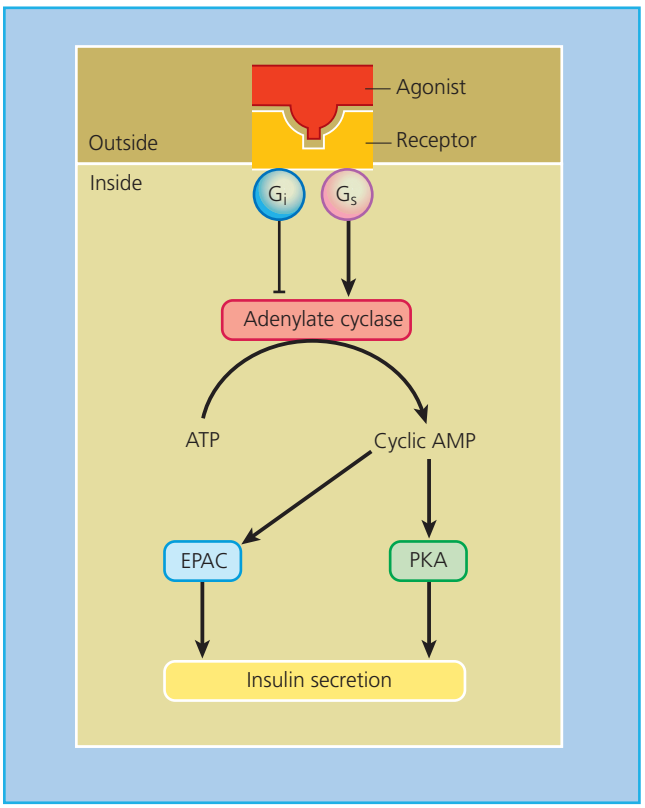

Figure 6.9 Adenylate cyclase and the regulation of insulin secretion. Some receptor agonists (e.g. glucagon, glucagon-like peptide 1, pituitary adenylate cyclase activating polypeptide) bind to cell-surface receptors that are coupled to adenylate cyclase (AC) via the heterotrimeric GTP-binding protein Gs. Adenylate cyclase hydrolyzes ATP to generate adenosine 5′ cyclic monophosphate (cAMP), which activates protein kinase A (PKA) and exchange proteins activated by cAMP (EPACs). Both of these pathways potentiate glucose-stimulated insulin secretion. Glucose also activates adenylate cyclase, but increases in intracellular cyclic AMP levels in response to glucose are generally smaller than those obtained with receptor agonists. Some inhibitory agonists (e.g. norepinephrine, somatostatin) bind to receptors that are coupled to adenylate cyclase via the inhibitory GTP-binding protein G_i, resulting in reduced adenylate cyclase activity and a decrease in intracellular cAMP.

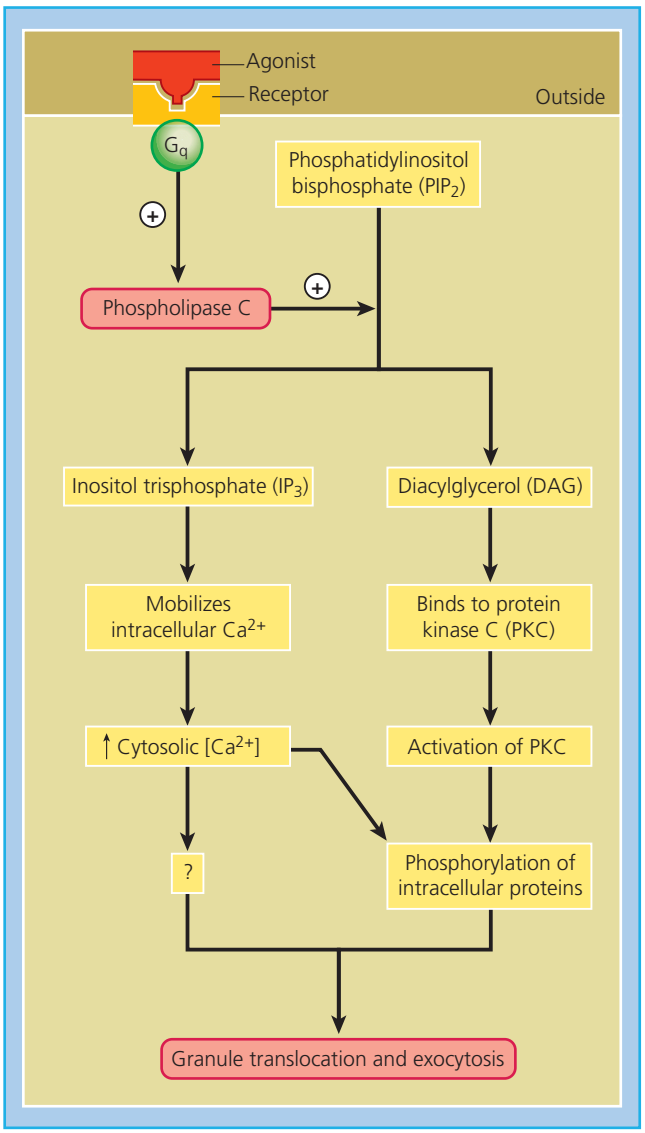

Figure 6.10 Phospholipase C and the regulation of insulin secretion. Some receptor agonists (e.g. acetylcholine, cholecystokinin) bind to cell-surface receptors that are coupled to phospholipase C (PLC) via the heterotrimeric GTP-binding protein G_q. Phospholipase C hydrolyzes phosphatidylinositol bisphosphate (PIP_2), an integral component of the membrane, to generate inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG). IP_3 mobilizes calcium from the endoplasmic reticulum and DAG activates protein kinase C (PKC), both of which enhance insulin secretion. Nutrients also activate PLC in a calcium-dependent manner but the importance of IP_3 and DAG in nutrient-induced insulin secretion is uncertain.

Somatostatin (SST) is expressed by islet δ cells and in numerous other sites, including the central nervous system and D cells of the gastrointestinal tract, where it acts predominantly as an inhibitor of endocrine and exocrine secretion [92]. The precursor, prosomatostatin, is processed by alternative pathways: in islets and the CNS SST-14 is generated, and SST-28, the major circulating form of SST in humans, is produced in the gastrointestinal tract [93]. SST secretion is regulated by a variety of nutrients and endocrine and neural factors [20, 92, 94, 95]. Islets express five different somatostatin receptor (SSTR) subtypes, and SST-14 released from islet δ cells has a tonic inhibitory effect on insulin and glucagon secretion [20], via activation of SSTR5 and SSTR2, respectively [96, 97]. SST receptors are coupled via an inhibitory G-protein(Gi) to the inhibition of adenylate cyclase and decreased formation of cAMP [98] (Figure 6.9), and to ion channels that cause hyperpolarization of the β-cell membrane and reductions in intracellular calcium [99].

Pancreatic polypeptide (PP) is a 36 amino acid peptide produced by PP cells that are found in the mantle of islets, predominantly those located in the head of the pancreas. PP secretion is mainly regulated via cholinergic parasympathetic stimulation [92], but the physiological function of PP as a circulating hormone, or as an intra-islet signal, is uncertain [100]. Peptide YY, which is structurally related to PP, is also expressed in islets and is mainly expressed by subpopulations of PP and δ cells [101]. PYY inhibits insulin secretion via the NPY family of receptors, the most abundant of which is Y1 in both mouse and human islets [84, 101]. It has recently been reported that ablation of PYY-expressing cells *in vivo* causes β-cell destruction and induction of diabetes, suggesting a role for islet PYY in maintaining β-cell mass [102].

Ghrelin is a 23 amino acid peptide first identified in the gastrointestinal system, but now known also to be expressed in islet ε cells that are localized to the islet mantle in rodents, and which appear to be developmentally distinct from the classic islet endocrine cells [103, 104]. The physiological function of ε-cell-derived ghrelin has not been established, but most experimental evidence suggests an inhibitory role in the regulation of insulin secretion [105], analogous to that of δ-cell SST [20].

Neural control of insulin secretion

The association of nerve fibers with islets was shown over 100 years ago by silver staining techniques [106], and since that time it has become well established that islets are innervated by cholinergic, adrenergic, and peptidergic autonomic nerves. Parasympathetic (cholinergic) fibers originating in the dorsal motor nucleus of the vagus and sympathetic (adrenergic) fibers from the greater and middle splanchnic nerves penetrate the pancreas and terminate close to the islet cells. The autonomic innervation of the islets is important in regulating insulin secretion, with enhanced insulin output following activation of parasympathetic nerves and decreased insulin secretion in response to increased sympathetic activity. The autonomic nervous regulation of islet hormone secretion is thought to be involved in the cephalic phase of insulin secretion during feeding, in synchronizing islets to generate oscillations of hormone secretion, and in regulating islet secretory responses to metabolic stress [5].

Neurotransmitters: acetylcholine and norepinephrine

The numerous parasympathetic nerve fibers that innervate islets are postganglionic and originate from the intra-pancreatic ganglia, which are controlled by preganglionic fibers originating in the dorsal vagal nucleus [5]. Acetylcholine is the major postganglionic parasympathetic neurotransmitter, and it stimulates the

release of insulin and glucagon in a variety of mammalian species [5, 84, 107]. Acetylcholine is also synthesized in and secreted from α cells in human islets where it primes the β cells to respond optimally to increases in glucose [108]. Acetylcholine acts predominantly via M3 receptors in β cells [107, 109] to activate PLC (Figure 6.10), generating IP_3 and DAG, which act to amplify the effects of glucose by elevating cytosolic calcium and activating PKC [67]. Activation of β-cell muscarinic receptors can also lead to the activation of PLA_2, with the subsequent generation of AA and lysophosphatidylcholine, which can further enhance nutrient-induced insulin secretion. Acetylcholine also depolarizes the plasma membrane by affecting Na^+ conductivity, and this additional depolarization induces sustained increases in cytosolic calcium [107].

Islets also receive an extensive sympathetic innervation from postganglionic nerves whose cell bodies are located in the celiac or paravertebral ganglia, while the preganglionic nerves originate from the hypothalamus [5]. The major sympathetic neurotransmitter norepinephrine (noradrenaline) can exert positive and negative influences on hormone secretion. Thus, norepinephrine can exert direct stimulatory effects on the β cell via β_2-adrenoreceptors [110], or inhibitory effects via α_2-adrenoreceptors [111], and the net effect of norepinephrine may depend on the relative levels of expression of these receptor subtypes. Differences between species in the expression levels of adrenoreceptor subtypes probably account for the differential effects of β-adrenergic agonists on human islets, where they are stimulatory, and rodent islets, where they are ineffective [112]. The stimulatory effects mediated by β_2-receptors occur by activation of adenylate cyclase and an increase in intracellular cAMP (Figure 6.9), while the inhibitory effect of α_2-receptor activation involves reductions in cAMP and of cytosolic calcium [98, 111], and an unidentified inhibitory action at a more distal point in the stimulus–secretion coupling mechanism [113]. Increased expression of α_2A adrenoreceptors and decreased insulin secretion are a consequence of an SNP in the human α_2A receptor gene [114], and an α_2A receptor antagonist has been used to improve the insulin secretion deficiency in individuals with type 2 diabetes [115]. In contrast to the inhibitory effects of norepinephrine on insulin release, it has direct stimulatory effects on glucagon secretion from α cells mediated by both β_2- and α_2-receptor subtypes [5]. Circulating catecholamines secreted by the adrenal medulla (mainly epinephrine) also have the potential to influence islet hormone secretion through interactions with the adrenoreceptors expressed on the α and β cells.

Neuropeptides

Parasympathetic nerve fibers in islets contain a number of biologically active neuropeptides, including VIP, PACAP, and gastrin-releasing polypeptide (GRP), all of which are released by vagal activation and they all stimulate the release of insulin and glucagon.

VIP (28 amino acids) and PACAP (27 or 38 amino acids) are abundantly expressed neuropeptides that are widely distributed in parasympathetic nerves that supply the islets and gastrointestinal tract [6]. VIP and PACAP have similar structures, and VIP1 and VIP2 receptors also have an affinity for PACAP. The stimulatory effects of VIP and PACAP on insulin secretion *in vitro* and *in vivo* are through β-cell VIP2 and PAC1 receptors, respectively, and are thought to involve increases in intracellular cAMP (Figure 6.9) and cytosolic calcium [6, 116, 117]. GRP is a 27 amino acid peptide that also stimulates the secretion of insulin, glucagon, SST, and PP [5]. These effects of GRP are mediated through specific receptors, and involve the activation of PLC and the generation of IP_3 and DAG (Figure 6.10).

Sympathetic nerves contain different neuropeptides to parasympathetic nerves, and these include NPY and galanin, both of which have inhibitory actions within islets. NPY (36 amino acids) and galanin (29 amino acids) are expressed in fibers innervating both the endocrine and exocrine pancreas [5, 118]. Both neuropeptides inhibit basal and glucose-stimulated insulin secretion [98, 118, 119], although differences between species have been reported. Both NPY and galanin act through specific G_i-coupled receptors to inhibit adenylate cyclase [84, 120, 121], and galanin may have additional inhibitory effects at an undefined late stage of exocytosis [98].

Regulation of insulin secretion by gut- and adipose-derived factors

Incretins

It has been known for over 50 years that insulin secretion from islets is greater following oral rather than intravenous administration of glucose [122], and it is now known that this enhanced insulin secretory output is a consequence of the release of gastrointestinal-derived "incretin" hormones [123]. The main incretins that have been implicated in an elevated insulin response to absorbed nutrients after food intake are glucagon-like peptide 1 (GLP-1), glucose-dependent insulinotropic peptide (GIP) and cholecystokinin (CCK), all of which are hormones secreted by specialized endocrine cells in the gastrointestinal tract in response to the absorption of nutrients [123, 124]. These hormones are carried to the islets in the blood and they interact with specific receptors on the β-cell surface to stimulate insulin secretion.

Glucagon-like peptide 1

After food intake, L cells of the distal gastrointestinal tract secrete GLP-1 in response to elevated levels of nutrients derived from carbohydrates, lipids, and proteins in the intestinal lumen [123, 124]. GLP-1 is generated by prohormone convertase 1–3 cleavage of proglucagon in the L cells and it is highly conserved in mammals, with identical amino acid sequences in humans and mice [93, 123]. GLP-1 is degraded by dipeptidyl protease 4 (DPP-4), which cleaves two amino acids from its N-terminus. Full-length GLP-1 (1–37) does not show biological activity, but the truncated peptides GLP-1 (7–36) amide and GLP-1 (7–37) are potent stimulators of insulin secretion *in vitro* and *in vivo* [123]. Observations that infusion of the peptide into individuals with type 2 diabetes before food intake improved insulin output and reduced the

postprandial increase in circulating glucose led to studies to determine whether GLP-1 or related peptides may be useful as therapies for type 2 diabetes. Reports of other beneficial effects of GLP-1, including its capacity to inhibit glucagon secretion, delay gastric emptying, and decrease food intake, indicated its positive effects on normalizing postprandial glycemia, but its half-life of less than 2 min precludes its use as a diabetes therapy. Nonetheless, exenatide, a synthetic version of a GLP-1 analogue present in the saliva of the Gila monster lizard, has been developed for clinical use for type 2 diabetes [125]. It has ~50% amino acid homology with GLP-1, thus allowing it to exert the same effects on islets as native GLP-1, but its resistance to degradation by DPP-4 increases its half-life to around 2 h *in vivo*, which ensures effective regulation of blood glucose levels. Another GLP-1 analog, liraglutide, has a greatly extended half-life (>12 h) as a result of incorporation of the fatty acid palmitate into the GLP-1 sequence, allowing it to bind to plasma albumin and reducing its exposure to DPP-4. Selective DPP-4 inhibitors such as sitagliptin are used clinically to normalize blood glucose levels in type 2 diabetes by extending the half-life of endogenous GLP-1. GLP-1, exenatide, and liraglutide act at islet GLP-1 receptors [84, 123] that are linked, via G_s, to adenylate cyclase activation, which ultimately increases insulin secretion (Figure 6.9). Although cAMP has been implicated in the majority of effects of GLP-1 in islets, including its stimulation of insulin secretion via activation of the β-cell TCF7L2/Wnt pathway [123] and upregulation of two β-cell microRNAs [126], GLP-1 may also close β-cell K_{ATP} channels in a cAMP-independent manner, reported in studies done in rats [127]. It has been proposed that improved glucose homeostasis following bariatric gastric bypass surgery results, at least in part, from more rapid delivery of food to the L cells through a shorter gastrointestinal tract, which results in enhanced postprandial secretion of GLP-1 [128]. See chapter 32 for additional discussion of GLP-1 physiology and therapeutic usage. See chapter 32 for additional discussion of GLP-1 physiology and therapeutic usage.

Glucose-dependent insulinotropic peptide

GIP, a 42 amino acid peptide, is released from K cells in the duodenum and jejunum in response to the absorption of glucose, other actively transported sugars, amino acids, and long-chain fatty acids [124]. It was originally called "gastric inhibitory polypeptide" because of its inhibitory effects on acid secretion in the stomach, but its main physiological effect is now known to be stimulation of insulin secretion in a glucose-dependent manner [123]. GIP receptors, like those activated by GLP-1, are coupled to G_s, with essentially the same downstream cascades leading to stimulation of insulin secretion (Figure 6.9). Although GLP-1 and GIP both enhance insulin output following their release in response to food intake, it seems unlikely that GIP-related peptides will be developed as therapies for type 2 diabetes because GIP stimulates glucagon secretion and inhibits GLP-1 release, and its infusion in individuals with type 2 diabetes is reported to worsen postprandial hyperglycemia [129].

Cholecystokinin

CCK is another gastrointestinal hormone that is released from I cells in response to elevated fat and protein levels [124]. It was originally isolated from porcine intestine as a 33 amino acid peptide and the truncated CCK-8 form stimulates insulin secretion *in vitro* and *in vivo* [130]. CCK-8 acts at specific G_q-coupled receptors on β cells to activate PLC (Figure 6.10), and its potentiation of insulin secretion is completely dependent on PKC activation [131]. However, the physiological role of CCK as an incretin has not been established because high concentrations are required for its effects on insulin secretion, and it is possible that its major function is in digestion in the duodenum.

Bile acids

Bile acids act as endocrine factors to enable signaling between the gut and other tissues involved in metabolic homeostasis, including islet cells. They signal via the nuclear receptor farnesoid-X receptor (FXR) and the G-protein-coupled receptor TGR5, both of which are expressed in islets [84, 132]. TGR5 activation is reported to stimulate insulin secretion from mouse and human islets *in vitro* [133], but *in vivo* studies using transgenic mice suggest that FXR mediates most, if not all, of the effects of bile acids to enhance insulin secretion [132]. The composition and plasma concentrations of bile acids are altered by gastric bypass surgery, perhaps as a consequence of changes in the gut microbiome, and these changes have been linked to improved β-cell function and metabolic control [134].

Decretins

Starvation studies in humans and other mammals suggest the existence of gut-derived factors that are released postprandially to suppress insulin secretion and thus prevent postprandial hyperinsulinemic hypoglycemia [135], these factors being referred to as "decretins" [136, 137] or "anti-incretins" [138]. Studies in baboons first identified gut-derived SST-28 as a putative decretin by demonstrating that immunoneutralization of SST-28 caused elevations in postprandial plasma insulin concentrations [136]. In *Drosophila* the neuropeptide limostatin (Lst) acts as a decretin by suppressing the activity of insulin-producing cells and reducing the secretion of *Drosophila* insulin-like peptides [137]. The mammalian homolog of Lst is neuromedin U (NMU), a neuropeptide that is expressed in foregut enteroendocrine cells, and which acts as a decretin by suppressing glucose-induced insulin secretion from human islets through a specific β-cell receptor, NMUR1 [137]. Foregut-derived dopamine (DA) has also been proposed as a physiological decretin that is released postprandially to inhibit glucose- and GLP-1-stimulated insulin secretion [139]. Decretins such as SST, NMU, and DA may be important in the pathophysiology of type 2 diabetes because it has been suggested that the rapid resolution of metabolic dysfunction following gastric bypass surgery is due, at least in part, to a reduction in overactive decretin signaling, with resultant improvements in β-cell secretory function [138].

Adipokines

Obesity is a risk factor for diabetes, and hormones (adipokines) released from fat depots have been implicated in insulin resistance associated with obesity and type 2 diabetes [140]. Some adipokines, such as leptin, resistin, and adiponectin, are also reported to influence islet function. Thus, β cells express Ob-Rb leptin receptors, which, when activated by leptin, lead to inhibition of insulin secretion [141], and specific deletion of β-cell Ob-Rb receptors is associated with enhanced insulin secretion [142]. The inhibitory effects of leptin on glucose-stimulated insulin secretion have been attributed to activation of β-cell K_{ATP} channels [143] or of c-Jun N-terminal kinases (JNKs) [144]. Leptin may also further impair β-cell function through reductions in β-cell mass [142, 144]. Resistin, another adipocyte polypeptide, also inhibits glucose-stimulated insulin release [145] and stimulates apoptosis of rat β cells [146], suggesting that it has similar functions to leptin. However, resistin is not considered to be a true adipokine because, although it is secreted at high levels from mouse adipocytes, it is not produced by human adipocytes, and high plasma resistin levels do not correlate with reduced insulin sensitivity [147]. However, it is possible that resistin has paracrine effects on β-cell function in humans as it has been identified in human islets [148]. Unlike leptin and resistin, adiponectin has protective effects by improving insulin sensitivity, and decreased plasma adiponectin levels may contribute to the development of type 2 diabetes [149]. Human and rat β cells express AdipoR1 and AdipoR2 adiponectin receptors [150, 151], and adiponectin is reported to stimulate insulin secretion [150, 151], protect against β-cell apoptosis [152] and stimulate β-cell regeneration [153]. The signaling cascades that couple adiponectin receptors to downstream effects in β cells have not been fully defined, but adiponectin is reported to activate the kinases Erk and Akt in islets [154], and it also stimulates expression of genes that regulate lipid transport and metabolism [155].

Conclusions

Islets of Langerhans are complex micro-organs containing several different types of endocrine cells, with extensive vasculature and autonomic nerve supply. Interactions between the islet cells, the autonomic nervous system, and hormones secreted by the gastrointestinal system and adipose tissue permit the appropriate release of islet hormones to regulate metabolic fuel usage and storage.

The insulin-secreting β cells within islets respond to changes in circulating nutrients by linking changes in nutrient metabolism to β-cell depolarization and the calcium-dependent exocytotic release of stored insulin. Islet β cells can also respond to a wide range of hormones and neurotransmitters through conventional cell-surface receptors that are linked to a variety of intracellular effector systems regulating the release of insulin. The ability to detect nutrient, hormonal, and neural signals allows β cells to integrate information about the prevailing metabolic status, and to secrete insulin as required for glucose homeostasis.

This detailed understanding of islet cell biology has informed the development of new treatments for type 2 diabetes, as exemplified by the introduction of GLP-1 agonists and DPP-4 inhibitors in the past decade. Recent studies have suggested associations between type 2 diabetes and polymorphisms in genes associated with β-cell development or function, and so current understanding of normal β-cell function may assist in identifying the β-cell pathologies in type 2 diabetes.

Key points

- Glucagon is predominantly made in islet α-cells and regulates systemic glycemia primarily through actions in the liver.
- Beyond endocrine actions in glucose counter-regulation and metabolism of protein rich meals, glucagon may have roles in the paracrine regulation of islet function and energy balance.
- Excess glucagon contributes to dysglycemia in people with diabetes and has a central role in diabetic ketoacidosis.
- Compounds that stimulate and block the glucagon receptor are under investigation for the treatment of metabolic disorders.

Introduction

Glucagon is a gluco-regulatory peptide made almost exclusively in the α-cells of the pancreatic islet and has a notable history in basic research, clinical physiology, and therapeutics. Discovered initially as a contaminant in pancreatic extractions of insulin [1], the demonstration of specific actions to raise blood glucose led to a physiological model in which glucagon was attributed a central role for providing fuel under circumstances of need [2]. The fundamental aspects of glucagon signaling at the cellular level formed much of the basis for the discovery of cyclic AMP (cAMP) and G-proteins [3]. Glucagon was one of the first hormones that could be measured in the circulation and tissues of humans and experimental animals. Early work demonstrated dramatic increases in circulating levels with hypoglycemia and extreme physical exertion [2], and smaller but consistent elevations during starvation [4]. Especially important was the observation that glucagon levels were elevated in people with diabetes, dramatically so during diabetic ketoacidosis [5, 6]. These findings raised the possibility that both islet hormones, insulin and glucagon, had a role in the pathogenesis of diabetes [7], a hypothesis that was supported by human experiments using somatostatin to inhibit α-cell secretion [8]. Notably, interest in glucagon as a central factor in diabetic pathophysiology waned for several decades as the focus of metabolic research and treatment of diabetes centered on insulin resistance and defects in β-cell function. However, in recent years glucagon has regained its status as a topic of interest in diabetes investigation, and renewed attention to glucagon physiology has been bolstered by the advent of new drugs that suppress glucagon as part of their glucose-lowering activity.

This chapter reviews basic concepts in α-cell biology and glucagon physiology with an emphasis on how these processes are altered in disease states, particularly diabetes. Relatively new findings that implicate glucagon in intra-islet signaling and energy balance are discussed, and descriptions of new uses for glucagon activity in drug development are presented. The role of glucagon in hypoglycemic counter-regulation is addressed in detail elsewhere in this book (Chapter 35) and will not be considered in depth here. The pharmacology of available diabetes drugs that affect glucagon secretion, such as dipeptidyl peptidase inhibitors and GLP-1 receptor analogs, are also covered elsewhere (Chapters 31 and 32). There are several recent reviews that cover the molecular and systemic physiology of glucose in more detail than in this chapter [9–12].

α-Cell anatomy and development

The function of glucagon and other α-cell products is based in great part on the anatomy of the pancreatic islet. New research implicates the α-cell in the paracrine regulation of the endocrine pancreas, and islet structure has an important bearing on this function. Recent studies demonstrating key differences in islet architecture between rodents and humans have provided new insights into pancreatic endocrine function. These differences include heterogeneity of islet size and organization within species

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

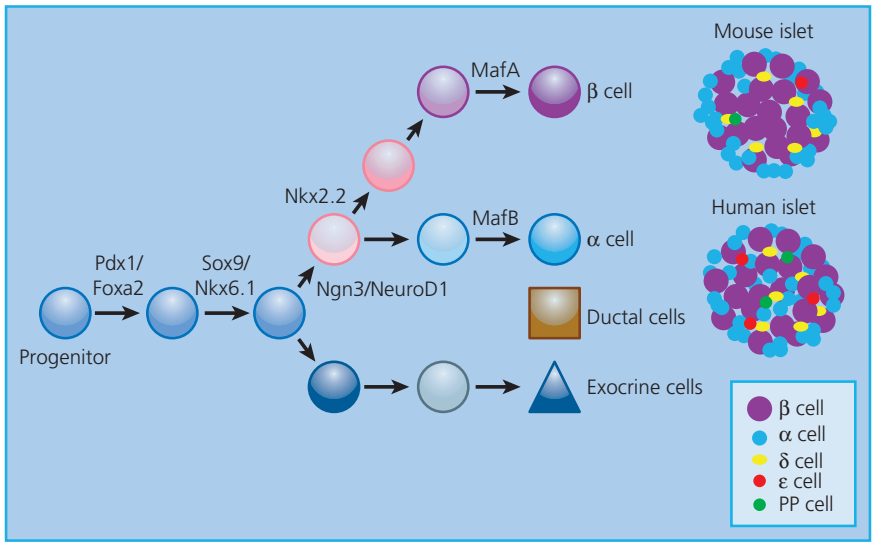

Figure 7.1 Islet development and anatomy. A simplified model of pancreatic islet–cell differentiation in the developing pancreas and the role of islet transcription factors during islet–cell development. Transcriptional factors such as neurogenin 3 (Ngn3) and pancreatic duodenal homeobox 1 (Pdx1) are critical for the endocrine cell fate determination, and aristaless-related homeobox (Arx) and forkhead box A2 (Foxa2) are important for the initial or terminal differentiation stages of α-cell differentiation, respectively. In mice and rats, the organization of the islet includes a mantle of α and δ cells on the periphery of the islet, surrounding a core of β cells. In humans, the major endocrine cell types are spread more diffusely throughout the islet and most β cells have contact with either α or δ cells.

[13, 14]. It is well established that in mice and rats the organization of the islet includes a mantle of α- and δ-cells on the periphery of the islet, surrounding a core of β cells (Figure 7.1). Estimates of the relative cell composition in rodent islets are ~75–80% β and 20–15% α cells, and most β cells have contact with other β cells [15–17]. In humans, the major endocrine cell types are spread more diffusely throughout the islet, most β cells have contact with either α or δ cells, and the proportion of β cells per islet is 40–60% [13–15] (Figure 7.1). Based on recent analyses of large numbers of human pancreata, the frequency of contacts between α and β cells appears to be much greater than previously estimated, as is the location of islet endocrine cells in close proximity to the microvasculature [13]. It is notable that in humans, smaller islets have a cellular architecture that resembles that of rodents, i.e. a mantle of α cells surrounding a β-cell core with a higher percentage of β cells than larger islets; these smaller islets also have greater relative insulin secretion [13, 14]. These recent studies on the organization of islet anatomy, particularly in humans, have shifted the focus from interactions mediated through the microcirculation to control through direct cell-to-cell contacts.

Neural regulation of islet function is well established, although the nature and magnitude of effects are still under debate. In general, sympathetic nervous system activity is thought to be important in settings where there is enhanced demand for glucose, i.e. hypoglycemia and physical activity, and parasympathetic activity is important before and during meal ingestion [18–20]. Recent data suggest a difference between the density of autonomic innervation of rodent and human α and β cells, with rats and mice having a greater density of neural fibers in islets [21]. Although this has led to the hypothesis that neural regulation of islet secretion is more important in rodents, and paracrine control in humans, this has not been formally tested, and not all studies have demonstrated reduced innervation of human islet cells [22].

α-Cells are formed within the concert of pancreatic development in early embryonic life, directed by the sequential and interacting effects of specific transcription factors. Most of the current knowledge on endocrine pancreatic development comes from studies in mice, and although there are general similarities with human islet development, some key differences exist [23–25]. In both mice and humans, pancreatic duodenal homeobox 1 (Pdx1) directs the differentiation of pancreatic epithelial cells, that will become the exocrine and endocrine pancreas, from the foregut endoderm [26]. Subsequent expression of neurogenin 3 (Ngn3) initiates the primary differentiation of endocrine precursors and their initial association into discrete cellular aggregates. The transcription factor aristaless-related homeobox (Arx) is critical for determining a definitive α-cell fate for developing endocrine progenitors, and in its absence normal α cells do not develop [27]. Both mice and humans also have a secondary transition of endocrine development where the various hormone-producing cells start to express the gene profiles that mark mature endocrine cells [26, 27]. In mice, glucagon-producing cells are the first endocrine cell type that is detected, whereas insulin-containing cells are the earliest form in humans [23]. Once the secondary transition has occurred, the formation of islets in the distinct murine and human forms progresses throughout the remainder of the prenatal period [23, 24]. The molecular physiology of islet development has assumed particular importance as efforts progress to generate β cells for potential use in therapeutics. In fact, there is evidence that mature α cells can be reprogrammed to insulin-producing cells in states of severe β-cell loss [28], and that diabetes induces dedifferentiation of β cells into α cells [29]. The plasticity of islet cells is only beginning to be understood but holds promise for understanding the mechanisms of various forms of diabetes.

Proglucagon gene transcription, translation and peptide processing

Preproglucagon (*Gcg*), the gene that encodes glucagon, is expressed in pancreatic islet α cells, but also within the hindbrain, specifically the nucleus of the solitary tract (NTS), and within the

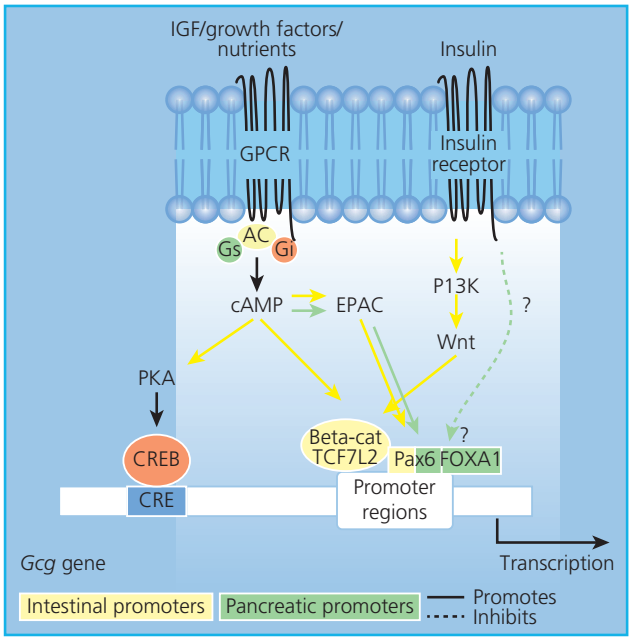

Figure 7.2 Regulation of *Gcg* gene expression. IGF (insulin-like growth factor), other growth factors, nutrients, and insulin are stimulatory factors for *Gcg* expression. IGF, growth factors, and nutrients activate a GPCR/cAMP signaling that has multiple downstream effects including activation of PKA and subsequently CREB (cAMP response element-binding protein). cAMP either directly or indirectly (via EPAC) activates other transcription factors (beta-cat/TCF7L2, Pax6/MafB, or Foxa1 depending on whether the activation occurs in the intestine or pancreas) that bind to promoter regions of the *Gcg* gene. Additionally, insulin signaling is also upstream of these transcription factors and can stimulate transcription in both the pancreas and intestine.

enteroendocrine L cell of the intestinal mucosa [30, 31]. Regulation of *Gcg* expression is complex (Figure 7.2), but involves elevations of cAMP, exposure to amino acids, and/or binding of several specific transcription factors [32–34]. Recent work also suggests that *Gcg* expression is differentially regulated in the pancreas and intestine (Figure 7.2). The most relevant example of this is related to nutritional state, with fasting increasing islet *Gcg* expression, while feeding promotes transcription in L cells [35]. As an extension of this level of regulation, insulin inhibits *Gcg* transcription in islet α cells [34, 36], but increases *Gcg* expression in intestinal endocrine cells [37, 38]. The latter effect is mediated in part by signaling related to transcription factor 7 like 2 (TCF7L2), a gene product linked to type 2 diabetes mellitus (T2DM) in genetic epidemiological studies [39], that seems to be specific for control of L-cell *Gcg* transcription [38]. It is also known that bowel resection or injury causes a large increase in intestinal *Gcg* expression [40]. Differential regulation of *Gcg* transcription in intestinal and islet endocrine cells is in keeping with their distinct patterns of prohormone processing and the predominant secretion of glucagon from the pancreas and GLP-1 and GLP-2 by the gut.

The differential synthesis and release of *Gcg* peptides from α cells compared with intestinal and neural cells expressing *Gcg* is due to tissue-specific post-translational modification by prohormone convertases (PCs). In the α cell, PC2 is the major convertase and it cleaves specific sites along proglucagon to release glucagon, but not the glucagon-related peptides [41]. In contrast, intestinal L cells have significantly more PC1/3 than PC2 activity, and process proglucagon into GLP-1, oxyntomodulin, and GLP-2 as the physiologically relevant products [42–44]. There is PC1/3 expression in α cells, albeit at lower levels than PC2, and increasing evidence for islet production of GLP-1. Although PC2 is expressed by some central nervous system (CNS) neurons, it is not co-localized with *Gcg*, and only trace amounts of glucagon have been detected in the CNS [42]. In addition to glucagon and the glucagon-like peptides, other proglucagon-derived peptides are measurable in tissue extracts and the circulation, and may have signaling properties. These include oxyntomodulin, glicentin, glicentin-related pancreatic polypeptide (GRPP), major proglucagon fragment (MPGF), and miniglucagon [12].

Regulation of α-cell secretion

Glucagon is the chief secretory product of α cells and concentrations of glucagon have been used as the principal measure of α-cell function *in vivo* and *in vitro*. There is no evidence that the other cell types that express *Gcg*, either enteroendocrine L cells or neurons in the hindbrain, contribute to plasma glucagon levels. Glucagon secreted from islets in the pancreas collects in the portal vein, where concentrations are higher than in other major vascular systems, and it is generally agreed that the liver is the primary target of glucagon signaling. Circulating glucagon is cleared by the liver and kidney, with roughly equal contributions by each organ, and 20–40% hepatic clearance of portal venous content [45–47]. Glucagon secretion is regulated by a complex interplay of nutrient, endocrine, paracrine, and neural factors (Figure 7.3). Although there is convincing evidence to support this diverse control of α-cell secretion, how this system is integrated, varies under different physiological states, and is altered by disease are still not well understood.

Similarly to β-cell secretion of insulin, α-cell release of glucagon is highly dependent on ambient glucose concentrations. Low glucose levels increase and high concentrations inhibit glucagon secretion, in part through changes in α-cell electrical activity involving K_{ATP} channels [48–50]. It remains a curiosity that α and β cells have similarities in key aspects of glucose transport, metabolism, and K_{ATP} channel activity, yet opposite secretory responses to changes in ambient glucose. Recent evidence suggests that differences in resting electrical characteristics and ion channel function downstream of K_{ATP} channel closure can explain much of the reciprocal pattern of glucagon and insulin secretion at relative hypo- and hyperglycemia [49, 51, 52] (Figure 7.3). Moreover, newer findings suggest that α cells, but not β cells, express sodium–glucose co-transporters (SGLTs)-1 and -2 [53], and that reduced flux through SGLT-2 increases glucagon secretion. It is not clear how SGLT function is integrated with other aspects of α-cell glucose metabolism, but observations that humans treated

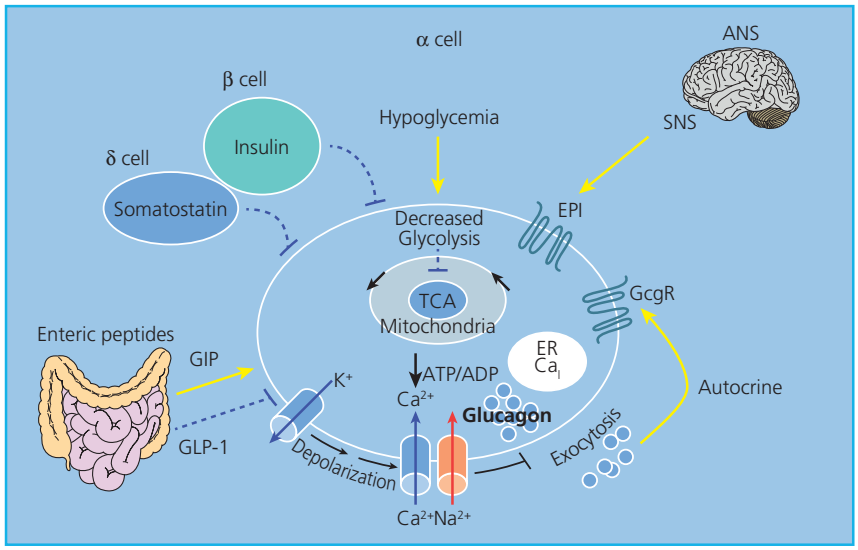

Figure 7.3 Regulation of glucagon secretion. Neural (SNS stimulates and PNS inhibits), paracrine (insulin and somatostatin inhibit), autocrine (glucagon stimulates its own secretion), endocrine (GIP stimulates and GLP-1 inhibits), and nutrient (low glucose stimulates) factors all regulate glucagon secretion. ADP, adenosine diphosphate; ANS, autonomic nervous system; ATP, adenosine triphosphate; EPI, epinephrine; SNS, sympathetic nervous system; TCA, tricarboxylic acid cycle.

with SGLT-2 inhibitors have increased plasma glucagon suggest that this is an active physiological mechanism [54, 55]. Beyond glucose, amino acids are another nutrient source that stimulates α cells. Protein meals or infusions of amino acids stimulate glucagon release, and arginine is commonly used to stimulate glucagon secretion in research studies.

Substantial differences exist between glucagon release from isolated α cells and intact islets [9, 56, 57], suggesting that other islet cells have important roles in α-cell regulation. Endocrine cells in islets are exposed to high concentrations of local products and both insulin and somatostatin are important inhibitors of glucagon release [9], acting either through the microvasculature or by local cell-to-cell contact. Insulin contributes measurably to the suppression of glucagon after meals [58] and during progressive hyperglycemia [59]. Other compounds released from β cells have been shown to inhibit glucagon release, including zinc [56], γ-aminobutyric acid [60], and glutamate [9], but the ultimate importance of these compounds is not clear. Exogenous somatostatin is a potent inhibitor of glucagon secretion [61], and a substantial body of experimental observations suggest that somatostatin secreted from islet δ cells is important in restraining α-cell secretion during exposure to circulating nutrients after meals. A final mechanism of intra-islet regulation of glucagon is autocrine, as recent work suggests that other α-cell products may regulate the α cells. Alpha cells from both primates and mice secrete glutamate and express ionotropic glutamate receptors (iGlutR) [62]. Glutamate stimulates glucagon release, and this seems to be important for the normal response to low plasma glucose since inhibition of iGlutR impairs hypoglycemic counter-regulation in mice [62].

The autonomic nervous system is critical for the regulation of glucagon secretion, particularly in the setting of hypoglycemic counter-regulation. Activation of both the parasympathetic and sympathetic limbs of the autonomic nervous system increase glucagon release [19]; adrenal epinephrine has a similar effect. Importantly, catecholaminergic signaling synergizes with low ambient glucose to stimulate glucagon release [52], and genetic disruption of autonomic neurons in the islet predisposes mice to hypoglycemia [63]. More recent studies suggest that the key regions in the CNS for sensing circulating blood glucose and initiating counter-regulation are located in the hypothalamus and hindbrain [64, 65].

Similarly to insulin, glucagon release is also affected by the actions of enteric peptides [9, 66]. Glucose-dependent insulinotropic polypeptide (GIP) stimulates glucagon release, possibly through direct actions on the GIP receptor expressed on α cells [67]. Of great importance, the other major *Gcg* peptide, GLP-1, inhibits glucagon secretion, although there is some question about the mechanism by which this occurs. GLP-1 increases the secretion of hormones from both β and δ cells, and so could act indirectly to reduce glucagon release [9, 66], and this is currently considered to be the primary means by which GLP-1 acts on the α cell. In addition, there is evidence that GLP-1 affects electrical activity and secretion of α cells even in the absence of changes in somatostatin or insulin [67].

Overall α-cell regulation is a complex, multilayered process with dense integration of control by nutrient substrates, neural, endocrine, paracrine, and autocrine inputs to secretion. Because glucagon has a key role across a range of physiological settings—fasting, exercise, hypoglycemia and following mixed nutrient meals—α cells are subject to a diversity of controlling factors. Although there appears to be some overlap in α-cell regulation, it seems likely that some of these also have specific roles. Further understanding of the regulation of glucagon secretion, and adaptation of therapeutic approaches to control this process, have great potential for the treatment of metabolic disease.

Glucagon actions: hepatic glucose and lipid metabolism

Glucagon action is mediated by the glucagon receptor (GCGR), a family class B G-protein coupled receptor that is highly conserved

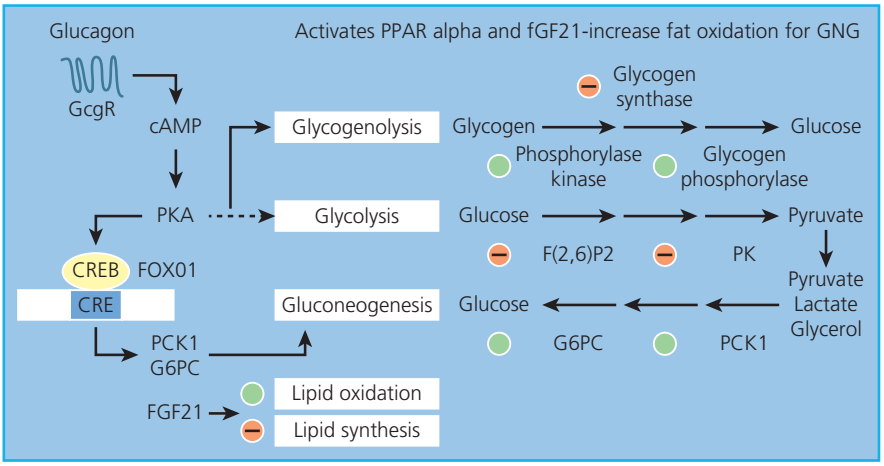

Figure 7.4 Glucagon GPCR signaling via PKA activates glycogenolysis (via inhibition of glycogen synthase; activation of phosphorylase kinase and glycogen phosphorylase) and inhibits glycolysis (via inhibition of fructose 2,6-bisphosphatase and pyruvate kinase) via regulation of major rate-limiting enzymes in these pathways. PKA also activates CREB, which increases transcription of Pck1 and G6PC, major enzymes regulating gluconeogenesis, and also FGF21, which activates several downstream genes that increase lipid oxidation and inhibit lipid synthesis.

across mammalian species [68]. Binding of glucagon to the GCGR activates adenylyl cyclase through the G_s subtype G-protein, generating cAMP and activating protein kinase A (PKA) as the major mode of intracellular signaling [69]. The richest source of glucagon binding is in the liver and kidney; lesser binding occurs in heart, adipose tissue, CNS, adrenal gland, and spleen [68]. Consistent with the relative receptor expression, the liver and kidney play the major role in glucagon clearance, accounting for ~70% of the removal from the circulation [46, 47, 68]. The half-life of glucagon in circulating plasma is relatively short, 2, 5 and 7 min in rats, dogs, and humans, respectively [68, 70].

The first known action of glucagon, to increase hepatic glucose production, was recognized nearly 100 years ago [3]. Subsequent work demonstrated effects of glucagon to counter hypoglycemia and led to the general principle that it has a role opposing that of insulin to maintain plasma glucose in times of stress, fasting, or exercise [3]. The endocrine mechanism of glucagon action is based on the effects of exogenous glucagon to increase hepatic glucose output in animals, humans, and a number of *in vitro* systems, and removal of circulating glucagon with a neutralizing antibody to reduce blood glucose [71, 72].

The cAMP/PKA signaling pathway is critical for the ability of glucagon to regulate hepatic glucose production [71, 73] (Figure 7.4). Subsequent activation of phosphorylase kinase and its downstream target glycogen phosphorylase activates glycogenolysis and inhibits glycogenesis [74, 75]. However, insulin also regulates these pathways. The result is that the balance between glycogen breakdown and synthesis results from the balance of insulin and glucagon effects on hepatocytes, the cAMP signal, and the level of glycogen stores [75]. Strategies that increase glycogen synthesis relative to glycogenolysis promote glucose tolerance [74, 76] and are potential therapeutic targets for hyperglycemia. GCGR signaling also regulates the flux between glucose-6-phosphate and fructose bisphosphate via action on fructose 2,6-bisphosphatase and consequent inhibition of pyruvate kinase activity [71] (Figure 7.4). The result of cAMP signaling is rapid inhibition of hepatic glucose metabolism and mobilization of stored glucose in order to deliver glucose to peripheral tissues.

Another critical aspect of glucagon-induced regulation of hepatic glucose production is via activation of the gluconeogenic pathway, an action mediated by PKA activation of CREB and Fox01. Glucagon upregulates phosphoenolpyruvate carboxykinase (*Pepck*) transcription (Figure 7.4), which varies with the metabolic state, increasing during fasting and decreasing in response to insulin [71]. PEPCK catalyzes a key step in gluconeogenesis by converting oxaloacetate, a product of the TCA cycle, into phosphoenolpyruvate. In animal models, gluconeogenesis is increased by overexpression of *Pepck* [77] and conversely decreased by deletion of *Pepck* [78, 79]. Other key genes involved in glucose production including peroxisome proliferator activated receptor-γ coactivator 1 (PGC-1), and glucose-6-phosphatase (G6P) are also activated by glucagon signaling. Overall, glucagon regulates several processes within the gluconeogenic pathway that enable sustained glucose production, an effect that is enhanced in the face of limited glycogen supply. Gluconeogenesis is an energy-demanding process, requiring 6 mol of high-energy phosphate bonds for each mole of glucose produced, and is tightly linked to TCA cycle activity and lipid oxidation for sources of ATP [79]. Indeed, glucagon contributes to hepatic fatty acid oxidation and ketogenesis at several metabolic steps [80, 81], and elimination of glucagon action increases the liver triglyceride content during fasting. These findings indicate that glucagon has broad effects on hepatic fuel metabolism, generating energy from lipids to support glucose production.

The lipid and glycemic effects of glucagon in the liver may also lead to pathological consequences if they are not counterbalanced by appropriate levels of insulin action. Increased glucagon during extended periods of fasting or uncontrolled T1DM stimulates fatty acid oxidation and contributes to ketogenesis [10]. The transcription factor Foxa2 has been suggested to play a central role in this process. Foxa2 controls the expression of genes involved in fatty acid oxidation and ketogenesis [82, 83] and is activated both by fasting and by glucagon. Notably, insulin has opposing effects on Foxa2 [84], presenting yet another example of coordinate and inverse regulation by insulin and glucagon

on glucose and lipid metabolism, with glucagon more active in the fasted state and insulin predominating during and after feeding.

Studies in humans using somatostatin to inhibit insulin and glucagon secretion, with selective replacement of one or both hormones, are consistent with the knowledge gained from preclinical animal studies. Glucagon is necessary to support normal fasting glucose levels [85, 86], and basal insulin replacement without glucagon results in hypoglycemia. However, regulation of hepatic glucose production by glucagon occurs in the context of hepatic insulin action [87]. At glucose levels of 4.5–5.5 mM plasma glucagon levels are relatively low and unchanging, whereas changes in glycemia within this range can affect insulin secretion. This suggests that the effect of glucagon to promote glycogenolysis and initiate gluconeogenesis during fasting occurs tonically, with the absolute level of fasting blood glucose determined by variations of hepatic insulin action. At a cellular level, this can be conceived as glucagon maintaining a threshold of cAMP, or other signaling mediators, that can be modulated by changes in hepatic insulin signaling.

Although glucagon-driven hepatic glucose productions includes both glycogenolysis and gluconeogenesis, these two processes follow different temporal patterns. As fasting progresses, the contribution of glyogenolysis to total hepatic glucose output wanes such that glycogenolysis contributes ~50% of liver glucose output in the postabsorptive state but less than 10% after 36 h of fasting [88, 89]. In acute experiments, where glucagon action can be selectively increased, glycogenolytic effects predominate [90]. This is because activation of gluconeogenesis by glucagon requires a supply of glucose precursors, primarily lactate, alanine, and glycerol. Increased delivery of these compounds to the liver is not directly regulated by glucagon, and requires a longer period of fasting to reduce plasma insulin and disinhibit lipolysis and proteolysis. With extended periods of starvation, gluconeogenesis becomes even more tightly controlled by precursor supply as preservation of protein stores becomes essential [91].

The hallmark of glucagon's function in homeostasis is to increase hepatic glucose production during hypoglycemic counter-regulation [92]. Glycogenolysis provides the most rapid source of glucose. However, the rise in catecholamines that also occurs with hypoglycemia provides a supply of glucose precursors for gluconeogenesis [93]. Hence there is an integrated, synergistic effect of catecholamines and hypoglycemia to stimulate glucagon release and glucagon action in order to return glucose levels to normal.

Glucagon also contributes to the maintenance of blood glucose during exercise, another metabolic stressor [94, 95]. Similarly to hypoglycemia, increasing catecholamines and glucagon in response to exercise, combined with the usually low circulating levels of insulin, enhance glucagon action and ensure an adequate glucose output to maintain the glucose supply to peripheral working muscles. With prolonged exercise, the impact of glucagon on promoting lipid oxidation becomes increasingly important to preserve limited glucose and provide energy [96].

Non-hepatic effects of glucagon

Although the liver is the principal target for circulating glucagon, recent work indicates that other tissues also respond to the hormone. The brain is one of these sites, and there is evidence that glucagon can affect feeding behavior. People given pharmacological doses of glucagon, or those with neuroendocrine tumors and neoplastic production of large amounts of glucagon, reduce their food intake significantly, and weight loss is a dominant feature of glucagonoma [97]. Moreover, glucagon excess contributes to negative energy balance by increasing energy expenditure [98]. Although the CNS centers that account for these effects have not been identified, it is now clear that pharmacological administration of glucagon increases resting energy expenditure and decreases food intake across multiple species [99–111].

Another recently discovered site of glucagon action is brown adipose tissue (BAT), a target organ that has been recognized as a mediator of energy expenditure. BAT is a highly metabolic tissue that generates heat when stimulated. In some studies, glucagon increases both core body temperature [112] and BAT mass and temperature [112–115], indicative of an increase in energy expenditure. BAT is highly activated during cold exposure as a way to maintain body temperature, and indeed, cold exposure increases both plasma and BAT glucagon levels [116], raising the possibility that glucagon contributes to thermogenesis. It has been suggested that the impact of glucagon on BAT is primarily a response to cold exposure as acclimatized animals have a greater response than those maintained at room temperature [112].

The GCGR is expressed by islet β cells and it has long been appreciated that supraphysiological amounts of glucagon stimulate insulin release *in vitro* and *in vivo* [117–119]. Similarly to other peptide secretagogues, glucagon amplifies glucose-stimulated insulin secretion primarily through mechanisms activated by increased cAMP, and does so in both rodent and human islets [118, 120]. In isolated human and rat islets studied in culture, antagonism of the GCGR impairs insulin secretion in response to increased media glucose, suggesting a tonic role for islet glucagon action to maintain normal stimulus–secretion coupling [71, 74, 75]. Consistent with glucagon effects to potentiate insulin secretion, dispersed β cells are more responsive to glucose when attached to an α cell [121]. Hence a body of evidence has been generated that supports islet glucagon in the potentiation of insulin secretion, most likely through paracrine and cell-to-cell interaction.

Other α-cell peptides

There is emerging evidence that glucagon is not the only important *Gcg* peptide with a role in intra-islet regulation. GLP-1 also seems to be produced by the α cell and contribute to the regulation of β-cell function. Early studies that focused on differential proglucagon processing were consistent with a general

theme in fashion at that time that α cells turned the majority of N-terminal proglucagon into glucagon, with the bulk of C-terminal prohormone left unprocessed as an inactive peptide containing both GLP-1 and GLP-2. More recent studies suggest that α-cell production of GLP-1 may also have a role in the regulation of islet function. Rodent islets studied in culture have demonstrable expression of PC1/3, and release fully processed, bioactive GLP-1 in culture [122, 123]. In cultured α-cell lines or isolated islets, high media glucose concentrations increase PC1/3 expression and cellular GLP-1 content [123–125]. Moreover, intact GLP-1 [7–36] amide is secreted from isolated rat islets [122, 125], and from isolated human islets and α cells [126]. Interruption of GLP-1 receptor (GLP-1R) signaling in isolated rodent islets or pancreata, using receptor antagonists or gene knockout techniques, reduces basal [122] and glucose-stimulated insulin secretion [127]. These findings have recently been corroborated in a mouse model with β-cell-specific deletion of the GLP-1R [128]. Finally, infusion of a GLP-1 receptor antagonist to fasting humans, with fixed, low circulating GLP-1 levels decreases glucose-stimulated insulin secretion [129, 130]. These findings can be taken as support for the action of local islet GLP-1. Overall, there has been an accumulation of evidence to support a role for local production of GLP-1 in the islet in the regulation of insulin secretion as a paracrine factor.

Beyond a role in normal islet function, α-cell GLP-1 also seems to be involved in response to stress and illness. In rats treated with the β-cell toxin streptozotocin, islet PC1/3 and ProG expression, and processing of the propeptide to GLP-1, were increased [131]. Moreover, increased GLP-1 signaling in the islet was implicated in the recovery from injury. Islet GLP-1 production and action are also mediated by the cytokine interleukin-6 (IL-6), which is released in response to exercise, obesity, and diabetes [132, 133]. Expression of the IL-6 receptor is relatively high on α cells, and IL-6 signaling increases ProG transcription and GLP-1 production in mice. There are as yet no data to support this pathway in humans, but a recent study has demonstrated elevated levels of IL-6 and GLP-1, which were significantly correlated, in humans with critical illness [134]. These data suggest that IL-6, released from adipose tissue and skeletal muscle, regulates insulin secretion in part through α-cell production of GLP-1. Overall, the findings from these and other studies suggest that a paracrine system of islet GLP-1 signaling plays a role in several adaptations to metabolic stress. Understanding the control of the relative production of α-cell GLP-1 and glucagon would seem to hold promise for therapeutic development.

More recently, the incretin GIP has been demonstrated to be produced and secreted from α cells [135]. This interesting finding builds on the coincident production of proGIP and ProG in K/L enteroendocrine cells and their coexpression has now also been demonstrated in the endocrine pancreas. In the α cell, proGIP is processed by proconvertase 2 into a truncated $GIP_{1–30}$ form that is distinct from the longer $GIP_{1–42}$ produced in the gut. However, $GIP_{1–30}$ is equipotent to full-length GIP as an insulin secretagogue. Also, like glucagon and GLP-1, $GIP_{1–30}$ appears to contribute to glucose competence since interference with its action attenuates glucose-stimulated insulin release. In keeping with this novel discovery in islets, mice with a deletion of ProG gene have increased circulating GIP levels, production and release of GIP from islets, and localization of GIP immunostaining to both α and β cells [136]. Expression of GIP in β cells seems to be ectopic as it is not seen in wild-type mice. These findings support the notion that a component of the incretin effect is mediated locally in the islet, by the classical incretins.

Abnormalities of glucagon secretion and action in diabetes

The potent effects of glucagon in promoting fasting hepatic glucose production can be amplified in the setting of diabetes, where insulin secretion is impaired and insufficient for normal opposition of glucagon effects [137–139]. The secretion of both of the principal islet hormones, insulin and glucagon, is abnormal in people with diabetes. Plasma glucagon levels tend to be substantially elevated in poorly controlled diabetes with severe insulin deficiency or ketoacidosis [10]. In T2DM, modest fasting hyperglucagonemia occurs even without metabolic decompensation, and clinical studies suggest that this increase is sufficient to contribute to the elevated hepatic glucose production in people with diabetes [139, 140]. In a classic study using somatostatin to inhibit α-cell secretion, individuals with T1DM had substantial improvements in hyperglycemia and ketogenesis when plasma glucagon was reduced [6]. Moreover, in individuals with T2DM, suppression of islet hormone secretion by somatostatin reduced basal hepatic glucose production significantly, and this effect was enhanced when insulin was given at basal levels [10]. Together, these findings exemplify the basis for concluding that glucagon action contributes to both pathogenic and physiological control of fasting glucose control.

Similarly to the diabetic β cell, the α cell in people with diabetes has abnormal sensitivity to glucose and is less suppressed during hyperglycemia. As a result, plasma glucagon levels after mixed nutrient meals are generally higher with T2DM [10, 141, 142]. In contrast, glucagon responses to hypoglycemia are also reduced [10, 143]. The mechanism for this is not clear, but the functional result suggests another form of α-cell glucose insensitivity. There is emerging evidence that α-cell dysfunction in diabetes has a genetic origin. Specifically, there is a common polymorphism in the KIR6.2 gene that predisposes people to T2DM and is related to blunted glucose-induced suppression of glucagon [144, 145].

In addition to the effects of hyperglucagonemia on fasting glucose levels, there is evidence that abnormal α-cell regulation also contributes to glucose intolerance. Following meals, glucagon levels remain abnormally elevated in persons with diabetes, rather than making the abrupt postprandial decline typical of those without diabetes [146]. In normal physiological regulation, the postprandial suppression of glucagon is a key factor in shifting hepatic metabolism from glucose production to glucose clearance [147],

and failure to make this shift disrupts normal glycemic control after meals. For example, people without diabetes have significantly greater glycemic excursions after a test meal when glucagon levels are maintained at fasting concentrations compared with when they are allowed to follow the normal postprandial decline [148]. Similar results can also be demonstrated in individuals with T2DM [149]. Thus, failure to suppress fasting levels of glucagon after a meal contributes to glucose intolerance, and this effect is magnified in the setting of diabetes where insulin secretion and action are reduced.

Pharmacology based on glucagon action

Exogenous glucagon has been used by persons with diabetes for the acute treatment of hypoglycemia for nearly 50 years. However, approaches to block glucagon action as a means of lowering blood glucose in people with diabetes goes back nearly as far. Mouse models with interruption of glucagon receptor function [150, 151] or absence of α-cell secretion [152, 153] have lower fasting glucose and significantly improved glucose tolerance than control mice and provide proof of principle that long-lasting blockade of glucagon signaling could be an effective means of reducing diabetic hyperglycemia. Despite these compelling findings, there is no approved drug that selectively blocks the effects of glucagon as a therapeutic strategy for diabetes. This is primarily due to several worrisome findings in preclinical models and safety concerns with compounds tested in humans. Animal models with genetic elimination of glucagon signaling develop α-cell hyperplasia and/or profound elevations of circulating proglucagon-related peptides [154]; this has also been reported in humans with GCGR mutations [155]. In addition to the expansion of endocrine cells, animals deficient in glucagon signaling also have increased total pancreatic weight, reflecting expansion of the exocrine compartment. Moreover, lack of glucagon action is associated with reductions in hepatic lipid oxidation [152, 156] and increased hepatic susceptibility to toxic injury [157]. Blockade of glucagon action in humans has been possible with several small-molecule GCGR antagonists. One of these compounds was demonstrated to block the actions of exogenous glucagon in persons without diabetes [158], but was not further developed and no information on the treatment of people with diabetes with fasting hyperglycemia or endogenous hyperglucagonemia was published. Other drugs have been reported to lower fasting [159] and postprandial [160] glucose in people with diabetes in a dose-responsive manner. As the pharmacological approach most analogous to genetic models of reduced GCGR signaling, antagonists have obvious potential as drugs to lower glucose and treat diabetes. However, the data from preclinical studies, and the failure of products tested in humans to progress from the trial stage, raise concerns that adverse effects such as α-cell hyperplasia, hepatic steatosis, or susceptibility to hepatic toxicity could occur in treated individuals (Figure 7.5). Moreover, the effects of these agents on glucose counter-regulation would need to be carefully assessed.

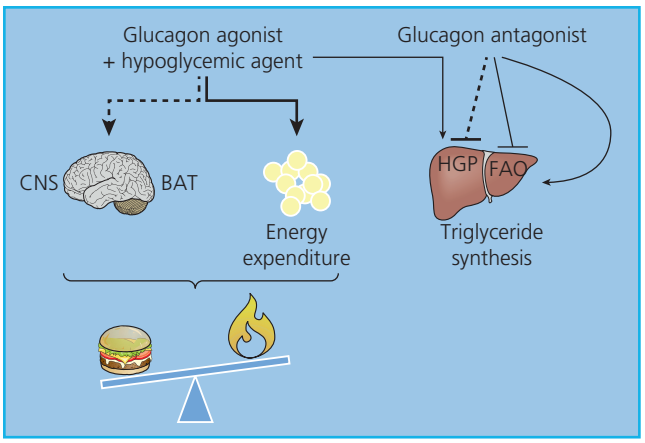

Figure 7.5 Pharmacological targeting of glucagon signaling. Approaches to block glucagon action to suppress the elevated hepatic glucose production (HGP) seen in T2DM has been explored for decades. However, the additional effect of inhibiting fatty acid oxidation (FAO) and increasing triglyceride synthesis may limit this therapeutic target. Newer hybrid peptides that favor glucagon's ability to suppress feeding and increase energy expenditure combined with hypoglycemic agents (such as GLP-1 agonists) have potent effects on weight loss in preclinical models. BAT, brown adipose tissue; CNS, central nervous system.

Importantly, drugs for diabetes are now available that work at least in part by inhibiting glucagon secretion. Glucagon-like peptide 1 (GLP-1) receptor agonists and DPP-4 inhibitors mimic the effect of endogenous GLP-1 to inhibit glucagon secretion and hepatic glucose production, and this contributes to their effect to improve glucose control in T2DM [161]. These compounds have achieved common usage in clinical practice. In fact, administration of pharmacological amounts of GLP-1 to hyperglycemic persons with T1DM with minimal β-cell function reduced blood glucose by ~4 mmol/L, and this was associated with a 40–50% decrease in plasma glucagon [162].

A novel and exciting recent approach to T2DM therapy is the development of hybrid peptides that activate more than one receptor to generate an effect [163]. Some of the first compounds developed using this strategy were targeted to the glucagon and GLP-1 receptors, for example peptides engineered to activate the cognate receptors of both peptides in different relative potencies [164, 165]. The rationale for this was that activating both glucagon and GLP-1, which bind to specific and distinct receptor populations in the brain to cause satiety [166, 167], might have synergistic results. Two different initial reports suggest that hybrid peptides with balanced GCGR and GLP-1R potency reduced body weight and fat, increased energy expenditure, and dramatically improved glucose tolerance in obese mice and rats [164, 168] (Figure 7.5). The effects on weight loss were significantly greater than those of a GLP-1R-agonist alone, and this additive response supports different activation of different neural pathways for glucagon and GLP-1 to cause weight loss. In humans, whereas GLP-1 infusion alone had no effect on energy expenditure, and glucagon infusion alone raised both blood glucose levels and energy expenditure, co-administration of both peptides increased

energy expenditure but did not raise glucose levels [169]. The potential for a GLP-1R/GCGR co-agonist to raise blood glucose has also been demonstrated with oxyntomodulin [170], a *Gcg* product that activates both receptors. Thus, the coupling of GLP-1 activity has promise to provide greater weight loss effects than either compound administered alone, with hyperglycemic actions of glucagon mitigated by GLP-1 signaling. Given the technology to engineer peptides with multireceptor effects, and the dramatic responses in preclinical models, this is likely to be an area of active diabetes drug development in the future.

8 Mechanism of Insulin Action

Morris F. White
Division of Endocrinology, Children's Hospital Boston, Harvard Medical School, Boston, MA, USA

Key points

- The insulin receptor is a transmembrane protein. The α subunits of the insulin receptor are entirely extracellular and create the ligand binding sites. The β subunits contain a transmembrane-spanning segment that separates the extracellular regions from the intracellular tyrosine kinase.
- Insulin and insulin-like growth factor signaling integrates the storage and release of nutrients with animal growth during development and tissue maintenance throughout life. The human genome encodes a superfamily of structurally related insulin-like peptides—including insulin, insulin-like growth factor-1 (IGF1) and insulin-like growth factor-2 (IGF2), which activate five receptor tyrosine kinases assembled from two genes.
- Insulin resistance, the reduced responsiveness of tissues to normal insulin concentrations, is an important risk factor for the metabolic syndrome—hyperglycemia, hyperinsulinemia, dyslipidemia and hypertension—and its progression to cardiovascular disease, non-alcoholic fatty liver disease, and type 2 diabetes.
- Insulin receptor substrates (IRS) proteins are composed of tandem structurally similar pleckstrin homology (PH) and phosphotyrosine-binding (PTB) domains followed by a long, unstructured tail of tyrosine and serine phosphorylation sites that coordinate insulin and insulin-like growth factor signaling. These domains are strongly conserved in IRS from *Drosophila* (Chico), zebra fish, mouse, chimpanzee, and humans.
- During insulin and IGF1 stimulation, some tyrosine residues in the IRS tail are phosphorylated and bind to the SH2 domains of various signaling proteins, including the 85 kDa regulatory subunit (p85) of the phosphatidylinositol 3-kinase (PI3K) and the RAS GTP exchange factor Grb2•Sos.
- IRS1 expression can be regulated by transcriptional repressors, including AP2β (transcription factor AP-2-beta), or the p160 family of nuclear receptor coactivators p/CIP (p300/CBP/cointegrator-associated protein) and SRC1 (steroid receptor coactivator-1).
- IRS2 transcription is regulated by multiple factors, including CREB (cAMP response element binding protein) and its coactivator CRTC2 (CREB-regulated transcription coactivator 2), FOXO1/3, NFAT (nuclear factor of activated T cells), TFE3 (transcription factor E3), HIF2α (hypoxia-inducible factor-2α encoded by Epas1), and SREBP1 (sterol regulatory element binding protein 1).
- IRS1 and IRS2 can be polyubiquitinylated during chronic inflammatory states, nutrient excess, and hyperinsulinemia through various tissue specific mechanisms. Several pathways are known to promote the degradation of IRS1 or IRS2: (1) proinflammatory cytokine-mediated upregulation of SOCS1/3 (suppressors of cytokine signaling); (2) the cullin-RING E3 ubiquitin ligase 7 (CRL7); (3) CBLB (Cbl proto-oncogene B), a RING-type E3 ubiquitin ligase; and (4) MG53 (mitsugumin 53), a TRIM (tripartite motif-containing) family E3 ubiquitin ligase.
- IRS1 and IRS2 can be regulated through a complex mechanism involving phosphorylation of more than 50 serine/threonine residues (phospho-S/Ts) located in the long tail regions.
- Pancreatic β cells have a special place in nutrient homeostasis as the unique source of insulin secretion, and like other cells they also require insulin and insulin-like growth factor signaling for growth, function and survival. Since β cells are always exposed to insulin and IGF, insulin and insulin-like growth factor signaling appears to be regulated through multifactor transcriptional control of IRS2 through the action of FOXO1/3, NFAT, and the CREB•CRTC2.

Introduction

Insulin and insulin-like growth factor signaling integrates the storage and release of nutrients with animal growth during development and tissue maintenance throughout life. The human genome encodes a superfamily of structurally related insulin-like peptides, including insulin, insulin-like growth factor-1 (IGF1), and insulin-like growth factor-2 (IGF2), which activate five receptor tyrosine kinases assembled from two genes. Circulating glucose enters pancreatic islet β cells, where it promotes insulin gene expression and insulin secretion. By contrast, endocrine IGF1 is secreted largely from hepatocytes during growth hormone stimulation; IGF1 and IGF2 are also produced locally in tissues and cells, including the central nervous system (CNS) and many tumors [1, 2]. This chapter focuses upon mammalian insulin and insulin-like growth factor signaling mechanisms, which originate at the receptor kinases, pass through the insulin receptor

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

substrates (IRS), and on to various effector systems largely through the class 1A phosphatidylinositol 3-kinase (PI3K).

The purification and genetic cloning of insulin signaling components and their analysis in cell-based assays have played a key role in the discovery of the insulin and insulin-like growth factor signaling network. Modern understanding of insulin signaling and its failure has been achieved largely with the use of genetically modified mice. Today, genetic or environmental causes are thought to underlie progressive insulin resistance that is associated with metabolic disease and type 2 diabetes. Although there are important physiological differences between humans and mice, the study of genetically modified mice continues to provide an integrative experimental model to guide the discovery of novel treatments for insulin resistance and its progression to diabetes [3].

Diabetes is a complex disorder that arises from various causes, including impaired glucose sensing or insulin secretion (MODY), autoimmune-mediated β-cell destruction (type 1 diabetes), or insufficient β-cell insulin secretory capacity to compensate for peripheral insulin resistance (type 2 diabetes) [4]. Type 2 diabetes is the most prevalent form of diabetes that usually manifests at middle age, but is becoming more common in children and adolescents in the developed world [5]. Physiological stress—the response to trauma, inflammation, or excess nutrients—activates pathways that promote chronic insulin resistance [6]. Insulin resistance, defined as the reduced responsiveness of tissues to normal insulin concentrations, is an important risk factor for the metabolic syndrome, the constellation of hyperglycemia, hyperinsulinemia, dyslipidemia, and hypertension, and its progression to cardiovascular disease, non-alcoholic fatty liver disease, and type 2 diabetes [7]. Variations in the human genome, which modulate individual responses to environmental and nutritional stress, appear to promote the metabolic disorders that progress to type 2 diabetes. GWAS (genome-wide association studies) reveals more than 60 genetic loci displaying modest or weak but significant effects upon the risk for type 2 diabetes [8–10]. In a few informative cases, mutations in downstream insulin and insulin-like growth factor signaling components such as the insulin receptor or AKT2 can explain severe forms of insulin resistance and hyperglycemia [11]. Mutations of *SH2B1* (SH2B Adaptor Protein 1), an adapter protein that interacts with insulin and other receptors, are associated with severe early-onset obesity and insulin resistance in people and mice [12]. Although numerous genetic and physiological factors interact to produce and aggravate insulin resistance, rodent and human studies implicate dysregulated signaling through the insulin receptor substrate proteins IRS1 and IRS2 as important nodes where chronic inflammation might act to disrupt the core insulin and insulin-like growth factor signaling mechanisms [13]. Regardless of the specific mechanisms, the full understanding of the integrated nature of insulin and insulin-like growth factor signaling including its systemic nuances can provide a flexible toolbox to resolve the pathophysiology of metabolic disease.

Insulin receptor

Introduction

The insulin receptor (InsR) tyrosine kinase was found through hard-won biochemical experiments using ^{32}P-labeled cells or partially purified insulin receptors incubated with insulin and [γ^{32}P]ATP [14]. The InsR cDNA was isolated and sequenced [15, 16], other mechanisms for signal transduction were proposed and many have found their place in the cascade as components of downstream effectors or feedback inhibition [17–20]. However, the discovery that rare cases of severe insulin resistance in humans are associated with InsR mutations that inactivate the tyrosine kinase without altering insulin binding supports definitively the central hypothesis of tyrosyl phosphorylation as the principal signal that drives insulin action [21].

Structure and function

The InsR is encoded by a 150-kb gene on human chromosome 19p13.3-p13.2 that contains 22 exons (Figure 8.1). Exon11 is alternatively spliced depending upon the tissue and developmental stage to produce two InsR isoforms: IRA lacks the residues encoded by exon11; IRB includes the 12 amino acid residues encoded by exon11 [22] (Figure 8.1). The homologous type 1 IGF receptor (IGF1R) is assembled without alternative splicing from its 19 exon gene located on human chromosome 15. The insulin and IGF1 receptor precursors are synthesized as a single polypeptide composed of a signal sequence followed by several well-defined extracellular modules including two leucine-rich motifs (L1 and L2) flanking a cysteine-rich (CR) region, three fibronectin-III motifs ($Fn_3$1, $Fn_3$2, and $Fn_3$3), and ending with the intracellular tyrosine kinase (Figure 8.1). $Fn_3$2 is

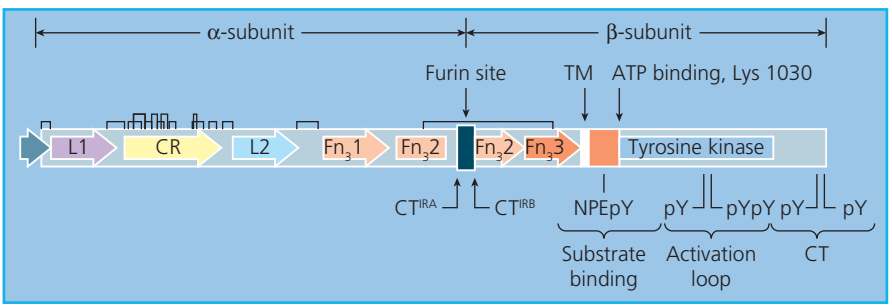

Figure 8.1 A linear diagram of the insulin receptor (IR) precursor protein showing the position of important modules in the α and β subunits including leucine-rich regions (L1 and L2), a cysteine-rich region (CR), disulfide bonds (⊔), the alternative IRA/IRB splice site that generates the short CT^{IRA} or long CT^{IRB}, a transmembrane region (TM), the furin cleavage site, the IRS binding motif (NPEpY), the kinase activation loop autophosphorylation sites, and C-terminal tyrosine phosphorylation sites (CT).

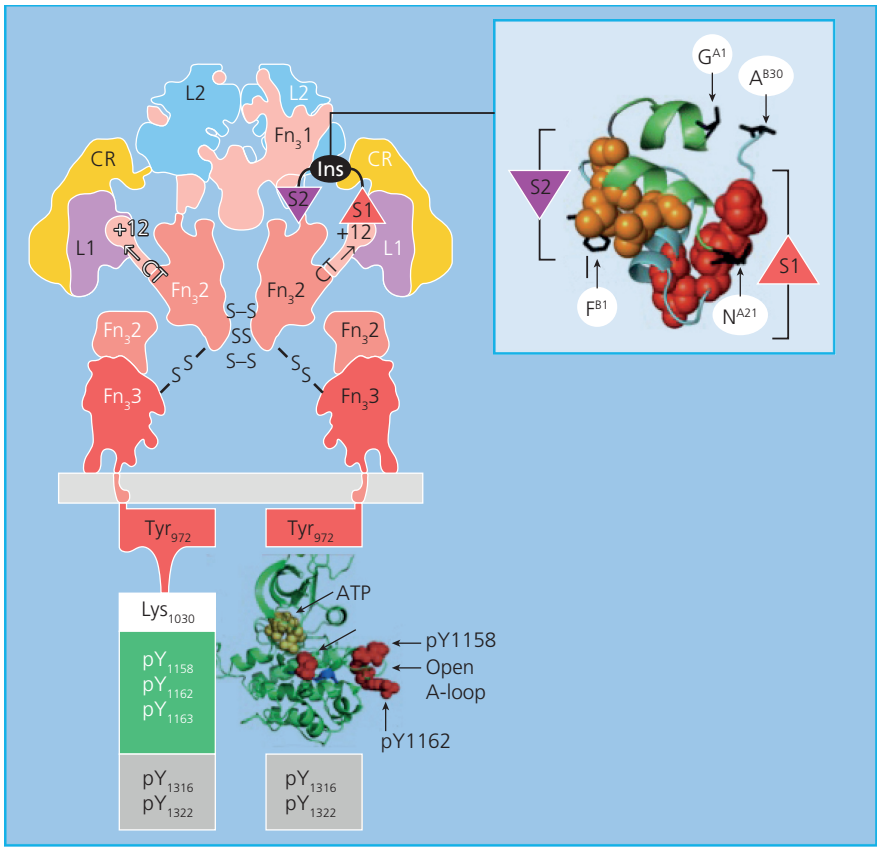

Figure 8.2 Diagram of the mature insulin receptor composed of two extracellular α-subunits and two transmembrane β-subunits. The juxtaposed α-subunit are labeled with either black or white (L1, CR, L2, $Fn_3$1, $Fn_3$2, $Fn_3$3) symbols to outline the two α-subunit. The holoreceptor is stabilized extracellularly by disulfide bonds between cysteine residues (S–S) in the α and β subunits, and also by non-covalent interactions. Two regions within the α subunit contribute to insulin binding including L1•CR (and the extra 12 amino acids encoded by exon-11 in the B form of the insulin receptor) that binds the S1 site of insulin; and the junction between $Fn_3$1 and $Fn_3$2 that binds the S2 site of insulin.
The β subunit contains the tyrosine kinase catalytic domain with an ATP binding site (Lys_{1030}) and a number of tyrosine phosphorylation sites, including those in the juxtamembrane region (pY_{972}), activation loop ($pY_{1158, 1162, 1163}$), and C-terminal regions (gray box). A structure of the catalytic domain is shown.
An inset shows the insulin structure with the position of some critical amino acids that compose the two binding surfaces (S1 and S2) that interact with the L1•CR•CT and $Fn_3$1•$Fn_3$2 regions of the insulin receptor, respectively. The A chain is shown in green and the B chain in blue, and some amino acids composing each binding site are shown as space-filling residues in red (S1) or orange (S2). The N- and C-terminal residues of each chain are labeled in black.

interrupted by a 120 amino acid insert containing a furin cleavage site that yields the α and β subunits upon cleavage. During translation, the pro-receptors for insulin and IGF1 can assemble as homodimers, which are linked by disulfide bonds to produce the InsR ($\alpha\beta^{IR}$•$\alpha\beta^{IR}$) or the IGF1R ($\alpha\beta^{IGF1R}$•$\alpha\beta^{IGF1R}$). However, when expressed together, the αβ dimer of each receptor can associate to form hybrid receptors ($\alpha\beta^{IR}$•$\alpha\beta^{IGF1R}$) [23]. Since the InsR occurs in two isoforms, a total of five receptors types can be produced from the two receptor genes.

The α subunits of the InsR or IGF1R are entirely extracellular and create the ligand binding sites. Each β subunit contains a transmembrane spanning segment that separates the extracellular $Fn_3$2–$Fn_3$3 regions from the intracellular tyrosine kinase (Figure 8.2) [15, 16]. The holoreceptor (αβ•αβ) has an approximate molecular mass of 350,000 by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and is larger than expected from the amino acid sequence owing to glycosylation of the α and β subunits [24, 25]. Upon reduction of the disulfide bonds, SDS-PAGE resolves the InsR and IGF1R into the α and β subunits that migrate near 135 and 95 kDa, respectively [26]. Hybrid receptors can be detected by specific immunoblotting strategies [23].

Insulin binds with high affinity (K_d < 0.5 nM) to the homodimeric IRB, which predominates in the classical insulin target tissues such as adult liver, muscle, and adipose. Liver and adipose are purely insulin responsive tissues as they express IRB without detectable IGF1R [1]. By comparison, IRA predominates in fetal tissues, the adult CNS, and hematopoietic cells [27]. Most cancers express IRA, IRB, and IGF1R, and the hybrid receptors [2]. IRA binds IGF2 with moderate affinity to promote embryogenesis and fetal development. IGF1 and IGF2 bind with high affinity (K_d < 1 nM) to the homodimeric IGF1R and to the hybrid receptors ($\alpha\beta^{IRA}$•$\alpha\beta^{IGF1R}$ and $\alpha\beta^{IRB}$•$\alpha\beta^{IGF1R}$). Insulin binds to IRA almost as well as to IRB, but insulin binds poorly to the hybrids [23]. Hence, under ordinary conditions, insulin never activates the IGF1R tyrosine kinase, whereas IGF1 and IGF2 can activate the InsR tyrosine kinase when it forms a hybrid with the IGF1R [28].

The insulin binding site

Insulin possesses two asymmetric receptor binding surfaces designated "S1" (the classical site) and "S2" (the novel site) (Figure 8.2) [22]. Natural insulin mutants together with alanine scanning mutagenesis show that "S1" is composed of residues from the A and B chains—including Gly^{A1}, Ile^{A2}, Val^{A3}, Glu^{A5}, Thr^{A8}, Tyr^{A19}, Asn^{A21}, Val^{B12}, Tyr^{B16}, Gly^{B23}, Phe^{B24}, and Phe^{B25} (Figure 8.2) [29]. By comparison, "S2" is composed of Ser^{A12}, Leu^{A13}, Glu^{A17}, His^{B10}, Glu^{B13}, and Leu^{B17}. Together, both sites are necessary to generate high-affinity insulin binding that activates the receptor tyrosine kinase.

Site-directed mutagenesis reveals the location of two insulin binding sites in the α subunit of the InsR [30]. Chimeric receptors between the α subunits of the insulin and IGF1 receptors reveal a

site in the first leucine-rich (L1) region of the InsR that creates a binding site together with the CR and C-terminal (CT) domains (L1•CR•CT site) [31]. Photoaffinity labeling of mutant insulin receptors reveals the other binding site near the $Fn_3 1 \rightarrow Fn_3 2$ interface [32]. Insulin binding apparently begins when "S2" on insulin binds at the $Fn_3 1 \bullet Fn_3 2$ interface followed by interaction of "S1" with the L1•CR•CT site (Figure 8.2) [33]. Although the α subunits are arranged symmetrically in the dimer, there is a sharp bend between the L2 and $Fn_3 1 \rightarrow Fn_3 2$ regions that juxtaposes the L1→CR→CT domain anti-parallel to $Fn_3 1 \rightarrow Fn_3 2$ (Figure 8.2) [34, 35]. When insulin binds to the L1→CR→CT site of one α subunit and to the $Fn_3 1 \rightarrow Fn_3 2$ region of the adjacent α subunit, a new "transient" cross-link activates the kinase [35]. Owing to space constraints, only one insulin molecule can bind with high affinity. Inclusion of exon-11 in IRB lengthens the C-terminus by 12 amino acids, which modifies the L1•CR•CT domain to exclude IGF1 and IGF2 while retaining insulin binding (Figure 8.2). These details have been investigated recently [36, 37].

Regulation of the InsR kinase

The tyrosine kinase activity of the InsR was found originally by hard-won biochemical experiments using ^{32}P-labeled hepatoma cells or partially purified insulin receptors incubated with insulin and [γ^{32}P]ATP [26]. The intracellular portion of the InsR β subunit is composed of three distinct regions that contain tyrosyl phosphorylation sites (numbered as in IRB): Y_{972} in the juxtamembrane region between the transmembrane helix and the cytoplasmic tyrosine kinase domain; Y_{1158}, Y_{1162}, and Y_{1163} in the activation loop (A loop) of the catalytic core; and Y_{1328} and Y_{1334} in the C-terminus [38, 39] (Figures 8.1 and 8.2). Most receptor tyrosine kinases are activated by ligand-induced dimerization, which brings two intracellular catalytic domains together to mediate tyrosine phosphorylation of the A loop and the other sites that recruit cellular substrates [40]. However, the homologous InsR and IGF1R reside in the plasma membrane as inactive covalent dimers that undergo an activating transition upon insulin or IGF binding [35].

Before insulin binding, the unphosphorylated Tyr_{1162}, the second of the three A loop tyrosine residues, is positioned near the catalytic site while the amino-terminal end of the A loop (D_{1150}FG motif) folds into the ATP-binding site, elevating the Michaelis constant (K_m) for ATP [35]. Apparently, this closed A loop is in equilibrium with an alternative conformation that can allow occasional access by ATP to mediate basal autophosphorylation [41]. Infrequent oscillation from the "closed" to the "open" conformation in the basal state might be coupled to complementary changes in the α subunits, which can be stabilized by insulin binding to promote ATP entry and drive additional autophosphorylation of Tyr_{1162} and Tyr_{1158} to lock the kinase in the active conformation [38]. Although autophosphorylation of Tyr_{1163} is relatively slow, it appears to stabilize the open conformation to allow unrestricted access by Mg-ATP and protein substrates [35]. The final autophosphorylation probably occurs through the interaction between the adjacent β subunits [35, 42].

This model of kinase regulation is supported by activation of the kinase upon substitution of Asp_{1161} in the middle of the A loop with alanine, which shifts the steady-state conformation of the unphosphorylated A loop towards the open configuration [41]. Moreover, replacement of Tyr_{1162} with phenylalanine increases basal autophosphorylation, consistent with its role in stabilizing the closed conformation or blocking ATP and protein substrates at the kinase active site [43, 44]. Whether other kinases can activate the InsR by direct phosphorylation of A loop tyrosine residues independently of insulin is an open question that deserves attention. For example, a hybrid receptor created through the interaction of the hepatocyte growth factor receptor (cMET) with the InsR promotes tyrosine phosphorylation and activation of the InsR [45].

Systemic deletion of the insulin or type 1 IGF receptor

InsR and IGF1R have many overlapping functions during development and adult life. In mice, the complete deletion of the InsR or the IGF1R has serious physiological consequences that cause death shortly after birth [46]. The IGF1/2→IGF1R signaling is the principle growth regulatory pathway in fetal mice, which is not influenced by growth hormone or augmented by the InsR until after birth [47]. IGF1R-deficient mice are born 50% smaller than normal littermates, and die after a few days owing to developmental defects [48]. By contrast, mice lacking the InsR have nearly normal size at birth, except for a reduced adipose tissue mass. Regardless, InsR-deficient mice also die a few days after birth owing to severe hyperglycemia, pancreatic β-cell failure and ketoacidosis [47]. Thus the *Insr* gene is necessary for postnatal fuel homeostasis but not for prenatal growth and metabolic control [49]. Mice retaining at least 20% of the normal InsR expression throughout the body can survive with severe postnatal growth retardation and hyperglycemia that resembles human leprechaunism [46]. This growth defect might arise, at least in part, from elevated hepatic IGF binding protein 1 (FOXO mediated) that reduces IGF1 bioavailability. Thus, small mice with severely reduced insulin or IGF-1 signaling have short life spans owing to developmental and metabolic defects. However, these mice can be rescued genetically by transgenic expression of the InsR in brain, liver, and pancreatic β cells [50].

Mouse knockout experiments are uninformative on the role of InsR during human gestation. Rodents are born at a developmental stage corresponding to about 26 weeks of human gestation, so the InsR-dependent phase of mouse embryonic growth is minimal [49]. Unlike mice, humans lacking InsR display intrauterine growth retardation, failure to thrive, and hypoglycemia [49]. Occasionally, InsR-deficient human neonates survive with extreme hyperinsulinemia that might activate homologous IGF1Rs [51]. Moreover, unlike mice, some IGF2 expression persists throughout human life [49].

Tissue-specific inactivation of the insulin receptor

Owing to metabolic interactions between various tissues and the lethal consequences of whole-body InsR knockout, it is difficult to

establish the tissue-specific behavior of insulin signaling in whole-body knockout mice. The best approach is to use Cre–loxP technology to delete the InsR in single tissues or organs [46, 49]. Even tissue-specific knockouts has limitations for our understanding of diabetes as the complete absence of insulin signaling is never involved in common metabolic disease. Regardless, conditional InsR knockout mouse models are remarkably informative regarding the role of insulin receptors in the liver, muscle, and adipocytes and in all other tissues investigated, including pancreatic β cells, endothelial cells, and brain (hypothalamus) [49, 52–54].

Liver

The liver is an important site of insulin action that plays a role in systemic glucose and lipid homeostasis. LIRKO (liver-specific InsR knockout) mice display moderately elevated fasting glucose and severe postprandial hyperglycemia and glucose intolerance [55]. This metabolic disorder is related, at least in part, to diminished hepatic glucose utilization and constitutive gluconeogenesis owing to dysregulated hepatic gene expression including decreased GCK (glucokinase, hexokinase 4) and elevated PCK1 (phosphoenolpyruvate carboxykinase 1), G6PC (glucose-6-phosphatase, catalytic subunit), and PK1 (pyruvate kinase) [3, 55]. Moreover, LIRKO mice exhibit marked hyperinsulinemia owing to a combination of decreased hepatic insulin clearance and increased insulin secretion associated with β-cell mass expansion. The chronic hyperinsulinemia might promote systemic insulin resistance, which could contribute to the postprandial hyperglycemia [56]. However, it is unlikely that the mechanisms of systemic insulin resistance are similar between LIRKO and more conventional models such as leptin-deficient *ob*/*ob* (obese) mice. Unlike *ob*/*ob* mice, LIRKO mice display reduced levels of circulating free fatty acids and triglycerides [55]. On an atherogenic diet, LIRKO mice develop dyslipidemia by 12 weeks of age including decreased circulating high-density lipoprotein (HDL) cholesterol and increased non-HDL cholesterol, which progresses to atherosclerosis [57]. Unexpectedly, glucose intolerance of the LIRKO mice resolves with age, which might be associated with hepatic failure and mitochondrial dysfunction. Thus, insulin signaling is essential for normal hepatic function beyond the expected regulation of glucose metabolism.

Muscle

One of the most informative and unexpected discoveries was obtained with skeletal muscle-specific InsR knockout (MIRKO) mice [58]. Whereas muscle insulin resistance promotes some aspects of metabolic disease including mild obesity and elevated circulating free fatty acids and triglycerides, elevated glucose and hyperinsulinemia never develop [3, 58]. This result might arise partly from insulin-independent glucose influx owing to the activation of AMPK (AMP-activated protein kinase), and the redistribution of glucose to liver and adipose [49]. Residual IGF1R signaling might compensate for the deletion of the InsR in muscle as genetic inactivation of insulin and insulin-like growth factor signaling in muscle with a dominant-negative IGF1R transgene causes a systemic insulin-resistant state, including β-cell dysfunction [59].

Adipose

Insulin has important effects on adipocytes to promote adipogenesis, stimulate glucose influx and lipid synthesis, and inhibit lipolysis [60]. White adipose tissue displays several important physiological functions, including the storage of postprandial glucose as triglyceride and the secretion of signaling factors that regulate appetite and energy homeostasis (leptin, adiponectin). Genetic insulin resistance of adipose tissue caused by the deletion of the InsR (FIRKO mice) reduces fat mass by 50% while consuming the same amount of food. Although adipose insulin signaling is eliminated, FIRKO mice display increased systemic insulin sensitivity and normal glucose tolerance that persists during aging. Hence it appears that insulin signaling in adipose tissue is not needed to maintain glucose tolerance in mice [61]. FIRKO mice also have a longer lifespan, suggesting that leanness and insulin sensitivity are associated with longevity even in the absence of reduced calorie intake [62]. These beneficial effects might arise from reduced adipocyte-related inflammation.

IRS-proteins coordinate insulin and insulin-like growth factor signaling

Structure and function

IRS proteins are composed of tandem structurally similar pleckstrin homology (PH) and phosphotyrosine-binding (PTB) domains followed by a long, unstructured tail of tyrosine and serine phosphorylation sites that coordinate insulin and insulin-like growth factor signaling (Figure 8.3). These domains are strongly conserved in IRS from *Drosophila* (Chico), zebra fish, mouse, chimpanzee, and humans. During insulin and IGF1 stimulation, some tyrosine residues in the IRS tail are phosphorylated and bind to the SH2 domains of various signaling proteins, including the 85 kDa regulatory subunit (p85) of the PI3K and the RAS GTP exchange factor Grb2•Sos (Figure 8.3). The interaction between IRS1 and PI3K was the first insulin signaling cascade to be reconstituted *in vivo* and *in vitro* [63]. Two highly conserved and closely spaced YMPM motifs that bind p85 are conserved in IRS1 and IRS2 from zebra fish, mouse, chimpanzee, and humans (Figure 8.3); however, different sites are used in Chico (Y_{411}IPM and Y_{641}LEM) to bind the 60 kDa regulatory subunit (dp60) in *Drosophila* [64].

Specific insulin-stimulated tyrosine phosphorylation of IRS is accomplished through at least two mechanisms. First, IRS proteins bind through their PTB domain to the InsR juxtamembrane autophosphorylation motif at $NPEY_{972}$ (Figures 8.1 and 8.2) [65, 66]. In vivo phosphorylation of $NPEY_{972}$ is very sensitive to insulin and can be detected before that of other regions [67]. The $NPEpY_{972}$ motif fills an L-shaped cleft on the PTB domain, while the N-terminal residues of the bound peptide form an additional strand in the β sandwich [66]. Regardless, the $NPEpY_{972}$ motif

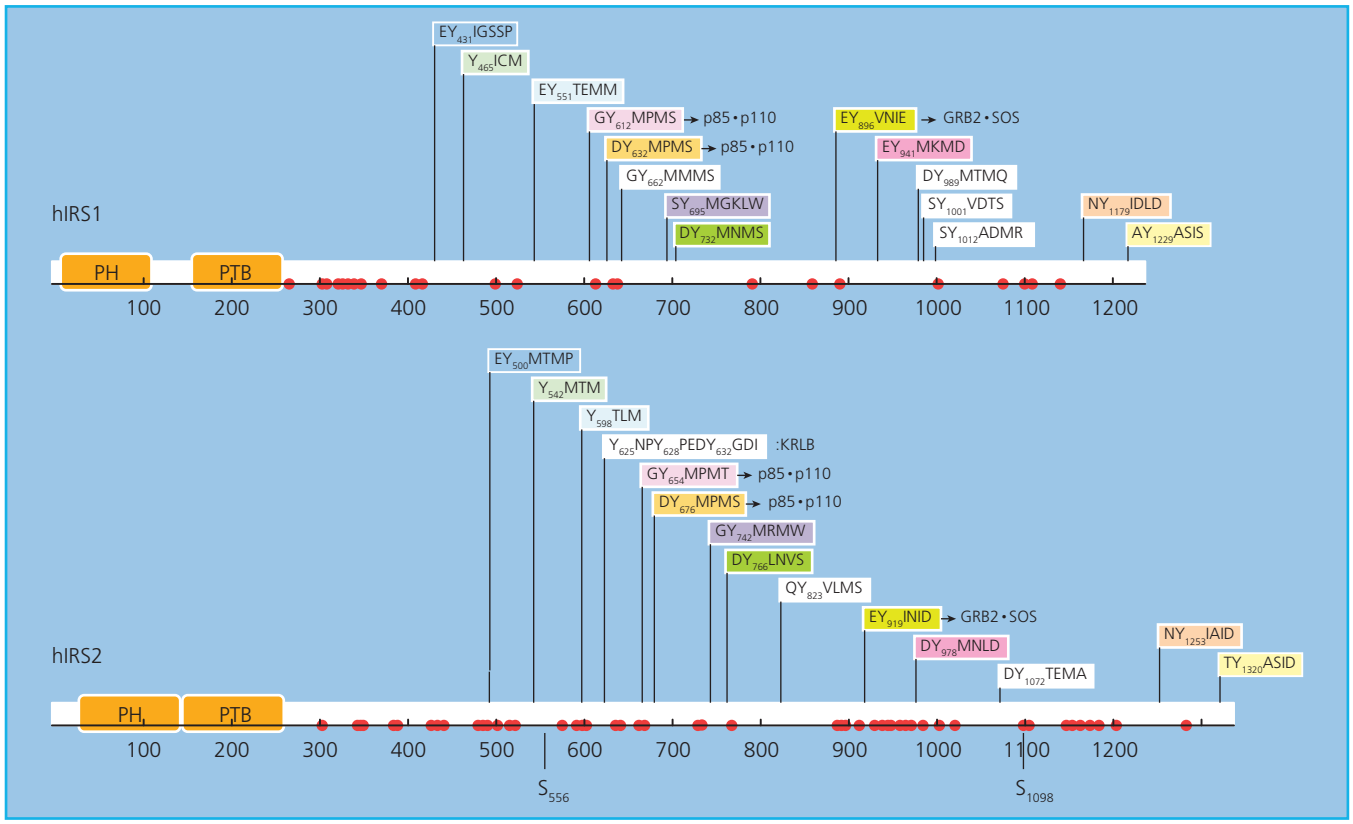

Figure 8.3 Alignments of IRS1 and IRS2 tyrosine phosphorylation sites relative to the N-terminal pleckstrin homology (PH) and phosphotyrosine-binding (PTB) domains. Conserved tyrosine phosphorylation sites—including their number in the human protein and the surrounding amino acid sequences—are color coded; white boxes indicates unique sites in IRS1 or IRS2. The relative position of serine/threonine phosphorylation sites in IRS1 or IRS2 revealed by MS/MS are indicated with red circles (•).

is a low-affinity binding site for the PTB domain of IRS1 ($K_d \approx$ 87 μM), owing to a destabilizing effect of E_{971} that is essential for its autophosphorylation by the InsR [35, 68]. By comparison, the PTB domain of another substrate SHC binds to $NPEpY_{972}$ with a much higher affinity ($K_d \approx 4$ μM). How competition between IRS and SHC might modulate insulin and insulin-like growth factor signaling is unclear.

Phosphorylation selectivity is also achieved by recognition by the catalytic domain of specific tyrosine phosphorylation motifs in the IRS tail including several YMXM motifs, and the YVNI, YIDL, and a YASI motif [69–72]. These motifs are targeted by the InsR catalytic domain as antiparallel β strands relative to the C-terminal end of the open A loop. This orientation positions the hydrophobic side-chain in the Y + 1 and Y + 3 positions into two hydrophobic pockets on the activated kinase. Tyrosine residues lying N-terminal to polar side-chains at the Y + 1 and Y + 3 positions fit poorly in this site, excluding them from phosphorylation [72]. Based upon these recognition features, there are many potential tyrosine phosphorylation motifs conserved in IRS1 and IRS2 (Figure 8.3).

IRS also contains a PH domain immediately upstream of the PTB domain, which helps recruit the IRS to the InsR (Figure 8.3) [73]. The PH domain is structurally similar but functionally distinct from the PTB domain [74]. Although the PH domain promotes the interaction between IRS and the InsR, its mechanism of action remains poorly understood as it does not bind phosphotyrosine. PH domains are generally thought to bind phospholipids, but the PH domains in the IRSs are poor examples of this binding specificity [75, 76]. However, the IRS1/IRS2 PH domain binds to negative patches in various proteins, which might also be important for InsR recruitment [77]. Regardless, the PH domain in the IRS protein plays an important and specific role as it can be interchanged among the IRS proteins without noticeable loss of bioactivity. By contrast, heterologous PH domains reduce IRS1 function when substituted for the IRS1 PH domain, confirming a specific functional role that still needs to be resolved [78].

IRS2 utilizes an additional mechanism to interact with the insulin receptor that involves a region, originally called the kinase regulatory-loop binding (KRLB) domain because trisphosphorylation of the A loop was required to observe the interaction, between amino acid residues 591 and 786 in IRS2 (Figure 8.3) [79, 80]. Structure analysis reveals the functional part of the KRLB-domain (residues 620–634 in murine IRS2) that fits into the "open" catalytic site of the InsR (Figure 8.3) [81]. With the A loop out of the catalytic site by autophosphorylation or other means, Tyr_{621} of IRS2 inserts into the receptor ATP binding pocket while Tyr_{628} aligns for phosphorylation. This interaction might attenuate signaling by blocking ATP access to the catalytic site, or it might

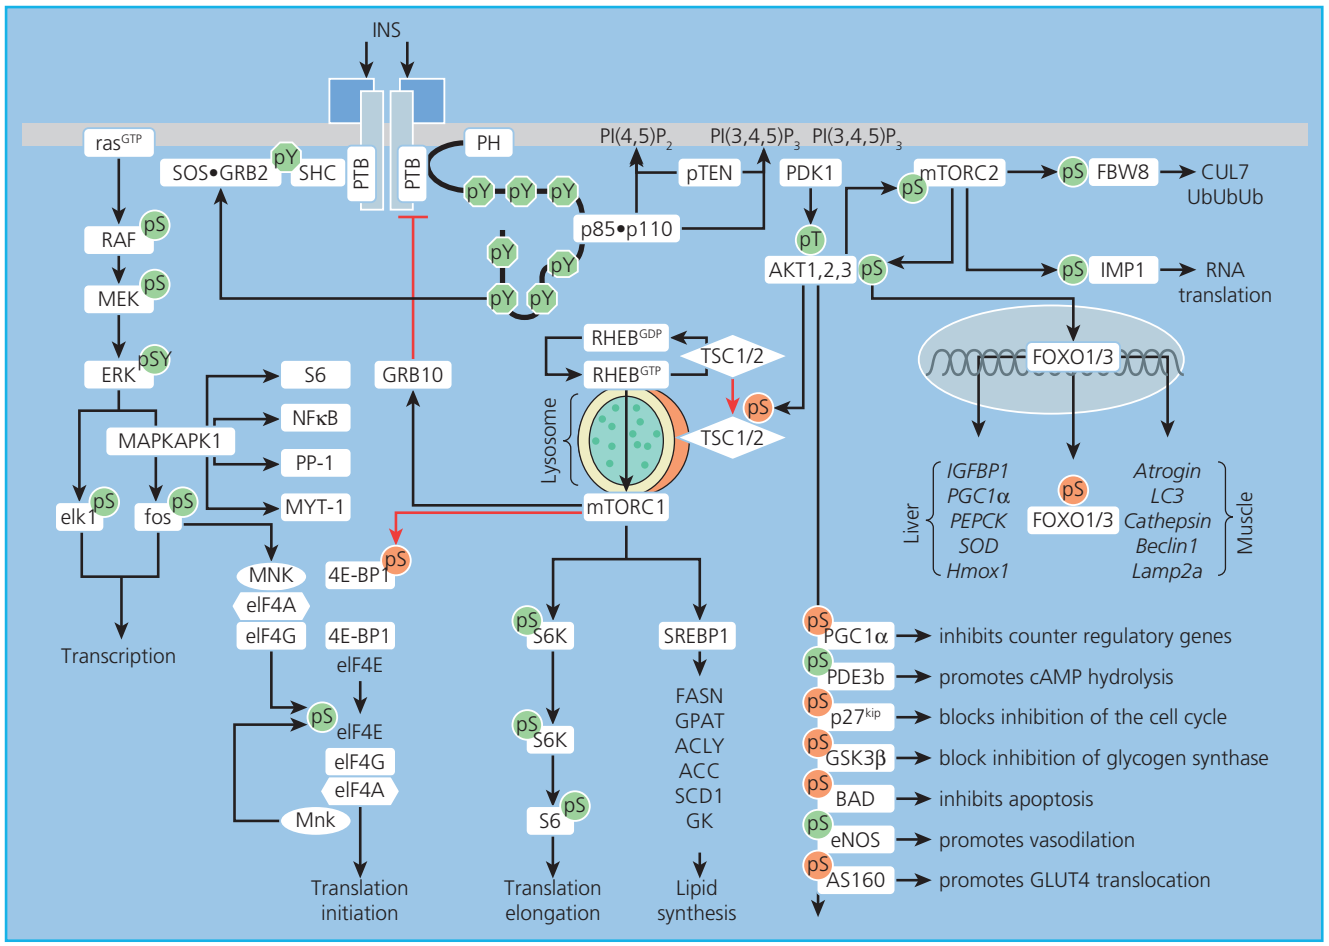

Figure 8.4 A canonical insulin/IGF signaling cascade. Two main branches propagate insulin signals generated via the IRS-proteins initiated by PI3K and GRB2•SOS. Activation of the receptors for insulin and IGF1 results in tyrosine phosphorylation of the IRS proteins, which bind PI3K and Grb2/SOS. The Grb2/SOS complex promotes GDP/GTP exchange on $p21^{ras}$, which activates the ras→raf→MEK→ERK1/2 cascade. Activated ERK stimulates transcriptional activity by direct phosphorylation of ELK1 (ETS domain-containing protein) and by indirect phosphorylation of cFOS through MAPKAPK1 (MAPK-activated protein kinase-1). MAPKAP1 also phosphorylates other proteins, including S6 (ribosomal protein S6), NFκB, PP1, and MYT1 (myelin transcription factor 1). The activation of PI3K by recruitment to IRS1 or IRS2 produces $PI3,4P_2$, and $PI(3,4,5)P_3$ (antagonized by the action of PTEN or SHIP2), which recruits PDK1 and AKT to the plasma membrane. AKT is activated upon phosphorylation at T308 by PDK1 and at S473 by mTORC2. mTORC1 is activated by $Rheb^{GTP}$, which accumulates upon inhibition of the GAP (GTPase-activating protein) activity of the TSC1•TSC2 complex following AKT-mediated phosphorylation of TSC2. The S6K is primed through mTORC1-mediated phosphorylation. AKT phosphorylates many cellular proteins, inactivating PGC1α, $p21^{kip}$, GSK3β, BAD, and AS160, and activating PDE3b and eNOS. AKT-mediated phosphorylation of forkhead proteins, including FOXO1, results in their sequestration in the cytoplasm, which inhibits their influence upon transcriptional activity. Insulin stimulates protein synthesis by altering the intrinsic activity or binding properties of key translation initiation and elongation factors (eIFs and eEFs, respectively) and also critical ribosomal proteins. Components of the translational machinery that are targets of insulin regulation include eIF2B, eIF4E, eEF1, eEF2, and the S6 ribosomal protein [215].

promote signaling by opening the catalytic site without insulin-stimulated tris-autophosphorylation. In the latter case, a basal level of insulin signaling might be sustained through IRS2 during starvation through a mechanism that depends more on the cellular concentration of IRS2 than the basal level of insulin.

Systemic inactivation of IRS genes

IRS1 and IRS2 are broadly expressed in mammalian tissues, whereas IRS4 is largely restricted to the CNS, mainly the hypothalamus [82, 83]. The IRS proteins are arguably the most important adapter molecules linking the InsR and IGF1R to downstream signaling cascades and heterologous regulatory components used by many signaling systems (Figure 8.4). Work with transgenic mice reveals that all insulin responses, especially those that are associated with somatic growth, carbohydrate, protein, and lipid metabolism, hepatic, adipose, skeletal muscle, and cardiovascular physiology, pancreatic β−cell function, and central nutrient homeostasis, are mediated through IRS1, IRS2, or both [84].

In many cell-based assays, IRS1 and IRS2 have similar roles to couple the receptors for insulin and IGF1 to the PI3K→Akt

and GRB2•SOS→RAS cascades. However, IRS1 and IRS2 can display unique signaling properties in various tissues, apparently owing to different regulation, function, or expression [85]. In this regard, the deletion of one or both alleles of IRS1 or IRS2 has been especially informative. Systemic deletion of IRS1 produces small insulin-resistant mice with nearly normal glucose homeostasis owing to β-cell expansion and life-long compensatory hyperinsulinemia [86]. These results suggest that IRS1 mediates most of the IGF1 signal for somatic growth, but is not essential for β-cell growth during insulin resistance. By contrast, mice lacking IRS2 display nearly normal body growth and even gain fat mass; however, male $IRS2^{-/-}$ mice develop life-threatening diabetes between 8 and 15 weeks of age owing to the progressive loss of β-cell mass that disrupts compensatory hyperinsulinemia [87]. Female mice progress more slowly to diabetes, developing severe hyperglycemia around 6 months of age, but the mechanism remains unknown. Whereas the complete deletion of IRS1 and IRS2 is embryonic lethal, littermates retaining one allele of IRS1 ($IRS1^{+/-}$•$IRS2^{-/-}$) or one allele of IRS2 ($IRS1^{-/-}$•$IRS2^{+/-}$) can be born alive [88]. $IRS1^{+/-}$•$IRS2^{-/-}$ mice develop severe fasting hyperglycemia and die by 4 weeks of age because IRS2 is required for pancreatic β-cell survival and growth. By contrast, $IRS1^{-/-}$•$IRS2^{+/-}$ mice reach only 30% of normal size, but display nearly normal glucose tolerance and circulating insulin concentrations at 6 months of age [88]. Regardless, the small $IRS1^{-/-}$•$IRS2^{+/-}$ mice are very fragile and require extraordinary care to live beyond this age. Hence IRS1 and IRS2 are essential for development and nutrient homeostasis.

Inactivation of IRS in liver

The central role of IRS in the PI3K→AKT signaling cascade is validated by a wide array of cell-based and mouse-based experiments (Figure 8.4). The simplest experiments employ an intraperitoneal injection of insulin into ordinary mice, or mice lacking hepatic IRS1, IRS2, or both [89, 90]. Insulin rapidly stimulates AKT phosphorylation and the phosphorylation of its downstream substrates FOXO1, GSK3α/β, and mTORC1 (mechanistic target of rapamycin complex 1) in wild-type mice (Figure 8.4). Although the deletion of the InsR alone can uncouple the PI3K→PDK1→AKT cascade from these downstream effectors, both IRS1 and IRS2 must be deleted before the InsR is uncoupled from the PI3K→PDK1→AKT cascade in hepatocytes [91]. These results reveal the shared but absolute requirement for IRS1 or IRS2 for the hepatic insulin response in mice. In general, IRS1 plays a dominant role in the liver because most nutrient sensitive transcripts, including gluconeogenic and lipogenic genes, are expressed nearly normally in liver lacking IRS2, whereas these transcripts are dysregulated significantly in liver lacking IRS1—or IRS1 and IRS2 together [92]. Even 50% less IRS1 in the absence of IRS2 is sufficient to maintain nearly normal gene expression, fasting glucose concentrations, and postprandial glucose tolerance [92]. Thus, IRS1 appears stronger than IRS2 for glucose tolerance, at least during nutrient excess. This distinction appears to be related to the stability of IRS1 expression compared with the progressive depletion of IRS2 during metabolic stress. Other aspects are also involved, including differential transcriptional regulation. Hence hepatic IRS1 is a principal mediator of the transition between fasting and postprandial glucose homeostasis, especially during chronic nutrient excess [92]. Regardless, IRS2 is important for normal metabolic regulation as its upregulation during fasting opposes the unrestrained counter-regulatory hepatic glucose production during fasting.

Inactivation of IRS in muscle

Like the liver, IRS1 and IRS2 display similar but not identical signaling functions in skeletal muscle. Insulin and insulin-like growth factor signaling in skeletal muscle is initiated by the activation of the insulin and/or IGF1 receptor tyrosine kinases [93], which can exist as hybrids linked to the downstream pathways through the IRS1 and IRS2 branches of the cascade. Based upon insulin- or IGF1-stimulated AKT→mTORC1 signaling, IRS1 has a stronger role than IRS2 for IIS in muscle. Without IRS1, AKT phosphorylation at $T308^{AKT}$ and $S473^{AKT}$ is mildly impaired, but AKT phosphorylation is nearly normal without muscle IRS2. Regardless, deletion of both IRS1 and IRS2 is necessary to eliminate insulin-stimulated phosphorylation of $T308^{AKT}$, which suggests that both IRS1 and IRS2 can promote AKT activity in muscle [94]. Consistent with these results, young mice without IRS1 display a small reduction in skeletal muscle mass and protein content, whereas no reduction is detected without IRS2 [94]. However, the deletion of both IRS1 and IRS2 strongly reduces skeletal muscle growth and causes cardiac arrest between 3 and 4 weeks of age owing to left ventricular failure. Since a single allele of either IRS1 or IRS2 in cardiac muscle can prevent sudden death, we conclude that either IRS1 or IRS2 contributes sufficient insulin-like signaling in muscle [94]. How IRS1 and IRS2 stabilize heart function during cardiovascular stress needs to be investigated.

PI3K→AKT cascade

The PI3K→AKT cascade begins when insulin stimulates tyrosyl phosphorylation of YMPM motifs in the IRS proteins (Figure 8.3), which directly recruit and activate the PI3K (Figure 8.4). PI3Ks are lipid kinases central to numerous signaling pathways, which are organized into three classes, I, II, and III [95]. The growth factor-regulated class IA PI3Ks are composed of two subunits. The catalytic subunit, p110α (PIK3CA), p110β (PIK3CB), or p110δ (PIK3CD), is inhibited and stabilized during association with one of several homologous 85 kDa regulatory subunits encoded by PIK3R1 (p85α) or PIK3R2 (p85β). Alternative splicing of PIK3R1 produces p55α or p50α, or a third gene PIK3R3 encodes p55γ, all of which lack some N-terminal regulatory features of p85 while retaining affinity towards the catalytic subunits [96–98]. All of the regulatory subunits contain two SH2 (src homology 2) domains that bind phosphorylated YMPM motifs in IRS to disinhibit the catalytic domain that produces PI(3,4,5)P3 (phosphatidylinositol 3,4,5-trisphosphate) [95, 99, 100]. Inhibition of the PI3K by

chemical or genetic means blocks almost all metabolic responses stimulated by insulin including glucose influx, glycogen and lipid synthesis, and adipocyte differentiation, confirming that the PI3K is a critical node coordinating insulin action [101].

Upon binding of p85 to phosphorylated YMPM motifs in IRS, the activated PI3K produces PI(3,4,5)P3, which binds to the PH (pleckstrin homology) domains in various signaling proteins to recruit and activate them at the plasma membrane including PDK1 (3′-phosphoinosotide-dependent protein kinase-1) and AKT (v-akt murine thymoma viral oncogene). AKT is activated by phosphorylation of Thr_{308} in its activation loop by the juxtaposed membrane-bound PDK1 (Figure 8.4). AKT isoforms have a central role in cell biology as they regulate by phosphorylation many proteins that control cell survival, growth, proliferation, angiogenesis, metabolism, and migration (Figure 8.4) [99, 102, 103]. More than 100 AKT substrates are known and several are especially relevant to insulin signaling including GSK3α/β (blocks inhibition of glycogen synthesis), AS160 (promotes GLUT-4 translocation), the BAD•BCL2 heterodimer (inhibits apoptosis), the FOXO transcription factors (regulates gene expression in liver, β cells, hypothalamus and other tissues), $p21^{CIP1}$ and $p27^{KIP1}$ (blocks cell cycle inhibition), eNOS (stimulates NO synthesis and vasodilatation), PDE3b (hydrolyzes cAMP), and TSC2 (tuberous sclerosis 2 tumor suppressor) that inhibits mTORC1 (Figure 8.4). An unbiased tandem mass spectrometry (MS/MS) approach implicates many more AKT substrates in insulin action, suggesting that the majority of PI3K-mediated growth factor (insulin) signaling is coordinated through AKT-dependent mechanisms (Figure 8.4) [104].

The mammalian genome contains three genes encoding AKT1, -2, and -3. The analysis of knockout mice shows that each isoform regulates important biological functions, including cell proliferation, cell growth and survival and differentiation, and glucose metabolism *in vivo*; however, the AKT isoforms are not redundant components of the insulin-like signaling cascade [95, 105, 106]. AKT1 has a major role in embryonic development, growth, and survival, but minor effects upon metabolism [107]. By comparison, systemic AKT2-deficient mice display metabolic defects, whereas AKT3-deficient mice display neural defects [102]. AKT2 is important for metabolic regulation largely because it mediates insulin-stimulated GLUT-4 translocation and regulates liver glucose and lipid metabolism [108, 109]. Humans with a dominant negative mutation in AKT2 display many features of type 2 diabetes including hyperglycemia, increased lipogenesis, elevated liver fat content, triglyceride-enriched very low-density lipoprotein, hypertriglyceridemia, and low HDL cholesterol levels [11, 110]. Consistent with this finding, targeted disruption of AKT2 impairs insulin-stimulated glucose uptake in murine muscle and adipocytes, and prevents the suppression of hepatic glucose output by insulin [111, 112]. Systemic AKT2 deletion causes glucose intolerance and insulin resistance that progress to diabetes and β-cell failure [107]. The related SGK3 (glucocorticoid-regulated kinase 3) synergizes with AKT2 in pancreatic β cells to stimulate proliferation and insulin release [112].

Work with IRS1/2 and AKT1/2 hepatic-specific knockout mice reveals their important role in the inactivation of FOXO1. As expected, mice without hepatic AKT1 and AKT2, or without IRS1 and IRS2, are glucose intolerant, insulin resistant, hyperinsulinemic, and defective in their transcriptional response to feeding in the liver [91, 113]. Remarkably, in both cases these defects are normalized upon concomitant liver-specific deletion of FOXO1. In the absence of both AKT1/2 and FOXO1, or without IRS1/2 and FOXO1, mice are no longer hyperinsulinemic and adapt appropriately to both the fasted and fed state even though insulin fails to promote a hepatic response [91, 113]. Gene expression analysis reveals close concordance for dysregulation of FOXO1-dependent gene expression upon deletion of AKT1/2 or IRS1/2, whereas deletion of FOXO1 restores a nearly normal metabolic response to nutrient intake. These results show that a major role of hepatic IRS→AKT signaling in the liver is to restrain the activity of FOXO1. Remarkably, in the absence of FOXO1, IRS→AKT signaling is largely dispensable for *in vivo* systemic insulin- and nutrient-mediated hepatic metabolic regulation [114]. The same result is observed upon deletion of the InsR and FOXO1 [115, 116]. It is unclear how liver metabolism can be normalized without direct insulin signaling, unless other insulin-dependent signals generated in heterologous tissues have indirect effects upon hepatic metabolism [117].

AKT→mTORC1 cascade

mTOR (mechanistic target of rapamycin) is a Ser/Thr kinase that is regulated through multiple mechanisms. It belongs to the PI3K-related kinase family and forms two large functionally distinct protein complexes, mTORC1 and mTORC2, composed of common and unique subunits. Both complexes are controlled by growth factors and insulin through the PI3K→AKT cascade, but are recruited to different compartments and respond distinctly to nutrients, stress, hypoxia/energy status, and other stimuli to coordinate a diverse array of biological processes including protein and lipid synthesis, liposome biogenesis, autophagy, and cell migration, growth, and proliferation [118]. In addition to the common catalytic subunit, mTORC1 and mTORC2 share mLST8 (mammalian lethal with sec-13 protein 8), DEPTOR (Dishevelled, Egl-10 and Pleckstrin domain containing mTOR-interacting protein), and Tti1 (telomere maintenance 2 interacting protein 1). However, mTORC1 is distinguished by two specific components, including RAPTOR (RPTOR, regulatory associated protein of mTOR, complex 1) and AKT1S1 (PRAS40, AKT1 substrate 1 proline-rich). mTORC2 lacks the mTORC1-specific components, but includes RICTOR (RAPTOR independent companion of mTOR, complex 2), SIN1 (MAPKAP1, mitogen-activated protein kinase associated protein 1), and PRR5 (protor1/2, protein observed with Rictor 1 and 2) [118]. mTORC1 is strongly regulated by nutrient concentration and inhibited by rapamycin, whereas mTORC2 is inhibited variably by rapamycin and appears to be insensitive to nutrient levels.

mTORC1 coordinates many growth factor (insulin) responses owing to its regulation by AKT, nutrient/amino acid concentrations, and subcellular/lysosomal targeting [118]. In addition to the stable complex of mTORC1 components, several additional proteins regulate mTOR activity. AKT-dependent activation begins with the phosphorylation of at least five sites (Ser_{939}, Ser_{981}, Ser_{1130}, Ser_{1132} and Thr_{1462}) on TSC2 (tuberin), which in complex with TSC1 (hamartin) functions as a GTPase-activating protein for the small G protein RHEB (Ras homolog enriched in brain) (Figure 8.4) [118]. AKT-mediated phosphorylation inhibits TCS1/2, allowing RHEB to accumulate in its GTP-bound form, which activates mTORC1 (Figure 8.4). In one possible mechanism, FKBP38 (FK506 binding protein 8) inhibits mTOR until RHEB-GTP promotes its dissociation from mTORC1 [119]. Regulation by TSC1/2→RHEB is also augmented by AKT-mediated phosphorylation of AKT1S1 [AKT1 substrate 1 (proline-rich); PRAS40], which promotes its dissociation from RAPTOR to activate mTOR [102]. Proinflammatory cytokines can activate mTORC1 through a similar mechanism where IKKβ (IκB kinase) phosphorylates TSC1/2, leading to the accumulation of RHEB-GTP [120].

The second important level of mTORC1 regulation by growth factors (insulin) depends upon its localization to the surface of lysosomes [118]. Lysosomal targeting of mTORC1 is coordinated by amino acid-dependent GTP loading of the RAGA•RAGB (Ras-related GTP binding) complex, which interacts with both RAPTOR and a multisubunit complex called RAGULATOR that is located on the lysosome surface [121]. RHEB resides on endomembranes including lysosomes where it can interact with mTORC1 only if sufficient amino acids are available to promote RAGA•RAGB-mediated recruitment (Figure 8.4) [118].

mTORC1 regulates various cellular anabolic and synthetic processes needed for growth and proliferation including the stimulation of glycolytic flux and mitochondrial function, protein and lipid synthesis, and the inhibition of autophagy and lysosomal biogenesis [122]. Protein synthesis is one of the best understood mTORC1-regulated processes that is controlled, at least in part, through the phosphorylation/activation of S6K1 and S6K2 (the ribosomal protein S6 kinases) and phosphorylation/inhibition of 4E-BP1 (eukaryotic translation initiation factor 4E binding protein 1) (Figure 8.4). The dependence upon amino acids and energy for full mTORC1 activity ensures that the cellular environment is sufficient to support growth factor (insulin) stimulation. At the whole animal level, the mTORC1→S6K cascade increases cell and animal size, including pancreatic β-cell growth that is needed for insulin action [123]. Although disruption of the *S6k1* gene in mice enhances peripheral insulin sensitivity, the reduced size of pancreatic islet β cells leads to glucose intolerance.

mTORC1 also promotes lipid synthesis required for membrane biogenesis in proliferating cells, and for energy storage and lipid secretion from the liver. mTORC1 promotes the expression of SREBP1 and its proteolytic cleavage to mediate translocation of the active transcription factors to the nucleus where they promote the expression of genes involved in hepatic fatty acid or cholesterol synthesis (Figure 8.4). mTORC1 also inhibits autophagy, which ordinarily degrades damaged proteins, lipid particles, and organelles to recycle nutrients required to maintain critical cellular functions. Thus mTORC1 controls many key cellular processes that balance cellular integrity and long-term survival.

AKT→mTORC2→AKT cascade

mTORC2 plays an important role in insulin signaling because it is a key regulator of ATK [122, 124]. Like most insulin responses, mTORC2 activation requires PI3K, but its role in insulin action has been difficult to understand owing to variable effects observed upon deletion of specific components. However, a central role for mTORC2 growth factor (insulin) signaling emerged when it was found to control several members of the AGC subfamily of kinases, including AKT and SGK1 [125]. Upon the initial step to activate AKT by PDK1-mediated phosphorylation at $T308^{AKT}$, some AKT substrates are phosphorylated, including TSC2, GSK3, and SIN1 (MAPKAP1) [118]. Judging from temporal dependence upon insulin stimulation, the SIN1 component of mTORC2 might be recruited to the plasma membrane by PI(3,4,5)P3, where it is phosphorylated at T86 by $pT308^{AKT}$ [124]. Phosphorylated SIN1 activates mTORC2, which promotes $S473^{AKT}$ phosphorylation [124]. Upon bisphosphorylation, AKT can phosphorylate a wider array of substrates, including FOXO transcription factors (Figure 8.4) [103]. This model fills a conspicuous gap in our understanding of PI3K-sensitive mTORC2 activation during insulin stimulation and its role in AKT regulation. The potential regulation of mTORC2 activity through multisite SIN1 phosphorylation reveals how mTOR signaling can be coordinated through feedforward and feedback mechanisms [122].

Much less is understood about downstream signaling mediated by mTORC2. mTORC2 plays a role in mRNA processing when it phosphorylates IMP1 (insulin-like growth factor 2 mRNA-binding protein 1) at Ser_{181}, which strongly enhances IMP1 binding to enable IGF2-leader 3′-mRNA translational initiation by internal ribosomal entry (Figure 8.4) [126]. Thus, mTORC2-catalyzed cotranslational IMP1 phosphorylation can promote organismal growth by regulating IGF2 production that can activate IRA in the mouse embryo. mTORC2 also regulates protein ubiquitinylation by phosphorylating FBW8 (F-Box And WD Repeat Domain Containing 8), a Cullin 7 E3 ubiquitin ligase recognition subunit (Figure 8.4). The phosphorylation of FBW8 stabilizes and promotes ubiquitinylation of targeted substrates, including IRS1 that contributes to insulin resistance in certain tissues and cells (Figure 8.5) [127]. Thus, important mTORC2 signaling might be mediated through its direct effect upon the activity of the PI3K→AKT cascade, and its indirect control of important regulatory points to integrate the insulin/IGF signaling cascade fully [126].

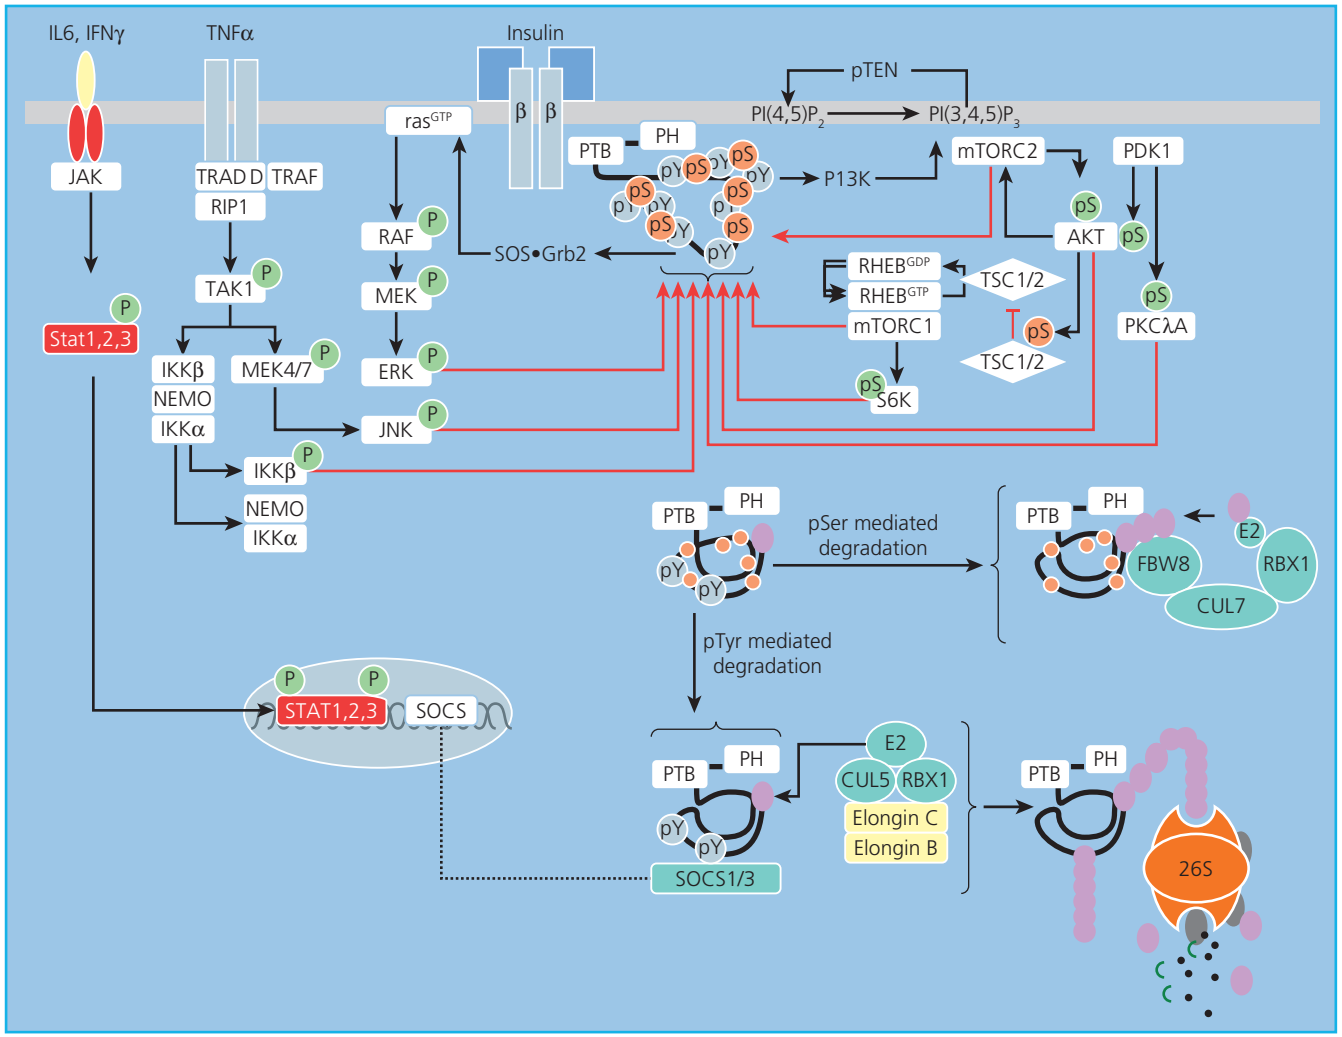

Figure 8.5 Schematic diagram of heterologous and feedback inhibition of insulin signaling mediated by Ser/Thr-phosphorylation and degradation of IRS1/IRS2. Various kinases in the insulin signaling cascade are implicated in this feedback mechanism, including PKB, mTOR, S6K, ERK, AKT, and atypical PKC isoforms. Other IRS kinases are activated by heterologous signals, including lipids, TNFα or other cytokines. Serine phosphorylation of IRS1 can recruit CRL7 ubiquitinylation (purple oval) complex to mediate degradation of IRSs through the 26S proteasome. Proinflammatory cytokines that cause insulin resistance also induce the expression of SOCS family members, which contain an N-terminal SH2 domain and a C-terminal SOCS box [216, 217]. SOCS1 or SOCS3 can target phosphotyrosine residues in IRS1 or IRS2 for ubiquitinylation and degradation, because the SOCS box associates with elongin BC-containing ubiquitin ligase E3 [218–220].

AKT→FOXO cascade

The forkhead box O (FOXO) subfamily of transcription factors, including mammalian FOXO1, FOXO3a, FOXO4, and FOXO6, regulate expression of target genes involved in DNA damage repair response, apoptosis, metabolism, cellular proliferation, stress tolerance, and longevity [128–130]. Nuclear FOXO regulates the transcription of target genes containing a consensus DNA binding sequence (TTGTTTAC). Nuclear localization is regulated by several post-translational modifications, including AKT-mediated phosphorylation, or by acetylation, methylation, glycosylation, and ubiquitinylation [131–133]. The modifications affect protein–protein and protein–DNA interactions that alter the DNA-binding characteristics that regulate transcriptional activity [131, 133–137]. AKT-mediated phosphorylation of FOXO1, FOXO3a, and FOXO4 causes their nuclear exclusion, leading to their sequestration by 14-3-3 proteins, or ubiquitinylation and degradation in the cytoplasm. Moreover, FOXO transcriptional activity can be inhibited by IKK (IκB kinase) and SGK (serum/glucocorticoid-inducible protein kinase) that also causes phosphorylation and nuclear exclusion [131, 138]. By comparison, methylation of arginine residues in FOXO blocks AKT-induced phosphorylation and inactivation [133], whereas addition of *O*-linked β-*N*-acetylglucosamine to FOXO promotes the expression of its target genes involved in stress resistance during hyperglycemia and cell stress [139]. Lysyl acetylation of FOXO can play both positive and negative regulatory roles, which appear

to depend upon effects to modify localization, AKT-mediated phosphorylation, or DNA binding [140, 141]. It appears that a specific pattern of FoxO post-translational modifications by acetylation or phosphorylation fine tunes interactions with specific binding partners to mediate cell- and tissue-specific effects [140].

Evidence from genetically modified mouse models suggests that the FOXOs have a distinct function during development, but considerable redundancy in adults [142–144]. Through the IR→IRS→PI3K→AKT signal cascade, FOXO integrates insulin action with the systemic nutrient and energy homeostasis and organism growth. FOXOs can regulate genes controlling hepatic glucose production, insulin secretion in β cells and β-cell growth and differentiation, survival and function, and fat and muscle mass (Figure 8.4) [145]. FOXO1 coordinates decreased nutrient availability with reduced somatic growth by increasing the hepatic expression of IGFBP1 (insulin-like growth factor-binding protein 1), a liver-secreted protein that binds to circulating IGF1 to limit its systemic availability [146]. FOXO could be a therapeutic target for metabolic disorders of insulin resistance, including β-cell function, obesity, diabetes, and non-alcoholic fatty liver diseases [130].

Heterologous regulation and dysregulation of the insulin and insulin-like growth factor signaling cascade

Concerted regulation of proximal insulin signals

Over a decade of genetic experiments in mice have established that changes in the relative function of a broad array of insulin signaling components, nutrient sensors, and their downstream metabolic effectors can have profound effects upon insulin sensitivity and nutrient homeostasis. Although this work is remarkably informative, the complexity of heterologous regulation complicates the identification and design of strategies for the treatment of insulin resistance and its pathological sequelae. Although the list of insulin signaling components and their interactions continues to grow, the IRSs retain a special position as a common integrating node that coordinates insulin responses in all tissues and cells. Indeed, a 50% reduction in the concentration of the IR, IRS1, and IRS2 achieved by genetic methods causes growth deficits and diabetes in mice [147]. We are now aware of many heterologous pathways that regulate the concentration and function of these proximal insulin signaling components, but how dysregulation of these mechanisms contributes to the progression of insulin resistance, metabolic disease, and type 2 diabetes is not understood well enough to guide the development of efficacious and safe treatments.

Many insulin and insulin-like growth factor signaling components are regulated by YY1 (Yin Yang 1), including IGF1 and IGF2, IRS1 and IRS2, and AKT1, -2, and AKT-3 in skeletal muscle [148]. YY1 is a ubiquitous homeobox transcription factor related to the polycomb family that can activate or repress these genes and many others. YY1 has many functions, including interactions with histone acetyltransferase and histone deacetylase complexes, which alter chromatin structure and function. In its active state, YY1 recruits PRC (polycomb repressive complex), PC2 (polycomb protein 2) and EZH2 (enhancer of zeste homolog 2) to the promoters of the proximal insulin signaling genes to promote histone acetylation that prevents the binding of the "transcription activator complex." YY1 also interacts with other proteins, including mTORC1, which phosphorylates and disrupts the acetylation complex leading to increased transcription of its target genes [148, 149]. This unexpected "feed forward" mechanism can explain, at least in part, why people treated with mTOR inhibitors might develop glucose intolerance, insulin resistance, and dyslipidemia, which compromises the long-term use of these drugs for the treatment of metabolic disease [148].

Transcriptional control of IRS1

Although the concerted repression of multiple signaling components can have strong effects, reduced expression of individual signaling molecules can also lead to insulin resistance. Decreased expression of IRS1 in humans and rodents is associated with diabetes, but few studies have investigated whether dysregulated transcription of IRS1 might be involved. Few studies have described transcription factors that promote IRS1 expression, leading to the view that IRS1 is a constitutive mediator of long-term insulin action. Regardless, recent work suggests that IRS1 expression might be regulated by transcriptional repressors, including AP2β (transcription factor AP-2-beta), or the p160 family of nuclear receptor coactivators p/CIP (p300/CBP/cointegrator-associated protein) and SRC1 (steroid receptor coactivator-1) [150, 151]. AP2β is expressed in adipose tissue, where it promotes adipocyte hypertrophy, inhibits adiponectin expression, and enhances the expression of inflammatory adipokines such as IL6 and MCP1 [150]. AP2β binds directly to the IRS1 promoter and decreases IRS1 mRNA and protein concentration in adipocyte cell lines [150]. Interestingly, GWAS reveals AP2β as a candidate gene for the risk of obesity and type 2 diabetes, which might involve negative regulation of IRS1 expression [152].

p/CIP and SRC1 serve as transcriptional coactivators for nuclear hormone receptors and certain other transcription factors [153]. Compound knockout of p/CIP and SRC1 in mice prevents obesity and increases energy expenditure, consistent with a role of nuclear hormone receptor target genes in these processes. Without p/CIP and SRC1, mice display increased glucose uptake and enhanced insulin sensitivity in white adipose tissue and skeletal muscle. Interestingly, IRS1 expression increases significantly in p/CIP and SRC1 knockout mice, suggesting that steroid-regulated nuclear receptors can regulate IRS1 transcription through the action of p160 coactivators [151].

Multiple factors regulate IRS2 transcription

IRS2 transcription is regulated by multiple factors, including CREB (cAMP response element binding protein) and its coactivator CRTC2 (CREB regulated transcription coactivator 2),

FOXO1/3, NFAT (nuclear factor of activated T cells), TFE3 (transcription factor E3), HIF2α (hypoxia-inducible factor-2α encoded by Epas1), and SREBP1 (sterol regulatory element binding protein 1) [154, 155]. Under fasting conditions, the cAMP-responsive CREB coactivator CRTC2 promotes glucose homeostasis by stimulating gluconeogenesis in liver upon assembly of CREB•CRTC2 on relevant CRE promoter sites, including a half-CRE on IRS2 [155]. The induction of hepatic IRS2 during fasting appears to modulate glucose homeostasis as it mediates a feedback response that limits glucose output from the liver even when the insulin concentration is low.

The IRS2 promoter also includes elements that bind FOXO family members. Upon deletion of AKT1/2 in the liver, nuclear FOXO accumulates and promotes IRS2 transcription, whereas the deletion of FOXO1/3 strongly reduces IRS2 transcription [113]. Thus, regulation of IRS2 transcription by AKT→FOXO establishes a direct feedback loop in the liver to promote insulin signaling during fasting and inhibit it during prolonged hyperinsulinemia. Moreover, an E-box overlapping the FOXO site binds TFE3 (basic helix–loop–helix transcription factor E3), which converges with FOXO to promote IRS2 expression [156]. These elements also overlap with an SRE that binds the SREBP-1c (sterol regulatory element-binding protein 1). SREBP-1c is an important transcriptional activator of lipid synthesis [157]. Active SREBP-1c concentrations increase during nutrient excess and chronic insulin stimulation [158, 159]; however, elevated hepatic SREBP-1c decreases IRS2 expression [159]. Upregulation of IRS2 expression by TFE3/FOXO and downregulation by SREBP-1c appear to coordinate starvation-induced glycogenolysis and gluconeogenesis with postprandial lipogenesis. However, an imbalance in this reciprocal regulation might contribute to pathophysiological effects of over-nutrition, leading to the development of insulin resistance, metabolic syndrome, and diabetes.

HIF2α also induces transcription of mouse or human IRS2 in the liver [160]. Under normal oxygen tension, HIF1α and HIF2α are destabilized upon hydroxylation of critical proline residues by prolyl hydroxylase domain-containing proteins (PHD1, -2, and -3). Interestingly, acute inhibition of hepatic PHD3 improves insulin sensitivity and resolves diabetes by specifically stabilizing HIF2α, which increases IRS2 transcription that promotes insulin-stimulated AKT activation [160]. Physiologically, the HIF2α-mediated mechanism of IRS2 transcriptional regulation might be important in the perivenous zone of the liver, which displays more hypoxia and less gluconeogenesis compared with other zones in the liver [161]. These results reveal the intersection between hypoxic sensing and IRS2-mediated hepatic insulin action.

miRNA-mediated post-transcriptional regulation

miRNAs are short (~20 nucleotides), non-coding RNA molecules that act as post-transcriptional regulators of gene expression, and bind to target sites in the 3′-untranslated regions (3′UTR) to form a complex that inhibits translation and renders the target mRNA molecule unstable. Several proximal components of the IR→PI3K→mTOR signaling cascade can be regulated by miRNAs. The LIN28a/b⊣ LET7 axis is a recent example [162]. LET7 miRNA interferes with many targets, including the translation of several proximal insulin signaling proteins, including IGF1R, INSR, IRS2, PIK3IP1, AKT2, TSC1, and RICTOR [162]. LIN7 interference is inhibited by the RNA-binding proteins Lin28a and Lin28b, which block the production of mature LET7 and increase translation of the insulin signaling components. LIN28 overexpression in mice can cause gigantism and a delay in puberty onset, consistent with human genome-wide association studies suggesting that polymorphisms in the human LIN28B gene are associated with human height and puberty timing [163]. Moreover, LIN28a/b can promote glucose homeostasis in mammals by increasing insulin→PI3K→mTOR signaling and insulin sensitivity [162].

Several other miRNAs can suppress the translation of IRS1, including miRNA-96, miRNA-128a, miRNA-126, miRNA-143, miRNA-144, miRNA-145, miRNA-487b, and miRNA489. In one example, chronic angiotensin II-induced hypertension can increase the expression of miRNA-487b in rat aorta [164]. In this case, down regulation of IRS1 might contribute to hypertension-induced cardiovascular disease, including aortic aneurysm formation due to the loss of medial smooth muscle.

Post-translational regulation of insulin and insulin-like growth factor signaling

Degradation of the IRS-proteins

Proteasome-mediated degradation regulates many biological processes, including signal transduction, gene transcription, and cell cycle progression [165]. Proteins targeted for destruction by the 26S proteasome are polyubiquitinylated by various complexes containing a ubiquitin-activating enzyme (E1), ubiquitin-conjugating enzyme (E2), and ubiquitin–protein ligase (E3). IRS1 and IRS2 can be polyubiquitinylated during chronic inflammatory states, nutrient excess, and hyperinsulinemia through various tissue-specific mechanisms [166]. One of the pathways is associated with proinflammatory cytokine-mediated upregulation of SOCS1/3 (suppressors of cytokine signaling). Cytokines such as INFγ or IL6 bind to receptors that recruit and activate JAK kinases, which promote phosphorylation and dimerization of STAT transcription factors that migrate into the nucleus to induce SOCS1/3 expression (Figure 8.5) [167]. SOCS1/3 can act as an adapter protein that uses an SH2 domain to bind to phosphotyrosine residues in IRS while its conserved "SOCS box" recruits an elongin BC-containing E3 ubiquitin ligase to ubiquitinylate IRS (Figure 8.5) [168–171]. Mutations in the "SOCS box" prevent degradation of IRS1 or IRS2 [168], and inhibition of SOCS1/3 expression by antisense oligonucleotides improves insulin sensitivity in obese and diabetic mice [169]. Thus, SOCS-mediated polyubiquitinylation can promote insulin resistance and glucose intolerance during infection, inflammation, or metabolic stress (Figure 8.5).

In another mechanism, the cullin-RING E3 ubiquitin ligase 7 (CRL7) can mediate IRS1 degradation downstream

of feedback serine phosphorylation signals generated by an PI3K→AKT→mTORC1 cascade [172]. CRL7 is a member of the Cullin-RING finger E3 ligases, which comprise the largest E3 family responsible for directing the polyubiquitinylation of substrate proteins for degradation by the 26 S proteasome [173]. The CRL7 complex contains CUL7 (cullin 7), a molecular scaffold to assemble FBW8 (F-box/WD repeat-containing protein 8) to recruit phosphorylated substrates, and Rbx1 (RING-box protein 1) associated with an E2 conjugating enzyme (Figure 8.5). FBW8 apparently binds to IRS1 through phospho-S/T residues generated by an mTORC1→S6K cascade including human pS307^{IRS1}, pS312^{IRS1}, and pS527^{IRS1}, but possibly also others, which leads to polyubiquitinylation of IRS1 that progresses to degradation (Figure 8.5) [172, 173]. However, ordinary mTORC1→S6K activity appears insufficient to engage the CRL7 pathways against IRS1, as unusually high levels of mTORC1→SK6 activity is required to drive IRS1 degradation [173].

Chronic consumption of high-calorie diets upregulates CBLB (Cbl proto-oncogene B), a RING-type E3 ubiquitin ligase that belongs to the Casitas B-lineage lymphoma family of proteins [6]. CBL proteins share a conserved N-terminal region containing a tyrosine kinase binding domain and a RING-finger domain to facilitate E3 ubiquitin ligase activity. Calorie excess induces ChREBP (carbohydrate-responsive element-binding protein) and SREBP1c, which upregulates in murine muscle and liver MSTN (myostatin) that induces CBLB expression to drive insulin resistance through the polyubiquitinylation and degradation of IRS1 [174].

Finally, MG53 (mitsugumin 53), a TRIM (tripartite motif-containing) family E3 ubiquitin ligase, can promote IRS1 and InsR degradation in muscle during calorie excess. MG53 is found in kidney, skeletal muscle, and heart, where it can act as a scaffold for assembly of repair complexes [175, 176]. However, metabolic stress induces MG53, which targets InsR and IRS1 for polyubiquitinylation and degradation [177, 178]. Although it is unclear how high-calorie diets upregulate MG53, mouse studies show that MG53-deficient mice fed a high-calorie diet are protected from degradation of InsR and IRS1 and insulin resistance [178]. Hence MG53 appears to play important repair functions during acute damage, whereas it might have detrimental metabolic effects during chronic inflammatory stress.

Multisite Ser/Thr-phosphorylation of IRS-proteins

IRS1 and IRS2 can be regulated through a complex mechanism involving phosphorylation of more than 50 serine/threonine residues (phospho-S/Ts) located in the long tail regions (see Figure 8.3) [179]. Understanding how phospho-S/Ts regulate signaling is a difficult problem because so many sites and phosphorylation mechanisms appear to be involved. Heterologous signaling cascades initiated by proinflammatory cytokines or metabolic excess, including tumor necrosis factor-α (TNFα), endothelin-1, angiotensin II, excess nutrients (free fatty acids, ceramides, amino acids, and glucose) or endoplasmic reticulum stress, are implicated in IRS1 phospho-S/Ts [180, 181]. Many biochemical and genetic experiments in cell-based systems suggest that individual phospho-S/T sites throughout the structure of IRS1 are associated with a reduction of insulin-stimulated tyrosine phosphorylation by up to 50% [182]. This level of inhibition is sufficient to cause glucose intolerance that could progress to diabetes, especially if pancreatic β cells fail to provide adequate compensatory hyperinsulinemia [147].

Numerous cell-based studies reveal IRS1 phospho-S/T to be a physiologically integrative mechanism modulating insulin sensitivity [179]. Insulin is clearly an important agonist of IRS1 phospho-S/T, as most sites are stimulated by insulin and diminished by inhibition of the PI3K→Akt→mTOR cascade [183]. Moreover, the IRS1 phospho-S/T patterns produced during drug-induced "metabolic stress" correlates significantly with that stimulated by insulin. These results suggest that IRS1 phospho-S/T is first and foremost a feedback mechanism that develops during insulin stimulation, which can be co-opted by metabolic stress to inhibit insulin signaling and promote metabolic disease (Figure 8.5) [179]. An implicit corollary is that hyperinsulinemia may be an important physiological mediator of insulin resistance in animals, and there is some experimental evidence that this is so [184].

Mouse S307^{IRS1} (human S312^{IRS1}) is one of the best studied regulatory phosphorylation sites in IRS1 that is often used as barometer of insulin resistance. Phosphorylation of S307^{IRS1}, located near the PTB domain, can inhibit insulin-stimulated IRS1 tyrosine phosphorylation by disrupting the association between the InsR and IRS1, which decreases the activation of the PI3K→Akt pathway during insulin stimulation [185, 186]. Insulin itself promotes rat/mouse S307^{Irs1} phosphorylation through activation of the PI3K revealing feedback regulation that can be mediated by many kinases, PKCζ, IKKβ, JNK, mTOR, and S6K1 (Figure 8.5) [183]. In some cases, PI3K-dependent degradation of IRS1 might depend on the pS307^{IRS1}, although other mechanisms can be involved [187]. Free fatty acids that contribute to insulin resistance promote pS307^{IRS1}; however, associated hyperinsulinemia has not been excluded as the principal agonist of IRS1 phospho-S/T levels [179]. S307^{Irs1} is poorly phosphorylated in *ob*/*ob* (obese) mice that lack Jnk1, suggesting that this kinase might be involved [188]. IRS1 can be phosphorylated by PKCδ on at least 18 sites in BL21 DE3 cells, including S307^{IRS1}, S323^{IRS1}, and S574^{IRS1}, which appear to play an inhibitory role [189]. Hyperactivated mTOR also promotes S307^{IRS1} phosphorylation, which is diminished in mice lacking S6K [190–192]. IKKβ inhibitors (aspirin and salicylates) block S307^{IRS1} phosphorylation [193], which is associated with improved insulin sensitivity in obese rodents and in persons with type 2 diabetes [194–196].

Regardless, only two studies have investigated directly the function of IRS1 phospho-S/T in mice using transgenesis or genetic knock-in to augment or replace endogenous (wild-type) IRS1 with a mutant version. In the first report, transgenic mice are generated to have moderate overexpression in skeletal muscle (about twofold versus littermates) of non-mutant IRS1 or mutant IRS1 with alanine substitutions to block phosphorylation at three serine

residues: S302/307/612A (hS307/312/616A) [197]. In the triple-mutant transgenic mice, possibly half of the total muscle IRS1 protein is endogenous in origin. Compared with mice expressing a wild-type IRS1 transgene, mutant mice fed a high-fat diet showed better glucose tolerance, increased total and muscle glucose disposal during clamp, and enhanced muscle IRS1 tyrosine phosphorylation and p85 binding in response to insulin. This experiment is consistent with the notion that $S302^{Irs1}/S307^{Irs1}/S612^{Irs1}$ phosphorylation in skeletal muscle contributes to the development of insulin resistance in animals and humans.

However, genetic knock-in experiments to replace wild-type IRS1 in mice with a single mutant ($A307^{IRS1}$) do not support this result [198]. Given the apparent sensitizing effect of the $A307^{IRS1}$ mutation in cell-based assays, homozygous $A307^{IRS1}$ mice show increased fasting insulin versus control mice, mild glucose intolerance, and decreased PI3K binding (p85 and p110) in insulin-stimulated primary hepatocytes. During the high-fat diet, $A307^{IRS1}$ mice exhibit higher fasting insulin and more severe glucose intolerance than wild-type mice. Thus, $S307^{Irs1}$ appears permissive rather than inhibitory for insulin signaling in mice. Among other, less prosaic explanations, it is possible that a serine is structurally required at $S307^{Irs1}$ for normal signaling. Alternatively, S307 phosphorylation could have a partial positive effect on insulin signal transduction that is more important in tissues or primary cells than its desensitizing function in continuous cell lines. $A307^{IRS1}$ phosphorylation might have mixed tissue-specific effects that are obscured by the standard knock-in approach [199]. In any case, the phenotype of $A307^{IRS1}$ mice confirms that S/T sites on IRS1 can affect whole-body insulin sensitivity.

Modulation of insulin signaling by protein and lipid phosphatases

Many phosphatases can modulate the action of insulin by dephosphorylating key proteins or lipids in the signaling cascade including PTP1B (PTPN1, tyrosine–protein phosphatase

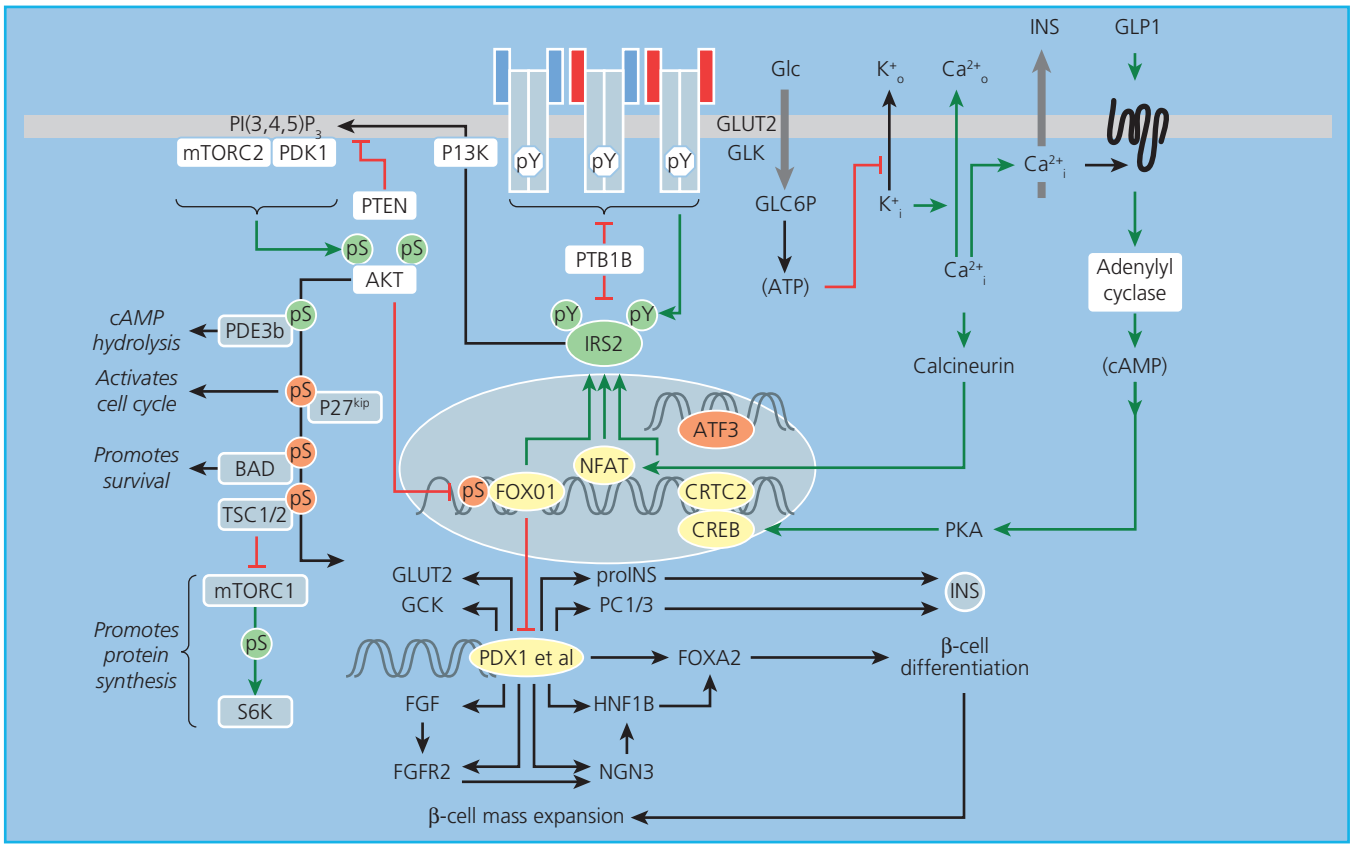

Figure 8.6 The integrative role of IRS2 signaling in pancreatic β-cell function. The diagram shows the relation between the IRS2 branch of the insulin signaling pathway and upstream and downstream mechanisms regulating β-cell growth and function. The production of $PI(3,4,5)P_3$ by the PI3K recruits the Ser/Thr-kinases PDK1 and AKT to the plasma membrane where AKT is activated by PDK1 and mTORC2-mediated phosphorylation. AKT phosphorylates many proteins that play important physiological roles in β cells including GSK3β (glycogen synthesis), the BAD•BCL2 heterodimer (apoptosis inhibition), TSC1/2 (protein synthesis and nutrient sensing), and FOXO (transcriptional regulation). Activation of GLP1→cAMP→PKA→CREB, glucose→Ca^{2+}→CRTC2 and calcineurin→NFAT induce IRS2 expression in β cells, revealing a mechanism that places β-cell growth, function, and survival under the control of glucose and incretins. Since insulin and IGF1R are constitutively active, IRS2 expression can act as the regulatory gateway to mTORC1, FOXO1, and $p27^{kip}$. Together, this integrated pathway shows how signals known to promote β-cell and islet growth and function can be integrated by the IRS2 signaling cascade into a common pathway.

non-receptor type 1), PTPN2, pTEN (phosphatase and tensin homolog), and PP2A (protein phosphatase 2A). PTP1B and PTPN2 are related phosphotyrosine phosphatases that attenuate insulin signaling by dephosphorylating the bisphosphorylated regulatory loop of the InsR [200]; however, their biological effects appear distinct owing to a different time course of action and differential expression (muscle expresses PTP1B, whereas liver expresses both enzymes) [201]. Both PTP1B and TCPTP can be inactivated by reactive oxygen species generated during insulin stimulation, which provides an additional level of regulation [20, 202]. $PTP1B^{-/-}$ mice display increased insulin sensitivity, lower circulating insulin concentrations, and decreased pancreatic β-cell mass [203]. Furthermore, PTP1B is a selective inhibitor of leptin signaling (LepRb→JAK2) as it dephosphorylates JAK2, but not JAK1 or -3, whereas TCPTP dephosphorylates JAK1/3, but not JAK2 [200]. Thus, CNS inhibition of PTP1B can protect against obesity, whereas peripheral inhibition of PTP1B promotes glucose tolerance [204]. In pancreatic β cells, PTP1B attenuates the IRS2→PI3K→AKT cascade that is important for growth, function, and survival of these cells [205]. The deletion of PTP1B maintains β-cell mass in mice lacking IRS2, which prevents the early onset of diabetes. Regardless, without IRS2 even the $IRS2^{-/-}$•$PTP1B^{-/-}$ mice lose β-cell mass between 8 and 9 months of age, suggesting that IRS1 alone is inadequate throughout life.

PTEN (phosphatase and tensin homolog) is a potent negative regulator of insulin action and cellular proliferation, and one of the most frequently mutated genes in many forms of human cancer [206, 207]. PTEN attenuates downstream insulin-like signaling by dephosphorylating $PI(3,4)P_2$ and $PI(3,4,5)P_3$ at the 3-position, which reduces the recruitment and activation of PDK1 and AKT (Figure 8.5) [207]. $PTEN^{+/-}$ mice are glucose tolerant even as β-cell mass and circulating insulin levels decrease [208]. PTEN heterozygosity also increases peripheral insulin sensitivity in $IRS2^{-/-}$•$PTEN^{+/-}$ mice and normalizes glucose tolerance, as the small islets in these mice produce sufficient insulin until death from lymphoproliferative disease between 10 and 12 months age. These experiments highlight the complex relation between nutrient homeostasis, insulin sensitivity and secretion, and cancer that emerges in rodents and humans. Despite this complexity, mild inhibition of PTEN, especially if it can be accomplished in a tissue-specific way, might have therapeutic value.

The serine–threonine phosphatase PP2A also plays an important regulatory role for insulin signaling as it dephosphorylates Ser/Thr residues on IRS1 and other proteins. By contrast, the inhibition of PP2A by okadaic acid strongly increases phospho-S/T and degradation of IRS-1, which is associated with reduced tyrosine phosphorylation and decreased insulin signaling [209]. Thus, compared with the effects of PTP1B, PP2A generally displays the opposite effect upon insulin signaling. The specificity of PP2A is largely coordinated through a scaffolding unit that recruits various substrates. The scaffolding unit is composed of HEAT (huntingtin-elongation-A subunit-TOR) repeats, which are thought to target PP2A to its substrates to confer specificity upon the constitutive catalytic domain.

IRS2 as a gateway to β-cell function

Pancreatic β cells have a special place in nutrient homeostasis as the unique source of insulin secretion, and, like other cells, they also require insulin and insulin-like growth factor signaling for growth, function, and survival. However, β cells are always exposed to insulin and IGF, so insulin and insulin-like growth factor signaling appears to be regulated through multifactor transcriptional control of IRS2 through the action of FOXO1/3, NFAT, and the CREB•CRTC2 (Figure 8.6) [154, 210–212]. In β cells, FOXO can account for as much as 80% of the basal IRS2 expression [210]. Since the IRS2→PI3K→AKT cascade phosphorylates and inhibits FOXO, insulin and IGF1 have inhibitory effects on FOXO-mediated transcription of IRS2, which can attenuate IRS2 expression. Since β cell mass and function must be protected during chronic nutrient excess, other mechanisms promote IRS2 expression, including glucose-stimulated Ca^{2+} influx and cAMP production. In addition to its immediate role in insulin secretion, Ca^{2+} activates calcineurin, which dephosphorylates NFAT to facilitate its entry into the nucleus, where it induces expression of IRS2 and other genes [211]. Glucose, glucagon-like peptide-1, and other GPCR agonists also increase the cAMP concentration in β cells, which has many important effects, including the activation of CREB•CRTC2 that promotes IRS2 transcription [213, 214]. Through this mechanism, the responsibility for insulin or IGF1 itself to trigger downstream insulin and insulin-like growth factor signaling in β cells has been replaced by indirect control through glucose, incretins, or neuronal signals, the physiologically relevant regulators of pancreatic β-cell function (Figure 8.6).

9 Control of Weight: How Do We Get Fat?

Arianne N. Sweeting and Ian D. Caterson

Boden Institute of Obesity, Nutrition, Exercise and Eating Disorders, University of Sydney, Camperdown, NSW, Australia

Key points

- The current obesity epidemic is a consequence of a positive "energy gap" arising from an imbalance between energy intake and expenditure.
- Complex genetic, environmental, behavioral, and neuroendocrine factors are responsible for this abnormal energy homeostasis.
- Environmental risk factors such as sedentary lifestyle, dietary consumption patterns, and the impact of advertising and globalization remain most responsible for the current obesity epidemic.
- Emerging pathophysiological mechanisms implicated in obesity include common single-nucleotide polymorphisms (obesity susceptibility genes), epigenetics, endocrine disruptors, neuroendocrine pathways, and the gut microbiome.
- Evolutionary counter-regulatory neuroendocrine pathways are a key factor in protecting against weight loss and promoting weight regain by decreasing energy expenditure and influencing appetite regulation and fat storage.

Introduction

The current obesity epidemic can be broadly conceptualized as the result of a positive "energy gap": the consequence of the progressive imbalance between energy intake and expenditure at a population level [1]. The underlying cause of this "energy gap" is complex, arising from the interplay of genetic, environmental, behavioral, and neuroendocrine determinants which are becoming better characterized.

This chapter provides a broad overview of several of these etiological factors that are implicated in the development of weight gain and obesity from either an epidemiological or an individual homeostatic and behavioral perspective.

Genetic factors

Heritability of obesity

Genetic factors have a major role in the development of overweight and obesity, although it is increasingly recognized that the gene–environment relationship frequently moderates the influence of these genetic factors. Early twin studies identified the heritability of obesity to be in the order of 40–70% [2–5]. Nonetheless, environmental factors such as physical activity and age are important genetic modifiers: for example, the heritability of fat mass in Finnish twins with low levels of physical activity is reported to be 90%, compared with only 20% amongst pairs of twins with high levels of physical activity [6]. Moreover, the heritability of body mass index (BMI) appears strongest in young adulthood [7].

Monogenic obesity

Monogenic and syndromic forms of obesity are rare but provide exceptions to the gene–environment obesity paradigm; in these conditions, genetic factors have such potent effects that their effect on body weight supersedes the influence of the environmental context. Examples include leptin deficiency caused by mutations in the leptin gene (*LEP*) or receptor (*LEPR*) or other genes involved in the hypothalamic leptin-melanocortin signaling pathway regulating appetite and satiety (i.e. *POMC* [pro-opiomelanocortin], *PCSK1* [prohormone convertase 1] and *MC4R* [melanocortin 4 receptor] [8–14]. *MC4R* mutations are the most common of these gene defects, with a prevalence of 0.5–1.0% in obese adults and 1.0–6.0% in obese children [15].

Common obesity "susceptibility" genes

More recently, genome-wide association studies (GWAS) have identified obesity "susceptibility" genes: common single-nucleotide polymorphisms (SNPs) associated with obesity within a population. However, so far these genes account for <2% of BMI variability within a population [14]. There are currently at least 75 obesity susceptibility loci that have been identified by GWAS [16, 17]. Interestingly, several of these loci are found near genes linked to severe monogenic obesity (i.e. *MC4R*, *SH2B1*, *BDNF*, *POMC*) [14]. The fat mass and obesity-associated (*FTO*) gene was the first to be identified and remains the most

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

common. It has been replicated across different ethnicities (with the strongest association seen in European followed by Asian and African populations), and has the largest effect on BMI and obesity risk, with each minor risk allele associated with a 0.39 kg/m^2 higher BMI and 1.2-fold increase in obesity risk within a population [18, 19]. Nonetheless, it accounts for only 0.34% of the variability in BMI in a population [20]. Evidence derived from animal studies suggests that *FTO* and other obesity susceptibility genes are principally involved in the regulation of food intake [14]. However, evidence is conflicting in human studies on the association of *FTO* with increased energy or fat intake [21–24], increased appetite [25, 26] and reduced satiety [27].

"Missing heritability"—epigenetics and intrauterine imprinting

Given the discrepancy between the estimated effect of these obesity "susceptibility" gene loci (<2%) and the known heritability of obesity (40–70%), there is increasing focus on the impact of gene–environment interactions via epigenetic and intrauterine effects on gene expression that may account for this "missing heritability" [14].

Prader–Willi syndrome is an extreme example of epigenetic-induced obesity, most frequently due to loss of expression of imprinted paternal genes on chromosome 15q11–13. Gene methylation is another example of epigenetic modification, and can be altered by maternal diet [28, 29]. Decreased methylation due to exercise has also been demonstrated in skeletal muscle biopsies of sedentary adults undergoing acute exercise, correlating with the degree of exercise intensity [30].

More broadly, the concept of intrauterine imprinting is also implicated in the development of obesity. The Barker-Hales Developmental Origins of Health and Disease hypothesis proposes that intrauterine and/or early childhood undernutrition lead to adult obesity and related cardiovascular sequelae [31]. This was first evident in the Dutch famine study, which found that nutrient deprivation during the first trimester, compared with later in pregnancy, increased the risk of obesity in the offspring in the long term [32]. Conversely, maternal obesity and increased gestational weight gain, especially in the first trimester, are associated with fetal macrosomia, large-for-gestational age (LGA) [33–35] and subsequent obesity in the offspring in the long-term [36]. Overall, higher rather than lower birth weight appears to be a much stronger predictor of high adult BMI [37].

Similarly, offspring of mothers with gestational diabetes mellitus (GDM) and pre-existing diabetes are more likely to be macrosomic and LGA at birth, with an increased risk of subsequent childhood and adolescent obesity and diabetes [38–40]. Moreover, offspring exposed to both maternal obesity and GDM are at an even greater risk of obesity in adolescence than that seen in those with GDM alone, suggesting that alterations in fatty acid metabolism and circulating inflammatory markers play a critical role in the development of obesity in the offspring [41]. From a pathophysiological perspective, maternal hyperglycemia causes fetal hyperglycemia, hyperinsulinemia, and increased leptin synthesis, influencing intrauterine hypothalamic energy homeostasis [42]. Moreover, maternal hyperglycemia may also alter the fetal epigenome, resulting in the expression of genes that regulate accumulation of body fat [43].

Antenatal maternal smoking has long been associated with subsequent risk of obesity in the offspring. For example, smoking in early pregnancy is associated with a more than twofold risk of overweight and obesity in the offspring at age 3 years [44]. Smoking throughout pregnancy increases the risk of elevated BMI in the offspring at the age when commencing school from <10% to >15%. This risk remains largely unchanged even if smoking is discontinued after the first trimester, indicating that the effect of smoking on fetal programming occurs predominantly early in pregnancy [45].

Environmental factors

Epidemiological evidence suggests that environmental changes promoting positive energy balance are those most responsible for the current obesity epidemic. These environmental risk factors include our increasingly sedentary lifestyle, the cost, quality, quantity, and changing patterns of dietary consumption, and the impact of advertising and globalization leading to progressively increased energy intake at a population level. Other environmental factors implicated in the obesity pathway include sleep and work patterns, medications, and environmental toxins.

Sedentary lifestyle

Epidemiological evidence indicates that moderate to high levels of physical activity protect against weight gain and obesity [46, 47], with physical activity particularly important for weight maintenance following initial weight loss [48]. Despite this, physical activity has been increasingly engineered out of our lifestyle, leading to the increasing prevalence of obesity via reduced energy expenditure.

Our increasingly sedentary lifestyle, from both occupational and recreational perspectives, arises from greater urbanization and technological advances that promote convenience and efficiency. Examples are the development of transport systems in which driving in cars or other transport is readily available, the mechanization and computerization of the workforce, and the increase in passive recreation and entertainment (e.g. shopping centers, television and movie watching, and the use of computers and other electronic devices).

The impact of such technological changes and urbanization on physical activity levels has been significant. A comparison of physical activity among Amish versus Colorado populations revealed that Amish men and women walk 18,000 and 14,000 steps daily, respectively [49], in contrast to men and women in Colorado who walk on average 6733 and 6284 steps daily, respectively; this equates to a difference in daily energy expenditure of 400–600 kcal/day [50]. Similarly, evidence shows that individuals in US

cities where more walking is required weigh less than those in other cities [51].

Energy intake—quantity of food consumed

Evidence suggests that a positive energy imbalance gap of 100–200 kcal/day is sufficient for body weight gain [52], although a recent US population-based study suggests that a mean daily energy imbalance gap of only 7 kcal/day could account for the current obesity epidemic [52]. Indeed, the increase in average daily energy intake since 1970 greatly exceeds these figures. Globally, the availability of calories per capita increased by ~450 kcal/day in developed countries and by over 600 kcal/day in developing countries [53], whereas the US National Health and Nutrition Examination Survey (NHANES) reported that the increase in average energy intake in the United States between 1971 and 2000 for men and women was 168 and 335 kcal/day, respectively [54].

This energy imbalance appears to be due predominantly to alterations in dietary composition, specifically the increased availability of foods, increased portion size, and the reduced cost of high-fat, energy-dense food (e.g. refined carbohydrates/sugar and vegetable oils).

Dietary composition: sugar versus fat

The impact of dietary composition on body weight remains controversial. It has been argued that as excess energy from dietary fat is more effectively stored than energy from carbohydrates, high dietary fat content may be a key factor driving weight gain [50]. Other postulated mechanisms include the high palatability of dietary fat and its associated weak impact on satiety, which can lead to overconsumption and increased energy intake [55]. This contention is supported by epidemiological studies correlating dietary fat intake with the percentage of the population that is overweight [56]. Longer term *ad libitum* feeding studies of high-fat diets also demonstrate a positive correlation between high fat intake and weight gain [55, 57]. However, there is evidence to suggest that obesity is more strongly associated with animal fat, saturated fat, and trans fat intake rather than total fat intake per se [58]. Despite this evidence, it appears that average daily fat intake has in fact remained relatively stable since the 1970s, with the net increase in energy intake instead likely accounted for by the increase in refined carbohydrate consumption [50].

US data reveal that of the 14.7% estimated increase in daily caloric intake (equivalent to 340 kcal/day) from 1984 to 1994, refined carbohydrates accounted for 6.2%, fats and oils 3.4%, fruits and vegetables 1.4%, and meat and dairy products 0.3% [59]. Despite this, studies consistently demonstrate an inverse relationship between sugar intake as a percentage of energy intake and obesity [60]. Possible explanations for this discrepancy include the inherent difficulty of differentiating between the relative influence of percentage dietary fat and carbohydrate owing to their reciprocal relationship in dietary intake; in combination, they contribute >80% of total energy intake [55]. Accurate assessment of dietary composition is also confounded by the known phenomenon of dietary under-reporting, particularly amongst the overweight and obese [61].

Calorically (sugar) sweetened beverages

Overall, there appears to be a positive association between calorically sweetened beverages (soda/soft drinks, fruit drinks or juice, and sports energy drinks) and weight gain, assuming that sugar (fructose) in beverages adds, rather than replaces, calories derived from other sources [50]. In the United States, calorically sweetened beverages are the fourth highest contributor of calories to energy intake [62]. NHANES data indicate that the mean energy intake from calorically sweetened beverages is ~180 kcal/day for children and 340 kcal/day for young adults [63].

A recent systematic review reported that after adjustment for energy intake and expenditure, the strength of evidence for the relationship between calorically sweetened beverages and obesity is inconclusive [64]. However, several cross-sectional and longitudinal studies have reported a positive association between calorically sweetened beverages and increased body weight, particularly in children and adolescents [65]. There is also evidence to suggest that in adults, soft drink consumption correlates with long-term increases in body weight [66]. Moreover, a randomized controlled intervention trial demonstrated that the use of a high-fructose soft drink increased total energy intake by 335 kcal/day, corresponding to a significant mean weight gain of 0.66 kg over 10 weeks. This compared with the weight loss seen in participants randomized to consumption of artificially sweetened (aspartame) soft drink [67].

Eating out and portion size

The increase in consumption of food that is prepared outside the home and the associated increased portion size are also significant contributors to the current obesity epidemic [68]. This relates particularly to the impact and influence of fast food establishments. Meals prepared outside the home are generally higher in total energy and fat, cholesterol, and sodium and consist of larger portion sizes (including snack foods), which promote a higher total energy intake [55, 68]. Studies have shown that those who tend to consume food prepared outside the home have a higher BMI [69] and that consumption of fast food is associated with corresponding overall unhealthier dietary intake for that day [70, 71].

The provision of unhealthy meals and the accessibility of vending machines at schools may also contribute to weight gain in children and adolescents [55]. Conversely, the availability and range of fruits and vegetables in the home have been shown to correlate with their consumption [72], and the mother's nutrition knowledge and behavior influence their children's dietary composition [73], which may have either positive effects with the presence of fruits and vegetables or better nutrition knowledge or behavior, or obviously the converse with the presence of less fruits and vegetables and lower nutrition knowledge or poorer behaviors.

Snacking

Snacking has a role in weight gain because of the high energy density of highly processed snack foods and their increasing

portion size, which result in increased daily energy intake [74]. In the United States, the prevalence of snacking is increasing, which has led to a greater contribution of snack foods to total energy intake, which is of the order of 20–25% of daily energy [75].

Eating patterns

The pattern and frequency of food consumption also influence weight gain. In particular, consuming smaller portions (as opposed to *ad libitum* consumption) more frequently throughout the day is associated with both normal BMI and maintenance of weight loss [76, 77]. In one study, adolescent boys who ate more than six times per day were more likely to have a BMI within the normal range compared with those who generally ate fewer than six times per day, and who were more likely to be overweight [78]. More generally, "binge-eating" behavior is associated with weight gain and this disordered pattern of eating is significantly more common in obesity [55].

Advertising

Highly visible advertising for fast food restaurants and energy-dense foods and beverages is also thought to contribute to their increased consumption, resulting in increased energy intake and weight gain [79]. This holds particularly true for children, with both the exposure to and the energy content of foods advertised to children being disproportionately high compared with their required daily energy intake.

Globalization and government regulation

Globalization, multilateral free trade agreements, and market liberalization have significantly impacted the global food system, promoting consumption-based growth. This has led to the greater availability and thus overconsumption of convenient, energy-dense processed foods [29], with processed foods now accounting for >80% of global food sales [80].

The overall effect of such trade and agricultural policies is a reduction in cost of processed energy-dense food, leading to their increased consumption [81, 82]. For example, between 1985 and 2000, the cost of fruit and vegetables rose by 188%, fish 77%, and dairy 56% compared with sugar, fats and oils, and calorically sweetened beverages, the cost of which rose by only 46, 35, and 20%, respectively [83].

More generally, globalization has led to the increasing presence of multinational retailers, manufacturers, and fast food chains in developing countries, heightening the influence of Western culture across the world [80]. This has resulted in the homogenization and westernization of traditional diets, with a transition towards energy-dense processed foods [84].

Government regulation of the food industry and the initiation of preventive public health policy in the midst of the obesity epidemic continue to be limited, in part because of the above economic policies that promote market and trade liberalization and the primacy of individual autonomy. Importantly, a recent systematic review concluded that government food policy is indeed effective in promoting improved dietary consumption, with taxes on soft drinks and subsidies for healthier food options particularly effective [82]. This also emphasizes the impact of cost of food on consumption. Specific examples include the enactment of legislation in Denmark in 2003 regulating the sale of many foods containing trans fats, essentially banning partially hydrogenated oils, and the 2013 proposed limit on soft drink size in New York, prohibiting the sale of calorically sweetened beverages of more than 16 oz (0.5 L) in volume, although this regulation was rejected by the New York judicial system in 2014.

Sleep patterns

The quality and duration of sleep are also implicated in weight gain and other metabolic and psychological adverse sequelae, through effects on appetite and energy homeostasis [85]. The factors contributing to chronic insufficient sleep are pervasive in modern society and include the use of electronic media, caffeine consumption, shift work, mental illness, and psychotropic medication [85].

Insufficient sleep is associated with alterations in hormonal mediators of appetite and metabolism, such as insulin, ghrelin, leptin, and cortisol [86], leading to insulin resistance, sympathetic nervous system overactivity, increased hunger, particularly for energy-dense food, reduced satiety, and decreased physical activity [86, 87].

This association between insufficient sleep and obesity appears particularly strong among children and adolescents, with an inverse dose-dependent relationship evident in several studies. For example, it has been estimated that for each hour of lost sleep, the odds of obesity in adolescents increase by 80%, and this appears most directly related to the influence of sleep loss on reduced physical activity [88]. Conversely, there is a positive correlation between longer sleep duration and lower BMI in children, with the prevalence of increased BMI in those who slept for less than 10 hours per night being 5.4% compared with 2.1% in children who slept more than 11.5 h per night [89].

Medications and toxins

Medications

Several classes of pharmacotherapy are associated with significant weight gain, including certain antidiabetes therapies, corticosteroids, anticonvulsants, antipsychotics, and antidepressants. Antihypertensives (α- and β-blockers), the oral contraceptive, and antihistamines have also been associated with lesser degrees of weight gain [90].

Older generation sulfonylureas such as chlorpropamide and glyburide are associated with significant weight gain over time (up to 5 kg) [91] compared with second-generation sulfonylureas such as gliclazide, which are associated with weight gains ~0.5–2.0 kg [92]. Similarly, insulin therapy can cause weight gains of between 2 and 10 kg generally within the first 12 months of therapy, correlating with glycemic control and insulin dose [91]. The mechanism of weight gain with these agents is multifactorial and includes appetite stimulation, increased snacking to prevent hypoglycemia,

reduced energy loss following correction of glycosuria, and the anabolic effect of insulin on muscles and adipose tissue [90].

Weight gain is the most frequent adverse effect associated with chronic corticosteroid therapy, with low-dose prednisone (5–10 mg daily) associated with a 4–8% mean increase in body weight [93]. Corticosteroids cause weight gain via several central and peripheral mechanisms, including effects on glucose, protein, and lipid metabolism and stimulation of reward and feeding pathways which promote increased appetite for energy-dense food [90, 94].

Several anticonvulsant agents are associated with significant weight gain. Sodium valproate causes progressive weight gain of up to 5.8 kg throughout the duration of treatment [95], whereas carbamazepine, gabapentin, and pregabalin are associated with lesser degrees of weight gain. Weight gain due to these agents results from a variety of mechanisms, including direct appetite stimulation via alterations to leptin synthesis, hyperinsulinemia, and their sedative effects, which result in decreased physical activity [95, 96].

Antipsychotic therapy is also strongly associated with weight gain in the order of 2–17 kg over the course of treatment [97]. This is most commonly a feature of the atypical (second-generation) antipsychotic, particularly clozapine and olanzapine. Antipsychotic-induced weight gain correlates with a significant increase in appetite for energy-dense foods, involving central serotonergic, histamine, and catecholamine pathways regulating appetite and reward pathways [98].

Antidepressants as a class have a variable impact on weight gain. Tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs) are most frequently associated with significant weight gain. Selective serotonin reuptake inhibitors (SSRIs) can often induce initial weight loss, but generally lead to weight gain in the longer term. The mechanism of antidepressant-induced weight gain appears to be increased appetite mediated via serotonergic pathways [99].

Toxins and endocrine disruptors

Adipose tissue can store toxins, which are mobilized following weight loss. For example, organochlorine compounds are implicated in decreasing basal metabolic rate and their storage is reduced following bariatric surgery [100]. Pesticides, flame retardants, plasticizers, and polychlorinated biphenyls (PCBs) have also been implicated in obesity in epidemiological and animal studies [101]. Potential mechanisms include inducing adipogenesis [102], altering sex hormone metabolism and thyroid hormone synthesis, and effects on fetal development [103].

From an epidemiological perspective, the decline in smoking prevalence since the 1970s corresponds to the increase in obesity rate, and it is thought that the weight gain associated with smoking cessation could account for approximately one-quarter to one-sixth of this increased prevalence [104]. Smoking is an established appetite suppressant, potentially mediated by the thermogenic effect and influence on eating behavior and resting metabolic rate of nicotine [105, 106]. Conversely, smoking cessation is associated with gender-specific effects on weight gain, with studies reporting weight gains of 3.8–4.4 and 2.8–5.0 kg for men and women, respectively [104, 107]. The weight gain is predominantly due to increased snacking. Predictive factors for weight gain following smoking cessation include younger age, lower socioeconomic status, previous heavy smoking, and genetics [105].

Neuroendocrine and behavioral regulation of energy homeostasis and the gut microbiome

Neuroendocrine and behavioral pathways

The relationship between energy intake, expenditure, and regulation of body weight is moderated not only by the above genetic, environmental, and behavioral factors but also by complex neuroendocrine feedback mechanisms that fundamentally seek to promote energy intake and protect against weight loss.

The hypothalamus is the central site for homeostatic regulation of body weight. It integrates peripheral homeostatic hormonal signals from the gastrointestinal tract (e.g. ghrelin, cholecystokinin, peptide YY, pancreatic polypeptide, and glucagon-like peptide 1 [GLP-1]), pancreas (insulin), and adipose tissue (leptin, adiponectin), with hedonic peripheral (e.g. leptin, ghrelin and insulin influence central dopaminergic and opioidergic pathways) and central reward pathways (cortex and reward circuits in the limbic system). The latter hedonic pathways strongly influence appetite behavior, particularly the consumption of energy-dense, highly palatable foods [108].

Arguably the key factor when considering regulation of body weight is that although weight loss can be readily achieved, maintenance of weight loss is inherently difficult owing to the above complex evolutionary counter-regulatory neuroendocrine mechanisms. These pathways are fundamentally protective against weight loss and promote weight regain by decreasing energy expenditure and influencing appetite regulation and fat storage [108]. A recent study demonstrated that by 1 year after initial weight loss, levels of the circulating mediators of appetite that encourage weight regain, such as leptin, peptide YY, cholecystokinin, insulin, ghrelin, gastric inhibitory polypeptide, and pancreatic polypeptide had not returned to their pre-weight loss levels, and increased hunger also persisted [109].

Endocrine feedback mechanisms regulating growth hormone (GH), thyroid hormone (thyroxine), gonadal and adrenal steroids (testosterone, estrogen, and adrenal androgens and glucocorticoids) are also critical in regulating weight gain. GH and thyroxine are predominantly responsible for regulating growth, while gonadal steroids during puberty alter the ratio and distribution of lean muscle mass to body fat: testosterone increases lean muscle mass and reduces visceral adiposity whereas estrogen has the opposite effect.

Gut microbiome

The role of the gut microbiome in regulating fat storage, obesity, and insulin resistance has become a burgeoning area of recent research. Obesity appears to be associated with alterations in the

ratio of the dominant gut microbiota, the Bacteroidetes and the Firmicutes [110]. It has been shown that colonization of germ-free mice with an "obese microbiota" results in a significantly greater increase in total body fat, despite an associated decrease in food consumption. This suggests that the obese microbiome has an increased capacity to obtain energy from the diet [111]. In animal studies, altering the gut microbiota via probiotic therapy has been shown to reduce fat mass and increase muscle mass, but does not impact overall body weight [111]. In humans, intervention studies assessing the role of probiotics (beneficial microorganisms) in weight loss suggest that *Lactobacillus gasseri* SBT 2055, *Lactobacillus rhamnosus* ATCC 53103, and the combination of *L. rhamnosus* ATCC 53102 and *Bifidobacterium lactis* Bb12 may reduce body weight and prevent weight gain in humans, potentially via effects on short-chain fatty acid production and low-grade inflammation that influence metabolism and affect body weight [112]. Additional information on the influence of the microbiome is diabetes is covered in Chapter 17.

Conclusions

This chapter has aimed to provide an overview of the multiple factors implicated in weight gain and obesity. As demonstrated, the regulation of energy intake and expenditure and consequently energy homeostasis is influenced by a complex interplay of genetic, environmental, neuroendocrine, and behavioral mechanisms operating at both individual and population levels. In consequence, addressing the current obesity epidemic requires multifaceted long-term strategies that target the multifactorial causes of obesity. In particular, a population perspective on the current drivers of weight gain requires policies that address the environmental context promoting excessive energy intake and sedentary lifestyle. From an individual standpoint, there is a need to conceptualize obesity as a chronic disease requiring long-term intervention and to develop treatment strategies that target the multiple complex counter-regulatory neuroendocrine mechanisms which continue to promote weight regain.

3 Pathogenesis of Diabetes

10 Autoimmune Type 1 Diabetes

Shehab Alshiekh, Helena Elding Larsson, Sten-A. Ivarsson, and Åke Lernmark
Department of Clinical Sciences/Paediatric Endocrinology, University Hospital MAS, Malmö, Sweden

Key points

- The prevalence and incidence of autoimmune type 1 diabetes mellitus (T1DM) continues to increase worldwide and the clinical onset tends to occur in younger children.
- Autoimmune T1DM is characterized by the appearance of a first β-cell autoantibody against either insulin (IAA) or GAD65 (GADA), or both, in early childhood.
- The etiopathophysiology of T1DM may be divided into three distinct stages: β-cell autoimmunity, asymptomatic loss of β-cell secretory capacity, and loss of β-cell function along with diabetes symptoms.
- Autoimmune T1DM results from a loss of immunological tolerance to β-cell autoantigens.
- HLA genes represent the strongest genetic determinants for the risk of both β-cell autoimmunity and T1DM.
- Environmental factors may trigger β-cell autoimmunity, accelerate the pathogenic process, or both.
- β-Cell destruction may occur prior to β-cell autoimmunity but the mechanism is not yet fully clear.
- β-Cell destruction occurs during the pathogenesis of β-cell autoimmunity mediated by cytotoxic T cells.
- Multiple β-cell autoantibodies (≥2) usually appear within 6–12 months following the appearance of the first autoantibody and markedly increase the risk for progression to T1DM.
- The appearance of either IA-2A, ZnT8A, or both, in IAA- or GADA-positive children is a strong marker of rapid progression to clinical onset of T1DM.
- The progressive destruction of β cells is likely to vary in intensity and duration, affecting the time of clinical diagnosis.

Introduction

The differentiation between the two main forms of diabetes mellitus, type 1 (previously known as insulin-dependent or juvenile-onset diabetes) and type 2 diabetes (non-insulin-dependent or adult-onset diabetes), has been deliberated for almost 50 years. In 1965, insulitis was rediscovered [1], supporting the view that autoimmune islet inflammation was associated with the etiopathology in type 1 diabetes mellitus (T1DM), a phenomenon absent in type 2 diabetes mellitus (T2DM) [2]. The evidence for islet autoimmunity was further supported during the last decade by the identification of cellular reactivity with islet autoantigens [3] and the association between T1DM and other organ-specific autoimmune disorders [4]. More importantly, long sought after antibodies against islet cells (ICAs) were finally detected in the sera of people with concomitant T1DM and autoimmune polyendocrine syndrome [5, 6]. At the same time, T1DM was found to be strongly associated with the human leukocyte antigen (HLA) [7]. It was also noted, however, that around 10% of adults classified with T2DM who were not achieving adequate glycaemic control with sulfonylurea treatment [8] were positive for ICA, a group of people now commonly known as having latent autoimmune diabetes of adults (LADA) [9]. Several genetic and autoimmune similarities are found between childhood T1DM and LADA; nevertheless, these two entities differ in other genetic and autoimmune processes [10]. Recent research, including studies of children followed from birth and extensive genetic studies, have resulted in a paradigm shift of the etiology and pathogenesis of type 1 diabetes [11–13]. In this chapter, we therefore summarize current knowledge of possible trigger(s) of β-cell autoimmunity (etiology) and factors affecting progression to clinical onset in individuals who have developed one or several β-cell autoantibodies (pathogenesis).

Autoimmune T1DM is characterized by the appearance of a first β-cell autoantibody against either insulin (IAA) or GAD65 (GADA), or both, in early childhood [11–13]. Rarely, the first islet autoantibody is directed against IA-2 (IA-2A) or ZnT8 (ZnT8A). These four biomarkers of T1DM (Table 10.1) are strong, since it has been found that the development of a first autoantibody (IAA or GADA) and the appearance of a second, a third, and often a fourth autoantibody will result in T1DM in 100% of subjects when followed for 20 years [11]. The epidemiology in different countries of β-cell autoantibodies in children or in the adult population is currently not known, as population screening for IAA, GADA, IA-2A, and ZnT8A is yet to be implemented.

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

Table 10.1 Characteristics of β cell autoantigens and autoantibodies.

	GAD65	IA-2	Insulin	ZnT8
Chromosome	10p11	IA-2: 2q35-36 IA-2β: 7q36	11p15	8q24
Molecular weight (kD)	64	IA-2: 40 IA-2β: 37	5.8	67
Tissue specificity	Pancreas, neuron, ovary, testis, kidney	Neuroendocrine cells (pancreas, brain, pituitary)	β-cell specific	β-cell specific
Function	GABA production (an inhibitory neurotransmitter)	Not clear (lack enzymatic activity)	Regulates glucose metabolism	Zn^{2+} transport and accumulation in β-cell vesicles
Genetic association	DR3 - DQ2 DR4-DQ8	DRB1*0401	INS - VNTR, DR4	SLC30A8
Antibody abbreviation	GAD65Ab	IA-2Ab	IAA	ZnT8Ab
Standardized assay	RBA, ELISA	RBA	RBA	RBA
Sensitivity (%)	RBA: 80 ELISA:89	RBA: 70 ELISA: 65	RBA:>60	RBA: 50 (C terminal)
Specificity (%)	RBA:96 ELISA:98	RBA: 99 ELISA: 99	RBA: 95	RBA: 98 (C terminal)
Variation with age	Higher detection with increase age	Less with increasing age	Higher predictivity in children	Increasing predictivity with age
Variation with gender	Female preference if onset <10 years	Male preference	None	None

ELISA, enzyme linked immunosorbent assay; RBA, radiobinding assay.
Workshop sensitivity and specificity for GAD65Ab and IA-2Ab were from the Diabetes Antibody Standardization Program [70].
Diagnostic sensitivity at 95% diagnostic specificity for insulin autoantibodies (IAA) were from [71].

It remains to be determined in multiple populations whether the incidence of β-cell autoantibodies eventually equals that of T1DM.

Epidemiology

The epidemiology of T1DM is detailed in Chapter 3. Briefly, the incidence of T1DM varies 50–100-fold worldwide, with the highest rates occurring in individuals of northern European descent. Both sexes are equally affected in childhood, but men are affected more commonly in early adult life [14]. The incidence of childhood T1DM is rising rapidly in all populations, especially in the age group younger than 5 years, with a doubling time of less than 20 years in Europe [15]. The increasing incidence of T1DM suggests a major environmental contribution, but the role of specific pathogenic factors remains largely unsettled. The distinction between T1DM and T2DM can become blurred in later life, and the true lifetime incidence of the condition is therefore unknown.

In Europe, the highest rates of childhood diabetes are found in Scandinavia, with an incidence for children from birth to 14 years of age ranging from 57/100,000 per year in Finland to 4/100,000 in Macedonia [15, 16]. In the United States, the overall annual incidence in young people is about 19/100,000. Prevalence rates are strikingly different among ethnic groups living in the same geographic region, probably because of genetic differences in susceptibility to the disease. Early-onset diabetes carries a higher familial risk, and affected fathers are more likely to transmit the risk for T1DM to their offspring than affected mothers are, with risks being 6–9% and 1–3%, respectively[15, 16].

The SEARCH for Diabetes in Youth multicenter study (funded by the US Centers for Disease Control and Prevention and the National Institutes of Health) examined diabetes among children and adolescents in the United States [17]. During 2008–2009, an estimated 18,436 people younger than 20 years in the USA were newly diagnosed with T1DM annually, and 5089 people younger than 20 years were newly diagnosed with T2DM annually. The prevalence estimates indicate that there are almost 500,000 children aged under 15 years with T1DM worldwide, the largest numbers being in Europe (129,000) and North America (108,700). Countries with the highest estimated numbers of new cases annually were the USA (13,000), India (10,900), and Brazil (5000) [18].

Etiopathophysiology

The etiopathophysiology of T1DM may be divided into three distinct stages in genetically susceptible individuals (Figure 10.1). Individuals are born with HLA-DR-DQ genotypes that confer risk for T1DM. The next step is that the individual is exposed to one or more environmental factors that trigger the immune system to mount an autoimmune reaction towards pancreatic β-cell autoantigens. At present, the β-cell autoimmunity is reflected by the appearance of a first autoantibody to either insulin (IAA), GAD65 (GADA), or both of them simultaneously [12, 13]. The disease then progresses in three stages:

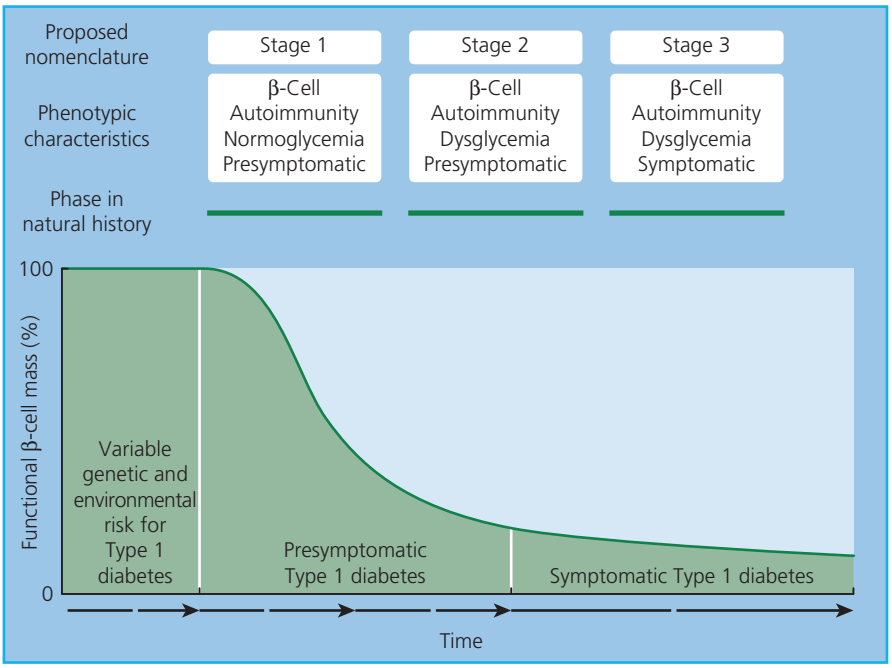

Figure 10.1 Schematic presentation of the early natural history of T1DM divided into three different disease stages.

Stage 1: Triggering of β-cell autoimmunity resulting in one or multiple β-cell autoantibodies associated with gradual β-cell destruction but no dysglycemia or symptoms of diabetes.

Stage 2: Loss of β-cell secretory function in autoantibody-positive individual. It may be manifested by a slowly increasing HbA_{1c} [19], loss of first-phase insulin release (FPIR) after intravenous glucose tolerance test (IVGTT), or reduced C-peptide levels, impaired glucose intolerance after an oral glucose tolerance test (OGTT) [20, 21], all referred to as dysglycemia, but still with no symptoms.

Stage 3: Loss of β-cell secretory capacity in β-cell autoantibody-positive individuals to the extent that symptoms of diabetes are discernible (Figure 10.1).

The continuing progress in the understanding of the natural history of T1DM will be dependent on several longitudinal studies starting from birth, aimed at detecting factors that predict (1) β-cell autoimmunity and (2) the clinical onset among β-cell autoantibody-positive individuals. The approach will permit both primary (prevention in the persons at genetic risk) and secondary (preventing diabetes onset in β-cell autoantibody-positive individuals) prevention or intervention (stop further loss of functional β cells after the clinical diagnosis).

Etiology

The etiology of T1DM is multifaceted and may be divided into genetic and environmental etiology and possible gene–environment interactions. Genetic susceptibility increases predisposition for a hypothetical trigger of β-cell autoimmunity (Figure 10.2). Genetic factors may also to contribute to either an accelerated β-cell failure in response to exogenous environmental factors such as obesity or to slowing down the process.

Genetic etiology

Longitudinal studies of newborns at increased genetic risk have demonstrated strong genetic association between HLA and the first β-cell autoantibody (Figure 10.2). IAA as a first islet autoantibody was strongly associated with HLA-DR4-DQ8. GADA as a first islet autoantibody was associated with HLA-DR3-DQ2 [12, 13]. The paradigm shift is that the primary association with HLA would be β-cell autoimmunity and not diabetes as such, as has been traditionally claimed since 1974 [7, 22, 23].

Throughout the years, the genetics of T1DM have been studied extensively despite the fact that the mode of inheritance remained uncertain. In persons with T1DM, the HLA genes represent almost 50% of the familial risk of T1DM [24]. Certain alleles of the HLA region, such as the HLA class II DR and DQ alleles, are mainly present in specific association with each other, a phenomenon known as linkage disequilibrium. The HLA association of T1DM is therefore often described by haplotype or genotype of the individual [25].

The genotype that confers the highest risk of T1DM is the heterozygosity of the two high-risk HLA class II haplotypes: DR3-DQ2 (*DRB1*03-DQA1*0501-B1*0201*) and DR4-DQ8 (*DRB1*04-DQA1*0301-B1*0302*) (Table 10.1) [25, 26]. One or both of these haplotypes were found in more than 95% of individuals with T1DM younger than 30 years but also in ~40–50% of the general population [26]. The concomitant inheritance of high-risk alleles and haplotypes appears to increase the risk of T1DM significantly through synergistic association of their single risks. For example, in persons with T1DM, DQ8 (*DQA1**

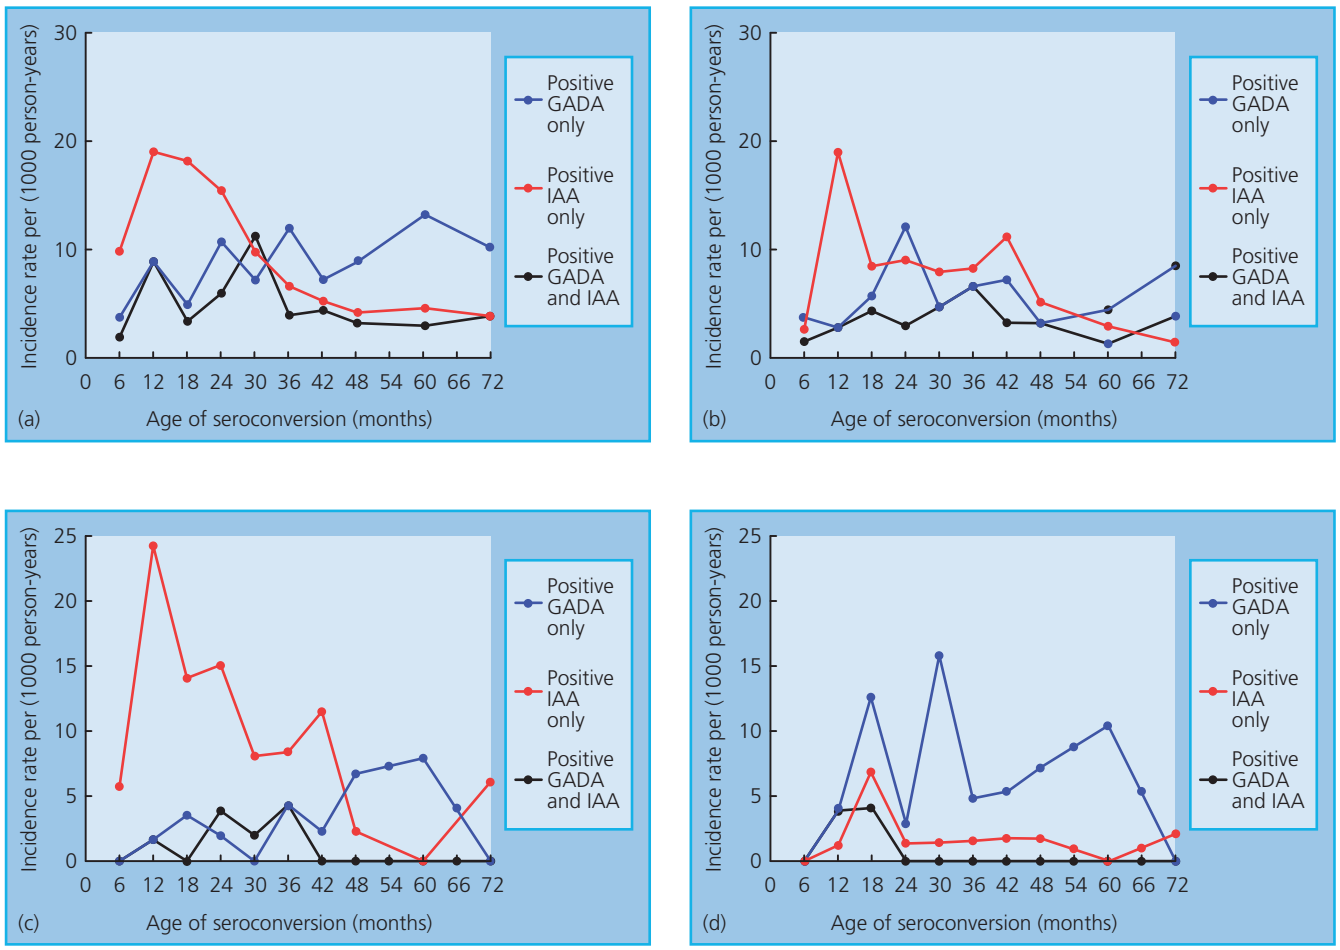

Figure 10.2 Incidence of the first islet autoantibody in relation to HLA-DQ genetic risk. In all four panels the red line represents IAA as the first β-cell autoantibody, the blue as GADA and the black simultaneously GADA and IAA. The Environmental Determinants of Diabetes in the Young (TEDDY) children in (a) were HLA-DQ2/8, in (b) HLA-DQ4/8, in (c) HLA-DQ8/8 and in (d) HLA-DQ 2/2. Source: Data from [12].

*0301-B1*0302*) is mostly inherited with certain variants of *DRB1*04*, especially *DRB1*0401*, *DRB1*0404*, and *DRB1*0402*, but not *DRB1*0403*, which has negative association [27] (Table 10.1). It cannot be excluded that the presence of the DR4-DQ8 haplotype in many people at the time of clinical diagnosis reflects the triggering of IAA by an environmental factor years before the clinical diagnosis of T1DM [11–13].

DQ2 (*DQA1*0501-B1*0201*) is mostly inherited with *DRB1*03* [25, 28]. Whereas certain alleles confer higher risk, such as *DQB1*0302*, *DRB1*03* and *DRB1*04:01*, which possesses an independent risk, others confer protection and may "neutralize" high-risk alleles when they are inherited together [29]. In this case, it cannot be excluded that one or more environmental factors triggered GADA as the first sign of β-cell autoimmunity years before the clinical diagnosis [12]. The most common protective haplotypes are DQ6 (*DQA1*0102-B1*0602* and *DQA1*0102-B1*0603*) and also *DQA1*0101-B1*0503* and *DQA1*0202-B1*0303* [25, 30]. Furthermore, other HLA class II (such as DPB1) and class I alleles have also been associated with T1DM risk and the search for new associations is continuing (for a review, see [28]).

The HLA-associated triggering of β-cell autoimmunity may reflect differences in the way in which children with DR4-DQ8 and DR3-DQ2 respond to virus infections, for example. It is well established that HLA-DR-DQ types are related to the immune response against virus or vaccines [31–34]. It cannot be excluded that the early sharing of environment contributes to the risk for β-cell autoimmunity, T1DM, or both, in families who are carriers of T1DM HLA risk haplotypes.

The sequencing of the entire human genome has made it possible in large genome-wide association studies (GWAS) to confirm the strong association with HLA but also to identify more than 50 non-HLA genes that are associated with the risk for T1DM (Figure 10.3) [35–38]. Their relative contribution to the risk in an individual is minor. It is notable that the T1DM non-HLA genetic factors are essentially all related to the function of immunocytes such T and B lymphocytes [39]. None of the T1DM genetic factors are shared with those identified in T2DM [40], which underscores the notion that T1DM and T2DM are two distinct entities with little genetic overlap. It cannot be excluded that some of the T1DM non-HLA genes are more

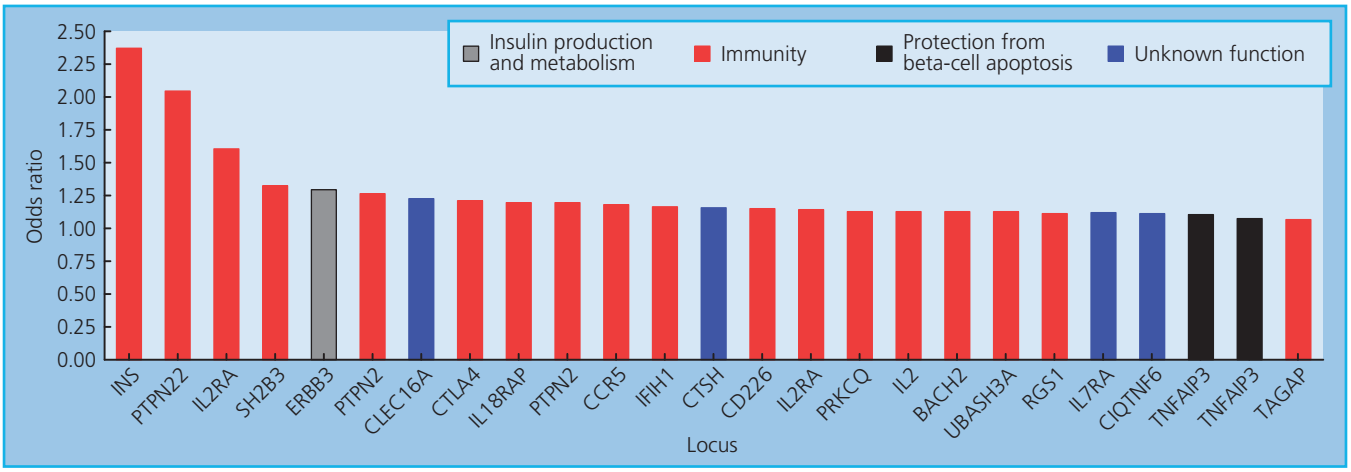

Figure 10.3 Putative genetic factors and proposed function for non-HLA type 1 diabetes genes determined by the Type 1 Diabetes Genetics Consortium.

important in triggering β-cell autoimmunity (stage 1) rather than diabetes [41] and that some contribute to stage 2 and stage 3 (Figure 10.1). Some genetic variants may slow (decelerate) or accelerate the disease pathogenesis during stages 2 and 3.

Environmental factors

Possible effects of environmental factors on the risk for T1DM will be considered in two parts. First, environmental factors may be important to the appearance of β-cell autoimmunity, i.e. to explain why children at increased genetic risk develop a first islet autoantibody. Recent data suggest that IAA only (Figure 10.2) in predominantly children with HLA DR4-DQ8 may appear as early as the first years of life but rarely after 5 years of age [12, 13]. Little is known about the role of environmental factors but enterovirus or upper respiratory virus are candidates [42, 43]. GADA only as the first islet autoantibody in children with DR3-DQ2 appears later, at 3–4 years of age (Figure 10.2). The incidence of GADA only seems to attain a steady state. It remains to be determined if environmental factors are able to trigger the appearance of GADA only. After the appearance of IAA only or GADA only, children may develop a second, third, or fourth islet autoantibody. The pattern of sequential appearance of islet autoantibodies is poorly understood and further studies are needed to determine the possible role of environmental factors when a child is progressing from a single autoantibody to multiple autoantibodies.

In children with multiple β-cell autoantibodies, it was reported that infection by Coxsackie virus accelerated progression to clinical onset [44]. It therefore cannot be excluded that a virus or perhaps other infections may have an accelerating effect on the disease pathogenesis, i.e. progression from β-cell autoimmunity to clinical onset of T1DM. It is speculated that the vast literature on infections prior to the clinical onset of T1DM is related to "accelerating infections" rather than to "triggering infections." Children with multiple β-cell autoantibodies are expected to have lost significant numbers of β cells. At the time of an infection, the insulin demand will increase and it is speculated that the conversion to clinical onset of T1DM may be explained by β-cell fatigue. Earlier literature on the concordance rate of 50–70% among identical twins [45, 46] and the seasonality of diabetes incidence may therefore be explained by an accelerating effect rather than by infections that may induce β-cell autoimmunity.

Environmental factors (Table 10.2) also include maternal factors [47], viral infections [48], dietary [49, 50] high birth weight and growth rate, psychological stress [51] and toxic substances [52]. The concurrent association of β-cell autoimmunity and factors increasing insulin resistance such as obesity and accelerated growth may boost the autoimmune destruction of β-cells [53]. The hygiene hypothesis proposes that better sanitation created a pathogen-free environment reducing the exposure to pathogens and their products. According to this hypothesis, the immune systems of children tend to be underdeveloped and therefore prone to autoimmune reactions. Additionally, it was also proposed that younger children received low-level antibodies from their mothers and, when exposed to infections such as enterovirus, it increased their T1DM risk [54]. It will be important in the future to distinguish environmental factors that trigger β-cell autoimmunity from those that accelerate the disease process in children with multiple islet autoantibodies.

Pathogenesis

Cellular autoimmunity

The genetic susceptibility of T1DM predisposes for a loss of immunological tolerance to certain β-cell autoantigens. The predisposition also include an eventual autoimmune killing of β cells perhaps explained by a disordered antigen presenting mechanism [55]. The HLA class II molecules are heterodimers that regulate the immune response and are expressed on the surface of APC such as macrophages. The heterodimer binds peptides generated intracellularly either from self-proteins or from exogenous antigens taken up by phagocytosis. The resulting

Table 10.2 The main putative environmental risk factors associated with T1DM.

Factor	Proposed effect mechanisms	Examples
Maternal factors	Triggering autoimmune response	Gestational infections
	Unknown	Higher maternal age
	Unknown	Higher birth order
	Unknown	ABO blood group incompatibility
Virus infections	Direct β-cell killing (cytolysis)	Mumps virus
	Mimicry of β-cell autoantigens	Rubella virus
	Autoreactive T- cell activation and subsequent β-cell killing	Enterovirus/Coxsackie B virus
	Inhibition of insulin production through inducing expression of HLA genes and interferon	Rotavirus
		Cytomegalovirus
		Epstein – Barr virus
Dietary factors	Triggering autoimmune response	Bovine milk/short breastfeeding
	Triggering autoimmune response	Cereals
	Unknown	High protein content
	Lack of possible protective effect of vitamin D	Vitamin D deficiency
Factors related to insulin sensitivity and/or resistance	Stressing β cells with excess demands "accelerator hypothesis"	Puberty
		High energy food
	Increased insulin resistance	Weight gain
Psychologic stress	Affect hypothalamic-pituitary-adrenal axis leading to disturbance in autonomic nervous system and autoimmune dysregulation	Stress during pregnancy
		Child – parent separation
		Behavioral deviances
		Difficult adaptation
Toxic substances	Direct damage to β cells	Alloxan
		Streptozocin
		Vacor

trimolecular complex represents the ligand for the T-cell receptor (TCR). The interaction between the trimolecular complex and the TCR activates the T lymphocyte. The HLA class II molecules on APC are responsible for antigen presentation to T-helper lymphocytes ($CD4^+$). Upon non-antigenic stimulation, macrophages from people with T1DM and the high-risk HLA DQB1*0201/*0302 genotype showed excessive secretion of proinflammatory cytokines and prostaglandin E_2 [56]. Cytokines may damage β cells directly or indirectly by activating other cells such as T and B lymphocytes [57]. The APC presenting β-cell autoantigens may thus be actively involved in the anti-self-autoimmune response that may result from failure to sustain self-recognition or from promoting an anti-self-response. APC, $CD4^+$ and $CD8^+$ T lymphocytes were all detected in pancreatic autopsies of people who died shortly after the onset of T1DM [58], indicating their role in insulitis. Autoreactive $CD8^+$ T lymphocytes may have the most significant role in the autoimmune destruction of β cells [59]. Natural killer (NK) cells [60] and also mast cells [61] may be found with abnormal activity and count. The detection of autoreactive T lymphocytes in insulitis and in the circulation at the time of diagnosis, in addition to the notion that immunosuppressive drugs such as cyclosporine or anti-CD3 monoclonal antibodies can temporarily abort disease progression, are all considered to support the role of cellular immunity in β-cell destruction [62].

The mechanism involved in β-cell destruction is not yet fully clear. Prior to stage 1 (Figure 10.1), one possible scenario is that β cells are first destroyed by an environmental factor such as a virus. The dying or dead β cell is next phagocytized by local dendritic cells (APC), which are then activated and migrate through the lymphatics to a pancreatic draining lymph node. The antigen presentation to and activation of $CD4^+$ T lymphocytes takes place in the lymph node to include activation of $CD8^+$ T lymphocytes specific for islet autoantigens. These β-cell autoantigen-specific $CD8^+$ T lymphocytes return to the blood circulation, eventually ending up in islets to destroy β cells. The β-cell killing will generate a new cycle of islet autoantigen presentation known as epitope spreading [57, 63]. $CD4^+CD25^+$ regulatory T lymphocytes are also thought to play an important role in the pathogenesis of T1DM as they may inhibit β-cell autoantigen-specific $CD4^+$ T lymphocytes [63, 64]. These cells express FOXp3 from the X chromosome and are important in the development of peripheral tolerance.

The identification of β-cell autoantigen-specific T lymphocytes has been challenging and the development of standardized assays of T lymphocytes specific to islet autoantigens (insulin, GAD65 and IA-2) is still difficult to achieve [62, 64]. Soluble HLA class II tetramer assays to assess autoantigen-specific T lymphocytes [65] and ELISPOT (enzyme-linked immunospot) [66] assays to measure cytokines of each T lymphocyte are tests to assess

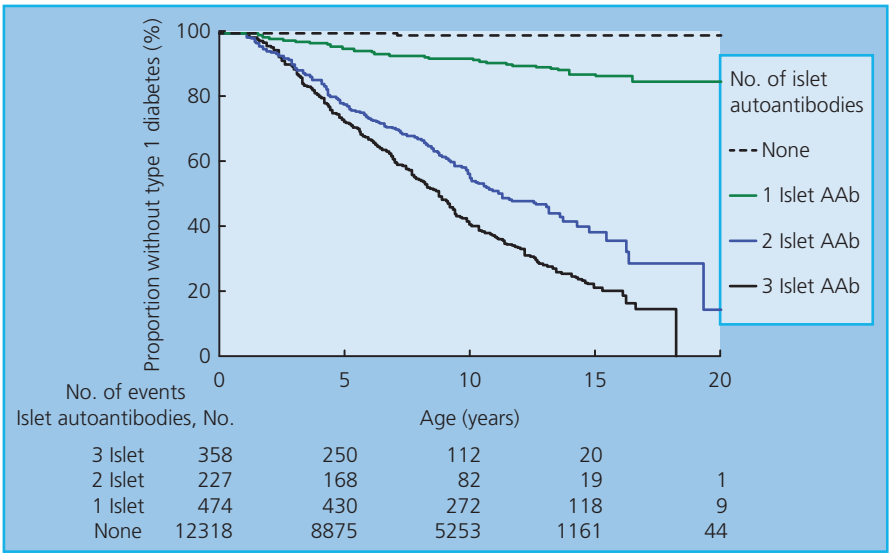

Figure 10.4 Probability of progression to symptomatic T1DM in relation to number of β-cell autoantibodies analyzed from birth. Source: Data from [11].

β-cell autoantigen T-lymphocyte reactivity. During β-cell autoimmunity prior to the clinical onset, these autoantigen-specific T lymphocytes may not be found in peripheral circulation; rather, they may accumulate in islets and are therefore difficult to detect [67]. More recent evidence indicates that B lymphocytes play a critical role in disease. This conclusion is based in part on the success of anti-CD20 (rituximab) therapy, which by broadly depleting B cells delays disease progression in people with new-onset T1DM [68, 69].

Humoral autoimmunity

Standardized assays specifically to detect autoantibodies to individual autoantigens are used to detect autoantibodies against GAD65, IA-2 [70], insulin [71], and ZnT8 (Table 10.1) [72, 73]. Multiple β-cell autoantibodies (≥2) usually appear within 6–12 months following the appearance of the first autoantibody (Figure 10.2) [13, 74] and markedly increase the risk for progression to T1DM (Figure 10.4). Nevertheless, some individuals develop transient islet autoantibodies but they are usually solitary and associated with lower risk [75], possibly because of the presence of protective genes [76]. One or more of these autoantibodies can be detected months to years before clinical onset in more than 95% of persons with newly diagnosed T1DM, even as early as the perinatal period [54]. Moreover, the detection of all four β-cell autoantibodies in addition to ICA demonstrate a diagnostic sensitivity of 91% [77].

Insulin autoantibodies

The most highly specific autoantigens of β cells are insulin and its precursor proinsulin. In 1983, using radioligand-binding assays, insulin autoantibodies (IAAs) were first identified in 50% of persons with newly diagnosed diabetes before initiating treatment with exogenous insulin [78]. IAAs, which react with both insulin and proinsulin, tend to be the earliest marker of islet autoimmunity [12, 13]. The predictive value for T1DM using IAAs alone appears to be related to age; it is higher among younger children, possibly related to a higher rate of β-cell destruction. IAAs are detectable in 90% of children who progress to T1DM before the age of 5 years compared with only 40–50% of adolescents older than 15 years (Table 10.1) [11].

DR4 is associated with a higher frequency of IAAs, which may be related to the linkage disequilibrium with the high-risk DQ8 haplotype [79]. IAAs are also associated with the insulin gene on chromosome 11p15 [80], where the number of tandem repeats (VNTRs) were found to be associated with T1DM whether IAAs were present or not.

Antibodies against exogenous insulin showed no correlation with IAA levels detected at the clinical onset of T1DM and appear to be independent of autoimmunity [81]; however, they do share some similar binding features [82]. Unlike IAAs, antibodies against exogenous insulin shows higher specificity, hence they may be detected using the enzyme-linked immunosorbent assay (ELISA) test, which does not predict T1DM [83]. The IAA fluid-phase radioimmunoassay shows high sensitivity and specificity to detect T1DM [71, 84]. Nevertheless, poor inter-laboratory concordance remains a problem that has delayed standardization of IAAs [71].

Glutamic acid decarboxylase autoantibodies

The enzyme glutamic acid decarboxylase (GAD) is found in neurons and β cells and produces γ-aminobutyric acid (GABA), which is a major inhibitory neurotransmitter. The 64K protein identified with GAD enzymatic activity after immunoprecipitation of human islets [85] was found to represent GAD65, not the previously known GAD67 isoform, which shares 65% of the GAD65 amino acid sequence [86]. Unlike GAD67 (encoded on chromosome 2q31.1), GAD65 (encoded on chromosome 10p11) is expressed primarily in human β cells [87].

Autoantibodies against GAD are most commonly to the GAD65 isoform (GADA), which were found in 70–80% of children with new-onset T1DM and 8% of T1DM first-degree relatives but also in about 1% of the general population [77, 88]. Unlike ICAs, GADA remain detectable for many years even after considerable loss of β-cell function [89]. Additionally, the GADA detection rate rises with age in new-onset T1DM (Figure 10.2). If the onset was before 10 years of age, some gender differences with female preference is observed [12]. Because GADA levels are persistent, more prevalent, and correlate well with plasma levels of C-peptide [90], they are currently considered good markers for both prediction and follow-up of β-cell dysfunction among individuals at risk.

GADA was the first islet autoantibody found to be associated with the high-risk HLA haplotype DR3-DQ2 (*DRB1*03-DQA1*0501-B1*0201*) [12, 13] Figure 10.2). Anti-idiotypic GADA were found to be markers that have lower frequency in T1DM and their absence was more predictive than the presence of GADA [91]. GADA can be detected with both radiobinding assays and ELISA, and these assays have been assessed and standardized in the Diabetes Antibody Standardization Program (DASP) [70]. The high and improved performance of these assays emphasizes the value of these autoantibodies in the prediction and classification of T1DM and also their value as screening tools in individuals at risk (Table 10.1).

Islet antigen-2 autoantibodies IA-2Ab and IA-2βAb

This autoantigen is a member of the plasma membrane protein tyrosine phosphatase family [92]. It is composed of two isoforms: IA-2 (formerly known as ICA512), which is a 40K protein encoded on chromosome 2, and IA-2β (phogrin), which is a 37K protein encoded on chromosome 7 (Table 10.1) [93]. The two isoforms share many common epitopes and are present in several neuroendocrine tissues in addition to pancreatic islets, with no clear function because they lack enzymatic activity.

The autoantibody reactivity of IA-2A is directed to the cytoplasmic portion of the autoantigen and the immunoreactivity in T1DM is directed against the C-terminal region of IA-2 [94]. IA-2A is detected in about 60–70% of people with new-onset T1DM and in less than 1% of the general population [30, 77]. IA-2A are often preceded by IAA, GADA, and ICA, respectively [12, 13], and the frequency decreases with increased age of onset [30]. This indicates that the predictive and screening abilities of IA-2A are more useful for younger children, especially when combined with IAA and GADA.

Using radiobinding assays to determine epitope-specific IA-2Ab/IA-2βAb among healthy siblings of children with T1DM, it was found that progression to T1DM was more common with autoantibodies to the juxtamembrane region of IA-2 (IA-2-JM-Ab) while IgE-IA-2A conferred protection even when IA-2-JM-Ab were positive [95]. Higher frequencies of IA-2A were found in association with *DRB1*0401* rather than with DQ8 [96]. Furthermore, persons with DQ2 had less association with IA-2A, indicating a role for additional mechanisms related to the HLA genetic component [30].

Assays to identify IA-2A were developed and standardized using radiobinding tests that can precipitate IA-2A and IA-2βA along with GADA. These assays have high levels of diagnostic sensitivity and specificity and were improved in subsequent DASP workshops [97]. Similarly, ELISAs combining IA-2A and GAD65A using biotin-labeled preparations were also standardized (Table 10.1) [97].

ZnT8 transporter (SLC30A8) autoantibodies ZnT8Ab

The zinc transporter (ZnT8 isoform-8 transporter) has developed into the fourth β-cell-specific autoantigen [72]. A polymorphism in the gene encoding this autoantigen, SLC30A8, is also associated with the risk of T2DM [98, 99]. ZnT8 is important for zinc–insulin crystallization and insulin secretion. It facilitates transport and accumulation of cytoplasmic zinc into the secretory vesicles of β cells. Inside these vesicles, insulin molecules are co-crystallized with two Zn^{2+} ions to form solid hexamers.

Nearly 60–80% of individuals with new-onset T1DM react positively to ZnT8A [77, 99, 100], which was detected in around 26% of people who were negative for GADA, IA-2A, and IAA [101]. Additionally, ZnT8A were also detected in 30% of persons with other autoimmune diseases associated with T1DM [72]. Being a target of humoral immunity in T1DM, the high β-cell specificity of ZnT8 is seen as an advantage over other non-specific β cell autoantigens such as GAD65 and IA-2. This high specificity and independence from other islet autoimmune markers, in addition to the fact that ZnT8A titers increase with age, all emphasize the value of ZnT8Ab in predicting T1DM, especially among older children. Detecting ZnT8 contributes to increasing the overall diagnostic sensitivity from 85.9 to 90.6%. ZnT8A showed the same sensitivity (61.1%) at disease onset as GADA (61.1%) and higher than IA-2A (53.7%), with only GADA showing much persistence in the long-term follow-up [102].

The polymorphic *SLC30A8* gene located on chromosome 8 encodes the ZnT8 [103]. This locus and other chromosome 8 loci have not been associated with T1DM risk as such but were associated with the risk of ZnT8A [99]. ZnT8A were found to react with the C-terminus of the autoantigen and variation at amino acid position 325 determines two important susceptibility markers of ZnT8A, which can be either arginine (ZnT8-R), tryptophan (ZnT8-W), or glutamine (ZnT8-Q) [99, 104]. Immunoprecipitation assays for ZnT8Ab were developed and fluid-phase radioassays for the C-terminus of ZnT8Ab were standardized and validated in the DASP workshop [73] (Table 10.1).

Candidate (minor) autoantigens

Several studies have reported associations of a group of molecules and substances with T1DM. This group included a wide variety of minor or candidate autoantigens that are thought to be associated with T1DM, β-cell autoimmunity, or both. Examples are ICA12/SOX13 [105], glima-38 [106], vesicle-associated

Table 10.3 Candidate minor β cell autoantigens.

Autoantigen	Molecular weight (kD)	Description	Autoantibody frequency
ICA12(SOX13)	—	SOX family protein present in pancreas, kidney and placenta. Anti-SOX-13-Ab found more in children	T1DM: 10–30% T2DM: 6–9% Healthy controls: 2–4%
Glima-38	38	Amphiphilic glycated β3-cell membrane protein. Specific expression on islet and neuron cells	New-onset T1DM: 19% Prediabetes phase: 14% Healthy controls: missing
VAMP2	12.6	β-cell secretory vesicles-related protein	T1DM: 21% Healthy controls: 4%
NPY	10.9	β-cell secretory vesicles-related protein	T1DM: 9% Healthy controls: 2%
CPH	43.4	Carboxypeptidase B-like glycoprotein present in islets and brain. Related to cleavage of insulin from proinsulin	ICA^+ relatives: 20% Healthy controls: missing
GLUT-2	55	Glucose transporter type 2 of β cells	New-onset T1DM: 32–80% Healthy controls: 6.6%
HSP 60	60	A "stress" protein which is thought to be produced and upregulated in response to cellular stress	T1DM: 15% Rheumatoid arthritis: 20% Healthy controls: 1.2%
Imogen 38	38	A protein found in β-cell mitochondria and to a lesser extent in α cells	No antibodies found
ICA 69	69	A peptide mainly present in islets and neuroendocrine, but also brain, kidney and lung	New-onset T1DM: 5–30% Healthy controls: 6% Rheumatoid arthritis 20%

membrane protein-2 (VAMP2) [107], neuropeptide Y [108], carboxypeptidase H [109], GLUT-2 [110], heat shock protein 60 [111], imogen 38 [112], ICA69 [113], INS-IGF2 [114, 115], and others (Table 10.3).

Pancreatic islet pathology before clinical diagnosis

During the period preceding the clinical onset, autoantibodies targeting specific β-cell autoantigens such as insulin, glutamic acid decarboxylase (GAD65), islet antigen-2 (IA-2), and zinc transporter (ZnT8) may be detectable for months to years before hyperglycemia becomes overt [11]. Autoimmune T1DM therefore results from a loss of immunological tolerance to β-cell autoantigens. The selective destruction of β cells implies specific mechanisms targeting these cells by autoimmune reactions. The process of β-cell killing seems not immediately to be associated with an infiltration by immune cells of the pancreatic islets [116, 117]. As the pathogenesis is progressing, more and more pancreatic islets are infiltrated by $CD4^+$ and $CD8^+$ T lymphocytes and macrophages, eventually leading to insulitis [1, 117]. It has been observed in IA-positive individuals that HLA Class I expression and also expression of INF-α were upregulated in pancreatic islets, but with no sign of a major mononuclear cell infiltration [58]. It has been assumed that the occurrence and number of islet autoantibodies were associated with insulitis [117]. Islet autoantibodies were detected among 62 (4%) individuals of 1507 pancreatic donors aged 25–60 years [117]. Although those 62 individuals also had HLA susceptibility, only two of them showed insulitis, indicating that the presence of islet autoantibodies was not a marker of insulitis. It needs to be established whether islet autoantibodies are more than biomarkers of β-cell destruction executed by $CD8^+$ T cells or if the cellular and humoral autoimmunity complement each other [117].

It has been widely claimed, based on autopsy studies, that around 80–90% of β cells are already lost at clinical onset [118]. Recent reanalysis of people who died soon after diagnosis, however, revealed that the level of β-cell loss required for hyperglycemia was age dependent, being about 40% in individuals aged 20 years [119]. Additionally, there are suggestions that β-cell regeneration may have taken place, contributing to the ~50% of viable β cells present at diagnosis [119]. The progressive destruction of β cells is likely to vary in intensity and duration depending on the age at diagnosis [120, 121].

Conclusions

Considerable progress has been made in the understanding of T1DM etiology and pathogenesis as it relates to the appearance of β-cell autoimmunity prior to the clinical onset of the disease. The development of standardized islet autoantibody tests (GADA, IA-2A, ZnT8A, and IAA) has made it possible to begin screening for people at risk to be included in clinical trials aimed at preserving residual β-cell function. Analyses of cell-mediated immunity need further development and standardization to be useful in clinical

trials. HLA-DQ on chromosome 6 remains the most important genetic factor for T1DM risk. It is well established that these HLA class II heterodimeric proteins are necessary but not sufficient for disease. Recent genome-wide association studies have provided a wide array of candidate factors to be explored for T1DM risk. We are still at a loss as to which environmental factors may be responsible for triggering β-cell autoimmunity and studies such as The Environmental Determinants of Diabetes in the Young (TEDDY) [12] are needed to test fully the multitude of candidate triggers.

11 Other Disorders with Type 1 Phenotype

Alice P.S. Kong, Elaine Y.K. Chow, and Juliana C.N. Chan

Department of Medicine and Therapeutics, Hong Kong Institute of Diabetes and Obesity, Li Ka Shing Institute of Health Sciences, The Chinese University of Hong Kong, Hong Kong SAR, China

Key points

- Persons with type 1 diabetes classically present early, require continuous insulin treatment, and carry autoimmune markers such as antibodies to glutamic acid decarboxylase (GAD).
- There are other types of diabetes with a type 1 phenotype due to heterogeneous etiologies, including maturity-onset diabetes of the young (MODY) and other forms of monogenic diabetes caused by mutations of mitochondria or amylin or pathways implicated in pancreatic β-cell function, latent autoimmune diabetes in adults (LADA), fulminant type 1 diabetes presenting with diabetic ketoacidosis after viral infections, and another form that reverts to a clinical course resembling type 2 diabetes after the initial ketotic presentation.
- Correctly diagnosing these disorders from a type 1 phenotype is clinically important owing to their different clinical courses, prognosis, and management.

Introduction

Classical type 1 diabetes mellitus is considered an autoimmune disease with pancreatic β-cell destruction. Those affected typically have onset of their disease at a young age with an acute presentation including diabetic ketoacidosis, requiring continuous insulin treatment [1]. However, with better understanding of the epidemiology and molecular mechanism of diabetes, clinical features such as the younger age of onset (e.g. less than 35 years old) or dependence on insulin treatment cannot adequately define the etiology of individuals presenting with hyperglycemia.

Furthermore, there are major ethnic differences in disease pattern in terms of presentation and natural progression. In white Europeans, over 90% of persons with diabetes diagnosed before the age of 35 years have type 1 disease [1]. By contrast, classical autoimmune type 1 diabetes with ketotic presentation is uncommon in non-white European populations [2–5]. Using as an example Hong Kong, which has a relatively homogeneous southern Chinese population leading an affluent lifestyle, fewer than 10% of adults presenting with diabetic ketoacidosis had autoimmune markers. Even among Hong Kong Chinese individuals with young onset of disease, only 10% had a classical type 1 diabetes presentation with antibodies to glutamic acid decarboxylase (GAD) [5]. Similar epidemiological findings have also been reported in other Asian populations in India, Malaysia, Singapore, and mainland China [7]. In most case series, 60–80% of white Europeans with type 1 diabetes had autoimmune markers such as autoantibodies to GAD and/or islet cell antigens (e.g. ICA-512). Despite the rarity of classical type 1 diabetes, 5–20% of young Asians with non-ketotic presentation had autoimmune markers with a wide range of insulin reserve. These findings suggest that latent autoimmune diabetes in adults (LADA) is not uncommon in young people with diabetes, especially those of Asian ethnicity, with considerable overlap between type 1 and type 2 diabetes phenotypes [6, 8] (Figure 11.1).

Our current understanding of the molecular pathways involved in the neogenesis, differentiation, and maturation of pancreatic β cells and also the intracellular signaling mechanisms leading to insulin synthesis, secretion, and processing are summarized in Figure 11.2. This large body of knowledge has provided the basis for the discovery and description of subtypes of diabetes with predominant β-cell failure due to causes other than autoimmunity, such as monogenic diabetes. Persons with monogenic diabetes often have young onset of disease and lean body mass. They may also have delayed presentation with complications due to the insidious nature of their symptoms [9, 10]. With the rising prevalence of young-onset diabetes, especially in developing countries [11], there is a need for healthcare providers to be aware of these non-classical presentations of "type 1 diabetes" characterized by insulin insufficiency, since they have important implications for clinical management and family screening.

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

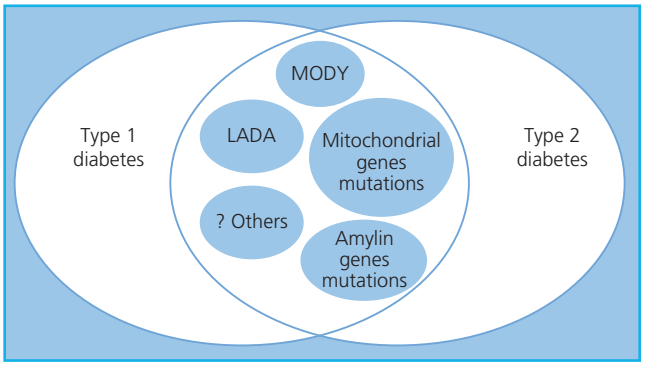

Figure 11.1 There are considerable overlaps between the phenotypes of type 1 and type 2 diabetes due to heterogeneous genetic and autoimmune etiologies. These include maturity-onset diabetes of the young (MODY), latent autoimmune diabetes in adults (LADA), and genetic variants affecting the insulin, amylin, and mitochondrial pathways. Other rare causes include fibrocalculous pancreatic diabetes and fulminant type 1 diabetes.

Atypical diabetes: heterogeneous etiologies of young-onset diabetes

In 1987, Winter et al. first described a cohort of 129 young African American with acute ketotic presentation, of whom 12 subsequently did not require insulin and followed a clinical course resembling type 2 diabetes [12]. Since then, a number of reports have shown that there is a poor correlation between the mode of presentation of hyperglycemia, clinical course, need for insulin treatment, and autoimmune status in different ethnic groups, including Asians [13–15]. Many of these individuals did not have human leukocyte antigen (HLA) genotypes or autoantibodies typical of autoimmune type 1 diabetes. Some individuals might be obese, with insulin resistance and glucotoxicity contributing to the initial ketotic presentation [16].

Monogenic diabetes due to genetic mutations encoding pathways implicated in insulin synthesis and secretion may lead to young-onset diabetes with atypical presentation. In young Chinese persons with diabetes, there is a higher prevalence of parental history of diabetes (32–47%), particularly a maternal history of diabetes, than in those with late onset of disease (12–19%) [10, 17, 18]. A progressively earlier age of onset of disease in successive generations has also been reported in some of these affected families [19]. These individuals may exhibit a mixed phenotype, including young age at diagnosis, insulinopenia, and normal body weight (as in type 1 diabetes), with a non-ketotic state typical of type 2 diabetes, despite a lack of insulin resistance and metabolic syndrome [20].

Monogenic diabetes

Maturity-onset diabetes of the young (MODY)

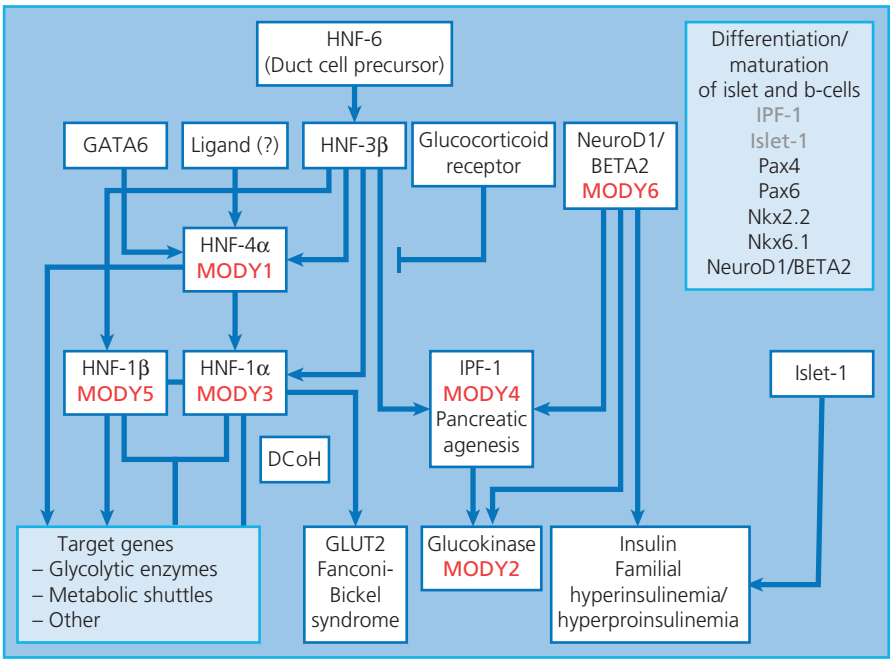
Persons with MODY typically present before the age of 25 years with a strong family history suggestive of autosomal dominant inheritance. Despite a non-ketotic mode of presentation, these individuals often have features of abnormal pancreatic β-cell function. Some people with MODY experience a rapid deterioration in glycemic control after initial presentation whereas others experience mild hyperglycemia and do not require insulin, despite having a long duration of disease.

To date, several subtypes of MODY have been reported (Chapter 18). These include mutations of transcription factors: *MODY 1*, hepatic nuclear factor (HNF) 4α; *MODY 3*, HNF-1α or transcription factor 1 (TCF1); *MODY 4*, insulin promotion factor 1 (IPF1); *MODY 5*, HNF-1β or transcription factor 2 (TCF2); *MODY 6*, neurogenic differentiation 1 (NeuroD1); and *MODY 7*, carboxyl ester lipase (CEL) and glucokinase, which is the glucose sensor of the pancreatic β cells (*MODY 2*). Transcription factors play key roles in pancreatic development, including differentiation and proliferation of β cells (Figure 11.2a). While genetic mutations in transcription factors typically cause significant insulin insufficiency and hyperglycemia, common polymorphisms of some of these transcription factors, e.g. HNF-1α [21], HNF-4α [22], and HNF-1β [23], have also been shown to be associated with increased risk of diabetes or metabolic traits that may interact with other genetic or environmental/lifestyle factors to give rise to overt diabetes. Interestingly, single-nucleotide polymorphisms in HNF-4α were associated with increased risk for type 2 diabetes in East and South Asians in genome-wide association studies [24, 25].

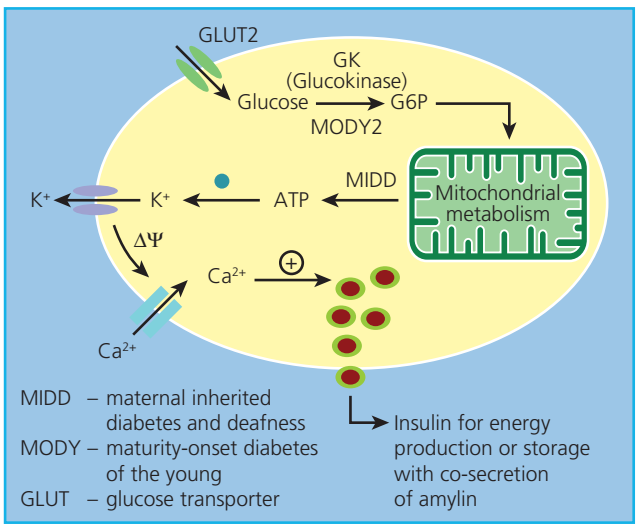
Over 80% of white European persons with classical MODY (i.e. age of onset less than 25 years with autosomal pattern of inheritance) have been reported to have mutations in HNF-1α or glucokinase, whereas other MODY subtypes (HNF-4α, HNF-1β and IPF-1 mutations) were less common [26]. There are clearly interethnic differences in MODY mutations. The frequencies of HNF-1α mutations ranged from 25 to 50% in French [27], 36% in German [28], 13–18% in British [29], 8% in Japanese [30], and 5% in Chinese people [9], although the selection criteria of index cases may influence these figures. In unrelated young Chinese people with type 2 diabetes, only 5–10% were found to have glucokinase or HNF-1α mutations [13, 31, 32]. This suggests that there may be other unidentified MODY genes in non-white European ethnic groups.

Given the mixed phenotypes, it is a clinical challenge to distinguish MODY from the large numbers of people with type 1 or young-onset type 2 diabetes. The costs of genetic analysis prohibit widespread screening for mutations in persons with diabetes. In 2008, a consensus group recommended clinical criteria for MODY testing that included onset of diabetes before age 25 years, parental history of diabetes, non-insulin dependence (for HNF-1α and HNF-4α MODY), and fasting plasma glucose of 5.5–8.0 and HbA_{1c} <8% (for GCK MODY) [33]. Although these criteria have high specificity, they have low sensitivity with other forms of familial monogenic diabetes yet to be discovered.

Extending the screening criteria to, for example, those diagnosed under the age of 30 years or with C-peptide positivity within 3 years of diagnosis (random or glucagon-stimulated C-peptide ≥0.2 nmol/L) may identify additional cases that were



(a)



(b)

Figure 11.2 (a) The cascade of transcription factors involved in pancreatic development and also neogenesis, differentiation, and maturation of pancreatic β cells. Maturity-onset diabetes of the young (MODY) includes subtypes with mutations in transcription factors, namely MODY 1 with mutations of hepatic nuclear factor (HNF-4α); MODY 3, HNF-1α; MODY 4, insulin promotion factor (IDF-1); MODY 5, HNF-1β; MODY 6, NeuroD1 (neurogenic differentiation 1); and MODY 7, carboxyl ester lipase (CEL), and also glucokinase, which is the glucose sensor of the pancreatic β cells (MODY 2). There are also involvement and interactions of glucose transporter 2 (GLUT-2) and endodermal factor, including GATA and various important genes and transcription factor governing the differentiation and maturation of pancreatic islet and β cells. These include Pax genes family and genes encoding the homeodomain transcription factors Nkx 2.2 and Nkx 6.1. In the Southern Indian population, interaction of the NeuroD1, neurogenin-3 (Neurog3), and HNF-1α genes has been observed to have a combined effect in controlling islet cell development and insulin secreting, thus contributing to the overall glucose tolerance [106]. (b) The multiple steps involved in regulation of insulin secretion commencing with sensing of ambient blood glucose level by GLUT-2, glycolysis by glucokinase (GK), and ATP production by mitochondria. The generated ATP particles then close the potassium channel, leading to membrane depolarization and opening of calcium channels. The intracellular calcium influx is associated with translocation of insulin- and amylin-containing vesicles to the cellular surface for extracytosis. During these processes, transcription factors are also activated, resulting in insulin gene transcription and production to replenish the insulin-containing vesicles and maintain continuous insulin secretion.

previously misdiagnosed [34]. Alternative biomarkers may help to distinguish MODY from other diabetes subtypes. For example, common variants near the HNF-1α gene have been shown to influence C-reactive protein (CRP) levels in healthy populations [35]. Low levels of high-sensitivity CRP (hsCRP) were found to distinguish HNF-1α MODY from type 1 and type 2 diabetes and increased the sensitivity of diagnosis up to 90% when combined with clinical criteria [36].

Accurate diagnosis of MODY has implications for choice of treatment. MODY is characterized by mild fasting hyperglycemia and does not necessitate treatment while HNF-4α and HNF-1α MODY are sensitive to sulfonylureas [37]. That said, many individuals with MODY may eventually require insulin with progressive β-cell failure due to factors such as aging, glucolipotoxicity, and inflammation. Although persons with some forms of MODY (e.g. *MODY 2*) show a mild clinical course and rarely develop complications, other forms of MODY may be associated with severe insulin insufficiency and complications often due to the late presentation and/or delayed use of insulin [10]. In light of the potential long duration of disease, young persons with diabetes are more prone to develop microvascular complications than those with late onset of disease [38], thus emphasizing the importance of family screening.

Furthermore, heterogeneous mutations in these transcription factors can be expressed sequentially in renal tubules with possible roles in various stages of their development [39]. Thus,

individuals with MODY may have heterogeneous phenotypes with metabolic and renal manifestations. Those with *MODY 3* due to mutations in HNF-1α were found to have a low renal threshold for glucose [40] whereas those with *MODY 5* due to mutations in HNF-1β may have mild diabetes, but increased susceptibility to severe renal disease and other urogenital malformations [41]. In a consecutive unrelated cohort consisting of 74 young Chinese persons with type 2 diabetes with nephropathy, a novel missense genetic variant in exon 3 (E260D, GAG→GAC) of the HNF-1β gene was identified. Extended family analysis revealed that four other siblings carrying this variant with heterogeneity in clinical presentation included one member with uncomplicated diabetes, one with impaired glucose tolerance, and one with microalbuminuria with normal glucose tolerance. A silent polymorphism Q378Q was identified in another unrelated person in this study. Although these findings will need replication in independent and larger cohorts, the phenotypic heterogeneity associated with these genetic variants is noteworthy [42].

Mitochondrial gene mutations

Mitochondria are important intracellular organelles in the maintenance of glucose homeostasis and energy balance. Mitochondria have their own genome and, unlike nuclear DNA, which is protected by histones, mitochondrial DNA is more vulnerable to oxidative stress and environmental toxins. Superoxide radicals generated by the mitochondrial respiratory chain are a major source of damage to mitochondrial DNA. Aged individuals with a positive family history of diabetes have a high frequency of mitochondrial mutations [43]. Owing to its maternal inheritance, mitochondrial DNA is a well-known cause of a subtype of maternally inherited diabetes mellitus [44].

In 1992, an A3243G mutation in the mitochondrial DNA coding for $tRNA^{Leu(UUR)}$ (mt3243) was first reported [45]. This form of diabetes was found in persons with both type 1 and type 2 diabetes and was characterized by maternal inheritance and deafness [45]. In a random cohort of Chinese individuals with diabetes, 1–3% had this mutation with either a type 1 or type 2 clinical course [46–48]. Other point mutations associated with increased risk of diabetes include sites at 3316, 3394, and 14577 and also deletion and rearrangement in mitochondrial DNA [43].

In keeping with its candidacy as a "thrifty gene," the frequency of a common polymorphism of the mitochondrial DNA (T16189C) is higher in Chinese people with metabolic syndrome than in those without (44% versus 33%), after adjustment for age and body mass index (BMI) [49]. In a meta-analysis, Asian people without diabetes had a higher frequency of the 16189C variant than their European counterparts (31.0% versus 9.2%) [50]. Despite negative reports in European populations [50], there are consistent data showing the risk association of the 16189C variant with type 2 diabetes in Asians [51, 52].

Amylin gene mutations

Amylin, a 37 amino acid polypeptide, is co-secreted with insulin by pancreatic β cells. It is the principal constituent of the amyloid deposits in the islets of Langerhans in type 2 diabetes [53, 54]. In autopsy series, pancreatic amyloidosis was associated with β-cell loss in both European and Chinese people [55–57]. It is now evident that the formation of intracellular islet amyloid polypeptide (IAPP) oligomers may contribute to pancreatic β-cell loss and progressive hyperglycemia [54]. Changes in metabolic milieu or genetic variants encoding proteins involved in amylin metabolism may lead to structural changes of amylin and increased oligomerization with β-cell death [58].

An S20G variant of the amylin gene has been shown to enhance cytotoxicity in transfected COS-1 cells and amyloidogenicity *in vitro* [59, 60]. This genetic variant is found in 2–3% of Japanese, Chinese, and Pacific Islanders with diabetes [9, 59, 61–64]. In Taiwanese Chinese, normoglycemic carriers of S20G variant had reduced early-phase insulin secretion [65]. However, cosegregation findings in family studies of S20G variant are inconclusive, suggesting that it is likely to be a risk-modifying factor rather than a major diabetes gene [9, 59, 65].

Other genetic mutations affecting pancreatic β-cell function

Genetic variants of transcription factors implicated in pancreatic β-cell development, structure, and function, such as Pax6, Nkx2-2, Nkx6-1, and NEUROG3, have also been reported in persons with type 1 or type 2 diabetes [66]. The Pax-4 gene is important for the differentiation of pancreatic β cells [67]; however, mutations in Pax4 have only been associated with monogenic diabetes in a few Asian families [68]. Recently, genome-wide analyses reported novel loci near Pax4 that may be associated with increased type 2 diabetes susceptibility in Chinese populations [69].

The pancreatic β-cell ATP-sensitive K^+ channels (K_{ATP} channels) comprise two subunits, the inwardly rectifying potassium channel Kir6.2 and the sulfonylurea receptor SUR1. This transmembrane channel plays an important regulatory role in insulin secretion (Figure 11.2b). Genetic variants encoding the K_{ATP} channel subunits Kir6.2 (KCNJ11) and SUR1 (ABCC8) are associated with reduced insulin secretion and diabetes in different ethnic populations [70–75] including Asians [66]. In the recent genome-wide association studies, polymorphisms encoding components of these K_{ATP} channels such as KCNJ11 and KCNQ1 have also been found to be associated with a 20–30% increased risk of diabetes in European and Asian populations [76, 77]. Additional information on genetic determinants of type 2 diabetes phenotypes is covered in Chapter 14.

Latent autoimmune diabetes in adults (LADA)

Autoantibodies to GAD are suggested to be sensitive markers of type 1 diabetes in white Europeans [13], although they can also be detected in individuals with type 2 diabetes such as those with LADA. In the UK Prospective Diabetes Study (UKPDS), ~10% of persons with type 2 diabetes had anti-GAD antibodies, the majority of whom eventually progressed to insulin dependence [78, 79].

Reports from different ethnic groups suggest an estimated 10% prevalence of LADA in populations with diabetes [78–80]. In Asians, 10–50% of persons with diabetes with acute or early onset of disease had anti-GAD antibodies depending on selection criteria of clinical definition, age at diagnosis, and assay methodologies [2, 6, 13, 81].

LADA is a slowly progressive form of autoimmune disease causing diabetes and is characterized by the presence of serum autoantibodies to pancreatic antigens [82, 83]. Similar to those with type 1 diabetes, individuals with LADA often carry other autoantibodies associated with celiac disease and adrenal and thyroid disorders [84, 85]. Hence it is plausible that LADA represents one end of a continuum of autoimmune diabetes with classical type 1 diabetes occupying the other end of the spectrum [86].

The nomenclature for this subtype of diabetes has been confusing, including type 2 diabetes with islet autoantibodies, slowly progressive insulin-dependent diabetes mellitus [87], type one-and-a-half diabetes [88, 89], latent autoimmune diabetes in children (LADC) [90], latent autoimmune diabetes in the young (LADY) [91], autoimmune diabetes [92], and autoimmune diabetes in adults with slowly progressive β-cell failure (ADASP) [80], although LADA remains the most commonly used term. The World Health Organization (WHO) and American Diabetes Association (ADA) acknowledged LADA as a slowly progressive form of type 1 diabetes [93, 94].

The correct diagnosis of LADA is clinically important since early use of insulin instead of sulfonylurea may prevent or reduce the rate of deterioration of β-cell function in these young persons with diabetes [95]. In individuals with LADA, impaired β-cell response is evident at diagnosis and early use of insulin may reduce the adverse effects of glucotoxicity on β cells [80, 92]. Apart from high clinical suspicions, HLA studies may distinguish LADA from classical type 1 diabetes. In white European populations, LADA is associated with HLA DQA1-DQB1*0102(3)-*0602(3)/X, which is uncommon in persons with typical type 1 diabetes [96].

Other subtypes of diabetes with type 1 phenotype

In 2000, a novel subtype of type 1 diabetes, known as fulminant type 1 diabetes in Japan, was reported [97]. Individuals with fulminant type 1 diabetes were characterized by a remarkably abrupt onset, absence of insulitis, non-autoimmune nature with negative autoantibodies, elevated pancreatic enzyme concentrations, and association with HLA haplotypes [97–99]. Since then, increasing numbers of cases have been reported in Japan and a nationwide survey found that ~20% of persons with type 1 diabetes in Japan indeed have fulminant type 1 diabetes [100]. Sporadic cases have also been reported in other Asian countries, including Korea, the Philippines, and China [98]. The pathogenesis of this new subtype of type 1 diabetes is not fully understood, with possible involvement of both genetic predisposition and viral infection in which antiviral immune responses lead to pancreatic destruction [98]. Diagnostic criteria were established by the Japan Diabetes Society [101] and intensive insulin therapy is the standard therapy.

In India, type 2 diabetes in youth often overlaps with monogenic forms of diabetes, fibrocalculous pancreatic diabetes, and diabetes associated with malnourishment, all of which are ketosis-resistant forms of youth-onset diabetes [102]. In Indian people with tropical calcific pancreatitis, the loss of endocrine function accompanying the exocrine damage may be an additional factor contributing to the clinical manifestation of diabetes in the presence of other stressors [103]. Using pancreatic specimens, Asian researchers have reported significant correlations between BMI and a relatively low volume of β cells [104], with amyloidosis, inflammation, and fibrosis as common pathological features [105].

Conclusion

Until recently, autoimmune type 1 diabetes was considered to be the predominant form of diabetes in children and young adults. With a better understanding of the pathogenesis of diabetes, it is now recognized that genetic or acquired factors that affect the pancreatic β-cell structure and function and also associated mechanisms such as amylin deposition and mitochrondrial damage may give rise to a broad range of clinical manifestations with considerable overlap between type 1 and type 2 phenotypes. Detailed medical history taking (e.g. family history of diabetes, mode of presentation, exposure to infection), a complete physical examination (e.g. body leanness, microvascular complications, metabolic syndrome, and associated cardiovascular risk factors), and the use of appropriate laboratory testing (e.g. hsCRP, autoantibodies against pancreatic antigens, and genetic markers) may help clinicians refine the diagnosis. This will help to guide correctly the treatment of these individuals, who are often young, with long disease duration, and with a high risk for complications of their diabetes.

12 Abnormalities of Insulin Secretion and β-Cell Defects in Type 2 Diabetes

Stefano Del Prato, Cristina Bianchi, and Giuseppe Daniele
Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy

Key points

- Type 2 diabetes mellitus (T2DM) is a heterogeneous, progressive disease due to the interaction of genetic and environmental factors, which adversely affect β-cell function and tissue insulin sensitivity.
- Physiological regulation of insulin secretion is controlled through a sophisticated integrated process encompassing finely tuned feedback mechanisms between the β cell, plasma glucose and other nutrient levels, insulin sensitivity, incretin hormones, neuropeptides, and neuronal control.
- β-Cell abnormalities are the main determinant of the rate of progression of T2DM. Worsening of the ability of the β cells to compensate for existing tissue insulin resistance sets the rate of progression of the disease.
- A predisposing genetic background is the most likely explanation for the evidence provided by multiple studies that β-cell function is altered well before the onset of overt T2DM.
- In predisposed normoglycemic individuals, loss of first-phase insulin secretion and loss of glucose sensitivity, i.e. the ability of the β cells to sense and respond properly to changes in glucose concentrations, represent the earliest abnormalities of β-cell function.
- An apparent reduction in β-cell volume of up to 60% has been found in people with prediabetes, with a further reduction in individuals with overt diabetes. The decrease in β-cell mass is the result of an increased rate of apoptosis, autophagy, and dedifferentiation. The increased β-cell death occurs without a compensatory increase in β-cell replication owing, at least in part, to the limited regenerative capacity of adult human β cells.
- Multiple factors contribute to the progressive loss of β-cell function and β-cell mass, including the characteristic alterations of the metabolic milieu of T2DM, i.e. hyperglycemia, hyperlipidemia, chronic β-cell stimulation, and impaired incretin effect.
- All factors that accelerate the decreased number and function of β cells promote common damage pathways, including oxidative stress, endoplasmic reticulum stress, inflammation, immune system activation, and amyloid deposition. These factors impair both the function and the survival of β cells, although abnormalities of β-cell function seem to be predominant compared with the reduction in the number of insulin-secreting cells.
- Preserving β-cell function is key to ensuring long-term glycemic control in people with T2DM.

Introduction

Type 2 diabetes mellitus (T2DM) is a complex, progressive disease. In the past 40 years or so, a number of alterations involving different tissues have been identified as contributing to the development and progression of hyperglycemia and concomitant metabolic disorders [1, 2]. Of the many pathogenic mechanisms, insulin resistance and impaired β-cell function remain the hallmarks of the condition. Insulin resistance is almost universally present in people with T2DM and it is already apparent in predisposed individuals. However, normal glucose tolerance is maintained in the face of insulin resistance provided that the β cell remains capable of compensating for the increased secretory demand. This simple observation highlights how the defect of insulin secretion plays a central role in the development of glucose intolerance, conversion to diabetes, and progression of the disease. Insulin secretion, indeed, is key to the maintenance of glucose homeostasis.

Physiological insulin secretion

Insulin is secreted from the β cells embedded in the islets of Langerhans of the pancreas, where they account for up to 60% of the entire islet cell population. The total weight of β cells in an adult of normal weight does not exceed 1 g. This minute amount of β cells contains sufficient insulin to ensure up to 8–10 days' supply of insulin [3]. Insulin is the key hormone maintaining

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

daily plasma glucose concentration within a tight range in spite of wide fluctuations in carbohydrate supply (i.e. food ingestion) and demand (e.g. resting conditions vs. physical activity). This implies a tightly regulated, dynamic and rapidly acting feedback between insulin secretion and plasma glucose concentration and also adaptation to insulin sensitivity [4].

Glucose is actively transported inside the β cell in a linear manner with plasma glucose levels through the activity of glucose transporter 2 (GLUT-2). Once inside the cell, glucose is promptly phosphorylated by glucokinase, allowing its entry into the glycolytic pathway leading to generation of adenosine triphosphate (ATP), the main driver of glucose-induced insulin secretion. Increased cytosolic ATP levels cause the closure of ATP-sensitive K^+ channels and depolarization of the plasma membrane, causing the opening of the voltage-dependent Ca^{2+} channels and Ca^{2+} influx. The rise in intracellular Ca^{2+} concentration triggers the exocytosis of insulin granules and the release of insulin (Figure 12.1).

Insulin secretion in response to glucose is biphasic in nature with a short-lasting (a few minutes) first-phase increase in insulin secretion followed by a more sustained second phase increase, which lasts as long as the glucose level remains elevated [5, 6]. This pattern can be clearly appreciated using the hyperglycemic clamp technique depicted in Figure 12.2 [7]. The biphasic response of insulin secretion is believed to reflect the dynamics of spatially and functionally distinct intracellular insulin granule pools. According to this view, first-phase insulin secretion reflects fusion to the cell membrane of predocked granules from a readily releasable granule pool [8]. This pool accounts for no more than 5% of the total granules in the cell. The second-phase involves the recruitment of granules from a more distant and larger reserve pool and stimulation of *de novo* insulin synthesis [9].

Insulin is secreted into the portal vein, exerting an immediate biological action on the liver. In the fasting state, the portal levels of insulin limit the supply of glucose from the liver into the systemic circulation to match the need of glucose-dependent tissues, primarily the central and peripheral nervous system and red blood cells. Basal insulin secretion is characterized by rapid oscillations with a 3–4 min frequency [10]. In the absorptive state, insulin is secreted in proportion to the increments in plasma

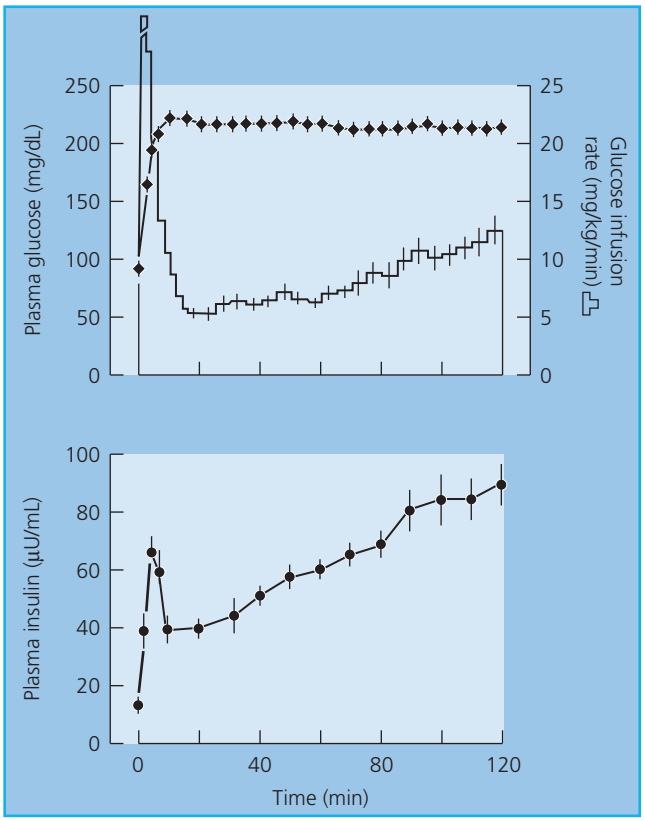

Figure 12.2 First- and second-phase plasma insulin response during hyperglycemic clamp in healthy individuals. Plasma glucose is acutely raised +125 mg/dL above baseline and maintained for the ensuing 2 h. Plasma insulin concentration is measured at regular intervals. Source: DeFronzo et al. 1979 [7]. Reproduced with permission of the American Physiological Society.

glucose levels subsequent to the entry of nutrients into the circulation following food digestion and absorption. The route of administration of glucose and other nutrients markedly influences insulin secretion. When glucose is administered via the gastrointestinal tract, a much greater stimulation of insulin secretion is observed compared with similar plasma glucose levels obtained with intravenous glucose infusion. This difference in insulin secretion between intravenous and oral glucose administration is referred to as the "incretin effect" [11]. Glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotropic peptide (GIP), the major incretin hormones in humans, play a predominant role in the postprandial incretin effect, thereby largely contributing to the maintenance of glucose homeostasis after the ingestion of a meal [12]. Other gut hormones, such as cholecystokinin (CCK), can contribute to the incretin effect, although the importance of these peptides is negligible under physiological conditions [13].

Insulin secretion is also stimulated by the ingestion of proteins and fat [14]. Amino acids regulate both the triggering and the amplification pathways of insulin secretion by acting as a substrate for the tricarboxylic acid cycle and/or redox shuttles with subsequent generation of ATP, and through direct depolarization of the plasma membrane (Figure 12.1). The latter is the consequence of the transmembrane transport of positively charged amino acids via specific amino acid transporters and Na^+ cotransport. Lipids and free fatty acids (FFAs) play a crucial role in β-cell function and insulin release [14]. In the presence of sufficient nutrients, FFAs influence insulin secretion through three distinct pathways: (1) tricarboxylic acid cycle/malonyl-CoA metabolic signaling, (2) glycerolipid/FFA cycling, and (3) direct activation of G-protein-coupled receptors [14]. Finally, many other factors, including neuropeptides and neuronal control, contribute to the modulation of insulin secretion through a sophisticated integrated process [15].

Long-term adaptation of insulin secretion is likely to be associated with changes in the number of β cells, as indicated by the progressive increase in β-cell mass occurring from birth to adulthood. Although β-cell mass expansion tends to become negligible after the age of 20–30 years [16, 17], an increase may occur under conditions of increased insulin demand such as obesity [18, 19] and pregnancy [20].

Although further details of the regulation of insulin secretion are given in Chapter 6, even from this brief discussion of the physiological regulation of insulin secretion, it is apparent how abnormal insulin secretion in T2DM may arise from defective β-cell function, reduced β-cell mass, or a combination of the two.

Natural history of β-cell failure

Because of its fine regulation, assessment of insulin secretion *in vivo* may require complex methodological approaches and sophisticated mathematical analysis [21, 22]. HOMA-B (homeostasis model assessment B) is a model-derived parameter reflecting β-cell function in the basal state [23]. This parameter has been instrumental in describing the natural history of β-cell dysfunction in T2DM in the United Kingdom Prospective Diabetes Study (UKPDS) [24]. The study showed that individuals with T2DM already had a significant reduction in β-cell function at the time of diagnosis. Moreover, it was apparent that β-cell function declined in an almost linear manner during the 10-year follow-up, irrespective of pharmacological treatment. Because of such a linear relationship, it was extrapolated that the defect in β-cell function was likely to antedate by many years the time of the development of hyperglycemia. By using the same HOMA-B parameter, a more articulated history of β-cell dysfunction was described in the Belfast Diet Study [25]. According to this analysis, individuals who eventually develop diabetes already have an intrinsic 40–60% reduction in β-cell function to start with. Over time, two phases were identified: phase A, which precedes overt diabetes and is characterized by a slow, constant decline of β-cell function (~2% per year), and phase B, characterized by a much faster decline (~18% per year), more commonly occurring with the development of diabetes. This view is of interest because it reflects three conditions that, in recent years, have received growing support and stronger evidence: (1) genetic predisposition, (2) early β-cell dysfunction, and (3) factors that accelerate the rate of loss of β-cell function.

Genetic predisposition

More light has been shed in recent years on the genetic predisposition to T2DM (See Chapter 14 and Figure 12.3). Early linkage and candidate gene studies and, more recently, genome-wide association studies (GWAS) have identified a large number of genetic variants associated with increased risk of developing T2DM, although most of them have limited size effects that seldom exceed 10–15% [26]. The only exception is represented by variants of the *TCF7L2* gene encoding for a transcription factor involved in the Wnt-β catenin-signaling pathway [27]. In particular, the T allele of the genotypes of the single-nucleotide polymorphism (SNP) rs7903146 confers a greater risk of developing T2DM in all the populations so far evaluated [27], except the Pima Indians [28]. More interestingly, the same genotype is associated with impaired *in vivo* [29, 30] and *ex vivo* [29] insulin secretion. The *TCF7L2* genetic variants may exert both direct and indirect effects on the β cell. Thus, the increased *TCF7L2* expression found in human pancreatic islets carrying the risk allele T was inversely correlated with glucose-stimulated insulin release [29]. Moreover, people carrying the risk alleles have impaired potentiation of insulin secretion in response to GLP-1 infusion [31] (Figure 12.4). In summary, the *TCF7L2* genetic variants may be associated with reduced insulin secretion in response to both glucose and incretin hormones. However, this is not clear cut as other studies have reported reduced expression of the *TCF7L2* gene in T2DM pancreatic islets along with impaired insulin secretion and β-cell survival [32].

A reduced early insulin response to both oral and intravenous glucose and greater susceptibility to diabetes have been reported for carriers of the SNP rs10830963 in the melatonin receptor gene (*MTNR1B*) [33]. These individuals have increased melatonin receptor expression in β cells, which may lead to increased melatonin binding and reduced cAMP/cGMP generation, accounting for impaired insulin secretion.

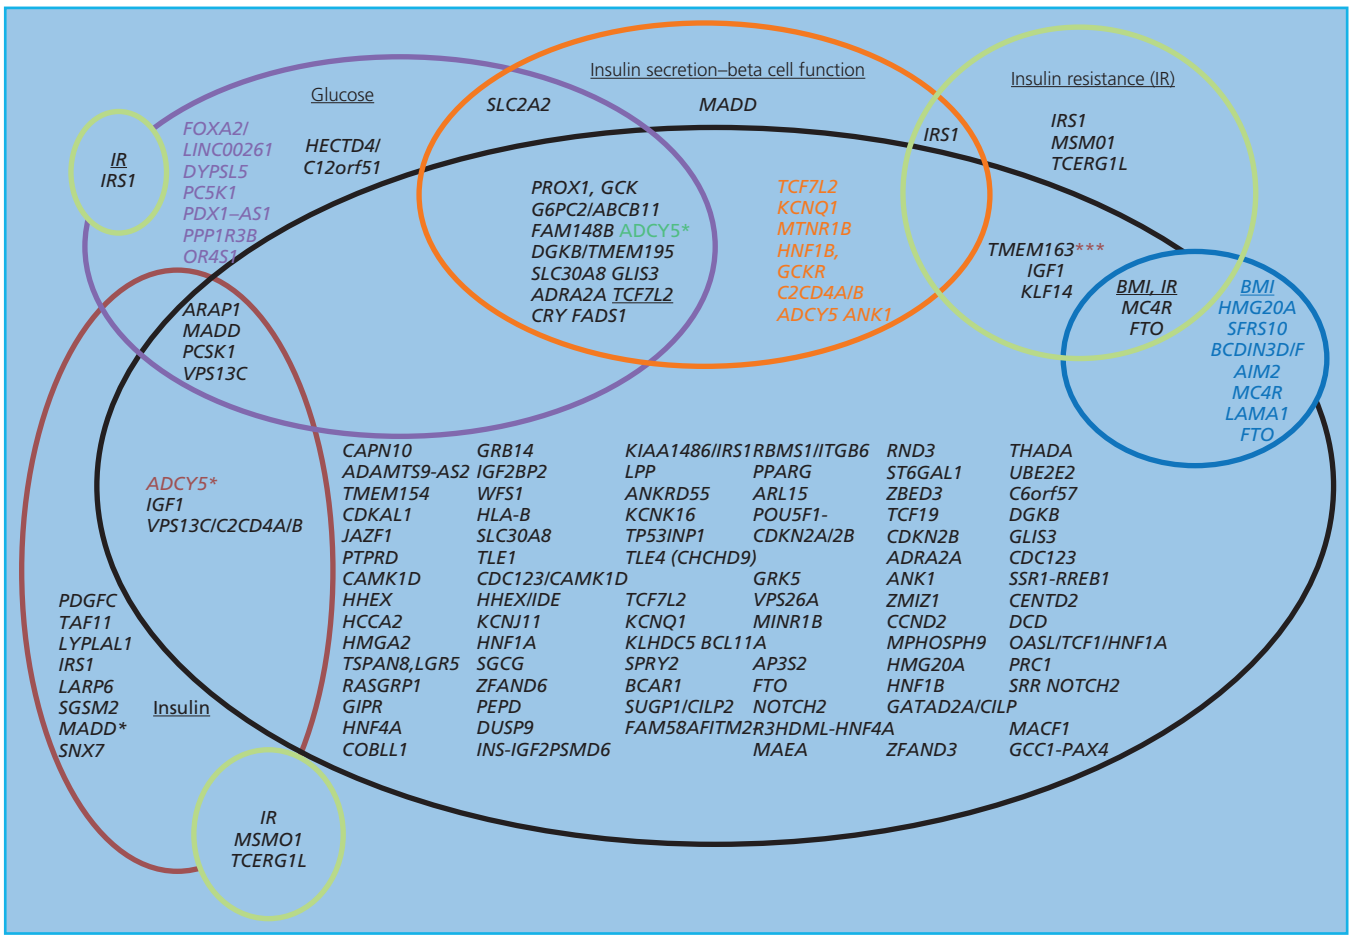

Figure 12.3 T2DM and glycemic trait-associated variants. The variants are represented by gene names here, which could indicate that the location is present either in the gene or in the vicinity of the gene. The white circle represents T2DM and the gene names in black in that circle represent variants only associated with T2DM. The overlapping circles indicate additional reporting associations for that variant. Figure 12.4 Associations between the genotypes of rs7903146 polymorphism in the *TCF7L2* gene with insulin secretion during a hyperglycemic clamp in 73 participants. Black lines, CC; red lines, CT and TT. AIR, acute insulin response. Arrow, administration of 5 g of arginine. The *p* values show the differences for the first- and second-phases of glucose-induced insulin secretion, first- and second-phases of GLP-1-induced insulin secretion, and acute insulin secretory response to arginine (AIR). Source: Schäfer et al. 2007 [31]. Reproduced with permission of Springer.

Other gene variants that have been associated with impaired insulin action include the G/G variants of calpain-10 gene (*CAPN10*) and *KCNJ11*. The G/G variant of SNP-43 of *CAPN10* was found to be associated with impaired insulin response to glucose in people without diabetes [34]. Variants of the *KCNJ11* gene may result in gain of function of the ATP-sensitive potassium channels, resulting in impaired depolarization of the β-cell membrane and altered insulin release, although such an effect becomes more apparent when the β cell is under stress conditions (i.e. glucotoxicity) [35].

Many other genes, including *HHEXZ/IDE*, *GIPR*, *PROX1*, *DGKB*, *CDKAL1*, *SLC30A8*, *CGK*, and *CDKN2A/2B*, have been associated with abnormalities of insulin secretion [36, 37]. Of interest, of the many gene variants so far associated with T2DM, the great majority seem to exert their main effect on insulin secretion, with only a minor proportion of genes being associated with insulin resistance [38]. However, some of the latter may also have an effect on the β cells as well. For instance, pancreatic islets carrying the $Gly^{972} \rightarrow Arg$ amino acid polymorphism of the insulin receptor substrate 1 (IRS-1) gene have impaired β-cell turnover [39] and reduced insulin secretion in response to glucose [40]. Similar findings have been reported for the ectonucleotide pyrophosphatase phosphodiesterase 1 (*ENPP1*) [41] and the *TRIB3* [42] genes. These observations not only support a genetic background associated with a "weaker" and more "vulnerable" β-cell phenotype but also point to a more complex picture where insulin secretion and insulin action might, to some extent, be dependent on a common genetic background.

In spite of the identification of many genes associated with impaired β-cell function and survival, they account for only a minority of the disease risk, suggesting that other mechanisms might be involved in the disease predisposition. Gene expression can be modified in the absence of alterations in the nucleotide sequence as occur with epigenetic DNA methylation and histone modifications triggered by nutritional, hormonal, and metabolic environments [43]. Impaired intrauterine environment and impaired fetal growth (small babies at birth) are associated with altered insulin secretion and/or reduced β-cell mass and increased risk of development of diabetes later in life [44]. Under these conditions, epigenetic modifications of key β-cell genes have been reported [45, 46]. Some evidence suggests that metabolic imprinting of offspring exposed to maternal undernutrition can be trans-generational, i.e. can be transmitted to offspring, generating a predisposition towards diabetes [47].

Overall, these observations suggest the existence, in predisposed individuals, of a genetic background that appears to be mainly associated with potential defects in β-cell function. In these individuals, insulin secretion, if properly assessed, can be expected to be impaired long before overt development of diagnostic hyperglycemia.

Abnormalities of β-cell function precede overt diabetes

A predisposing genetic background is the most likely explanation for the evidence provided by multiple studies that β-cell function is altered well before the onset of overt T2DM [48, 49]. For instance, abnormalities of β-cell function have been described in normoglycemic first-degree relatives of people with T2DM [50, 51]. These early alterations in insulin secretion are more qualitative than quantitative in nature. The plasma insulin concentration after an oral glucose load in predisposed individuals may not differ from those obtained in people with no such predisposition. Nonetheless, in white European people at risk for T2DM, β-cell response to oral glucose, adjusted for prevalent plasma glucose levels and insulin sensitivity, declines as a function of glucose tolerance [52]. Of interest, β-cell function worsens significantly with an increase in the 2-h plasma glucose level even in people with normal glucose tolerance (i.e. 2-h plasma glucose <140 mg/dL) [52, 53]. In both lean and obese individuals with 2-h plasma glucose levels of 120–140 mg/dL, β-cell function is already reduced by 60% compared with those with a 2-h plasma glucose level of <100 mg/dL (Figure 12.5) [53]. The abnormalities of β-cell function become fully apparent when the insulin secretion rate is plotted against prevalent plasma glucose levels [53, 54]. This analysis clearly shows how the β cells of people with a predisposition to diabetes secrete much less insulin than healthy individuals for

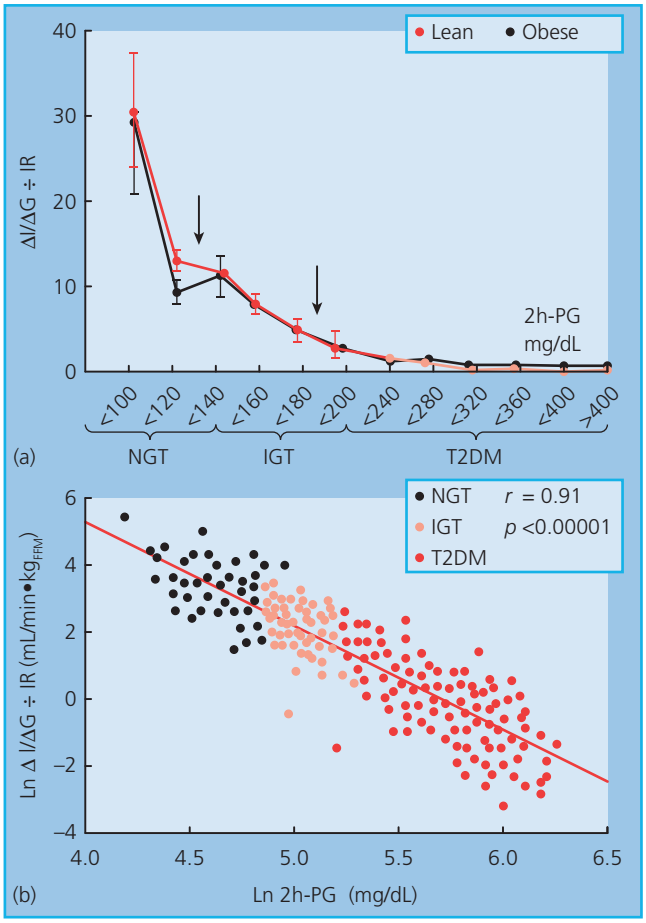

Figure 12.5 Relationship between the insulin secretion/insulin resistance index (ΔI/ΔG factored by the severity of insulin resistance measured with the euglycemic insulin clamp) and (a) the fasting plasma glucose (FPG) and (b) the 2-h plasma glucose (2-h PG) concentration (log–log scale). Source: Gastaldelli et al. 2004 [53], Figure 4. Reproduced with permission of Springer.

the same glucose stimulus [54]. This abnormality is often referred to as impaired glucose sensitivity [55] and it is better defined when mathematical modeling approaches are applied [56].

Loss of first-phase insulin secretion is a very early feature of β-cell dysfunction. Individuals with isolated impaired fasting glucose (IFG) show a decrease in first-phase insulin secretory response to intravenous glucose and early-phase insulin response to oral glucose [57]. The late-phase insulin response after an oral glucose tolerance test (OGTT) is less severely impaired than in people with impaired glucose tolerance (IGT) who have severe defects in both early- and late-phase insulin responses. First-phase insulin secretion plays an important role in priming the liver to inhibit endogenous glucose production in response to glucose or nutrient ingestion [58, 59]. Therefore, the defect in early-phase insulin secretion in IFG and IGT results in inadequate suppression of hepatic glucose production and contributes to an excessive early rise in plasma glucose in response to an oral glucose load. In people with IGT, the combination of deficient second-phase (late-phase during OGTT) insulin secretion and peripheral insulin resistance translates into less efficient glucose disposal. As a result, after the ingestion of a glucose load, the plasma glucose concentration will continue to increase after the initial 60 min to remain elevated at 120 min. The loss of first-phase insulin not only contributes to impaired hepatic glucose metabolism [60] but also is an independent predictor of development of T2DM [61, 62].

In summary, the natural course of β-cell function suggests that the acute insulin response and glucose sensitivity play a major role in determining glucose tolerance [63]. Longitudinal studies of Pima Indians relating changes in insulin sensitivity and acute insulin response have clearly demonstrated that it is the worsening of the latter rather than the development of insulin resistance that marks the progression from normal glucose tolerance to IGT and, eventually, T2DM [64].

The extent to which these functional abnormalities are also linked to loss of β-cell mass is still a matter of discussion [65]. Assessment of β-cell mass is largely dependent on methodological approaches [66], but several reports claim that an apparent reduction in β-cell volume of up to 60% is present in individuals with prediabetes [18, 67, 68]. The decrease in β-cell mass is the result of a greater rate of apoptosis [18, 19, 66, 69, 70] and, to a lesser extent, autophagy [71]. An increase in β-cell death occurs without a compensatory increase in β-cell replication owing, at least in part, to the limited regenerative capacity of adult human β cells [72, 73]. It has been suggested that β-cell dedifferentiation, rather than cell death, may account for the loss of β cells in the pancreatic islet of an individual with diabetes [74, 75].

Insulin secretion progressively worsens after development of T2DM

Impaired insulin secretion and insulin secretory capacity are the major determinant in the development of T2DM. Neither hyperglycemia nor glucose intolerance develop in insulin-resistant individuals provided that sufficient insulin is secreted from β cells to compensate for the insulin resistance, which is the other characteristic pathogenic condition underlying the loss of glucose homeostasis. The β-cell dysfunction progresses over time and is well established by the time the plasma glucose level achieves the diabetic range and continues to worsen after diabetes has developed [24]. Multiple factors contribute to the progressive loss of β-cell function and β-cell mass, the most important being the direct consequences of an altered metabolic milieu characterizing T2DM.

Hyperglycemia

A large number of *in vivo* and *in vitro* studies have shown that elevation of glucose concentrations impairs β-cell function (and insulin action), a phenomenon known as "glucotoxicity." Conversely, improvement in glycemic control both under experimental conditions and in clinical studies has always been associated with improvement in β-cell function [76]. The

main mechanisms accounting for the negative effect of high glucose levels is activation of oxidative stress, the consequence of increased glucose oxidation in the mitochondria, mitochondrial dysfunction, and overproduction of reactive oxygen species (ROS) [77]. In T2DM, pancreatic islet markers of oxidative stress are significantly increased [77] compared with non-diabetic islets and inversely related to glucose-stimulated insulin secretion. In contrast, overexpression of antioxidant factors reduces the level of markers of oxidative stress and increases the β-cell response to insulin [77, 78]. The β cell is particularly susceptible to the negative effect of oxidative stress owing to an intrinsic low expression of antioxidant enzymes and reduced DNA repair capacity [79].

Increased glucose availability is also associated with activation of the glycolytic pathway in β cells and with excessive formation of fructose-6-phosphate with subsequent increased flux through the hexosamine pathway. *In vitro* studies have clearly shown how the activation of the hexosamine pathway interferes with the expression of genes involved in β-cell regeneration and differentiation [80] and triggers apoptosis [81].

Therefore, chronic exposure to hyperglycemia can affect both β-cell function and β-cell mass, although such an effect is likely to be more prominent when exerted on a predisposed β-cell, since in healthy individuals, 72 h of hyperglycemia does not impair β-cell function [82].

Hyperlipidemia

Obesity is a common condition in people with T2DM and it is considered one of the main causes of the progressive increase in the global prevalence of the disease [83]. Obesity, and concomitant insulin resistance, are often associated with dyslipidemia, increased circulating leptin concentrations, and chronic inflammation [84].

Leptin receptors are present in β cells, and their activation directly inhibits insulin secretion [85]. Moreover, leptin inhibits insulin gene expression and affects proliferation, apoptosis, and β-cell size [85]. Expansion of adipose tissue is associated with increased cytokine release [86]. TNF-α and interleukin-6 (IL-6) have been shown to affect both β-cell function and survival [87]. Moreover, apoptosis can stimulate the innate immune system with mobilization of T cells and macrophages [88]. Of interest, under stress conditions, such those generated by excessive stimulation by glucose and FFAs, the concentrations of proinflammatory factors are increased in the pancreatic islets [89, 90] where they can trigger Fas-dependent apoptosis through activation of nuclear factor kB (NFkB). Plasma FFA concentrations are commonly increased in persons with T2DM and they contribute to sustaining insulin resistance [91] as well as impaired β-cell function [92], a phenomenon also known as lipotoxicity. The effects of FFAs on β-cell function are complex as they also are physiological modulators of insulin secretion. Hence, under fasting conditions, an increase in plasma FFAs becomes essential for the maintenance of basal insulin levels and to ensure a normal insulin response to glucose [93]. Nonetheless, the toxic effect of FFAs can be easily demonstrated *in vitro*; even a short exposure of human pancreatic islets to an excessive FFA concentration is sufficient to impair glucose-stimulated insulin release [94]. High levels of FFAs can contribute to β-cell dysfunction through intracellular accumulation of triglycerides as a response to the activation of the sterol regulatory element binding proteins (SREBPs) [95], or by increased expression of uncoupling protein 2 (UCP-2), which regulates cellular ATP production [96]. The impact on β-cell function is paralleled by a cytostatic effect due to activation of caspase-mediated apoptosis [97]. FFAs also induce the expression of nitric oxide (NO) synthase, causing marked overproduction of NO. Of interest when NO production is limited by the use of inhibitors of inducible NO synthase, insulin secretion is significantly ameliorated [98]. NO also contributes to apoptosis through the activation of c-Jun N-terminal kinase (JNK), p38 mitogen-activated protein kinase (MAPK), and Akt inhibition [99].

In summary, similar to chronic hyperglycemia, lipotoxicity can accelerate the progressive loss of β-cell function and β-cell mass. However, such an effect seems to be more apparent when the two conditions coexist, as commonly occurs in individuals with T2DM. For this reason, it may be more appropriate to refer to the combination of these effects as "glucolipotoxicity" [100]. The adverse metabolic milieu may also affect gene expression through epigenetic mechanisms. For instance, increased methylation of the PGC1-α gene promoter has been reported in pancreatic islets from cadaveric donors with T2DM; the greater the degree of methylation, the lower is the expression of the protein and the lower the glucose-stimulated insulin release [101].

Chronic β-cell stimulation

Chronic hyperglycemia is associated with persistent β-cell stimulation and insulin biosynthesis. This process requires the activation of the endoplasmic reticulum (ER), which is responsible for the biosynthesis and folding of newly synthesized insulin [102]. Because of glucolipotoxicity, the ER folding capacity is impaired, causing accumulation and aggregation of unfolded proteins, a condition known as ER stress [103]. Up to a certain point, ER stress can be compensated via the so-called "unfolded protein response." This adaptive and protective pathway, however, can become ineffective if ER stress is persistent and may lead to the generation of proapoptotic signals. A number of studies have documented ER stress in *ex vivo* pancreatic islets of cadaveric donors with T2DM [104, 105]. In these islets, ER stress is marginally increased if they are incubated in the presence of normal glucose concentration. In contrast, exposure to higher glucose levels causes more ER stress than in islets from cadaveric donors without diabetes (Figure 12.6) [105]. These findings suggest a greater susceptibility to proapoptotic mechanisms in the diabetic β cell. In summary, increased and persistent insulin secretion can contribute to β-cell dysfunction and survival through insulin protein misfolding in the ER.

Chronic stimulation of β cells also results in an increase in the synthesis of islet amyloid polypeptide (IAPP). This peptide is

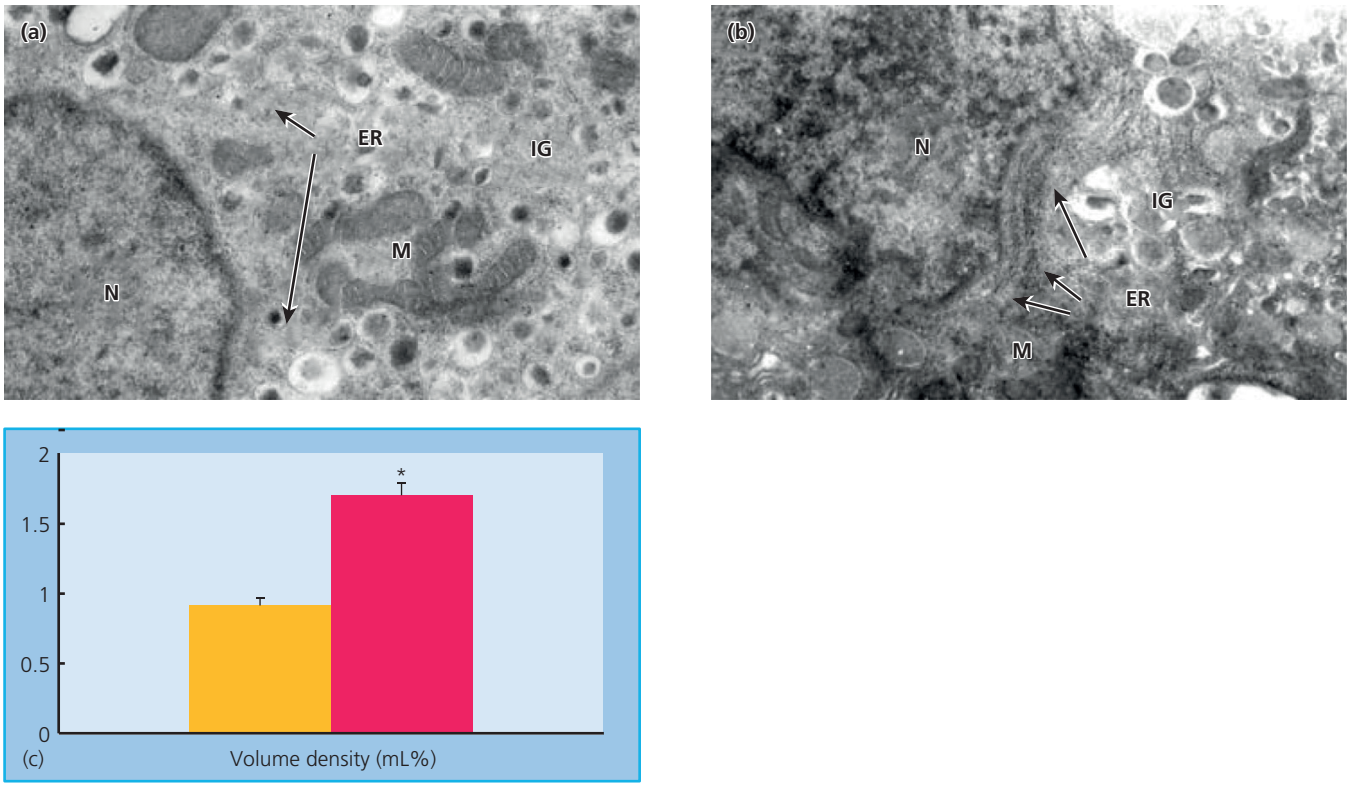

Figure 12.6 (a, b) Electron microscopy images showing the ER in (a) non-diabetic β cells and (b) T2DM β cells. The ER components (arrows) are scarcely visible in non-diabetic cells and more apparent in T2DM cells. Magnification ×10,000. IG, insulin granules; M, mitochondria; N, nucleus. (c) The ER density volume was significantly higher inT2DM β cells (red box) than non-diabetic β cells (yellow box). *p <0.05 (Student's t-test for unpaired data). Source: Marchetti et al. 2007 [105], Figure 3. Reproduced with permission of Springer.

co-localized with insulin secretory granules [106] and its production parallels that of proinsulin. IAPP can form aggregates and fibrils [107], leading to deposition of amyloid plaque that triggers an inflammatory response [108], recruitment of macrophages [109], and apoptosis [110]. The mechanism through which IAPP forms amyloid and results in β-cell damage is not completely understood. Amyloid deposition has been found in other hypersecretory conditions, such as non-diabetic obesity [111] and insulinoma [112], with no apparent negative impact on β-cell function. One possible explanation for this paradox is that the negative effect of amyloid may require concomitant glucolipotoxicity. In line with this hypothesis is the observation that pancreatic islet amyloid can be found in up to 90% of people with T2DM [113] and the degree of deposition correlates with the duration and severity of the disease [114].

Impaired incretin effect

GLP-1 and GIP are physiological factors involved in β-cell function and survival [115] and they are the main players in the incretin effect [12]. This effect is characteristically lost in T2DM, although it is still a matter of discussion whether this alteration is a primary defect or an acquired one [116]. In both cases, the loss of the incretin effect results in poor potentiation of the insulin release in response to the ingestion of a meal and excessive postprandial glucose excursion [117]. Whether this defect can also contribute to loss of β-cell mass in unclear, at least in humans, and preclinical studies have provided evidence for an effect of GLP-1 in reducing apoptosis and stimulating β-cell regeneration and differentiation in experimental murine models [118].

GLP-1 is mainly secreted by the L cells of the lower intestine. However, more recent data have provided evidence that GLP-1 can be synthesized by the α cells of the pancreatic islet [119, 120]. These cells also express dipeptidyl peptidase 4 (DPP-4), the peptidase responsible for GLP-1 inactivation [121]. GLP-1 production has been found to be increased [120] in pancreatic islets from cadaveric donors with T2DM, whereas DPP-4 activity is reduced [121]. The extent to which these mechanisms may ensure an *in vivo* increase in local GLP-1 levels is difficult to ascertain, but the increase in intra-islet GLP-1 availability could be seen as an attempt to protect the β cells [122].

Antihyperglycemic treatment

Improved glycemic control can relieve glucotoxicity and restore, to some extent, β-cell function [76]. However, there is some discussion on the potential direct effects that the currently available glucose-lowering agents may exert on the preservation of β cells. Potential protective effects have been claimed with the use of DPP-4 inhibitors [123, 124], GLP-1 receptor agonists [125, 126],

and pioglitazone [127]. Incubation of pancreatic islets of individuals with T2DM in the presence of therapeutic concentrations of metformin has been found to increase insulin content, to increase the number and density of mature insulin granules, to improve glucose-induced insulin release, and to reduce apoptosis along with normalization of several markers of oxidative stress [128]. In *ex vivo* studies, concern has been expressed with respect to the effects of sulfonylureas on the β cell. *In vitro* experiments have shown increased β-cell apoptosis [128], although some difference may exist among different sulfonylureas. In isolated human pancreatic islets, glibenclamide but not repaglinide was found to activate β-cell apoptosis [129]. Other observations have indicated a reduced insulin content in pancreatic islets incubated in the presence of glimepiride, glibenclamide, and chlorpropamide, although no change in insulin release in response to glucose was observed with glimepiride [130]. In cultured β-cell lines, no activation of apoptosis was found with gliclazide treatment along with some antioxidant effect noted in human pancreatic islets [131].

The real impact of these findings is still unclear. In the clinical setting, the durability of the glucose-lowering efficacy of sulfonylureas is claimed to be poorer than with other antihyperglycemic agents [132]. These findings may appear to be in agreement with animal studies showing that chronic glibenclamide treatment causes loss of insulin secretory capacity due to β-cell hyperexcitability [133]. However, the same studies also revealed rapid reversibility of this secretory failure, arguing against β-cell apoptosis or other cell death induced by sulfonylureas. In contrast, these findings support earlier observations showing *in vivo* restoration of β-cell response to sulfonylureas, once sustained therapy with sulfonylureas was discontinued [134].

In summary, upon development of overt hyperglycemia, a number of factors, including chronic hyperglycemia, obesity, increased FFA availability, persistent stimulation of β cells, and, potentially, the use of specific drugs, may contribute to the acceleration of the decline in insulin secretory capacity of individuals with T2DM and progression of the disease. These accelerating factors promote common damage mechanisms, including oxidative stress, ER stress, inflammation, and immune system activation (Figure 12.7) [135]. Because of these mechanisms, a vicious cycle develops by which the ability of the β cells to cope with hyperglycemia and insulin resistance becomes weaker and the impact of the accelerating factors becomes greater. These factors impair both the function and the survival of the β cells, although the relative contribution of the two remains to be established.

β-Cell dysfunction: exhaustion or insufficient mass?

At the time of diagnosis of T2DM, the β-cell mass is already reduced by 30–40% [18, 67–69]. However, the decreased number of cells is unlikely to account for the distinctive defect in insulin secretion that characterizes T2DM even before the time of diagnosis. Experimental data have shown that, at least in rodents, no disturbances in glucose homeostasis arise provided that the β-cell mass remains >20% [136]. In humans, diabetes has been shown to develop when the β-cell area declines by ~65% [137]. The suggestion that the reduction in β-cell mass may not be sufficient per se to result in glucose intolerance is supported by the simple observation that a large overlap exists between the β-cell mass of individuals with and without diabetes [138] (Figure 12.8). Moreover, hemi-pancreatectomy performed in normal individuals for the purpose of pancreas donation is not followed

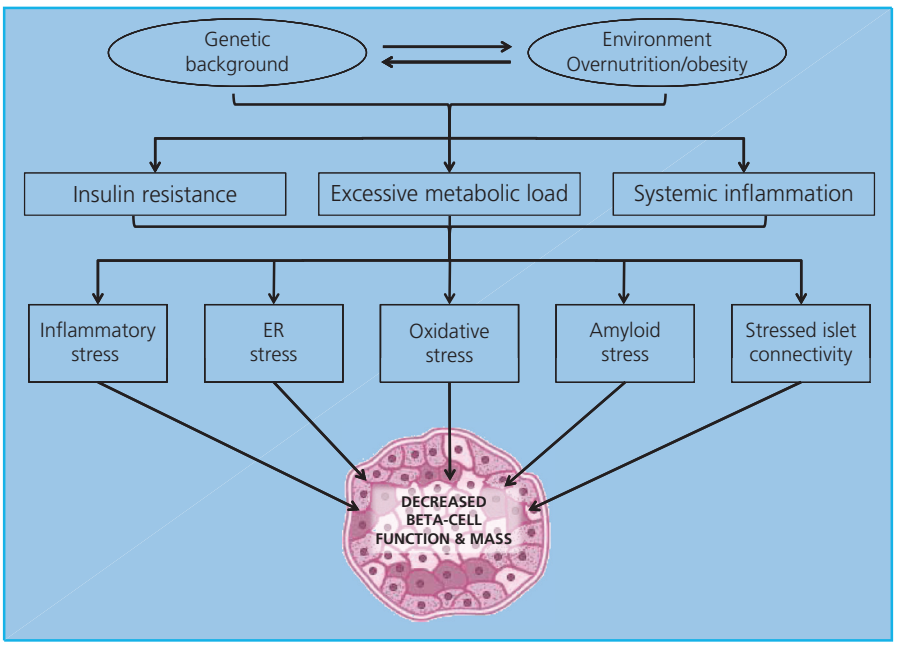

Figure 12.7 Mechanisms of β-cell damage in T2DM. Environmental factors and genetic backgrounds interact to activate stress processes that contribute to functional abnormalities and also progressive loss/dedifferentiation of β cells. Source: Adapted from Halban et al. 2014 [135].

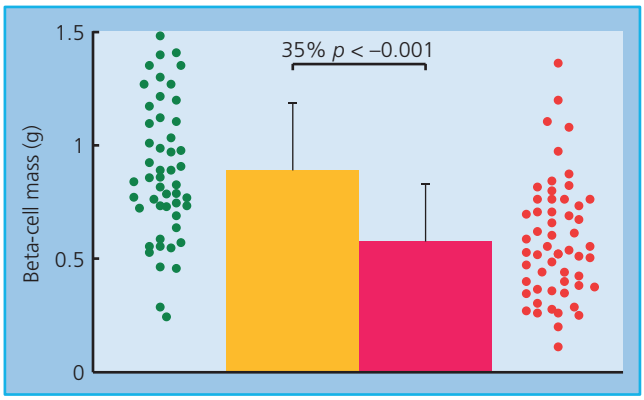

Figure 12.8 β-Cell mass in the pancreas of people without (left) and with T2DM (right). Data are presented for individual values as scatterplots and mean values ± SD as columns. Although on average the β-cell mass is about 40% less in people with T2DM, there is some degree of overlap between the two groups. Source: Rahier et al. 2008 [138], Figure 2B. Reproduced with permission of John Wiley & Sons.

by major disturbances in insulin secretion [139]. The β-cell mass may also be a misleading measurement as one may argue whether it is the number of β cells (or cell area) or the insulin content per cell (and therefore the total insulin content in the pancreas) that is of importance. Relevant to this issue is the finding that the β-cell mass declines with the duration of the disease, although the insulin content per cell tends to increase [138]. The progressive loss of β cells in diabetes is likely to be the consequence of even a mild elevation of plasma glucose levels and concomitant increased secretory demand sustained by insulin resistance, particularly if these mechanisms operate on a genetically predisposed β cell. Consistent with this view are animal experiments showing how a 60% pancreatectomy in dogs does not result in an alteration of insulin secretion unless the plasma glucose levels are modestly increased by intravenous glucose infusion [140]. These results are also in keeping with the few available human studies. In healthy people with no family history of diabetes, a 72-h glucose infusion resulting in constant elevation of post-absorptive plasma glucose levels just above 110 mg/dL was associated with a potentiation of both first- and second-phase insulin secretion rather than an impairment [82]. In contrast, when normo-tolerant first-degree relatives of individuals with T2DM were infused with fat emulsions to increase circulating FFA levels, a marked impairment of insulin secretion became apparent [141] (Figure 12.9).

Such a rapid worsening of insulin secretion is unlikely to be due to a sudden reduction in the number of β cells; rather, this is much more congruent with a further impairment of the mechanisms responsible for glucose sensing and insulin response. Finally, the results of bariatric surgery in people with diabetes provide stronger support to the primacy of impaired β-cell function rather than loss of β cells. Even in individuals with T2DM with long-standing duration of the disease, the surgical procedure is followed by an almost immediate improvement of β-cell function associated with simplification, if not withdrawal, of pharmacological glucose-lowering therapy [142–144]. β-Cell dysfunction may also be the result of the loss of islet organization. As mentioned, insulin secretion is pulsatile in nature, with a slow ultradian periodicity (<140 min) and a high-frequency periodicity [145]. These oscillations requires a sophisticated coordination of the secretory activity of the individual β cells dispersed through the ~1 million pancreatic islets present across the pancreatic tissue. Such connectivity recognizes a number of mechanisms operating in concert, including neural circuits, gap junctions, activity of primary cilia, and paracrine signaling [146]. Recently it has been suggested that lipotoxicity may disrupt the incretin effect on this connectivity [147], possibly through downregulation of connexin 36, a component of gap junctions [148].

In conclusion, the available evidence indicates that abnormalities of insulin secretion in T2DM are accounted for by β-cell dysfunction to a greater extent than can be account for by defects in β-cell mass. Alternatively, one can hypothesize an effect on β-cell differentiation and more efficient stocking and maturation of insulin granules. This view fits with the recent observation that β-cell dedifferentiation rather than β-cell death contributes to the reduction in β-cell mass [149, 150] and degranulation [151]. Further, experimental animal data suggest that insulin granules

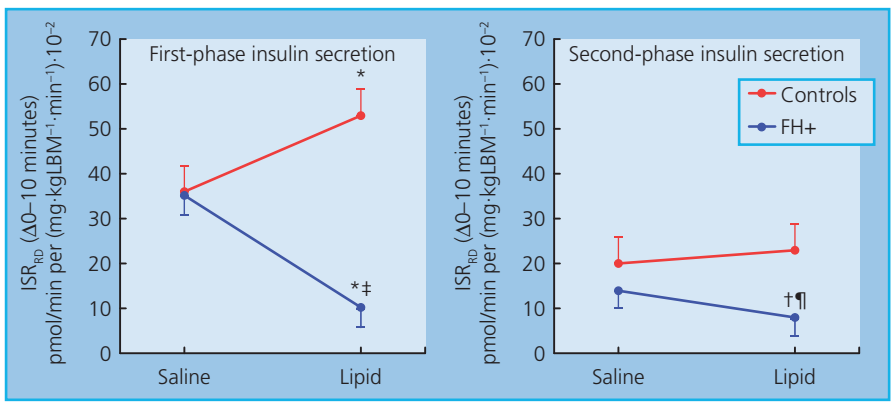

Figure 12.9 Insulin secretion rates (ISRs) during the hyperglycemic clamp studies related to the prevailing severity of insulin resistance (ISR_{Rd}). On comparing control participants with healthy participants with a strong family history of T2DM (FH+), the first-phase ISR_{Rd} is similar during the saline studies; with lipid infusion, the first-phase ISR_{Rd} deteriorates in FH+ participants, whereas it increases in control participants. The second-phase ISR_{Rd} is also reduced by lipid infusion in the FH+ group but is unchanged in healthy control. *p <0.01 vs. saline; †p <0.05 vs. saline; ‡p <0.001 vs. control participants; ¶p <0.05 vs. control participants. Source: Adapted from Kashyap et al. 2003 [141].

can be restored through a decrease in blood glucose [152] and insulin secretion recovered even in islets from individuals with T2DM [1198,153].

Conclusion

β-Cell dysfunction is an early feature in the natural course of T2DM and plays a critical role in the development of glucose intolerance and progression of the disease. This distinctive alteration recognizes a genetic background, with a number of genetic variants specifically associated with impaired β-cell function and survival. In people predisposed to diabetes and in those with prediabetes, both a reduction in β-cell mass and, to a greater extent, impaired insulin secretion are fully apparent. A minimal increase in fasting plasma glucose levels is already accompanied by a typical loss of first-phase insulin secretion. Obesity, development of hyperglycemia and dyslipidemia (in particular increased plasma FFA concentrations), and chronic overstimulation of insulin secretion can activate pathogenic mechanisms (glucolipotoxicity, oxidative stress, inflammation, ER stress, epigenetic modifications, amyloid deposition) that can accelerate the progression of β-cell impairment. The same mechanisms activate apoptosis and, to some extent, autophagy, which in the face of a lack of a compensatory increase in β-cell regeneration/differentiation can result in a decrease in β-cell mass. Based on this view, preservation of β-cell function is key to preventing deterioration of glucose tolerance and development of diabetes. Moreover, tight control of the accelerating factors may slow the progression of the disease and result in more durable glycemic control over the years.

Keypoints

- Insulin resistance is a major factor in the pathogenesis of type 2 diabetes, but it is also observed in type 1 diabetes.
- Impaired insulin-stimulated muscle glycogen synthesis, due to defects in glucose transport, is the major factor contributing to whole-body insulin resistance.
- Ectopic fat storage leads to increases in intracellular diacylglycerol and activates novel protein kinase isoforms (PKCθ in muscle and PKCε in liver), which inhibits insulin signaling at the level of the insulin receptor kinase.
- Reduced mitochondrial function is a predisposing factor for ectopic lipid deposition and insulin resistance.
- Macrophage-induced lipolysis promotes increased hepatic gluconeogenesis, hepatic insulin resistance, and fasting hyperglycemia in poorly controlled diabetes by increasing hepatic acetyl-CoA content which in turn activates pyruvate carboxylase activity and increased glycerol conversion to glucose.

Definition and measurement of insulin resistance in humans

The sensitivity to insulin results from its biological effects in the insulin-responsive tissues, predominantly skeletal muscle, liver, and adipose tissue. Impaired insulin sensitivity, also termed insulin resistance, is generally defined as reduced glucose clearance in skeletal muscle, impaired suppression of glucose production by the liver, and decreased rates of lipolysis in adipose tissue or by decreased combined action on whole-body glucose disposal (Figure 13.1).

In 1936, Himsworth [1] provided the first protocol for standardized *in vivo* determination of insulin sensitivity from the glycemic response upon intravenous insulin application. Decades later, the hyperinsulinemic–euglycemic clamp test [2–4] became the gold standard for measuring whole-body insulin sensitivity *in vivo* and for identifying insulin-resistant persons [5, 6]. This steady-state method relies on constant insulin and glucose concentrations, which disrupt the physiological feedback loop between blood glucose concentrations and insulin secretion. The glucose infusion rates required to maintain a defined level of glycemia will then reflect whole-body insulin sensitivity, given as the *M* value [3]. Combined with other techniques, including indirect calorimetry, isotopic tracer dilution, and nuclear magnetic resonance (NMR) spectroscopy of muscle, liver, and brain, the clamp allows the assessment of oxidative and non-oxidative glucose metabolism, systemic, and even tissue-specific fluxes of glucose and other metabolites under *in vivo* conditions (Figure 13.1). In contrast to the steady-state clamp test, other techniques such as the intravenous [7] or oral [8] glucose tolerance tests [5, 6] describe parameters of insulin action such as the S_i or OGIS (oral glucose insulin sensitivity) values from modeling of the dynamic changes of plasma glucose and insulin concentrations over time. These tests can also provide measures of insulin secretion and kinetics during the same experiment.

As these techniques are time consuming and laborious and require experienced personnel, simpler tests have been developed for assessing insulin sensitivity in epidemiological studies. The most common indices, the homeostasis model assessment (HOMA-R, HOMA-S) [9] and the QUICKI [10], are calculated from fasting plasma glucose and insulin or C-peptide concentrations [11]. The general limitation of this approach

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

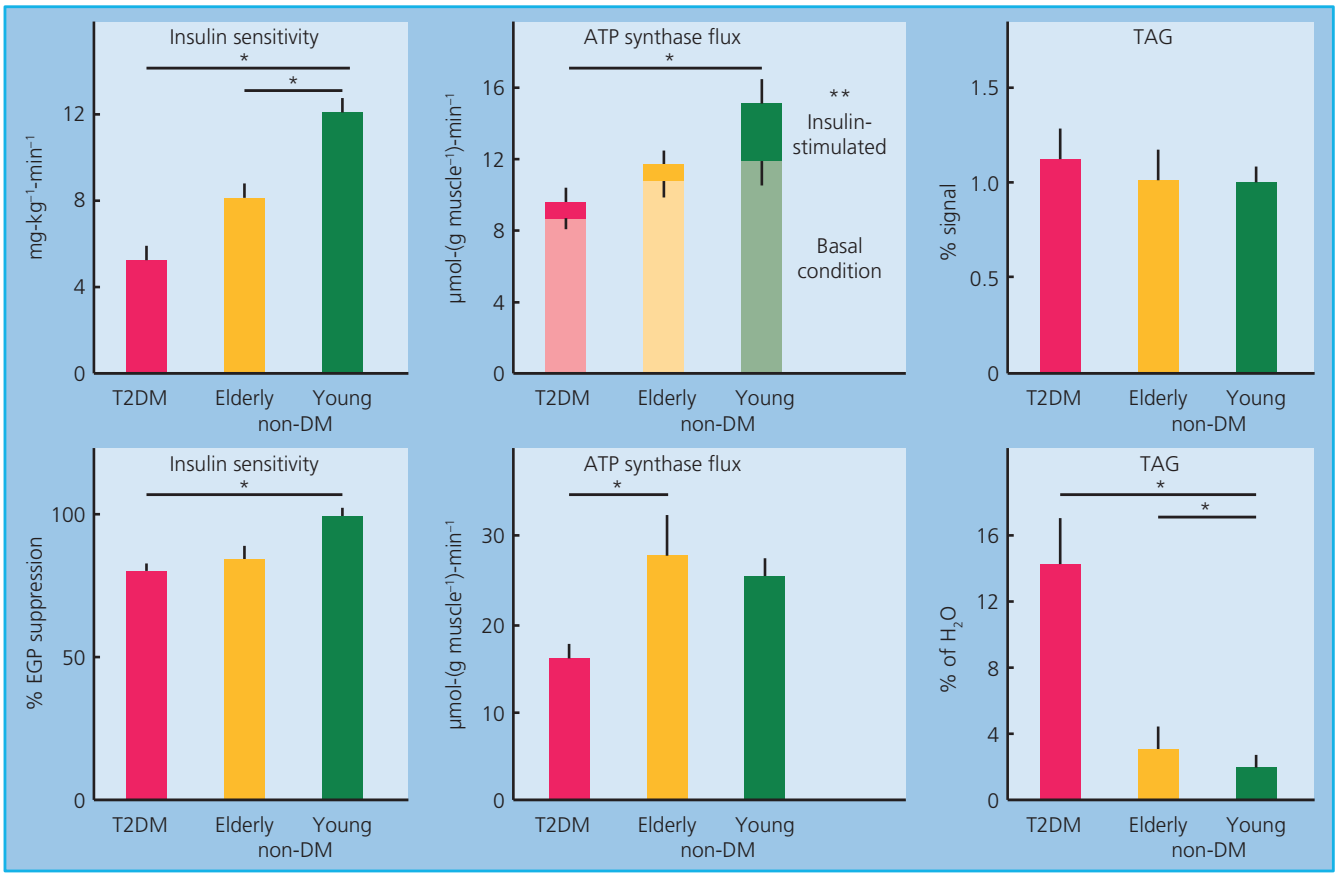

Figure 13.1 Basal and insulin-stimulated muscle and liver metabolism. In skeletal muscle (top left), insulin-stimulated glucose disposal is reduced in insulin-resistant non-obese elderly individuals and in those with type 2 diabetes mellitus (T2DM) compared with insulin-sensitive, lean, young individuals without diabetes. Both basal and insulin-stimulated ATP synthase flux show similar patterns (top middle), whereas intracellular triacylglycerols (TAGs) are frequently higher in insulin resistant persons (top right). In the liver, insulin-mediated suppression of glucose production is reduced in the insulin-resistant individuals (bottom left). ATP synthase flux is also lower only in persons with T2DM (bottom middle), whereas intracellular TAGs are markedly increased (bottom right). Source: data from Schmid et al. 2011 [138] and Szendroedi et al. 2007 [58] and 2009 [138].

results from the fact that the liver is responsible for providing fasting plasma glucose [12]. Under these conditions, glucose is utilized by 60% in non-insulin-dependent tissues, such as the brain, and to lesser extent in insulin-sensitive tissues, such as muscle and liver [13]. The insulin resistance indices obtained during fasting therefore do not correlate closely with clamp-derived glucose disposal [14, 15]. Finally, these indices are not valid for describing insulin sensitivity in states of overt diabetes, when the physiological relationship between circulating glucose and insulin is disrupted.

Insulin resistance as a risk factor for type 2 diabetes mellitus (T2DM)

Insulin resistance may occur independently of inadequate insulin secretion and be a prerequisite for incident T2DM [16–19]. The direct evidence for a time-dependent association between insulin sensitivity and deterioration of glucose tolerance preceding T2DM comes from comparison of population trajectories of fasting and post-glucose challenge plasma glucose concentrations with HOMA-S and insulin secretion (HOMA-B) in persons developing or remaining free of diabetes in the longitudinal Whitehall II study (Tabak et al., 2009) [20]. This study found that individuals had 29% lower HOMA-S but 13% greater HOMA-B values at 13 years before onset of diabetes. HOMA-S decreased linearly until 5 years before diagnosis and with an even steeper slope during the last 5 years prior to diagnosis. Thus, insulin resistance represents an early abnormality, which is compensated by augmented β-cell function for a long time before the insulin–glucose feedback loop fails. Insulin resistance not only predicts T2DM, but also correlates with cardiovascular disease and outcomes [21, 22].

The most important factors predicting T2DM are male sex, increasing age, overweight and obesity [23]. Insulin resistance is frequent in persons with the so-called metabolic syndrome, which, in addition to visceral obesity, comprises dyslipidemia, hypertension, and dysglycemia. Hyperuricemia, arteriosclerosis, microalbuminuria, platelet hyperaggregation and antifibrinolysis,

sleep apnea, and male hypogonadism have also been associated with this syndrome. The risk of T2DM is also markedly higher in first-degree relatives of individuals with T2DM and in women with a history of gestational diabetes mellitus (GDM) or polycystic ovary syndrome (PCOS), all of whom are mostly insulin resistant [14, 15, 24–27]. These associations raise the question of whether chronic insulin resistance represents an inherited or an acquired abnormality. Despite the fact that a family history of T2DM raises the risk of T2DM in the relatives, even the combination of all currently known genes associated with diabetes adds only little to the prediction of T2DM based on gender, age, and body mass index [23]. Interventions improving insulin resistance also markedly reduce the incidence of T2DM [28], which underscores the predominant role of lifestyle in the pathogenesis of insulin resistance.

As a result, several metabolic factors related to lifestyle associate or predict insulin resistance and T2DM. These factors are mainly related to lipid metabolism, such as plasma concentration of non-esterified or free fatty acids (FFAs) [29], serum triacylglyceride-to-serum high-density lipoprotein (TAG/HDL-C) [30, 31], and ectopic fat content in skeletal muscle (intramyocellular TAGs) [32–34] or in the liver (hepatocellular lipid content, HCL) [35, 36]. In addition, intake of red meat was among the best predictors of T2DM in a large epidemiological study [37] and plasma concentrations of amino acids also predict T2DM [38]. There is also evidence that altered secretion patterns of cytokines, mainly derived from adipose tissue, and elevation of circulating proinflammatory markers such as C-reactive protein may predict insulin resistance and T2DM [39, 40]. On the other hand, adiponectin is the only anti-inflammatory cytokine with lower circulating levels before the onset of T2DM [41], while concentrations of others such as interleukin-1 receptor antagonist (IL-1RA), transforming growth factor-β1 (TGF-β1) and growth differentiation factor-15 (GDF-15) are increased [42] and indicate the presence of a compensatory, but eventually futile, counter-regulation of proinflammatory stimuli. Although all metabolic and inflammation-related variables also circulate systemically and may cause effects in several tissues simultaneously, insulin resistance may sequentially affect certain insulin responsive tissues, such as skeletal muscle, liver, and adipose tissue.

Insulin resistance in skeletal muscle

^{13}C NMR spectroscopy permitted for the first time non-invasive, direct assessment of rates of insulin-stimulated muscle glycogen synthesis *in vivo*. Using this approach, it was found that muscle glycogen synthesis accounts for about 90% of insulin-stimulated whole-body glucose disposal and for virtually all of the non-oxidative glucose disposal in healthy insulin-sensitive humans [43]. Persons with T2DM exhibit a 60% reduction in insulin-stimulated muscle glycogen synthesis, which represent the main abnormality underlying their insulin resistance [43, 44]. Similarly, after ingestion of mixed meals, the increase in muscle glycogen synthesis was ~30% lower in persons with T2DM despite doubled serum insulin concentrations compared with insulin-sensitive individuals [45–47]. Applying combined ^{13}C/^{31}P NMR spectroscopy to measure directly the time course of intracellular concentrations of key metabolites in the pathway of muscle glycogen synthesis (intramyocellular glucose, glucose-6-phosphate [G-6-P] and glycogen) revealed diminished increases in G-6-P [48] and intramyocellular glucose concentrations [44] in skeletal muscle of T2DM during hyperinsulinemia (Figure 13.2). This indicates that an abnormality in insulin-stimulated glucose transport via glucose transporter 4 (GLUT-4) are the main abnormalities responsible for muscle insulin resistance in persons with T2DM and/or obesity and in insulin-resistant first-degree relatives of persons with T2DM [49]. Further studies to delineate the mechanism by which insulin resistance affects recruitment of GLUT-4 have indicated that upstream defects in the insulin signaling cascade are responsible for the impaired GLUT-4 translocation [50, 51].

It has been suggested previously that hyperglycemia may cause these abnormalities by a mechanism summarized as "glucose toxicity" [52, 53], which seems to be supported by similar impairments of insulin-stimulated glycogen synthesis and G-6-P increases in skeletal muscle in individuals with poorly controlled type 1 diabetes mellitus (T1DM) [54, 55]. However, since insulin-resistant but normoglycemic humans, such as lean relatives of obese or elderly persons with T2DM exhibit identical effects, mechanisms other than glucose toxicity have to explain the insulin resistance in the skeletal muscle of these groups [49, 56–58].

Most insulin-resistant but normoglycemic humans feature dyslipidemia with elevated very-low density lipoproteins (VLDLs), TAGs and/or FFAs, which also predict not only T2DM [29, 59–61] but also cardiovascular mortality [62]. Excess lipid storage in the form of obesity has long been associated with insulin resistance, but ^{1}H NMR studies provided evidence for an even stronger relationship between intramuscular [63] and intramyocellular TAG content and muscle insulin resistance than for body fat content [34, 63–65]. Intramyocellular TAG concentrations can be measured non-invasively by ^{1}H NMR spectroscopy and have also been termed ectopic lipid accumulation or metabolic obesity. The observation of augmented ectopic lipid deposition in insulin-resistant states infers that intracellular TAGs or lipid metabolites could mediate the effect of circulating lipids on insulin action (Figure 13.1a). From early preclinical studies, Randle explained the impaired glucose metabolism in T2DM by an interaction with FFAs, termed the "glucose–fatty acid cycle" [66]. This hypothesis postulated that FFA oxidation first raises the mitochondrial concentration ratio of acetyl-coenzyme A (acetyl-CoA)/CoA, which would inhibit the pyruvate dehydrogenase (PDH) complex. The subsequent rise in citrate would inhibit phosphofructokinase-1 and raise G-6-P, which would then inhibit hexokinase and finally increase intracellular glucose concentrations and reduce muscle glucose uptake. In contrast, short-term elevations of plasma TAGs and FFAs resulted in marked muscle insulin resistance but

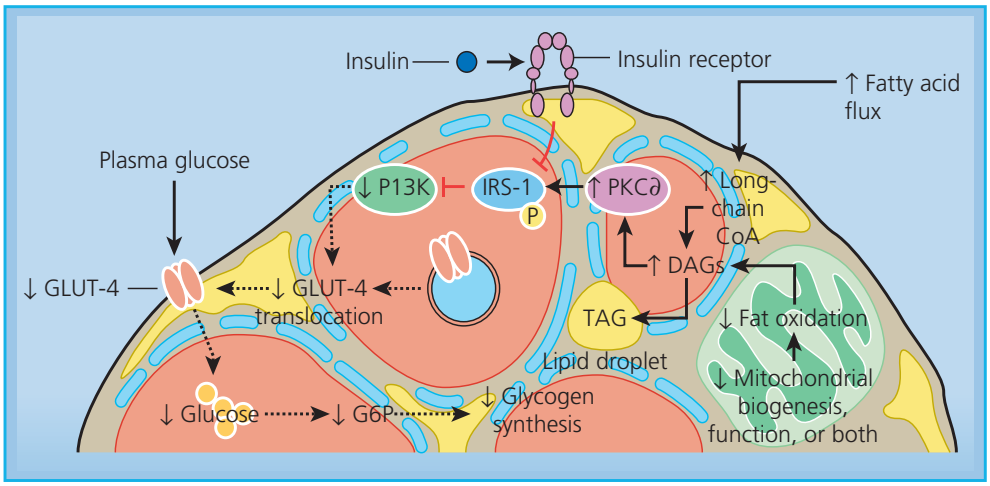

Figure 13.2 Cellular mechanism of insulin resistance in human skeletal muscle. Augmented lipid availability, mainly increased fatty acid flux, raises the intramyocellular pool of the long-chain fatty acyl (CoA) pool, which fuels mitochondrial oxidation or serves to synthesize diacylglycerols (DAGs) for storage as triglyceride (TAG) lipid droplets. When fatty acid delivery and uptake exceed the rates of mitochondrial long-chain fatty acyl-CoA oxidation and incorporation of DAGs into TAGs, the intramyocellular DAG content transiently or chronically increases. Specific, mainly C_{18}-containing, DAGs in the membrane and cytosol promote the activate novel protein kinase C (nPKC) isoforms. Translocation of the PKCθ isoform to the membrane leads to increased serine phosphorylation of insulin receptor substrate 1 (IRS-1) on critical sites (e.g. Ser 1101), which in turn blocks insulin-stimulated tyrosine phosphorylation of IRS-1 and the binding and activation of phosphatidylinositol 3-kinase (PI3K). This results in reduced recruitment of glucose transporter type 4 (GLUT-4) units to the membrane with impaired insulin-stimulated glucose uptake and phosphorylation to glucose-6-phosphate (G-6-P) and ultimately decreased insulin-stimulated glycogen synthesis. a blunted rise in intramyocellular glucose and G-6-P as measured using $^{13}C/^{31}P$ NMR spectroscopy during insulin stimulation in healthy humans. Lipid-induced muscle insulin resistance in humans thereby results from reduction of insulin-stimulated glucose transport into the muscle cells with subsequently impaired glucose phosphorylation and decreased insulin-stimulated glycogen synthesis [50, 67, 68] (Figure 13.2). Thus, lipids cause insulin resistance in humans via direct inhibition of glucose transport, but not via inhibition of the PDH complex [50, 69, 70]. Some studies [71, 72], but not others [73], suggest that lipid-induced insulin resistance may be more pronounced in men than in women, which would support the known greater diabetes risk for men.

Of note, intramyocellular TAGs are an even better predictor of insulin resistance in muscle and liver than circulating plasma FFAs [34]. Indeed, lipid-induced insulin resistance is reflected by impaired insulin signaling via reduction in tyrosine phosphorylation of insulin receptor substrate-1 (IRS-1) [50, 74], IRS-1-dependent phosphatidylinositol 3-kinase (PI3K) activation, and serine phosphorylation of Akt [75]. This could result from accumulation of intramyocellular long-chain fatty acyl-CoA (LCFA-CoA), diacylglycerols (DAGs), or ceramides [76] (Figure 13.2). Studies on transgenic and knockout animal models provide compelling evidence that FFA elevation increases intramyocellular LCFA-CoA, CoA, and DAGs, but not ceramide content, along with stimulation of TAG synthesis by DAG *O*-acyltransferase-1 (DGAT-1) and of novel protein kinase C (PKC) θ with subsequent serine phosphorylation of IRS-1 via the serine–threonine kinase cascade [77, 78]. However, studies employing other animal models showed that the ceramide pathway could also be involved in lipid-induced insulin resistance [79–81]. Several studies in humans reported conflicting results, likely due to differences in the design, cohorts, and analytical methods [72, 82, 83]. A recent study shed more light on the time course of events of lipid-induced insulin resistance by performing serial biopsies in humans during lipid infusion and comparing the results obtained from biopsies from insulin-resistant individuals with obesity or T2DM [73]. Lipid infusion resulted in a transient increase in intramyocellular DAGs, followed by activation of PKCθ and increased phosphorylation of the serine 1101 residues of IRS-1, with subsequent inhibition of insulin signaling and insulin-stimulated muscle glucose disposal (Figure 13.1). Similar increases in myocellular DAGs and PKCθ activation were found in obese individuals with T2DM without lipid infusion. Of note, DAG subspecies containing C_{18}-acyl residues correlated best with insulin resistance in all conditions of insulin resistance, whereas total ceramides and their subspecies were not affected either by lipid infusion or in common insulin resistance of obesity and T2DM [73].

In addition to lipids, dietary excess of protein has also been related to insulin resistance [84] and circulating branched-chain amino acids also predict T2DM [85]. In analogy with FFAs, short-term elevation of plasma amino acids indeed reduces insulin-stimulated G-6-P and glycogen synthesis [84] by activating the mammalian target of the rapamycin (mTOR)/p70 S60 kinase pathway with subsequent serine phosphorylation of IRS-1 [86, 87]. This pathway would further favor ectopic lipid storage [88]. In conclusion, the lipid-induced insulin resistance or lipotoxicity hypothesis proposes that in the absence of a balance between FFA delivery and muscle TAG synthesis via DGAT-1 as well as

oxidation in the mitochondria, lipotoxic species such as DAGs will accumulate and activate PKCθ in skeletal muscle. This in turn will activate a serine/threonine cascade, leading to impaired insulin signaling and impaired insulin-stimulated glucose uptake. Any mechanism by which lipid delivery to the muscle is reduced, lipid oxidation is increased, and/or TAG synthesis is stimulated will likely reduce LCFA-CoA and DAG concentrations and prevent lipid-induced muscle insulin resistance.

Consequently, decreases in muscle lipid oxidation could serve as another contributor to lipid accumulation in the skeletal muscle and thereby insulin resistance. Indeed, flux rates through muscle ATP synthase, reflecting basal mitochondrial phosphorylation, were found to be ~40% lower in lean insulin-resistant first-degree relatives of individuals with T2DM than in insulin-sensitive but otherwise matched people [89]. During insulin stimulation, muscle ATP synthase flux doubled in insulin-sensitive humans, but was almost abolished in the offspring of persons with T2DM [56]. Similarly, non-obese individuals with T2DM featured ~25% lower mitochondrial phosphorylation rates in the basal (fasting) state [58, 90] and no increase during insulin stimulation even in the presence of increased availability of glucose as a substrate [58, 90] (Figure 13.1a). This may be due to reduced capacities of the electron-transport chain and/or the phosphorylation system [90] and/or reduced insulin-stimulated phosphate transport into the myocytes.

Aging as one central risk factor of T2DM associates with impaired biogenesis and accelerated apoptosis of mitochondria [91]. Non-obese elderly humans are not only frequently insulin resistant but also feature higher intramyocellular TAG contents and ~30-40% lower rates of both muscle ATP synthase flux and tricarboxylic acid (TCA) cycle oxidation [92, 93]. Hence age-associated reductions in mitochondrial function may predispose elderly people to ectopic lipid accumulation and muscle insulin resistance [92], possibly owing to damage by accumulating reactive oxygen species (ROS). In line with this contention, similar reductions were reported for neural mitochondrial activity in healthy elderly individuals [94]. The hypothesis of age-associated ROS-induced reductions in mitochondrial function contributing to age-associated muscle insulin resistance was further supported by findings in transgenic mice with overexpression of human catalase targeted to the mitochondria (MCAT mice) [95]. These mice were protected from age-associated abnormalities in muscle mitochondrial function and DAG/PKCθ-induced muscle insulin resistance along with reduced mitochondrial oxidative damage, preserved muscle ATP synthesis, and adenosine 5′-monophosphate-activated protein kinase (AMPK)-induced mitochondrial biogenesis [96, 97]. Moreover, measurements of basal and insulin-stimulated rates of muscle pyruvate dehydrogenase (V_{PDH}) flux relative to citrate synthase flux (V_{CS}) employing [1-^{13}C]glucose incorporation into glutamate relative to alanine in muscle biopsies from healthy, lean, elderly and young humans revealed a blunted rise of insulin-stimulated V_{PDH}/V_{CS} fluxes in the elderly along with 25% lower muscle glucose uptake and 70% higher accumulation of intramyocellular TAGs [98]. These findings indicate a marked inability of mitochondria to switch from lipid to glucose oxidation during insulin stimulation. Taken together, combined acquired and age-associated reductions in features of mitochondrial function may promote intramyocellular lipid accumulation and insulin resistance in T2DM.

In addition to aging per se, other metabolic factors such as hyperglycemia and dyslipidemia may impair mitochondrial function and thereby contribute to muscle insulin resistance. In this context, insulin-resistant individuals with type 1 diabetes have lower insulin-stimulated ATP synthase flux, which negatively relates to glucometabolic control [55]. Short-term lipid infusion also leads to lower muscle ATP synthase flux, but only upon the onset of insulin resistance in healthy humans [99]. Of note, the reduced rates of insulin-stimulated ATP synthase flux were associated with impaired insulin-stimulated increases in muscle G-6-P concentrations due to lower insulin-stimulated glucose uptake [99, 100]. Also, lipid lowering via inhibition of lipoprotein lipase (LPL) by acipimox improves insulin resistance independently of changes in oxidative capacity in T2DM [101]. These findings suggest that glucose- and lipid-induced abnormalities in muscle mitochondrial function are not primary events in the development of insulin resistance in common T2DM.

A series of studies addressed the role of mitochondrial function independently of age and metabolic control [89, 102]. Young, lean, but severely insulin-resistant first-degree relatives of persons with T2DM were identified with 30% lower basal rates of muscle ATP synthase and TCA cycle fluxes compared with to age- and body mass-matched insulin-sensitive individuals [89]. This abnormality of mitochondrial oxidative phosphorylation was found in the presence of 38% lower mitochondrial density, indicating that the reduction in mitochondrial function may be attributed to lower muscle mitochondrial content [103]. In contrast to previous reports on skeletal muscle of persons with T2DM [104, 105], this was not explained by reduced expression of the peroxisome proliferator-activated receptor (PPAR) γ-coactivator 1α (PGC1α) [103], a key regulator of mitochondrial biogenesis. Likewise, in another cohort of first-degree relatives of individuals with T2DM, the stimulatory effect of exercise training on insulin sensitivity and ATP synthesis did not depend on common single-nucleotide polymorphisms (SNPs) of PGC1α, but was modified by a G/G-SNP of the gene encoding NADH dehydrogenase (ubiquinone) 1β subcomplex (NDUFB6), a component of complex I of the mitochondrial respiratory chain [55]. The finding that the insulin resistance in relatives of T2DM is related to lower fasting and insulin-stimulated rates of muscle ATP synthesis in a similar fashion as in persons with overt T2DM strongly underlines the role of inherited factors in the pathogenesis of insulin resistance and T2DM [58, 106]. Taken together, at least in this cohort of insulin-resistant first-degree relatives of individuals with T2DM, it is likely that a reduction in mitochondrial content, due to reduced mitochondrial biogenesis, is responsible for the reduced mitochondrial oxidative and phosphorylation activity and may be an acquired abnormality [107, 108]. Nevertheless, given the key role of mitochondrial activity in the regulation of fat metabolism in

muscle cells [109–113], these data suggest that the reduced mitochondrial function may be an important predisposing factor that promotes DAG accumulation in muscle cells and insulin resistance in muscle among persons with insulin resistance whose parents have T2DM.

Insulin resistance in the liver

The liver plays a key role in the transition from the fasted to the fed state by its unique ability to switch rapidly from a glucose-producing organ to a glucose-storing organ. After ingestion of a mixed meal, the liver suppresses glucose production and takes up glucose for storage in the form of glycogen [114, 115]. In insulin-resistant individuals with T2DM, the excessive postprandial hyperglycemia results from impaired suppression of glucose production along with ~45% lower hepatic glycogen accumulation than in healthy people [46]. This cannot be explained simply by the impaired prandial insulin secretion, but rather results from other mechanisms such as defective insulin-stimulated flux through glycogen synthase, because this abnormality persists during hyperinsulinemic–hyperglycemic clamps, which maximally favor glycogen synthesis [46]. Insulin-mediated hepatic glycogen synthesis correlates inversely with ectopic lipid content in the liver not only in persons with T2DM but also in those without, in line with a close link between hepatic lipid content and hepatic insulin resistance [46, 93] (Figure 13.1). Hepatic lipid accumulation, previously termed steatosis, is another form of ectopic lipid accumulation and is now included in the definition of non-alcoholic fatty liver disease (NAFLD). Steatosis relates closely to whole-body insulin resistance and is present in obesity, the metabolic syndrome, and women with a history of GDM or with T2DM [116, 117]. Although it has been discussed that NAFLD develops in the setting of or secondary to prevailing insulin resistance [118, 119], increased lipid availability per se could also induce hepatic triglyceride storage and insulin resistance [35]. This hypothesis is supported by studies in humans where short-term lipid infusions caused hepatic insulin resistance as reflected by impaired insulin-mediated suppression of glucose production [120]. Recent reviews have summarized the data from animal models that indicate that lipid intermediates such as DAGs also inhibit insulin signaling and stimulate triglyceride accumulation in the liver, similarly to the mechanism of lipid-induced insulin resistance in skeletal muscle [51, 77, 83] (Figure 13.3). In particular, one study in rats inducing selective hepatic steatosis by a 3-day high-fat diet found that hepatic insulin resistance corresponds to impaired tyrosine phosphorylation of IRS-2 and increased activities of PKCε and c-Jun N-terminal kinase (JNK) 1, which act as serine/threonine kinases and can phosphorylate serine residues of IRS-2 [121]. One study of human liver biopsies detected increases in some PKC isoforms (ε, α, and ζ) in obese persons with T2DM [122]. Human fatty livers also contain more stearoyl-CoA desaturase 1 (SCD1) activity and DAGs but not ceramide, which positively relate to hepatic fat content [123]. Recent intraoperative liver biopsy studies provided evidence that increases in hepatic DAG content [124, 125] and PKCε activity [124] correlate negatively with hepatic insulin sensitivity in obese individuals with NAFLD, thereby underlining a critical role of the DAG/nPKC pathway also in hepatic insulin resistance in humans (Figure 13.3).

Although NAFLD is most often associated with obesity, there are important exceptions where NAFLD and hepatic insulin resistance coexist in lean individuals [126, 127]. Healthy, young, lean Asian Indian men have a markedly greater risk of hepatic steatosis associated with hepatic insulin resistance than men of other

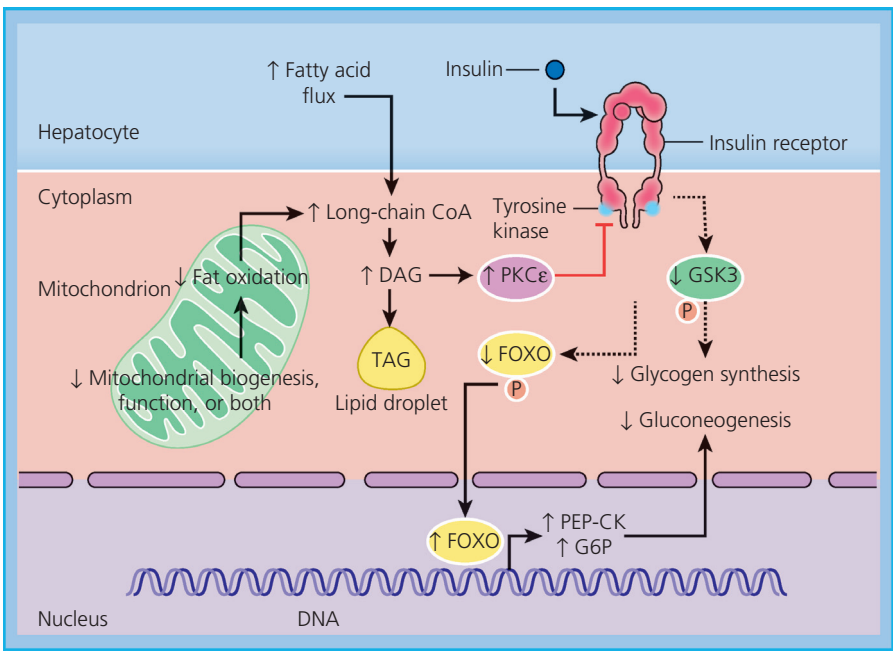

Figure 13.3 Cellular mechanism of insulin resistance in human liver. An imbalance of intrahepatocellular fluxes gives rise to hepatocellular diacylglycerols (DAGs), particularly when DAG synthesis, from both fatty acid re-esterification and *de novo* lipogenesis, exceeds the rates of mitochondrial oxidation of long-chain fatty acyl-coenzyme A (CoA) and/or the rates of DAG incorporation as triglycerides (TAGs) into lipid droplets. This activates the epsilon isoform of protein kinase C (PKCε), which likely phosphorylates the insulin receptor tyrosine kinase. In turn, phosphorylation of glycogen synthase kinase 3 (GSK3) phosphorylation increases, while that of forkhead box subgroup O (FOXO) decreases. This results in inhibition of glycogen synthase activity and thereby lower insulin-stimulated glycogen storage and in FOXO-mediated gene transcription of the gluconeogenic enzymes (e.g. phosphoenolpyruvate carboxykinase [PEP-CK] and G6P), with decreased insulin suppression of hepatic gluconeogenesis. ethnic groups. Two polymorphisms (rs2854116 and rs2854117) in the apolipoprotein C3 (ApoC3) gene seem to predispose these individuals and lean men of Asian ethnic backgrounds to NAFLD and insulin resistance [128]. In these carriers of the APOC3 variant alleles (C-482T, T-455C, or both), higher fasting plasma apolipoprotein C3 and plasma TAG concentrations are 30% and 60% higher, respectively, than in wild-type homozygous humans [128, 129]. These findings can be explained in part by the inhibitory effect of apolipoprotein C3 on LPL activity resulting in reduced plasma triglyceride clearance, leading to increases in postprandial hypertriglyceridemia and increased postprandial chylomicron remnants. This mechanism was validated genetically in transgenic mice with hepatic overexpression of human ApoC3, which were more prone to develop hepatic steatosis than their wild-type littermate counterparts when fed a high-fat diet [130]. Of note, this ApoC3 gene–environment interaction has only been observed in male individuals, likely reflecting a protective effect of estradiol on inhibition of LPL activity [131]. Furthermore, this ApoC3 gene–environment interaction is not observed in obese individuals in whom this relatively subtle gene–environment effect to promote hepatic steatosis in lean individuals is masked by the dominant effect of obesity and insulin resistance to promote NAFLD [132].

A genome-wide association study identified a missense mutation I148M within a patatin-like phospholipase domain containing 3 (PNPLA3/adiponutrin) that is more prevalent in Hispanic individuals and associates with NAFLD [133]. The rs738409 polymorphism PNPLA3 also leads to impaired TAG hydrolysis [134]. Although the association between this polymorphism and hepatic steatosis has been reproduced in other populations, there is no association with insulin resistance with the limitation of these studies that all the participants were obese and likely insulin resistant [135]. Finally, alterations in other genes that regulate lipogenesis leading to lipodystrophy (e.g. AGPAT2, PPARγ) [136] or lipolysis (e.g. perilipin, ATGL, CGI-58) [137] may also lead to ectopic lipid deposition and insulin resistance. Hence there is growing evidence that gene–environment interactions can predispose even lean individuals to hepatic insulin resistance, NAFLD, and T2DM. Of note, there are few exceptions in which ectopic lipid content dissociates from insulin resistance. A mutation in the *ABHD5* gene with consecutive deficiency in the protein comparative gene identification 58 (CGI-58) leads to Chanarin–Dorfman syndrome [92, 94, 95], which is characterized by excessive lipid deposition in the liver, muscle weakness, and central nervous symptoms in the absence of insulin resistance. In this condition, DAGs are restricted to storage in lipid droplets and thereby cannot promote PKCε translocation to the plasma membrane, which is required for its binding to the insulin receptor and inhibition of insulin signaling in the liver.

Similarly to skeletal muscle, non-obese persons with T2DM also show reductions in hepatocellular ATP concentrations as measured with non-invasive ^{31}P NMR methods [138] compared with age-matched and young persons without diabetes [139] (Figure 13.1). Even with adjustments for liver fat content, hepatic ATP concentrations correlated closely with hepatic insulin sensitivity but not with whole-body insulin sensitivity. Non-obese persons with T2DM also had 40% lower flux rates through hepatic ATP synthase, which relate to both peripheral and hepatic insulin sensitivity but negatively with body fat content [140]. Nevertheless, other features of hepatic mitochondrial function are not uniformly impaired in insulin-resistant humans [141–143]. Using high-resolution respirometry to quantify directly mitochondrial respiration in liver biopsies, it was found that despite similar mitochondrial contents, obese persons with or without steatosis had 4.3–5.0-fold higher maximal respiration rates in isolated mitochondria than lean persons, whereas persons with non-alcoholic steatohepatitis (NASH) featured 30–40% lower maximal respiration associated with greater hepatic insulin resistance [144] (Figure 13.4). These individuals also had higher degrees of mitochondrial uncoupling and leaking activity together with augmented hepatic oxidative stress paralleled by reduced antioxidant defense capacity and increased inflammatory response. These findings suggest an adaptation of the liver at early stages of obesity-related insulin resistance, which is subsequently lost during progression of NAFLD and insulin resistance. In line with this hypothesis, obese insulin-resistant individuals with steatosis had a sixfold greater increase in hepatic ATP concentrations than in lean insulin-sensitive individuals after ingestion of a single mixed meal [145].

Taken together, these findings suggest that loss of adaptation of hepatic energy metabolism to increased lipid flux from large visceral adipose tissue depots and/or adaptation-related hepatic oxidative stress could cause hepatic lipid accumulation and subsequent hepatic insulin resistance in the context of T2DM.

Insulin resistance in adipose tissue

Adipose tissue is highly sensitive to the action of insulin on lipolysis in healthy humans, but not in states of insulin resistance and T2DM [146–148], which are also characterized by elevations in plasma concentrations of TAGs and FFAs. These alterations will contribute to lipid-mediated effects on insulin sensitivity in other organs such as liver and skeletal muscle. On the other hand, obesity and the metabolic syndrome have been linked to a state of so-called "subclinical inflammation" arising from adipose tissue and leading to an imbalance of the secretion of adipocytokines with anti-inflammatory and insulin-sensitizing properties such as adiponectin and proinflammatory cytokines such as leptin, tumor necrosis factor-α and interleukin-6 (IL-6), and many others [149] (Figure 13.5). The latter adipocytokines may cause insulin resistance in liver and muscle by stimulating increased serine phosphorylation of IRS1 by activation of JNK1 and activation of Iκ kinase β (IKKβ)–nuclear factor-κB (NF-κB) kinase β, both of which are involved in chronic insulin resistance. Anti-inflammatory treatment either acutely with acetyl salicylate or chronically with salsalate promotes a modest improvement in glycemic control and insulin resistance in obese persons with

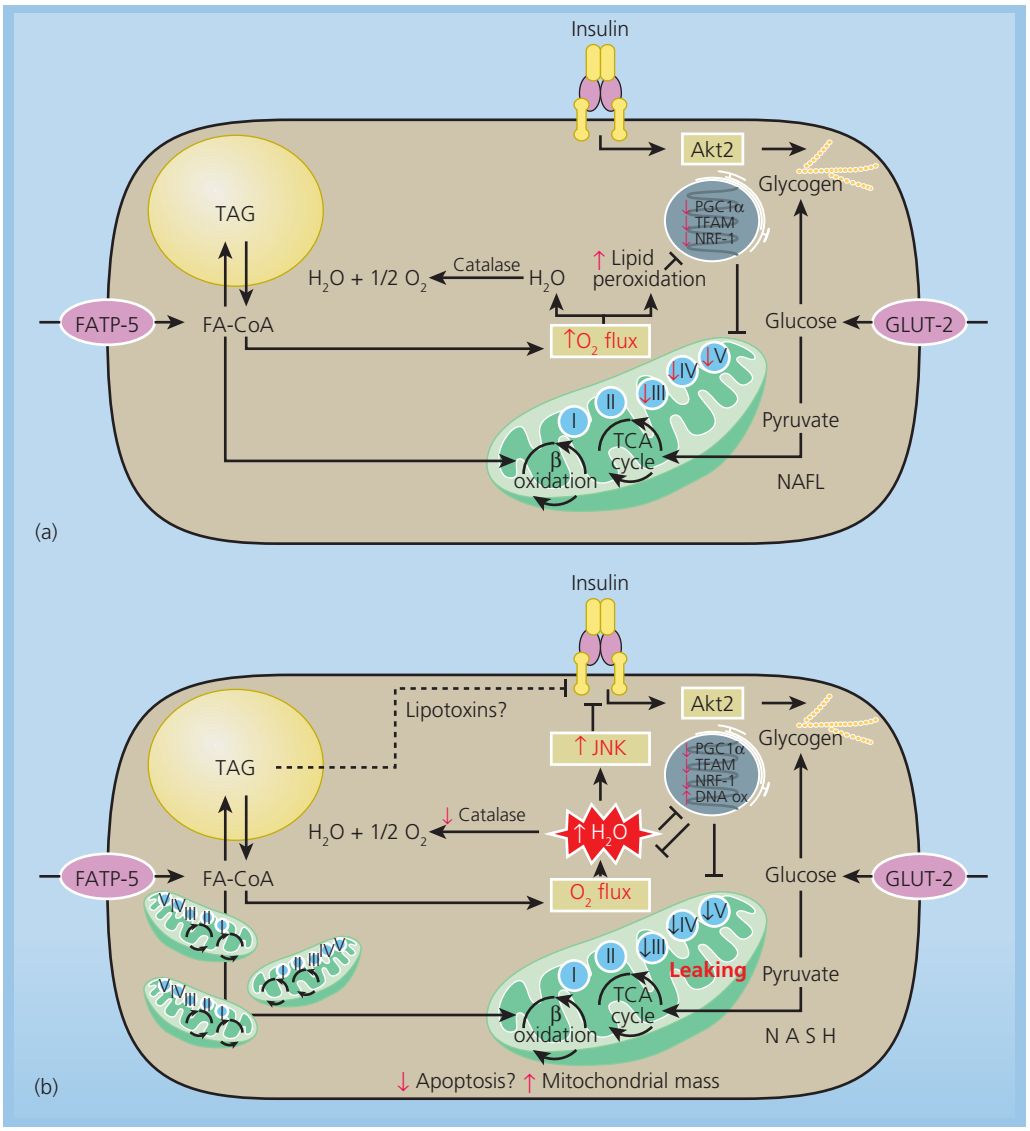

Figure 13.4 Hypothesis of adaptation of hepatic energy metabolism in the pathogenesis of non-alcoholic fatty liver disease and progression of hepatic insulin resistance. (a) In states of obesity, increased fatty acid delivery upregulates hepatic mitochondrial oxidative capacity, which prevents excessive storage of triacylglycerols (TAGs) but promotes the accumulation of reactive oxygen species and lipid peroxides, which are scavenged by hepatic catalase activity. (b) During the development of non-alcoholic fatty liver disease (NAFLD), the efficiency of mitochondrial coupling fails, which accelerates the generation of hydrogen peroxide (H_2O_2) in the face of decreasing catalase activity. Finally, oxidative stress decreases mitochondrial biogenesis, but increases leakage of mitochondria and activates c-Jun N-terminal kinase (JNK), which drives cellular inflammation and progression to steatohepatitis (NASH). T2DM [150, 151], indicating that activation of inflammatory pathways can contribute to obesity-associated insulin resistance and hyperglycemia in T2DM. Endoplasmic reticulum stress may serve as another cause of cellular inflammation and insulin resistance via JNK activation [152, 153]. In humans, weight loss following bariatric surgery improves insulin sensitivity [150, 154], which has been further associated with altered gut microbiota or hormone secretion [155] and also with reductions in endoplasmic reticulum stress. These hypotheses are currently under further investigation. Finally, chronically increased lipid availability may also cause mitochondrial and endoplasmic reticulum stress with release of reactive oxygen species, which in turn activate proinflammatory NF-κB [23]. Under these conditions, intracellular lipid metabolites (DAGs, ceramides, acyl-CoA) or even incomplete β-oxidation raising acylcarnitines can also contribute to the resulting insulin resistance [70, 156, 157].

Syndromes of lipodystrophy or lipoatrophy made it possible to study the roles of peripheral or visceral adipose tissues for insulin resistance and ectopic lipid deposition [126, 158–160]. Both inherited and acquired forms of generalized lipodystrophy are

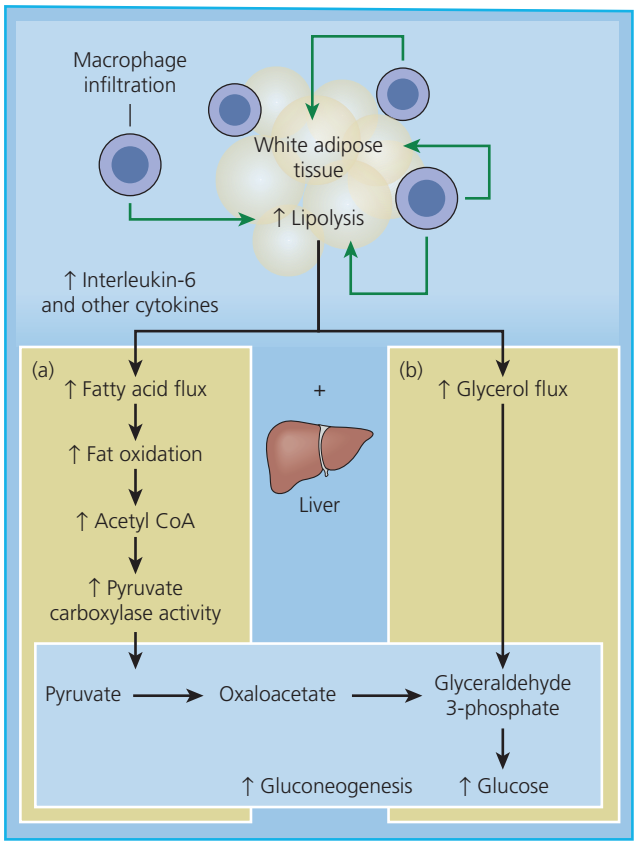

Figure 13.5 Hypothesis of macrophage-induced lipolysis in the pathogenesis of fasting hyperglycemia and insulin resistance. During the development of obesity, macrophage infiltration of white adipose tissue results in increased lipolysis by release of macrophage-derived cytokines such as interleukin-6. Increased rates of lipolysis lead to accelerated rates of hepatic gluconeogenesis by two mechanisms. (a) First, increased fatty acid delivery to the liver gives rise to hepatic acetyl-CoA levels, when its production through fat oxidation exceeds its rates of oxidation in the TCA cycle. This leads to increased pyruvate carboxylase activity. (b) Second, increased delivery of glycerol promotes its conversion to dihydroxyacetone (glyceraldehyde) 3-phosphate, which serves as precursor of glucose. Source: Shulman 2014 [51]. devoid of relevant amounts of adipose tissue and develop excessive hypertriglyceridemia and ectopic fat deposition owing to fat overflow from the negligible triglyceride storage in adipocytes. Furthermore, these individuals have lower levels of inflammatory cytokines and leptin, resulting in hyperphagia [127]. Individuals with severe, generalized lipodystrophy have severe steatosis along with hepatic and muscle insulin resistance or even overt T2DM, which completely resolves after 3–8 months of leptin replacement therapy, as demonstrated previously in rodent models of lipodystrophy [77, 83]. Thus, visceral lipid may be a marker of hepatic steatosis rather than a causal player in the development of insulin resistance [127].

Although these findings also demonstrate that the important role of lipid-induced alterations at the onset of insulin resistance can be dissociated from inflammation, they do not exclude the operation of other mechanisms promoting the progression to impaired glucose tolerance and fasting hyperglycemia. According to the canonical view, impaired pancreatic β- and α-cell function first leads to reduced hepatic activation of Akt and exclusion of forkhead box (FOXO1) from the nucleus of the hepatocyte, with consequent transcription-mediated hepatic gluconeogenesis [161]. Second, subclinical inflammation would diminish insulin action through secreted (adipo)cytokines, which subsequently interfere with insulin signaling and increase hepatic gluconeogenic protein transcription by activating the NF-κB/JNK/ceramide pathways. Recently, an alternative mechanism has been proposed, by which macrophage-induced lipolysis may regulate hepatic gluconeogenesis independently of canonical insulin receptor signaling and thereby link subclinical inflammation to the onset of fasting hyperglycemia [51, 162] (Figure 13.5). Using a novel *in vivo* metabolomics approach in rodent models, it was demonstrated that IL6, released from macrophages within adipose tissue, inhibits insulin-mediated lipolysis in white adipose tissue (WAT) with augmented delivery of FFAs and to a lesser extent of glycerol to the liver [163]. This resulted in increased hepatic acetyl-CoA concentrations, due to increased fatty acid β-oxidation, which stimulated hepatic gluconeogenesis through allosteric activation of pyruvate carboxylase. In line with these studies in rodents, insulin-resistant obese adolescents displayed increased circulating IL6 concentrations and a more marked, 50% rise in IL-6 concentration in WAT along with impaired insulin-mediated suppression of lipolysis and endogenous glucose production compared with age- and body mass-matched insulin-sensitive humans. These studies collectively support the concept of an indirect action of insulin on hepatic glucose production via adipocytes [164, 165]. Some further observations underline that transcriptional control of hepatic gluconeogenesis cannot be due simply to direct insulin action on the liver to suppress glucose release. Insulin-mediated reduction in endogenous glucose production occurs rapidly, within minutes, even in individuals withT2DM [34], and there is a lack of any relationship between hepatic expression of gluconeogenic protein and fasting hyperglycemia in obese humans with and without T2DM [124].

Stepwise development of tissue-specific insulin resistance

The close association between obesity, ectopic fat accumulation, and insulin resistance makes it difficult to identify skeletal muscle, liver, or adipose tissue as the primary cause of insulin resistance. Nevertheless, the earliest development of insulin resistance occurs most likely in skeletal muscle, particularly in cohorts with inherited risk of insulin resistance or T2DM [89, 166] (Figure 13.6). The observation of rapid reversibility of hepatic but not muscle insulin resistance with moderate weight loss in individuals with NAFLD, and leptin replacement in generalized lipodystrophy [127] and T2DM [126], is in agreement with this contention. As detailed

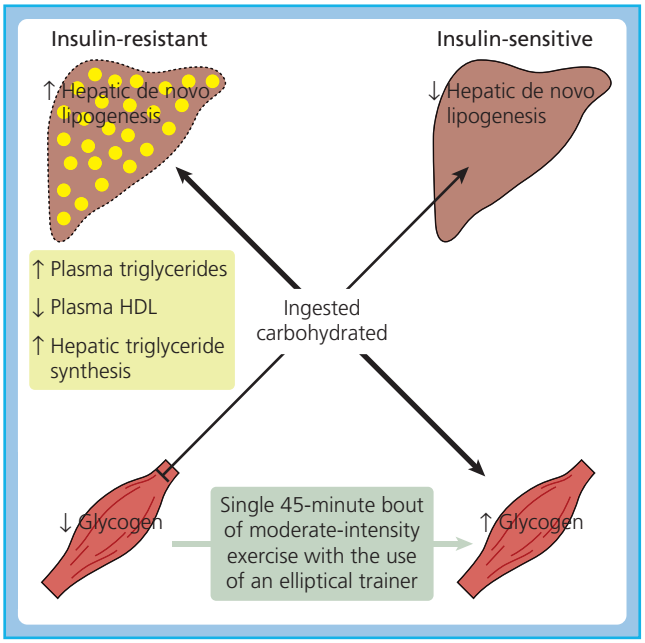

Figure 13.6 Concept of the stepwise development of insulin resistance from skeletal muscle to atherogenic dyslipidemia and non-alcoholic fatty liver disease. In healthy, young, lean persons, selective insulin resistance in skeletal muscle results in diversion of ingested carbohydrates from muscle glycogen synthesis to the liver. Combined with compensatory hyperinsulinemia, this stimulates hepatic de novo lipogenesis, synthesis of triglycerides and secretion of very low-density lipoproteins (VLDL) resulting in hypertriglyceridemia and reduced plasma high-density lipoprotein (HDL) levels. Of note, even one bout of exercising is able to restore the abnormal pattern of energy storage after carbohydrate ingestion by stimulating glucose uptake and glycogen synthesis in muscle through insulin-independent adenosine 5′-monophosphate-activated protein kinase (AMPK) activation of glucose transporter 5 (GLUT-4) recruitment. above, the principal mechanism involves tissue-specific accumulation of lipid species such as specific membrane and cytosolic but not droplet-bound DAGs, which occurs owing to an imbalance between substrate influx and oxidation (mitochondrial activity) and/or synthesis of TAGs in insulin-responsive tissues. Accordingly, any situation that will disrupt the balance between delivery and removal of DAG species to the muscle and the liver will lead to the accumulation of these lipid species, resulting in insulin resistance. This likely explains the high prevalence of obesity-associated insulin resistance, where lipid delivery exceeds storage and oxidation, the impaired adipocyte storage capacity in lipodystrophy, and the decreased substrate oxidation in certain forms of inherited insulin resistance such as lean, insulin-resistant relatives of individuals with T2DM or in acquired insulin resistance occurring during aging [135].

Evidence for the specific role of inefficient substrate oxidation during the onset of insulin resistance comes from the human model of lean, young, severely insulin-resistant relatives of persons with T2DM, who are devoid of any other confounding factors such as obesity, hyperglycemia, or subclinical inflammation. In these individuals, inherited abnormalities in muscle mitochondrial biogenesis and/or function can cause or at least contribute to muscle insulin resistance due to decreased substrate oxidation and subsequent accumulation of intracellular lipid metabolites with diminished insulin signaling [103, 167]. The impaired adaptation of insulin sensitivity to exercise training in carriers of the rs540467 polymorphism of the *NDUFB6* gene in such relatives of persons with T2DM is in line with this hypothesis [168]. Likewise, the rs2267668 A/G SNP in *PPARD* gene and the Gly482Ser SNP in the *PGC1A* gene also have independent and additive effects on the effectiveness of aerobic exercise training to increase physical fitness and insulin sensitivity in humans at risk for T2DM [169]. Impaired mitochondrial function as assessed from ATP synthesis was also found in other non-obese groups at increased risk for T2DM such as individuals with previous acromegaly [170] or gestational diabetes [117]. All these alterations in skeletal muscle metabolism would lead to lower rates of insulin-stimulated glucose disposal and accelerated rates of anaerobic glycolysis with release of lactate and alanine as substrates of hepatic gluconeogenesis.

Chronic overnutrition will increase the size of WAT and recruit macrophages to adipose tissue. As described above, local inflammation of adipose tissue leads to macrophage-induced lipolysis with release of TAGs and FFAs, which in turn elevates the WAT-derived hepatic acetyl-CoA pool and drives hepatic gluconeogenesis. This mechanism could potentiate the transition from whole-body insulin resistance to impaired glucose tolerance and T2DM. Chronic increases in hepatic gluconeogenesis would then impair insulin secretion by the pancreatic β cells and inappropriate glucagon secretion by the α cells due to glucose toxicity and ultimately exacerbate both fasting and postprandial hyperglycemia in the context of overt T2DM.

Finally, excessive flux of FFAs to the liver will promote NAFLD through increased hepatic esterification, which occurs in a mostly insulin-independent manner [171]. Hepatic mitochondria may transiently adapt to the increased substrate availability by upregulating their oxidative capacity at the expense of decreased coupling efficiency until NAFLD develops [143]. Ongoing substrate overloading will blunt the liver's antioxidant capacity and increase hepatic oxidative stress, with subsequent leakage of mitochondria and decreased mitochondrial biogenesis resulting in NASH and aggravated insulin resistance.

Recent studies provided experimental support for the concept of the stepwise development of insulin resistance in humans (Figure 13.6). Monitoring energy distribution employing $^{13}C/^{1}H$ NMR spectroscopy and hepatic *de novo* lipogenesis after ingestion of a high-carbohydrate meal revealed that postprandial muscle glycogen synthesis was reduced by ~60% in insulin-resistant compared with insulin-sensitive young, lean individuals [171]. On the other hand, liver TAG content and hepatic *de novo* lipogenesis were doubled in the insulin-resistant group. This was accompanied by 60% higher plasma TAG and uric acid contents and 20% lower fasting HDL-C but with no changes in circulating adipocytokines. These data confirmed that muscle insulin resistance per

se shifts the distribution of postprandial energy storage away from muscle glycogen and leads to upregulation of hepatic lipid synthesis and hepatic lipid storage and export of VLDL, thereby contributing to the development of atherogenic dyslipidemia; these are features of the metabolic syndrome independently of visceral obesity or subclinical inflammation. Meal-dependent increases in liver glycogen synthesis were comparable in insulin-resistant and insulin-sensitive individuals, which is in accordance with the low amount of liver lipids and normal hepatic insulin sensitivity in these individuals with muscle insulin resistance [90, 172]. Noteworthy, a single bout of moderate-intensity exercise abrogated the abnormal pattern of energy storage, which promoted muscle glycogen synthesis after carbohydrate ingestion through increased glucose transport activity [166, 173] (Figure 13.6). Moreover, non-obese insulin-resistant women with a history of GDM also feature doubled fasting liver TAGs without NAFLD, which correlates with insulin resistance and fat mass [117]. Of note, hepatic, but not visceral, fat mass relates to hepatic insulin resistance and increased TAG release [174]. Obese humans can further be identified as insulin resistant on the basis of liver and muscle lipid content, but not subcutaneous or visceral obesity [175].

Conclusion

Insulin resistance is likely the initial event preceding T2DM by decades before the onset of any relevant insulinopenia. Skeletal muscle insulin resistance results from accumulation of specific lipid intermediates, such as DAGs, which accumulate due an imbalance between delivery and removal by oxidation and TAG storage. Excess delivery of substrates is currently the most common reason for muscle insulin resistance. The impaired muscle insulin action distributes postprandial energy away from muscle glycogen storage towards hepatic *de novo* lipogenesis, NAFLD, the metabolic syndrome, and T2DM. During the onset of obesity, macrophage-induced lipolysis in the WAT-derived hepatic acetyl-CoA pool enhances hepatic gluconeogenesis and causes a transition from insulin resistance to impaired glucose tolerance and T2DM. Finally, loss of adaptation of hepatic mitochondria to excessive substrate delivery may accelerate steatosis and promote the progression of NAFLD, which is a major and independent predictor of cardiovascular morbidity and mortality in the context of T2DM [176].

14 Genetic Architecture of Type 2 Diabetes

Rashmi B. Prasad[1] and Leif Groop[1,2]

[1] Lund University Diabetes Centre, Department of Clinical Sciences, Diabetes and Endocrinology, Lund University, CRC, Skåne University Hospital SUS, Malmö, Sweden

[2] Finnish Institute of Molecular Medicine (FIMM), Helsinki University, Helsinki, Finland

Keypoints

- Diabetes can be considered as a spectrum of disorders with type 1 diabetes mellitus (T1DM) and type 2 diabetes mellitus (T2DM) as two ends of the spectrum, and maturity-onset diabetes of the young (MODY), latent autoimmune diabetes in adults (LADA) and other types being intermediates.
- T2DM is a complex disease characterized by impaired insulin secretion, insulin resistance, or both, and is caused by the intricate interplay between genetic, epigenetic, and environmental factors.
- The genetic architecture of a complex phenotype is defined by the number, frequencies, and effect sizes of causal alleles. The current understanding of the genetic architecture of T2DM points towards a combination of common single-nucleotide polymorphisms (SNPs), protective and rare variants, parent-of-origin effects, structural polymorphisms, and microRNAs, which can further be complicated by gene–gene and gene–environment interactions and also epigenetics.
- The technical revolution in the field of genetics such as genome-wide association studies (GWAS) and next-generation sequencing has allowed identification of >100 genetic variants in risk and protection of T2DM and many more with diabetes-related traits.
- Reported associations of SNPs significantly associated with T2DM account for <20% of the heritability of T2DM. There may be several reasons for these shortcomings: too simple assumptions have been made about the genetic architecture of the disease, ignoring additive and intrauterine effects, and restricting the analysis to only SNPs associated at 5×10^{-8}.
- The *CAPN10* gene on chromosome 10 encoding calpain 10 was the first T2DM susceptibility gene to be identified through linkage studies. The greatest success in linkage studies relates to the discovery of variants in the TCF7L2 as being associated with T2DM, but not the cause of linkage.
- The first candidate gene reproducibly associated with T2DM was *PPARG*, encoding the nuclear receptor PPAR-γ. The PPAR-γ receptor is a molecular target for thiazolidinediones, a class of insulin-sensitizing drugs used to treat T2DM, making it a very compelling candidate gene.
- In 2007, several GWAS on T2DM were published. Uniquely, for the first time most of them reported associations to the same SNPs and genes such as *TCF7L2*, *FTO*, *CDKAL1*, *HHEX*, *SLC30A8*, *IGF2BP2*, and *CDKN2A/2B*. These discoveries were therefore denoted Breakthrough of the Year 2007 by *Science*. Most of these variants have very modest risks. An exception was published recently from Greenland, where a common variant in the *TCFCB4* gene was strongly (odds ratio close to 10) associated with glucose tolerance as measured from an oral glucose tolerance test.
- Most T2DM-associated risk variants seem to influence β-cell function (e.g. *TCF7L2*, *CDKAL*, *SLC30A8*).
- Whereas monogenic forms of diabetes (MODY) have been successfully ascribed to highly penetrant mutations in more than 10 genes, only a few rare variants have been associated with T2DM, among them rare variants in the *PAM* and *PDX1* genes.
- A few variants protecting against T2DM have also been reported, including variants in the *SLC30A8* and *TCF2* genes. Mimicking how these variants protect against T2DM represents an ideal scenario for the development of new drugs.
- To describe the full genetic architecture of T2DM, a systems genetic approach will be needed, combining GWAS, DNA methylation and histone modifications, and expression profiling including mRNA, proteins, and metabolites.

The diabetes epidemic

Diabetes refers to a group of metabolic diseases characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both [1]. The chronic hyperglycemia of diabetes is associated with long-term damage, dysfunction, and failure of different organs, especially the eyes, kidneys, nerves, heart, and blood vessels. Diabetes is currently the fastest growing epidemic. Worldwide prevalence figures estimate that there were 415 million people living with diabetes in 2015 and that by 2040 this number will have risen to 642 million [2]. India and China have the highest reported prevalences of diabetes, with 69.2 and 109.6 million in 2015, respectively, more than 90% of which is considered as type 2

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

diabetes mellitus (T2DM). In Europe, ~8% of the population is affected by diabetes, 90% of which is accounted for by T2DM, making T2DM the fastest increasing disease in Europe and worldwide [2, 3].

The T2DM epidemic can largely be ascribed to the worldwide increase in obesity during the last 30 years; for instance, more than 60% of individuals older than 15 years in the United Kingdom and United States are overweight (body mass index [BMI] >25 Kg/m^2) [4]. This has been attributed to a collision between genes and the environment. The social determinants of environmental factors tend to vary across populations and have changed rapidly over recent decades. A high energy-consuming lifestyle has been replaced by a Western sedentary one, with little or no exercise and energy-dense diet consumption. Meanwhile, genetic factors evolve at a slower rate across generations, and tend to favor the selection of "energy-saving thrifty genotypes," which might have been beneficial for individuals living in times of unstable food supply by storing energy in times of surplus [5]. While this hypothesis provides an appealing explanation of the obesity and T2DM epidemic, formal proof of this hypothesis is still lacking.

The diabetes spectrum

Diabetes encompasses a range of heterogeneous metabolic disorders characterized by the inability of the body to assimilate glucose and maintain glucose homeostasis. Diabetes has been traditionally subdivided into T2DM and type 1 diabetes mellitus (T1DM). However, this is a gross oversimplification of a rather complex situation. The concept of diabetes has grown over recent decades to the understanding that several different overlapping contributions from genetics and the environment can lead to manifestations of varying forms of disease. Contrary to being dichotomously distinct disorders, T1DM and T2DM can be considered rather as the two ends of a diabetes spectrum, with intermediates comprising of maturity-onset diabetes of the young (MODY), latent autoimmune diabetes in adults (LADA), and other subtypes.

T1DM, previously known as juvenile diabetes or insulin-dependent diabetes, is a chronic condition which is due to autoimmune destruction of pancreatic β cells and is characterized by (nearly) complete absence of insulin secretion, and the presence of autoantibodies including glutamic acid decarboxylase (GAD) antibodies, leading to dependence on insulin injections. It is most often diagnosed in children, adolescents, or young adults less than 35 years old. The incidence of T1DM varies based upon geography, age, gender, and family history [2]. Interestingly, the risk in offspring of an affected mother is 2–4% whereas the risk in those of an affected father is as high as 5–8% [6, 7]. The sibling relative risk of T1DM is estimated at 15 [8–10]. T1DM results from an interplay between genetic, epigenetic, and environmental factors [11]. Genetic studies have been able to explain 80% of the heritability of T1DM [12]. The main susceptibility genes currently accepted for T1DM are the HLA class II alleles, which account for up to 50% of genetic T1DM risk, and non-HLA loci including the insulin gene, *CTLA4*, *PTPN22*, interleukin 2 receptor a (*IL2RA*), and others [13]. Environmental factors suggested so far include enterovirus infections such as viruses of the picorna family, as they are seen more often among individuals with newly diagnosed T1DM than in the general population, and they precede the appearance of autoantibodies. Furthermore environmental pollutants, gut flora variations, and vitamin D exposure has all been implicated (See Chapter 10) [14–16].

LADA is a common subgroup of diabetes accounting for about 7% of all persons with diabetes in Europe. LADA is usually defined as GAD antibody-positive diabetes with onset at greater than 35 years of age and no insulin requirement during the first 6 months after diagnosis [17–19]. LADA with high antibody titers are found to the left of the spectrum close to T1DM, whereas LADA with lower titers are to the right of the spectrum close to T2DM [20]. A family history of any form of diabetes is a strong risk factor for the development of LADA [21]. Further discussion of clinical disorders with a type 1 phenotype can be found in Chapter 11.

MODY refers to monogenic forms of diabetes with well-defined high penetrance mutations in more than 10 different genes, and this number is still increasing (See Chapter 18). The disease is characterized by autosomal dominant transmission of early-onset (<25 years) diabetes and varying degree of β-cell dysfunction [22]. It was long debated whether the MODY genes would harbor common, less penetrant variants increasing the risk for T2DM; now, this seems to be the case for most of them, including *HNF1A*, *HNF4A*, *HNF1B*, *GCK*, and *PDX1* [23–25]. MODY shows extreme allelic heterogeneity, meaning that most MODY mutations are unique; to date, more than 200 mutations have been described in the *GCK* (MODY2) and *HNF1A* (MODY3) genes [26, 27]. The appropriate diagnosis of MODY requires sequencing. With the advent of next-generation sequencing technologies, accurate MODY diagnoses are much more feasible today.

Maternally inherited diabetes and deafness (MIDD) is due to the A3242G mutation in mitochondrial DNA (mtDNA) [26, 28]. As mtDNA is only transmitted from the mother, MIDD shows maternal transmission. In addition to hearing loss, many individuals also display neurological problems similar to those in persons with the MELAS syndrome (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke), which is also caused by the same mutation in mtDNA.

Neonatal diabetes is defined as diabetes with onset at birth or during the first 6 months of life with both transient and permanent forms [26]. Mutations in several genes have been shown to cause neonatal diabetes (*KCJN11*, *SUR1*, *GCK*, *INS*, etc.), and an appropriate genetic diagnosis is a prerequisite for optimal treatment. Individuals with mutations in the *KCJN11* gene have not only severe diabetes but also developmental defects (e.g. developmental delay, epilepsy, and neonatal diabetes [DEND]). These conditions are improved after switching from insulin treatment to treatment with large doses of sulfonylureas [29].

Diabetes can also develop secondary to pancreatic disease (See Chapter 21) or other endocrine disorders (See Chapter 20) and is referred to as *secondary diabetes*.

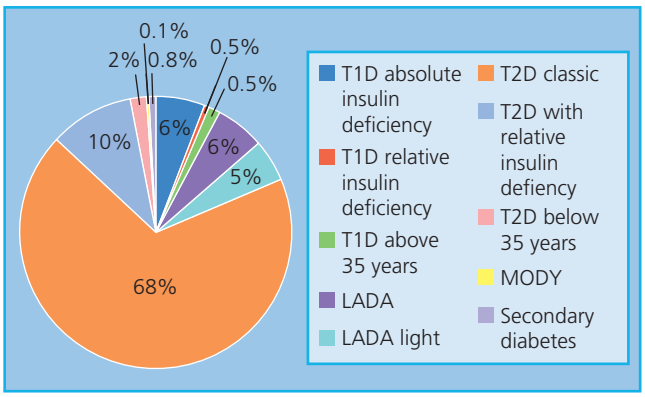

Figure 14.1 The spectrum of diabetes subgroups. The data are from the ANDIS project (All New Diabetics in Scania) (http://andis.ludc.med.lu.se) in April 2012, which at that time included 5800 individuals aged 0–100 years with newly diagnosed diabetes. The criteria used for diagnosis are as follows. T1DM: age at onset <35 years, C-peptide <0.2 nmol/L, and GAD antibodies >20; T1DM with relative insulin deficiency if C-peptide 0.2–0.6 nmol/L. T2DM: age at onset >35 years, C-peptide >0.6 nmol/L, GAD antibodies <10; T2DM with relative insulin deficiency C-peptide 0.2–0.6 nmol/L. LADA: age at onset >35 years, GAD antibodies >20; LADA light if GAD antibodies 10–20. The data clearly illustrate the difficulty in classifying persons with diabetes at diagnosis, with 19% unclassifiable. Source: Prasad RB, Groop L. Genetics of type 2 diabetes—Pitfalls and possibilities. *Genes* 2015; **6**:87–123 (this is an open-access article distributed under the Creative Commons Attribution License [CC BY]).

Type 2 diabetes is the most prevailing form, constituting 80–90% of all reported diabetes cases. T2DM is the result of a complex interplay between genetic, epigenetic, and environmental factors. T2DM develops when pancreatic β cells can no longer produce enough insulin to compensate for the insulin resistance. There is no formal definition of T2DM; individuals who do not fulfill criteria of T1DM, LADA, secondary diabetes, or monogenic forms of diabetes are considered to have T2DM. T2DM is more often associated with increased age, the age of onset usually being over 35 years [12]. However, it is increasingly reported in adolescents in high-risk countries such as India and China [3]. Heritability of T2DM is discussed below.

All these forms of diabetes represent a range of genetic etiologies from the monogenic MODY variants to T2DM, which is a complex heterogeneous polygenic disease with a strong environmental component. The ANDIS (All New Diabetics in Scania) project in southern Sweden represents a new attempt to reclassify diabetes into subgroups based upon genetic markers and biomarkers (Figure 14.1). A similar project has been initiated in Uppsala, Sweden, with the same goal (ANDIU: All New Diabetics in Uppsala).

Heritability of T2DM

T2DM clusters in families and it is well established that the risk of developing T2DM depends on both genetic and environmental factors. Heritability parameters facilitate understanding the genetic architecture of complex traits such as T2DM. However, heritability estimates have varied between 25 and 80% in different studies; the highest estimates are seen in those studies with longest follow-up period. The lifetime risk of developing T2DM is 40% for individuals who have one parent with T2DM and almost 70% if both parents are affected [30]. Further, the concordance rate of T2DM in monozygotic twins is about 70%, whereas that in dizygotic twins is only 20–30%. The proband-wise concordance rates (number of affected twins having a co-twin with diabetes) for monozygotic twins vary between 34 and 100% [31–34].The relative risk for first-degree relatives, i.e. the risk for developing T2DM if the person has an affected parent or sibling compared with the general population, is ~3, and ~6 if both parents are affected [35]. However, these figures vary depending on the cohort and population studied.

The prevalence of T2DM varies widely among populations, from a few percent among white Europeans to as high as 50% among Pima Indians in Arizona [36]. While part of the observed ethnic variability could be attributed to environmental and cultural factors, some of the variation seems to depend on genetic differences.

In spite of these reservations, there is no doubt that the risk of T2DM is partly determined by genetic factors, many of which have already been identified, and although each identified variant explains only a very small proportion of the risk of T2DM in the human population, they have contributed to our understanding of disease pathogenesis. One should also keep in mind that the variance explained by a risk allele in a population is not necessarily an indicator of its importance in specific persons, nor is it proportional to the affected pathway's importance or potential as a therapeutic target.

The >80 loci identified (see Tables 14.1–14.3 for lists of loci) explain less than 20% of the heritability of T2DM. There are many possible explanations for the missing heritability, including assumptions made about the genetic architecture of the disease and the definitions of heritability. The estimations of heritability explained assume that only additive affects determine disease risk and that the risk follows the liability threshold model, i.e. that the genetic and environmental effects sum up to form a normal distribution of liability and that disease arises in individuals surpassing a certain threshold in the distribution [86]. If these assumptions are not true, the estimate of heritability explained will not be correct.

Intrauterine effects can also affect heritability estimates because monozygotic twins are often monochorionic, which results in growth retardation compared with dizygotic twins and low birth weight is associated with increased risk of T2DM later in life. Furthermore, there could be other explanations to the "missing heritability" problem. However, one should keep in mind that heritability can only be estimated from the most recent generations for which information on affected status is available, whereas most of the variants studied thus far are ancestral variants hundreds of generations old. We do not know whether these ancestral variants (that have modest effects and have escaped purifying selection)

can really explain the diabetes epidemic that we see in the most recent generations or whether this can be ascribed to rare variants with stronger effects.

Moreover, heritability estimates are based on "top" SNPs from GWAS associations; novel methods have been proposed that take into account the (i) 0–1 scale as opposed to liability, (ii) ascertainment bias, and (iii) quality control of the GWAS SNPs. Estimating the proportion of variance explained by all SNPs in GWAS as opposed to only the most significantly associated SNPs could result in a more detailed estimate of heritability [87]. Applying an approach that considers all SNPs on the chip could in fact explain a much larger proportion of the "narrow-sense" heritability (>50%) supporting the existence of numerous yet unidentified loci with smaller effects [23, 88, 89].

The genetic architecture of T2DM

The genetic architecture of a complex phenotype is defined by the number, frequencies, and effect sizes of causal alleles. Many hypotheses have been proposed to define the genetic architecture of T2DM; one suggested that the unexplained heritability lies in a large number of common variants with low additive effects and that the disease represents the extremes of a normal distribution [69]. Another proposed that rare alleles might be responsible for effects observed with common variants (synthetic associations) and explain a majority of the heritability [59, 70, 71]. One argument against common and, more so, against rare variants is that they would have been removed from the population by natural selection [36]; however, this is not a valid argument for a disease such as T2DM where the penetrance of the genetic effect depends strongly on interactions with the environment, especially since this environment has changed in recent years and the genetic risk variants could have been neutral or even beneficial before the introduction of the westernized lifestyle.

Although extreme models are excluded by the present data based on epidemiological, linkage, and GWAS, models in which rare variants explain a little (<25%) or a lot (>80%) of the heritability remain consistent [72]. It is hoped that large next-generation sequencing studies in families will answer the questions about the role of rare variants in complex diseases. There is already substantial evidence for parent-of-origin effects on T2DM risk, and studies are ongoing to explore this further. Structural polymorphisms and microRNAs add a further layer of complexity and have not yet been exhaustively studied.

The genetic architecture could also be influenced by gene–gene interactions (epistasis) where rare variants with high penetrance could act jointly with common alleles to increase the risk of disease. The extent of allelic heterogeneity seems to be less pronounced for the common form of T2DM than for monogenic forms such as MODY. Moreover, there could be differences in the genetic predisposition to T2DM due to phenotypic heterogeneity within T2DM cases. For instance, lean people with T2DM are likely to carry a disproportionately high load of T2DM risk alleles [73].

Linkage studies

The *CAPN10* gene on chromosome 10 encoding calpain 10, a cysteine protease with largely unknown functions in glucose metabolism, was the first T2DM susceptibility gene to be identified through linkage studies. Unfortunately, this locus has been difficult to replicate in subsequent studies. The greatest success in linkage studies relates to the discovery of variants in the *TCF7L2* gene that are associated with T2DM. The DeCode team observed a rather modest linkage at a 10.5 Mb region on chromosome 10q, but decided to pursue and fine map it, thereby identifying the variant showing the strongest association with T2DM at the time. This was an intronic variant (rs7903146) in the *TCF7L2* gene that contributed to, but did not fully explain, the original linkage [37–39]. This association has since been confirmed in African, Asian, and European populations, rendering it the most consistently replicated genetic association with T2DM to date, conferring a relative risk of ~1.4 [40].

Candidate genes for T2DM

The first candidate gene reproducibly associated with T2DM was *PPARG*, encoding the nuclear receptor PPAR-γ [41]. The PPAR-γ receptor is a molecular target for thiazolidinediones, a class of insulin-sensitizing drugs used to treat T2DM, making it a very compelling candidate gene. The transcript expressed in adipose tissue has an extra exon B and a substitution of a proline for alanine at position 12 of this protein, which is seen in about 15% of the European population. This variant has been shown to be associated with increased transcriptional activity, increased insulin sensitivity, and protection against T2DM [41].

T2DM-risk variants in *KCJN11* were also discovered through candidate association studies [42, 43]. *KCNJ11* codes for four subunits of the ATP-sensitive potassium (K-ATP) channel, the other four coded by another gene (*ABCC8*). The E23K polymorphisms in *KCNJ11* and P12A in *PPARG* putatively acted in an additive manner to increase T2DM risk [44]. In pancreatic β cells, K-ATP channels are crucial for the regulation of glucose-stimulated insulin secretion and are the target for the sulfonylureas which are oral antidiabetes agents widely used in the treatment of T2DM, and for diazoxide, a potassium channel opener. Activating mutations in this gene also caused neonatal diabetes. Additionally, loss-of-function mutations in *KCNJ11* and *ABCC8* caused hyperinsulinemia in infancy [45].

Genome-wide association studies (GWAS) identify common variants associated with disease

The development of new genotyping technologies and the realization that we inherit stretches of the genome together as haplotypes facilitated the cataloguing of common variants (HAPMAP, 1000

genomes) and allowed for new possibilities of applying unbiased global approaches to screen millions of common variants for association with complex diseases. Several GWAS for diabetes were published in 2007, coined "Breakthrough of the Year" by *Science* magazine. The first was a GWAS on early-onset T2DM reporting two new diabetes loci: *HHEX* and *SLC30A8* [46]. The ultimate proof of the value of GWAS for T2DM came from three GWAS published back-to-back in *Science* in 2007; for the first time in the genetics of T2DM, three different studies reported the same top findings! [47–49].

The first wave of GWAS was followed by a second wave combining existing or new GWAS into meta-analyses of >50,000 individuals [23]. A prerequisite for this was that many research groups could work together in consortia such as DIAGRAM (DIAbetes Genetics Replication And Meta-analysis consortium) and MAGIC (Meta-Analyses of Glucose-and Insulin-related traits Consortium). GWAS do not inevitably lead to the identification of a gene or genes in a given locus associated with disease. Since the most strongly associated SNPs are often only markers for the functional variant responsible for the observed genetic effect and most associated regions harbor several genes, additional fine mapping of the loci in even larger sample sets is often necessary. To do this cost-efficiently, a custom-designed chip, the so-called CardioMetabochip (Illumina), was been developed for metabolic/cardiovascular gene mapping. This chip contains ~200,000 polymorphisms selected to cover association signals from a wide range of metabolic disorders (T2DM, lipid disorders, obesity, and cardiovascular disease), and was designed to perform both deep replication of major disease signals and fine mapping of established loci. Meta-analysis of previous GWAS by the DIAGRAM consortium with an additional 22,669 individuals with T2DM and 58,119 controls genotyped using the CardioMetabochip has recently added a further eight new loci associated with T2DM in the European population and two novel loci not previously reported in populations of European descent [50].

Recently, a number of GWAS and meta-analysis studies have also been performed with non-European cohorts, adding several new loci to the list of genome-wide significant associations [51–58]. Interestingly it seems that most associations found in one ethnic group also show some evidence of association in populations with other ethnicities. In total, GWAS have provided ~153 variants for T2DM mapping to >120 loci (Table 14.1, Figures 14.2 and 14.3) and also numerous loci for glucose- or insulin-related traits (Table 14.2), and more are likely to come.

Most studies to date have been limited to SNPs, leaving structural polymorphisms relatively unexplored. However, since common structural variants are likely to be tagged by surrounding SNPs, they are unlikely to explain a large proportion of missing heritability. A recent study identified a common copy number variant (CNV), CNVR5583.1 (*TSPAN8*), as associated with T2DM [65]. This association could be convincingly replicated by previously typed SNPs that tag the CNV [66].

Rare variants with stronger effects are often rare

Rare variants are more recent and therefore more likely to be those that arose recently in an extended pedigree. Of course, natural selection removes the more deleterious variants before they reach a high frequency, so risk alleles for diseases should be enriched at lower frequencies. The idea that there are unique rare variant combinations in families that play a role in disease etiology is referred to as "clan genomics" [59]. Recent data suggest that combined effects of rare and common variants contribute to varying extents to disease causation, not least linkage, and rare alleles may, in fact, explain the majority of heritability [60]. Next-generation sequencing provides an even denser coverage of genetic variation, rendering the detection of causal rare variants more feasible. Whole-genome sequencing (WGS) of 2630 Icelanders and imputation into 11,114 Icelandic individuals and 267,140 controls followed by testing in Danish and Iranian samples revealed variants in *PAM* and *PDX1* in risk of T2DM [61] (Table 14.3). Array-based genotyping and exome sequencing on a small founder population from Greenland revealed a nonsense p.Arg684Ter variant (allele frequency of 17%) in *TBC1D4* associated with higher concentrations of 2-hour glucose and serum insulin [62]. Whole exome sequencing in a Latino population revealed that a rare missense variant in *HNF1A* (c.1522G>A [p.E508K]) was associated with type 2 diabetes prevalence [63]. Additionally, rare variants associated with glycemic traits were discovered through exome sequencing of 9717 individuals from the METSIM study in Finland [64] (Table 14.3).

Protective variants

The average T2DM risk variant frequency in the general population is 54%, which raises the question of whether T2DM is the default condition. If so, then does carrying protective variants makes a difference in the disease susceptibility? Studies have been performed to address this question by including people without diabetes who, despite having clustering of risk factors for T2DM, have escaped the disease. A rare (0.66%) loss of function mutation (R138X) was detected in the *SLC30A8* gene in the Botnia region of Finland and subsequently replicated in a massive effort applying the Exome chip to >150,000 individuals in other European countries. Also, the DeCode group had identified another loss of function mutation, a frameshift mutation that was also enriched in the non-diabetic Icelandic population. The *SLC30A8* gene encodes the islet zinc transporter 8 with a putative effect on insulin secretion. Notably, a common variant in the same gene increases susceptibility to T2DM whereas autoantibodies to T1DM predispose to T1DM.

Collectively, carriers of these protein-truncating mutations have a 65% lower risk of T2DM [67]. Other studies based on Icelandic, Danish and Iranian populations identified a low-frequency variant in *CCND2* that reduced T2DM risk by half [61]. Moreover, variants in *TCF2* were found to be protective against T2DM [68]. It is also likely that more recent such variants that are only a few generations old segregate in families and could be detected though sequencing in families (Table 14.3).

Gene–gene and gene–environment interactions

Gene–gene interactions, or epistasis, have been suggested as a possible explanation for difficulties in replicating genetic association in complex diseases [106]. The standard statistical methods used in association studies are usually limited to the analysis of single marker effects and thereby do not account for interactions between markers. Previous attempts to study epistasis in complex diseases have focused on interactions between candidate regions [107, 108]. However, the recent abundance of GWAS data has made a comprehensive search across the genome more feasible. Some studies have attempted to account for epistasis in GWAS using a two-step approach in which significant SNPs are tested against each other or against all other SNPs in the study, with variable results [109, 110]. The main problem when studying epistasis is power, since interaction between loci with modest effects is difficult to detect without extremely large sample sizes. However, some studies have pointed at novel tests to increase power [111]. Thorough studies in diabetes addressing epistasis using this approach are lacking. Further, a recent paper by Lander and co-workers provided compelling evidence that gene–gene

Table 14.2 Genetic loci associated with glycemic traits.

interactions can also contribute to missing heritability by causing "phantom heritability" that inflates the estimated narrow sense heritability of the trait [112].

Gene–environment interactions are equally difficult to study but are likely to play an important role in T2DM development. The epidemic of T2DM dates back only 50 years, and it is obvious that during this period only the environment, not the genes, has changed. However, the genetic architecture determines our response to the environment. Genetic variants could affect specific metabolic processes to make an individual more susceptible to the harmful effects of a poor diet but also personality traits that make an individual more or less likely to over-consume and live a sedentary lifestyle. It will be a formidable task, however, to identify the environmental triggers for most of the genetic variants increasing susceptibility to diabetes, as this will require very large studies with precise information on diet, exercise, energy expenditure, etc.

Parent-of-origin effects

The risk of T2DM in offspring is greater if the mother has T2DM than if the father is affected, in contrast to T1DM, where the risk of T1DM in offspring is greater if the father is affected [90, 91]. Sex-specific parental effects have been reported for insulin response to the oral glucose load, with male offspring of mothers with diabetes showing the lowest insulin values, and also influencing HDL concentrations [90]. One potential explanation for this could be preferential parental specific transmissions of risk alleles to offspring, which is often associated with DNA methylation and imprinting. Epigenetic modifications have the potential to be stable and heritable across cell divisions [92, 93] and manifest as parent-of-origin effects. Insulin was the first gene reported to show parent-of-origin effects. The paternally transmitted class III alleles of the variable number tandem repeat (VNTR) region upstream of the insulin gene (*INS*-VNTR) showed association with T2DM [94]. Interestingly, class III alleles

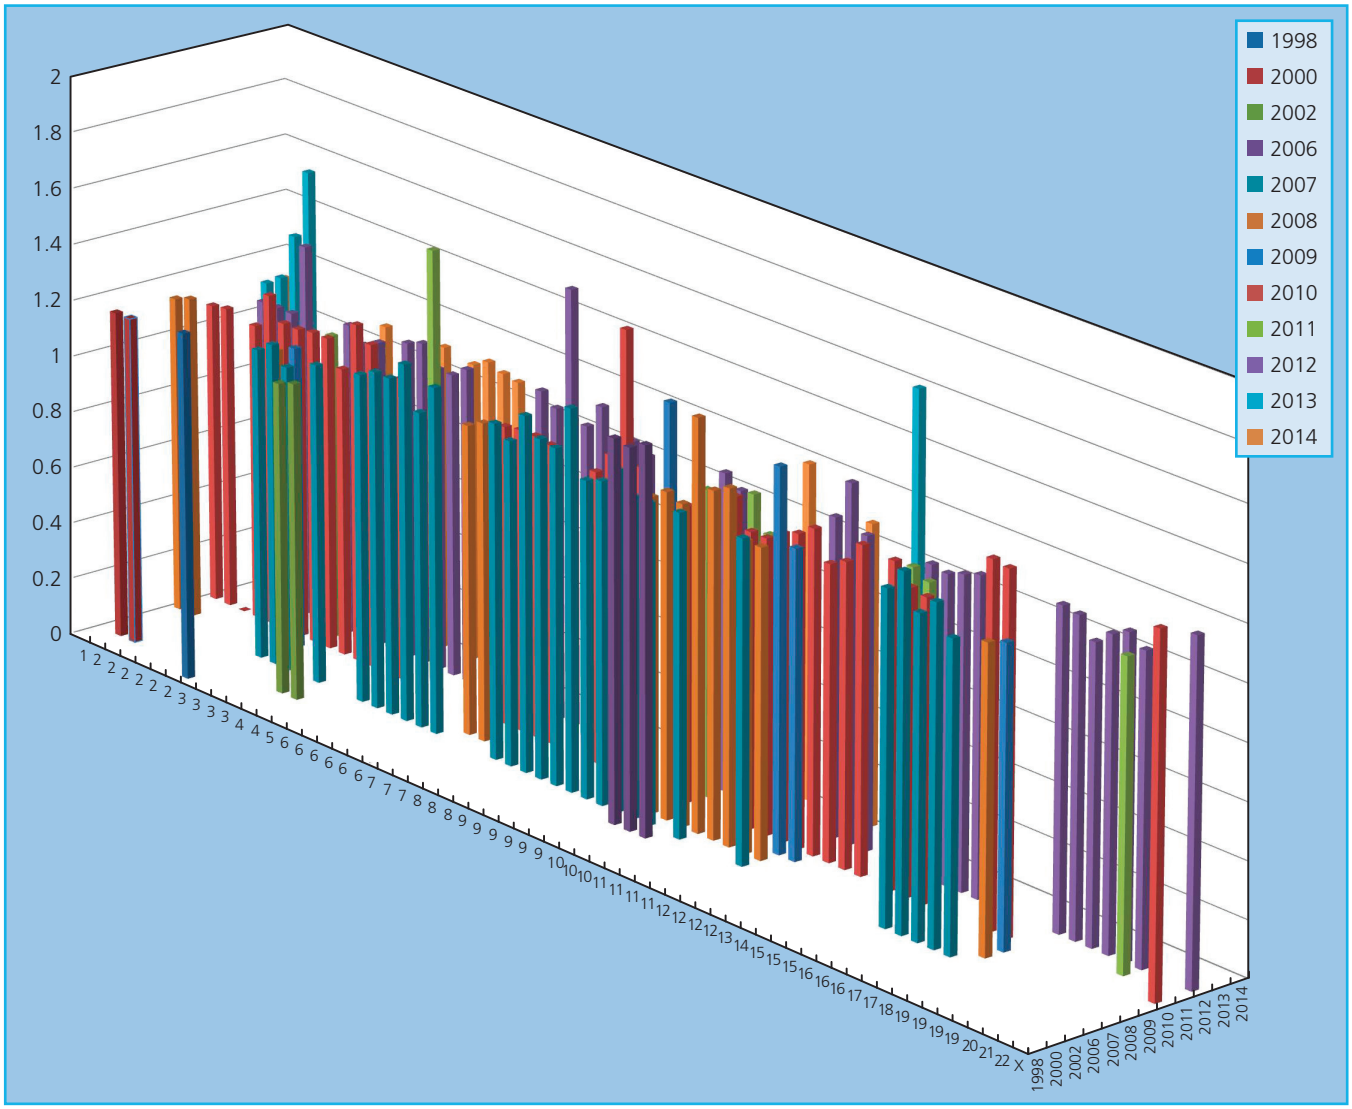

Figure 14.2 T2DM risk variants. The *x*-axis shows the chromosomal location, the *y*-axis shows the effect sizes, and the *z*-axis shows the year of discovery. One risk variant was reported in 1998, two in 2002, to a total of 153 T2DM variants that we have today. Source: Prasad RB, Groop L. Genetics of type 2 diabetes—Pitfalls and possibilities. *Genes* 2015; **6**:87–123 (this is an open-access article distributed under the Creative Commons Attribution License [CC BY]).

(one of the two main classes of *INS*-VNTR allele length, with 141–209 repeats) were also associated with increased length and weight at birth [95] and were protective against type 1 diabetes compared with type I alleles [96]. A large-scale family-based study on an Icelandic population determined that variants in *KCNQ1* and *KLF14* show stronger effects on T2DM when the risk allele is transmitted from the mother than from the father [97, 98] and this was replicated in later studies [99], including our own.

The conflict hypothesis suggests that imprinting arose due to a genomic tug-of-war between mothers and fathers over the use of maternal resources in the fetus. The paternal imprinting maximizes the utilization of intrauterine resources to the offspring which would increase their evolutionary fitness whereas the maternal imprinting tries to minimize this in order to conserve it for her future offspring [100]. Conversely, the co-adaptation hypothesis suggests that imprinted genes coevolve to optimize parental care of offspring. Although there is insufficient evidence to support either theory, nevertheless, the significant role of imprinting in defining paternal and maternal effects has been consistently established [101].

The intrauterine environment plays a significant role in determining fetal programming. It has been shown that poor nutrition can affect fetal growth, can produce permanent changes in glucose–insulin metabolism, and often results in low birth weight [102] This can induce permanent changes in metabolism and affect chronic disease susceptibility as proposed by the Developmental Origin of Health and Disease hypothesis [103]. If this intrauterine programming results in a reduced β-cell mass, it could predispose to diabetes later in life when the insulin requirements increase as a consequence of obesity resulting

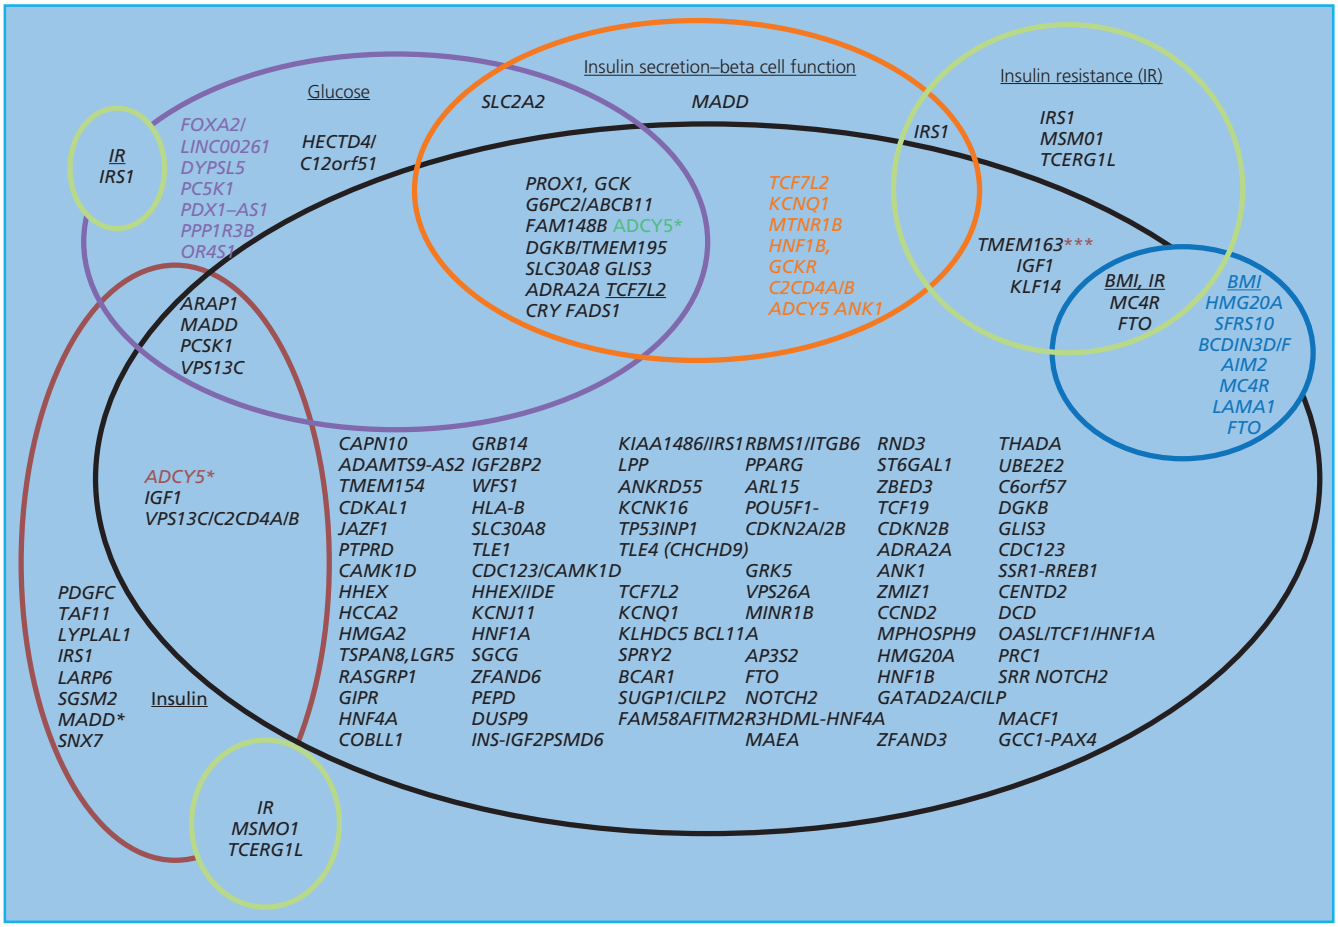

Figure 14.3 T2DM and glycemic trait-associated variants. The variants are represented by gene names here, which could indicate that the location is present either in the gene or in the vicinity of the gene. The black circle represents T2DM, and the gene names in black in this represent variants associated only with T2DM. The overlapping circles indicate additional reporting associations for that variant; for instance, *TCF7L2*, *KCNQ1*, *MTNR1B*, etc., are associated with T2DM and also with β-cell dysfunction. An ADCY5 variant is associated with 2-h insulin adjusted for 2-h glucose, 2-h glucose/T2DM (in brown) ***Variants in TMEM163 are also associated with fasting insulin, *TCF7L2*, associated with fasting and 2-h glucose, and *MADD* variants, associated with fasting proinsulin, fasting glucose and HOMA-B. Source: Prasad RB, Groop L. Genetics of type 2 diabetes—Pitfalls and possibilities. *Genes* 2015; **6**:87–123 (this is an open-access article distributed under the Creative Commons Attribution License [CC BY]).

in insulin resistance. *KCNQ1* could represent an example of fetal programming wherein the maternally expressed gene was monoallelically expressed in fetal tissues and biallelically expressed in adult tissues [104].

Dissection of genetic parent-of-origin effects requires genotype data from families and only heterozygous parents are informative, yielding reduced power for relatively rare variants. However, long-range phasing and imputation methods allow the prediction of genotypes with a great likelihood, thus making this a valuable method for finding "surrogate" parents even if DNA exists from only a few family members. When the paternal and maternal alleles have effects in opposite directions, for instance a situation where the maternal allele could confer risk whereas the paternal allele could be protective, such an association would be almost impossible to detect in a traditional case–control GWAS. However, novel parent-of-origin detection methods allow the detection of imprinting effects from differences in the phenotypic variance of heterozygotes in very large case–control studies [105]. Parent-of-origin effects could explain a large proportion of the missing heritability and must be taken into consideration in investigations of genetic T2DM susceptibility.

Epigenetics

The environment can also influence the expression of the genome, and ultimately the phenotype, via the epigenome. Even though the DNA sequence is not changed, the phenotype is altered by epigenetic modifications of gene expression by mechanisms including methylation of DNA, post-translational modification of histones, or activation of microRNAs. Changes to the phenotype can be at the level of the cell, tissue, or whole organism.

It is tempting to speculate that environmental factors such as diet and exercise can change the level of DNA methylation and thereby cause changes in gene expression, but evidence that DNA methylation contributes to the increase in T2DM is still

lacking. Epigenetic mechanisms may, however, play a role in progression of the disease by inducing glucotoxicity in islets and predispose to diabetic complications [113]. Elevated glucose is a prerequisite to this condition and it is well established that cells can memorize changes in glucose concentrations. For example, two large studies, the UKPDS and DCCT studies, showed that initial good metabolic control was associated with reduced frequency of diabetic complications decades later. The advanced "metabolic memory" hypothesis suggests that this is because glucose can induce histone modifications in endothelial cells that can be remembered long after [114].

Non-coding RNAs – microRNAs and lincRNAs

Non-coding RNAs have recently emerged as important regulators of gene expression and function. MicroRNAs (miRNAs) naturally regulate programs of gene expression. Altered miRNA function has been shown to contribute to human disease, and manipulation of specific miRNAs is now being explored as a novel therapeutic modality [115]. The efficiency of miRNAs binding to target transcripts depends on both the sequence and the intramolecular structure of the transcript. SNPs can contribute to alterations in the structure of regions flanking them, thereby influencing the accessibility for miRNA binding. Several studies have implicated miRNAs in diabetes and inflammation and common SNPs change the target sequence of miRNAs in several T2DM susceptibility loci (http://omictools.com/dbsmr-tool) [116, 117]. Other forms of non-coding RNAs, such as piRNAs (PIWI-interacting RNAs), snoRNAs (small nucleolar RNAs), lincRNAs (long intergenic non-coding RNAs), and lncRNAs (long non-coding RNAs), might also contribute to the development of diabetes. For example, the *CDKN2A/B* region on chromosome 9 is associated with T2DM, and also in cardiovascular disease and a number of other disorders. This region harbors a lincRNA, *ANRIL* (non-protein coding *CDKN2B-AS1 CDKN2B* antisense RNA 1), which can potentially modify and explain some of these associations [118].

Difficulties in assigning functions to associated genes

Most identified diabetes loci have not been tied mechanistically to the disease. While loci are commonly referred to by the names of genes located close to them, only a few are close to strong biological candidates, e.g. the melatonin receptor (*MTNR1B*) and the insulin receptor substrate-1 (*IRS1*). For others, such as *TCF7L2* and *GIPR*, the evidence is fairly strong that an intronic

SNP is the causal SNP. Melatonin receptor 1B (*MTNR1B*) has been associated with both fasting glucose and T2DM risk [74–76]. Melatonin works as a chronobiotic factor, adjusting the timing of the biological clock. Its receptors are present in the pancreas and melatonin is proposed to contribute to the nocturnal lowering of insulin in humans. The *MTNR1B* risk genotype is associated with impaired early insulin release to both oral and intravenous glucose and insulin secretion deteriorates over time in the risk allele carriers [74]. The proposed mechanism by which *MTNR1B* polymorphism could predispose to T2DM involves altered expression of *MTNR1B* in pancreatic β cells, leading to decreased cAMP/cGMP concentrations via G-proteins and, thereby, impaired insulin secretion.

The insulin receptor substrate 1 (*IRS1*) gene encodes a protein that mediates insulin's control of various cellular processes by transmitting signals from the insulin receptor to intracellular signaling pathways. The C allele of rs2943641 has been shown to be associated with insulin resistance and increased risk of diabetes. The genetic variant causes reduced basal levels of IRS1 protein and decreased insulin induction of IRS1-associated phosphatidylinositol-3-hydroxykinase activity in human skeletal muscle biopsies [77].

TCF7L2 is a transcription factor playing an important role in the Wnt signaling pathway. The risk allele is associated with decreased insulinogenic index and lower disposition index, suggesting a reduced capacity for insulin secretion in relation to insulin sensitivity. Since it was identified as a diabetes gene, it has been shown to be important for several vital functions in the pancreatic islet, including pancreas development, determination of β-cell mass, maintenance of the secretory function of mature β cells, and regulation of insulin production and processing [78, 79].

The incretin hormone GIP (glucose-dependent insulinotropic polypeptide) promotes pancreatic β-cell function by potentiating insulin secretion and β-cell proliferation. The GIP receptor (*GIPR*) locus showed association to postprandial insulin levels in a meta-analysis performed by the MAGIC consortium but was surprisingly not associated with risk of diabetes in the DIAGRAM+ study [23, 80]. The reason seems to be that the same variant results in decreased BMI, which neutralizes the effect of the SNP on risk of T2DM. GIP influences expression of the inflammatory cytokine OPN in islets, which in turn has protective effects on β-cell proliferation and potentially apoptosis [81].

Many of the other identified loci can be subgrouped based on their association with other phenotypes with a key role in T2DM etiology. Exploration of the effects of T2DM-associated variants on glucose and insulin traits in non-diabetic populations has shown that most of the known loci act through an effect on insulin secretion rather than insulin resistance (Table 14.1) [23, 82–84].

Fasting glucose-raising alleles of the *MADD*, *GIPR*, *GCK*, *FADS*, *DGKB*, *PROX1*, *TCF7L2*, *SLC30A8*, and *C2CD4B* loci have all been associated with either abnormal insulin processing or secretion, whereas *GCKR* and *IGF1* are associated with OGTT-based disposition indices and β-cell function [83]. The DIAGRAM+ consortium observed that three loci (*TCF7L2*, *ARAP1*, and *CDKAL1*) were associated with reduced fasting insulin, also suggestive of β-cell dysfunction, whereas the T2DM risk alleles at *PPARG*, *FTO*, *IRS1*, and *KLF14* were associated with higher fasting insulin, indicating a primary effect on insulin action [23].

Genotype-based treatment

The *ADRA2A* (adrenergic receptor alpha 2) locus was recently identified as a T2DM risk locus after first having been positionally mapped in congenic GK rats, where it was associated with impaired insulin granule docking and reduced β-cell exocytosis [82]. Human carriers of the *ADRA2A* risk variant (rs553668) have reduced fasting insulin and decreased insulin secretion as a consequence of increased expression of the ADRA2 receptor in pancreatic islets. It is well known that excess epinephrine can suppress insulin secretion and cause diabetes. The α_{2A}AR antagonist yohimbine enhances insulin release *in vitro* in islets from organ donors carrying the risk allele to levels similar to those in non-risk carriers. A randomized clinical study was performed blocking α_{2A}AR pharmacologically to increase insulin secretion in individuals with T2DM with the rs553668 risk allele. Yohimbine administration enhanced 30-min insulin, corrected insulin response, and disposition index in the risk group, making secretion similar to that in persons carrying the low-risk allele. Insulin secretion defect in individuals carrying the *ADRA2A* risk genotype could be corrected by α_{2A}AR antagonism [85]. This demonstrated the potential application of genetic risk variants to guide therapeutic interventions that target the underlying pathophysiology, one step closer to individualized medicine.

Little common genetic basis for T1DM and T2DM

T1DM and T2DM can be considered two extremes of the diabetes spectrum and share a few similarities in manifestation of underlying physiology, including hyperglycemia, insulin deficiency, and development of complications. However, the genetics of T1DM and T2DM differ greatly, with very few T2DM susceptibility loci showing an association with T1DM. Notable exceptions include the *PPARG* Pro12Ala variant, *MTNR1B*, *HNF1A*, *GLIS3*, 6q22.32, and novel loci near the major histocompatibility complex (MHC), which harbor the HLA class II genes associated with about half of the T1DM risk [58, 119–121]. Based on these studies, the mechanisms underlying T1DM and T2DM appear to be intrinsically distinct. The distribution of T2DM risk SNPs should be more random in a person with T1DM; however, this does not seem to be the case. The strongest T2DM SNP in the *TCF7L2* gene almost seems to protect against T1DM. T1DM risk variants for *BCAR1*, *GLIS3*, and *RAD51L1* were protective for T2DM whereas for those in *C6orf173*, *COBL*, and *C10orf59*, the effects were concordant [50]. Also, it has been reported that *APOC3* haplotypes increase the risk of T1DM, but the same variants increase the risk of T2DM in lean carriers while having a protective effect

in overweight carriers [122]. Common variants in *SLC30A8* are associated with an increased risk of T2DM, and rare variants with a protective effect [46, 67]. Puzzlingly, SLC30A8 was also found to be a major autoantigen, eliciting 60–80% autoantibodies in individuals with new-onset T1DM [123].

Curiously, gene variants associated with T1DM underwent recent positive selection and have been increasing in prevalence. There is more selection in alleles increasing, rather than decreasing, susceptibility to T1DM. This is indicative of an evolutionary benefit, wherein these variants were possibly protective against viruses and bacterial infections. However, no such link has been reported for T2DM risk variants, as could be expected from the thrifty genotype hypothesis [124]. In terms of genetics, T2DM seems to have more in common with cancer rather than T1DM [125]. It has been suggested there may rather be a specific yin–yang relationship between cancer and T2DM, with too much cell proliferation resulting in cancer and insufficient proliferation of pancreatic islets resulting in T2DM [125].

LADA is considered an intermediate form between T1DM and T2DM, and is also referred to as type 1.5 diabetes. There is much less information available on the genetic basis of LADA compared with T1DM and T2DM. One way to understand this would be to assess the extent LADA to which shares genetic similarities with T1DM and T2DM. The HLA locus, conferring 50% of the genetic susceptibility of T1DM, also shows similar associations with LADA, with a few differences. The T1DM variant *PTPN22* shows a weak association with LADA. Data on the *INS* class I VNTRs have been inconclusive and associations reported with both T1DM and T2DM wherein the short tandem repeat was associated with T1DM and the long repeat with T2DM. Although previously several T1DM-associated variants could be tested for association with LADA, it was not until the discovery that the common variant in the *TCF7L2* gene was strongly associated with T2DM that the genetic contribution of T2DM to LADA could really be tested. This variant is clearly associated with LADA and T2DM but not with T1DM. This indicates that LADA is indeed a genetic admixture of T1DM and T2DM.

There are more lessons to be learned from differences between T1DM and T2DM rather than similarities. Elucidating the genetic heterogeneity of the spectrum of diabetes disorders will help us in understanding the mechanisms underlying the phenotypic heterogeneity of diabetes and would be a step towards individualized therapy.

A holistic view – systems genetics

A restricted focus on the genome through GWAS provides limited insights into the molecular mechanisms driving disease and is akin to a snapshot of the genetics of the disease. To obtain an understanding of disease pathogenesis, it is important to analyze the GWAS data in the context of complementary follow-up analyses, including DNA methylation and histone modifications, expression profiling under conditions relevant for the disease, related protein analysis, and analysis of genotype–phenotype associations. Global transcriptome profiling in relevant tissues such as the pancreas has facilitated identification and cataloguing of a wide array of transcription based events in the pathogenesis of T2DM [126]. For example, by combining GWAS information with metabolomics, it has been possible to identify strong associations between SNPs and metabolic reactions that otherwise would have been missed [127]. Network- or pathway-based approaches, including enrichment in predefined pathways by, for example, KEGG [128] (http://www.genome.jp) and Gene Ontology (GO) (http://www.geneontology.org), have also been used to identify disease genes for various diseases. Thus, an integrative approach with several data types is likely to discover disease genes that would not be identified by the use of classical GWAS approaches alone. This was also illustrated in recent studies of human islets identifying novel candidate genes for T2DM based upon expression differences and coexpression with known T2DM genes and also protein–protein interaction analyses [129, 130]. Integration of GWAS data with such data could thus facilitate a systems-based understanding of the pathogenic mechanisms.

Conclusions

Advances in genomic technology have initiated a myriad of novel genetic discoveries including more than 100 common variants contributing to risk of complex disease. This has led to a deeper understanding of the underlying biology and pathogenesis of these diseases. The genetic landscape of T2DM susceptibility is as yet incomplete, so far explaining only a small proportion of the total heritability of diabetes. Many possibilities for dissecting the architecture of T2DM etiology have emerged in the form of large-scale genetic studies, meta-analyses and sequencing in families. This work has already contributed greatly to our understanding of disease mechanisms by identifying pathways that could not be linked to diabetes by existing hypothetical models, even though many genetic findings are very recent and have yet to make their contribution to our knowledge about diabetes pathogenesis. However, one must bear in mind that diabetes is probably a much more diverse disease than the current subdivision into T1DM and T2DM implies, and a more precise subdivision into subgroups may both facilitate the investigation of T2DM genetics and pave the way for more individualized treatment. A holistic systems biology approach will also be required to obtain a complete picture of how genetic variation leads to diabetes. The rapid technology development during recent years holds promise that this will be possible in the not too distant future.

15 Metabolic Disturbances in Diabetes

Adrian Vella and Robert A. Rizza

Division of Endocrinology, Diabetes, Metabolism and Nutrition, Mayo Clinic, Rochester, MN, USA

Key points

- Type 1 diabetes mellitus (T1DM), or immune-mediated diabetes, is characterized by evidence of immune-mediated destruction of the insulin-secreting β cells in the islets of Langerhans.
- In type 2 diabetes mellitus (T2DM), although the endocrine pancreas can produce insulin, secretion and circulating concentrations of insulin are inappropriate for the prevailing glucose concentrations.
- Glucose disposal depends on insulin secretion, insulin action, suppression of glucagon, and the ability of glucose itself to stimulate glucose uptake and suppress glucose release.

Introduction

Hyperglycemia, for better or for worse [1], is the metabolic abnormality that has been used to define the presence of, and characterize, diabetes. Diabetes comprises a heterogeneous group of disorders characterized by fasting and/or postprandial hyperglycemia. The underlying abnormalities that lead to the development of hyperglycemia, however, differ amongst subgroups. Conventionally, diabetes has been categorized into two subgroups that, from a metabolic standpoint, differ in the degree of insulin deficiency present. This broad dichotomy is simplistic as a given individual may exhibit metabolic abnormalities previously considered unique to each category [2].

Type 1 diabetes mellitus (T1DM), or immune-mediated diabetes, is characterized by evidence of immune-mediated destruction of the insulin-secreting β cells in the islets of Langerhans. Usually this leads to absolute insulin deficiency, which is insufficient to prevent unrestrained lipolysis during systemic illness or severe physical stress. In type 2 diabetes mellitus (T2DM), however, although the endocrine pancreas can produce insulin, secretion and circulating concentrations of insulin are inappropriate for the prevailing glucose concentrations. T2DM has traditionally been considered a disorder of insulin signaling (exacerbated by poor diet, obesity, and lack of physical activity) rather than a deficiency of insulin.

It is important to remember that obese individuals with T1DM can behave in a fashion similar to those with long-standing T2DM and that metabolic differences between the two categories may be more imagined than real.

Carbohydrate metabolism

In the fasting state, glucose appearance is determined by the rate of endogenous glucose release from the liver and to a lesser extent the kidney. This is collectively referred to as endogenous glucose production. Glucose concentrations increase when glucose appearance exceeds glucose disappearance and continues to increase until these rates are equal. In humans without diabetes, glucose concentrations average 4.5–5.5 mmol/L following a 6–12-h overnight fast.

Gluconeogenesis is responsible for ~50–60% of endogenous glucose production following an overnight fast, with the proportion increasing with increasing duration of the fast [3]. Gluconeogenesis utilizes three-carbon precursors such as lactate, alanine, and glycerol to synthesize glucose molecules.

Following an overnight fast, ~80% of glucose disposal is insulin independent and occurs in the brain, splanchnic tissues, and erythrocytes [4]. The majority of insulin-mediated glucose disposal occurs in muscle [5]. Because insulin levels are low in the postabsorptive state, muscle tissue predominantly uses free fatty acids (FFAs) for fuel [6]. In the presence of low insulin concentrations, glucose taken up by tissues predominantly is oxidized or undergoes glycolysis to release alanine and lactate, which can be reutilized by the liver for gluconeogenesis [7].

Sensitivity to insulin varies amongst tissues. Low concentrations of insulin limit lipolysis and prevent unrestrained breakdown of fat. The insulin concentrations sufficient to prevent lipolysis are insufficient to stimulate significant muscle glucose uptake. Whereas maximal suppression of endogenous glucose production

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

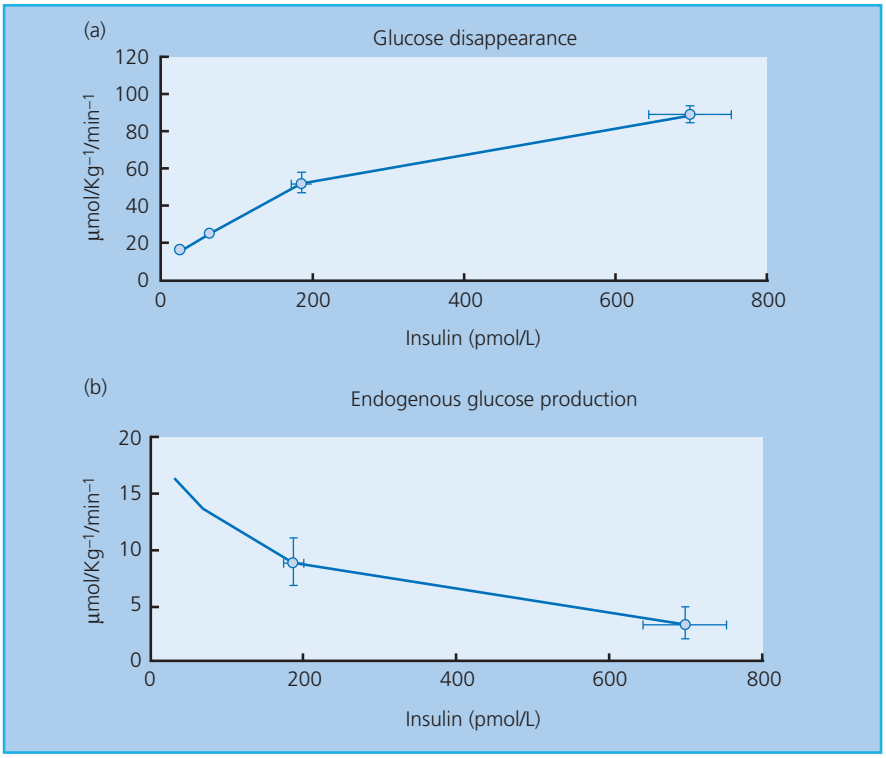

Figure 15.1 Insulin dose–response curves for glucose production and utilization in individuals without diabetes. Source: Adapted from Vella A. *Diabetologia* 2002; **45**:1410–1415. Reproduced with permission from Springer-Verlag.

occurs at insulin concentrations of ~250 pmol/L, these concentrations result in only half maximal stimulation of glucose uptake (Figure 15.1) [8].

Increases in plasma glucose, which occur within 5–10 min after eating, stimulate insulin secretion and suppress glucagon secretion. The reciprocal changes in hepatic sinusoidal insulin and glucagon concentrations in concert with the elevated glucose concentrations enhance hepatic glucose uptake and suppress hepatic glucose production [9, 10]. The splanchnic tissues initially extract 10–25% of ingested glucose and eventually dispose of ~40% of ingested glucose, with muscle accounting for most of the remainder [11]. It is important to note the significant variability in the reported splanchnic extraction of glucose, a significant proportion of which is explained by limitations of the tracer methodology used [12]. These coordinated changes in hepatic and extrahepatic glucose metabolism generally limit the postprandial rise in glucose to 7–8 mmol/L. Late postprandial hypoglycemia is avoided by a smooth increase in hepatic glucose output to rates that closely approximate glucose uptake.

In the transition from normal glucose metabolism to overt diabetes, the relative contribution of alterations in glucose disappearance or appearance is uncertain. Most [13–16] but not all [17] epidemiological studies that have attempted to elucidate the pathogenesis of impaired fasting glucose (IFG) (defined as a fasting glucose of 5.8–6.9 mmol/L) have reported that insulin action is decreased in individuals with IFG. Weyer et al. [16] reported that fasting endogenous glucose production was increased in people with IFG. Bock et al. [18] subsequently established that insulin-induced suppression of endogenous glucose production and gluconeogenesis are impaired in people with IFG, indicating hepatic insulin resistance. Epidemiological studies have shown that 20–30% of people with IFG will develop frank diabetes within 5–10 years [19, 20]. Indeed, individuals with a fasting glucose between 5.3 and 5.7 mmol/L have an 8% risk of developing diabetes within the next 10 years.

Regulation of glucose concentrations after meal ingestion is more complex. The pattern of change of postprandial plasma glucose concentrations is determined by the extent to which glucose entering the systemic circulation (equal to the sum of endogenous glucose production and the systemic appearance of ingested glucose) exceeds or is exceeded by the rate at which glucose leaves the systemic circulation (glucose disappearance). Therefore, differences in postprandial glucose concentrations could theoretically arise because of differences, alone or in combination, in rates of meal glucose appearance, suppression of endogenous glucose production, or stimulation of glucose uptake [21, 22].

Postprandial hyperglycemia is primarily caused by reduced postprandial glucose disappearance because suppression of endogenous glucose production and the rate of appearance of ingested glucose do not differ in people with IFG and normal fasting glucose [18]. The insulin secretion in response to higher postprandial glucose concentrations is impaired in people with IFG with accompanying defects in glucose disappearance and consequent postprandial hyperglycemia. A further reduction in insulin secretion eventually results in overt T2DM [18].

Endogenous glucose production is regulated (inhibited) by insulin, which increases hepatic glucose uptake by stimulating glucokinase activity and decreases hepatic glucose release by

decreasing the conversion of glucose-6-phosphate to glucose. The latter step is regulated by glucose-6-phosphatase. Insulin can also stimulate glycogen synthesis, inhibit glycogen breakdown, and suppress gluconeogenesis. Postprandial hyperglycemia and hyperinsulinemia stimulate hepatic glycogen synthesis, thereby replenishing hepatic glycogen stores. Hepatic glycogen synthesis occurs via both the direct (i.e. glycogen synthesis utilizing glucose-6-phosphate derived directly from extracellular glucose) and indirect pathway (i.e. glycogen synthesis utilizing glucose-6-phosphate derived from gluconeogenesis). The relative contribution of these two pathways appears to be determined by multiple factors, including the duration of fast, composition of the meal, and the prevailing insulin and glucagon concentrations [23, 24].

In the presence of euglycemia, rising hepatic sinusoidal concentrations of insulin suppress endogenous glucose production by decreasing glycogenolysis. Insulin concentrations within the physiological range in healthy humans do not appreciably suppress gluconeogenesis and direct glucose-6-phosphate (derived from gluconeogenesis) into glycogen [25].

Carbohydrate metabolism in type 1 diabetes

T1DM is characterized by insulin deficiency as a result of autoimmune destruction of the pancreatic β cells. Fasting hyperglycemia does not develop until most (>80%) of the β cells are lost to the underlying autoimmune process. Defects in insulin secretion, however, are evident years before the development of diabetes in asymptomatic affected individuals. For example, siblings of people with T1DM who are islet antibody positive (a group at high risk for the development of T1DM) frequently exhibit a decreased first phase of insulin secretion in response to intravenous glucose injection [26, 27]. This usually occurs at a time when the response to other stimuli such as oral glucose or mixed meal ingestion is intact, suggesting that incretins and other secretagogues are capable of compensating for decreased islet cell mass.

Impaired insulin secretion is frequently accompanied by impaired insulin action [28, 29]. The severity of insulin resistance is related to the degree of glycemic control. People with poorly controlled T1DM may exhibit the same degree of insulin resistance as people with T2DM [29, 30]. In people with T1DM, the defect in insulin action is tissue specific; for example, glucose uptake in cardiac muscle, as opposed to skeletal muscle, is normal [31]. Glucose oxidation and non-oxidative storage in people with T1DM are decreased in proportion to glucose uptake, suggesting that glucose transport and/or phosphorylation (after transport across the membrane) are the sites of defective insulin action [32]. In contrast, insulin-induced suppression of glucose production is not impaired and may in fact be increased in people with T1DM [33, 34].

Insulin binding and action have been reported to be decreased in adipocytes [35, 36] but normal in fibroblasts [37, 38] of people with T1DM. This may be explained by the fact that insulin binding in adipocytes is measured immediately after biopsy whereas insulin binding to fibroblasts is measured following several days of culture. Decreased insulin binding in the former but not the latter suggests an effect of abnormal metabolic milieu rather than an intrinsic defect of insulin action. This is supported by several observations that improved chronic glycemic control is accompanied by improved whole-body insulin action [39, 40]. It should be noted that when insulin action is measured by means of a hyperglycemic hyperinsulinemic clamp, hyperglycemia may compensate for small defects in insulin action by means of its ability (glucose) to stimulate its own uptake and suppress its own release (glucose effectiveness) [34].

Because insulin is typically delivered via the subcutaneous rather than the intraportal route, treatment with insulin leads to systemic hyperinsulinemia, which has been shown to impair insulin action in humans without diabetes [41]. The improved insulin action observed in people with T1DM following treatment with insulin, however, suggests that any negative effects of systemic hyperinsulinemia on insulin action are more than offset by the lowering of glucose concentrations and the reversal of glucose toxicity.

In the absence of insulin-stimulated muscle glucose uptake, substantial glucose disappearance in insulin-deficient people with T1DM occurs by glucose excretion in the urine and by glucose uptake via non-insulin-mediated pathways [42]. Food ingestion does not result in a rise in insulin or a reciprocal decrease in glucagon concentration [43]. Because of this, the increase in splanchnic glucose uptake and the decrease in endogenous glucose production are not appropriate for the prevailing glucose concentration. Postprandial glycogen synthesis is markedly decreased, with most of the glycogen being synthesized by the indirect gluconeogenic pathway [44, 45].

Consequently, because of abnormal hepatic glucose handling, excessive amounts of glucose reach the systemic circulation. The excessive rise in postprandial glucose concentrations is compounded by the low insulin concentrations and defective insulin action present in people with poorly controlled T1DM [42, 46]. In contrast, the ability of glucose to stimulate its own uptake and suppress its own release (glucose effectiveness) is normal in T1DM and most postprandial glucose disposal occurs predominantly via non-insulin-mediated pathways and by glucose excretion in the urine [47].

Postprandial glucose metabolism in the splanchnic and extrasplanchnic tissues can be almost completely normalized by insulin administration, which increases circulating insulin concentrations and prevents the excessive rise in counter-regulatory hormones that accompanies insulin deficiency. Insulin administration also restores postprandial suppression of glucose production and stimulation of glucose uptake to rates similar to those observed in persons without diabetes [42, 48].

Animal studies have shown diabetes to be associated with hypertrophy of the intestinal mucosa and increased intestinal glucose transport [49, 50]. By contrast, when glucose, insulin, and glucagon concentrations are matched in individuals with

T1DM and age- and weight-matched controls, initial splanchnic glucose extraction and uridine diphosphate (UDP)–glucose flux (an index of hepatic glycogen synthesis) do not differ between groups. This demonstrates that relative insulin deficiency, glucagon excess, or both, rather than an intrinsic defect in splanchnic glucose metabolism, are the primary causes of postprandial hyperglycemia in people with poorly controlled T1DM [34].

Carbohydrate metabolism in type 2 diabetes

People with T2DM have elevated fasting glucose levels and excessive glycemic excursions following carbohydrate ingestion. Insulin secretion in those with T2DM is typically decreased and delayed following food ingestion [9, 22]. Defects in insulin secretion are observed early in the evolution of T2DM. In fact, alterations in both the timing and amount of insulin secreted have been reported in relatives of persons with T2DM prior to the development of hyperglycemia [51, 52].

Chronic hyperglycemia alone or in combination with elevated FFA impairs insulin secretion. Abnormalities in glucose sensing, insulin processing, or intracellular signaling can alter insulin secretion [53]. In addition, β-cell mass decreases with increasing duration of diabetes [54, 55]. Alterations in β-cell morphology occur in most people with T2DM, with extensive intra-islet deposition of amylin commonly being observed [56, 57].

Prolonged elevations in glucose concentration following ingestion of a carbohydrate-containing meal occur because postprandial glucose appearance exceeds disappearance. The more significant the defects in insulin secretion and action, the higher glucose concentrations have to rise to balance glucose appearance and disappearance [58]. Glucose appearance is elevated owing to failure to suppress hepatic glucose production because the systemic rate of appearance of ingested glucose does not differ from that observed in individuals without diabetes [9, 11, 18, 59]. Although glucose disappearance is commonly higher in people with diabetes than in those without diabetes following a meal, in large part this is accounted for by elevated rates of urinary glucose excretion. Furthermore, although elevated, the rates of glucose disappearance are not appropriate for the prevailing glucose concentrations [60, 61].

Defects in insulin secretion and action both contribute to postprandial hyperglycemia. A delay in the early rise in insulin concentrations causes a delay in suppression of glucose production, which in turn results in an excessive glycemic excursion. In contrast, a decrease in insulin action results in sustained hyperglycemia but has a minimal effect on peak glucose concentrations. Whereas an isolated alteration in either hepatic or extrahepatic insulin action impairs glucose tolerance, a defect in both results in severe hyperglycemia [58].

Glucose is also an important regulator of its own metabolism. In the presence of basal insulin concentrations, an increase in plasma glucose stimulates glucose uptake and suppresses glucose production. The ability of glucose to regulate its own metabolism is impaired in T2DM. This is commonly referred to as a defect in "glucose effectiveness." Whereas intravenous infusion of 35 g of glucose in individuals without diabetes whose insulin concentrations are clamped at basal levels produces only a modest rise in plasma glucose concentration, infusion of the same amount of glucose results in severe hyperglycemia in people with T2DM [62]. The excessive rise in glucose is caused by impaired glucose-induced stimulation of glucose uptake because glucose-induced suppression of glucose production is normal [62, 63].

Inhibition of glucagon secretion lowers both fasting glucose and postprandial glucose concentrations. Failure to suppress glucagon secretion appropriately, however, has minimal effects on glucose production and glucose tolerance when insulin secretion is intact [64, 65]. In contrast, it causes marked hyperglycemia when insulin secretion is decreased and delayed, as is typical in T2DM. Taken together, these data suggest that agents that simultaneously improve insulin secretion, insulin action, glucose effectiveness, and glucagon secretion are likely to have a profound effect on glucose metabolism in people with T2DM (Figure 15.2) [65, 66].

Amylin is a 37 amino acid polypeptide that is co-secreted with insulin by the pancreatic β cells in response to nutrient stimuli and other secretagogues. Human studies have shown that the plasma concentrations of amylin and insulin rise and fall in parallel in both the fasted and fed states [67]. Because amylin is potentially toxic to β cells, it has been suggested that excessive amylin secretion may contribute to β-cell destruction in T2DM [68, 69].

The secretion of incretins such as glucagon-like peptide 1 (GLP-1) in response to meal ingestion is decreased in T2DM [70–72]. Supraphysiological concentrations of GLP-1, achieved by either intravenous infusion or subcutaneous injection, lower both fasting and postprandial glucose concentrations in people with T2DM. GLP-1 does so by increasing insulin secretion, inhibiting glucagon secretion, and delaying gastric emptying [73–76]. By contrast, GLP-1 does not appear to alter insulin action or glucose effectiveness in T2DM [77].

In addition to defects in insulin secretion, people with T2DM commonly exhibit defects in insulin action. Numerous studies have shown that insulin-induced stimulation of glucose uptake in muscle and adipose tissues and also insulin-induced suppression of glucose production are impaired in T2DM [78, 79]. The severity of insulin resistance is influenced by multiple factors, including exercise, obesity, and diet, and also genetic factors. Insulin resistance increases with increasing severity of diabetes and improves but is not normalized by improved glycemic control [80]. Defects in the ability of insulin to regulate muscle and fat glucose metabolism are evident in normoglycemic relatives of people with T2DM, strongly implying a genetic basis for at least some degree of insulin resistance [51, 81].

Both glucose production and the contribution of gluconeogenesis to glucose production are increased in people with "mild" in addition to "severe" T2DM [82]. The increase in glucose production is correlated with the severity of hyperglycemia [22, 59, 83].

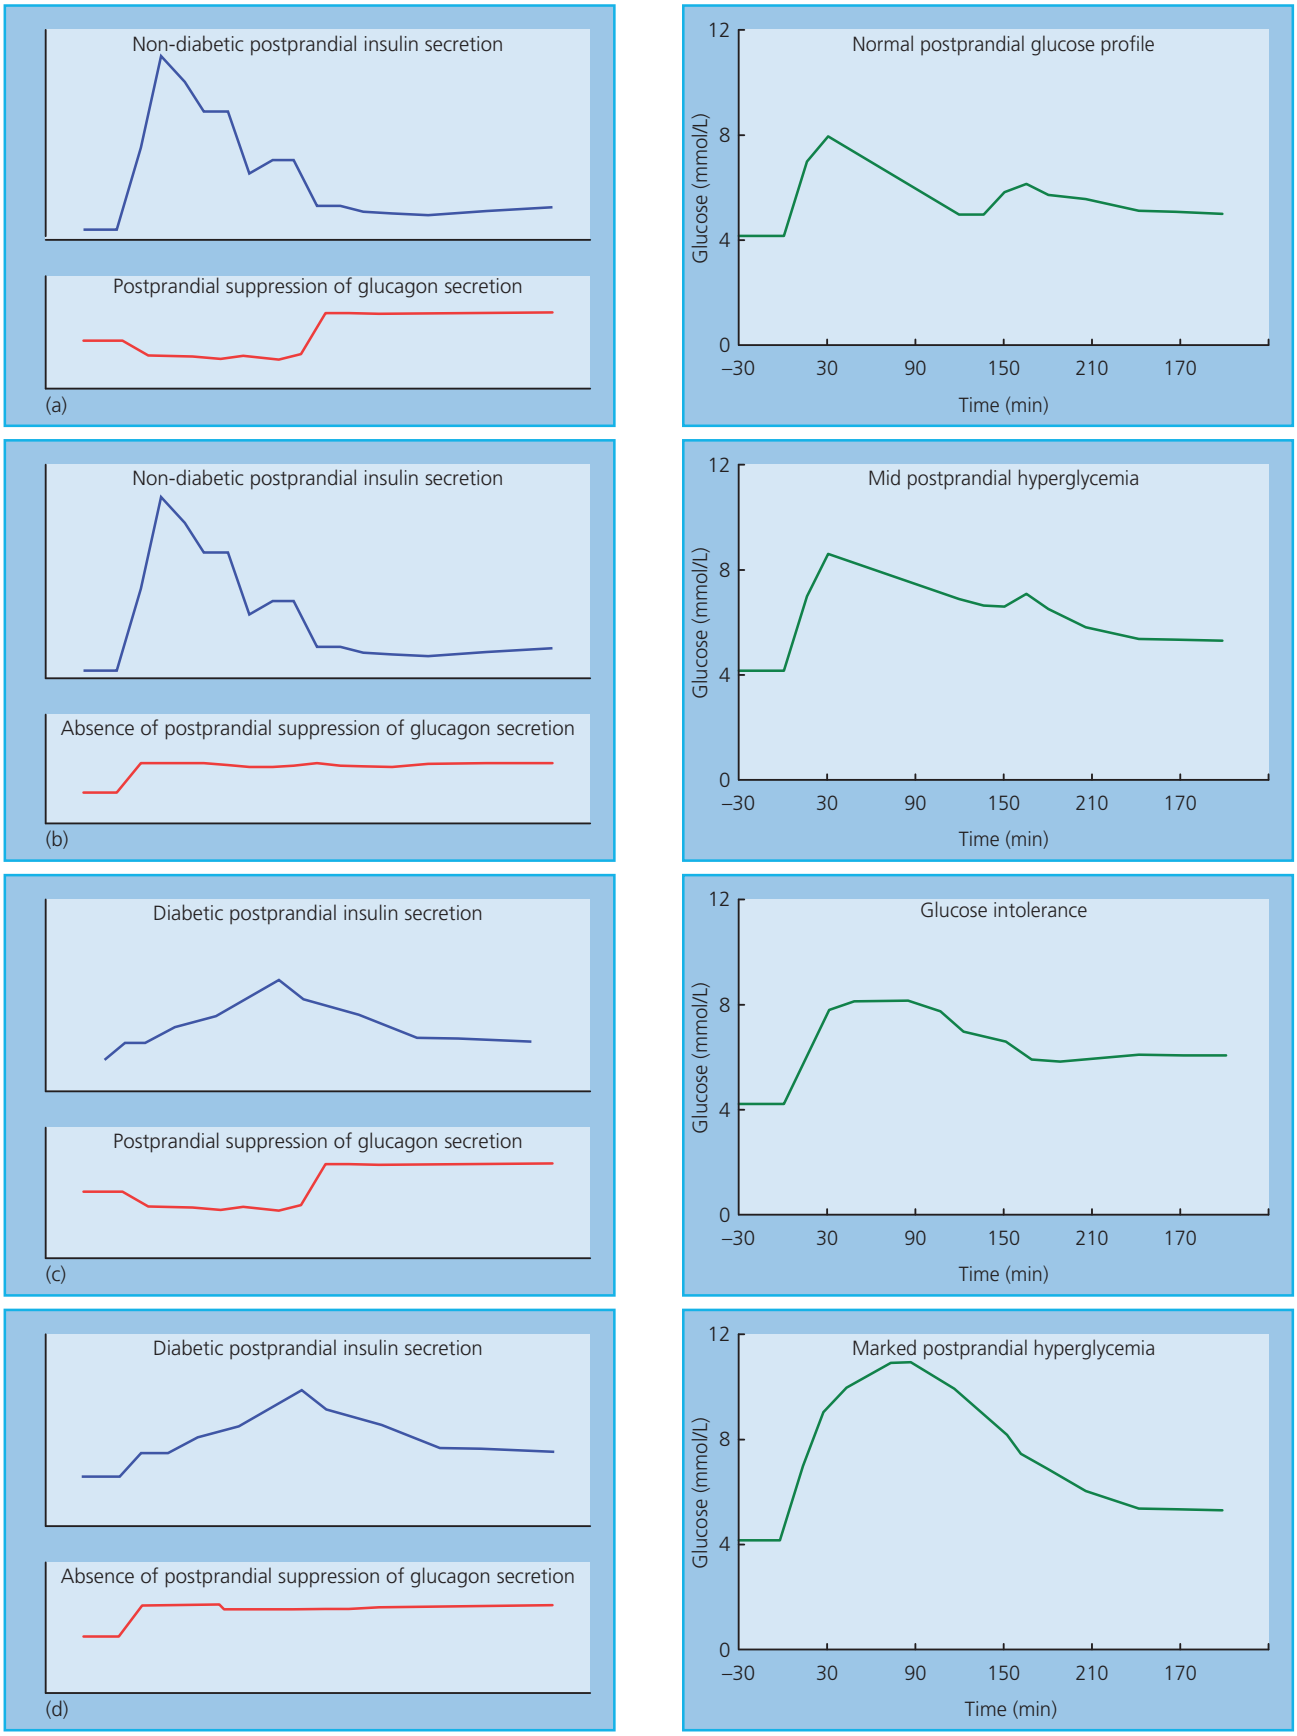

Figure 15.2 In an experiment in otherwise healthy volunteers, a non-diabetic postprandial insulin profile coupled with postprandial glucagon suppression results in a normal postprandial glucose profile (a). In the same individuals, absent postprandial glucagon suppression in the presence of a non-diabetic postprandial insulin profile resulted in a minimal increase in postprandial glucose (b). On the other hand, a diabetic insulin profile produced glucose intolerance (c), which was markedly worsened by the absence of postprandial glucagon suppression (d).

Insulin-induced stimulation of splanchnic (and therefore presumably hepatic) glucose uptake is also impaired in T2DM. The lower rates of hepatic uptake in people with diabetes are almost entirely accounted for by decreased uptake of extracellular glucose, suggesting lower glucokinase activity [84, 85].

Lipid metabolism in type 1 and type 2 diabetes

Dietary fat is an essential component of the human diet. However, excessive consumption of fat can have deleterious consequences on overall health. Part of the problem is that fat is a calorically dense macronutrient and excess caloric intake promotes obesity, with its attendant metabolic consequences. Dietary fat regulates *de novo* lipogenesis through nutrient control of transcription factors regulating expression of enzymes, including fatty acid synthase (FAS) and acetyl-CoA carboxylase (ACC) [86]. Elevated *de novo* lipogenesis and esterification of FFAs into triglycerides contribute to triglyceride elevation in the diabetic and prediabetic states.

Triglycerides are an important source and storage form of energy and are mobilized as FFAs. Plasma FFA concentrations represent a balance between release and disposal. FFAs are taken up by and re-esterified in adipose and hepatic tissues, or oxidized in muscle (cardiac and skeletal) or the liver. They are released by intravascular lipolysis of triglyceride-rich lipoproteins and intra-adipocyte lipolysis of triglyceride stores. In the fasting state, FFA concentrations are determined largely by the rate of entry into the circulation whereas in the postprandial period the rate of uptake by adipose and hepatic tissue is also a major determinant in FFA concentrations [87].

Hormone-sensitive lipase is the principal regulator of FFA release from adipose and is exquisitely sensitive to insulin. Insulin is the main hormonal regulator of lipolysis. Increasing plasma glucose concentration (e.g. after a meal) normally leads to increased insulin secretion, which inhibits lipolysis [88]. Rising insulin concentrations suppress lipolysis, leading to a fall in FFA concentration. This insulin-induced suppression of FFA concentration enhances insulin-dependent glucose disposal and insulin-induced suppression of endogenous glucose production [89].

Conversely, in individuals without diabetes, falling blood glucose concentrations increase lipolysis because of suppression of insulin secretion [90]. The resulting rise in FFA concentration will stabilize or raise glucose concentrations. Hypoglycemia caused by exogenous hyperinsulinism will also suppress lipolysis and impair counter-regulation.

Absolute or relative insulin deficiency is responsible for most of the excess FFAs available for oxidation in T1DM. Elevated FFA concentrations directly impair peripheral glucose uptake [91] and, at least acutely, stimulate endogenous glucose production [92]. Another consequence of elevated FFA flux is increased ketogenesis, a precursor to ketoacidosis [93]. Insulin is able to counteract the lipolytic effects of other hormones so that growth hormone or cortisol has little effect on lipolysis unless insulin availability is reduced [94]. Similarly, the lipolytic effect of catecholamines is blunted by hyperinsulinemia and accentuated by hypoinsulinemia [95]. Although glucagon has no effect on systemic FFA availability, increased concentrations, as seen in uncontrolled diabetes, may drive hepatic metabolism towards ketogenesis [93].

Moderate-intensity exercise is normally accompanied by a fall in insulin and a rise in catecholamine concentrations, which increases FFA availability and fatty acid oxidation [96]. Plasma insulin concentrations do not decrease with exercise in T1DM and, depending on the timing of exercise in relation to insulin administration, may not allow the normal increase in FFA concentration that accompanies exercise [97]. In these instances, people with T1DM become dependent on the catecholamine response to exercise to mobilize FFAs, a response that may be impaired in individuals with long-standing diabetes [98]. In people with fasting hyperglycemia, low insulin concentrations, and, consequently, elevated resting FFA flux, exercise will increase the FFA flux further [99]. This, combined with the high glucagon concentrations commonly present in these situations, will result in high rates of ketone body production.

FFA concentrations commonly are increased in the postabsorptive and postprandial state in people with T2DM [78, 100]. The ability of insulin to suppress lipolysis is impaired, likely because of decreased sensitivity of hormone-sensitive lipase to insulin [101]. Insulin also promotes FFA disposal, however, by stimulating re-esterification in adipocytes to form triglyceride. This process is dependent on the provision of glycerol-3-phosphate derived from glucose uptake (also insulin driven) and intra-adipocyte glycolysis. It is unknown, however, whether defects in adipose FFA esterification contribute to the FFA elevation observed in diabetes [87].

Circulating plasma triglycerides are dependent on the activity of lipoprotein lipase (LPL) to deliver FFAs to the adipocyte. Insulin and glucose preferentially stimulate adipose LPL and inhibit muscle LPL, thereby partitioning triglyceride and lipoprotein-derived fatty acids away from muscle and into adipose tissue [102]. By contrast, in T2DM, insulin-induced activation of adipose LPL is delayed while skeletal muscle LPL is activated [103]. Given that elevated FFA concentrations decrease muscle glucose uptake, this is especially of consequence in individuals with already diminished insulin action. FFAs decrease muscle glucose uptake by inhibiting glucose transport, glucose phosphorylation, and muscle glycogen synthase [104].

Although elevated FFA concentrations have been reported to decrease hepatic insulin metabolism in animals, direct measurement of splanchnic insulin clearance suggests that this may not be the case in humans [105]. Elevated FFA concentrations stimulate both hepatic gluconeogenesis and triglyceride synthesis. Acute increases in FFA concentration stimulate insulin secretion whereas chronic elevations inhibit insulin secretion [106]. Thus, elevated FFA concentrations have been implicated in many, but not all, of the metabolic abnormalities associated with T2DM.

Protein metabolism in type 1 and type 2 diabetes

Substrate availability and the hormonal milieu regulate protein synthesis and breakdown at any given time. Insulin is an important hormone in this regard and profound changes in body composition occur after the initiation of therapy in people with T1DM, especially if insulin deficiency has been severe and prolonged [107]. Urinary nitrogen excretion, a marker of protein catabolism, increases during insulin deprivation. If this is sufficiently prolonged, cachexia and a loss of muscle mass occur [108, 109]. Insulin deprivation increases the concentration of circulating amino acids because of the net increase in protein breakdown with an accompanying decline in amino acid disposal (utilization in protein synthesis or amino acid oxidation) [110, 111]. Of note, insulin-resistant states are characterized by an increase in circulating branched-chain amino acids (BCAAs). Indeed, plasma concentrations of BCAAs and their metabolites can predict the development of type 2 diabetes [112].

Glucagon secretion is enhanced by ingestion of protein and facilitates the disposal of glucogenic amino acids such as alanine or glutamine. The elevated glucagon concentrations present in poorly controlled T1DM stimulate alanine and glutamine uptake, resulting in normal or low concentrations despite increased appearance from protein breakdown from insulin deprivation [113]. Concentrations of BCAAs are elevated in these situations but are rapidly lowered to non-diabetic levels by treatment with insulin [110, 114].

In contrast, the effect of T2DM on protein metabolism is less clear cut, with some studies showing no evidence of increased catabolism [115, 116]; indeed, withdrawal of insulin for 10 days in people with type 2 diabetes does not change amino acid concentrations or protein metabolism [115]. On the other hand, others have reported increased protein turnover and/or amino acid catabolism [117–119]. In the presence of hyperinsulinemia and hyperaminoacidemia, people with T2DM exhibit impaired protein synthesis [120]. This observation might explain in part the reduced mitochondrial protein synthesis and ATP production observed in T2DM [121]. Insulin's stimulatory effects (and glucagon's opposite effects) on protein synthesis are mediated through mammalian target of rapamycin (mTOR) signaling and therefore defective insulin action would be expected to impair protein synthesis to some extent [122]. This may also have relevance to impaired synthesis of cardioregulatory molecules such as nitric oxide in the diabetic state [123].

The difference in protein metabolism between T1DM and T2DM likely occurs because people with T2DM have sufficient residual insulin secretion to limit protein catabolism and preserve lean body mass. Nevertheless, whole-body nitrogen flux and protein synthesis and breakdown are increased in people with poorly controlled diabetes. These defects are restored to normal when glycemic control is improved by treatment with either oral agents or insulin [117, 118].

Relatively few studies have examined regional protein dynamics in T2DM. Increased 3-methylhistidine excretion, an index of myofibrillar protein breakdown, has been demonstrated in people with poorly controlled T2DM when compared with healthy and obese individuals without diabetes [117]. Improved glycemic control reduced 3-methylhistidine excretion. People with T2DM and/or insulin resistance have been noted to have elevated circulating concentrations of certain clotting factors such as tissue plasminogen activator and plasminogen activator inhibitor 1 (PAI-1). This would imply that the synthesis of certain proteins by the liver and endothelium is clearly abnormal [124]. Preliminary evidence suggests that agents that improve the ability of insulin to regulate muscle and hepatic glucose metabolism (e.g. thiazolidinediones) will also restore concentrations, and possibly the activity, of these proteins to normal [125, 126].

Counter-regulatory hormones

In humans without diabetes, insulin and glucagon exhibit coordinated and reciprocal changes in concentration in response to glucose ingestion [22]. In people with T1DM, however, carbohydrate ingestion fails to suppress glucagon [127, 128], whereas protein ingestion commonly results in an excessive rise in glucagon concentrations [129]. The cause of these abnormalities in glucagon secretion is thought to be intra-islet insulin deficiency as insulin infusion inhibits glucagon secretion [130] and neutralization of intra-islet insulin with anti-insulin antibodies stimulates glucagon secretion [131]. Treatment with exogenous insulin rapidly lowers glucagon concentrations in people with T1DM but does not restore hypoglycemia-induced glucagon secretion [132].

Glucagon excess exacerbates hyperglycemia by increasing hepatic glucose release and decreasing hepatic glucose uptake [133, 134]. In humans without diabetes, any increase in glucose concentration is promptly accompanied by an increase in insulin secretion, which antagonizes the effects of glucagon on the liver. In contrast, in people with diabetes who cannot increase insulin secretion (and consequently glucose disposal) to compensate for the increase in glucagon concentrations, increased hepatic glucose release is accompanied by further increases in glucose concentration [133].

Fasting epinephrine and norepinephrine concentrations may be elevated in individuals with poorly controlled diabetes [135, 136] and may cause further deterioration in glycemic control by impairing insulin action at the hepatic and extrahepatic tissues [137]. Epinephrine also stimulates glucagon secretion, leading to further increases in endogenous glucose production [138]. In the absence of circulating insulin, catecholamines will enhance lipolysis, thereby increasing FFA concentrations and production of ketone bodies [139].

In the presence of severe defects in endogenous insulin secretion, as usually encountered in people with T1DM, the normal diurnal variation in plasma cortisol concentrations can adversely

affect glycemic control [140]. Cortisol increases endogenous glucose production while decreasing tissue glucose uptake. The nocturnal rise in cortisol also increases ketone body concentrations, gluconeogenesis, and lipolysis [140,1415].

Growth hormone release increases in both amplitude and frequency in people with poorly controlled diabetes [142, 143]. Growth hormone stimulates gluconeogenesis, proteolysis, and lipolysis while impairing insulin-induced suppression of endogenous glucose production and stimulation of glucose uptake [144]. This is likely to occur in situations where insulin secretion cannot rise to match the increased insulin requirements because of excessive growth hormone secretion.

Diabetic ketoacidosis

Insulin deficiency to a degree sufficient to allow unrestrained lipolysis and hepatic ketogenesis is a necessary condition for the development of diabetic ketoacidosis [145]. Because of this, ketoacidosis is more commonly encountered in people with T1DM than in those with T2DM because the latter generally have some degree of residual insulin secretion. Although insulin deficiency is a necessary condition for the development of ketoacidosis, the condition is often triggered by physical stress such as infection or surgery.

Glucagon concentrations rise in the presence of insulin deficiency and during physical stress. A decrease in effective circulating volume may also increase glucagon concentrations because glucagon is cleared by the kidneys. The concentrations of other counter-regulatory hormones also rise, which in turn further increases lipolysis [146].

Ketone bodies and glucose produce an osmotic diuresis that exacerbates the hypovolemia and electrolyte disturbances caused by metabolic acidosis. Furthermore, ketone bodies can induce vomiting, causing electrolyte and fluid losses. These losses also can directly contribute to metabolic acidosis. Cardiovascular collapse can occur if acidosis is sufficiently severe. Intracellular metabolic acidosis interferes with the activity of several enzymatic processes, which exacerbates the consequences of circulatory failure. Death is often caused by underlying comorbidities, the physical illness that precipitated ketoacidosis—myocardial infarction, pneumonia—or as a direct consequence of severe metabolic acidosis [147].

16 Obesity and Diabetes

Hans Hauner
Else Kröner-Fresenius-Center for Nutritional Medicine, Technical University of Munich, Munich, Germany

Key points

- Obesity is characterized by an excess of body fat mass and is defined by a body mass index equal to or greater than 30 kg/m^2. Its prevalence has increased considerably over the past decades in all parts of the world and currently affects 15–30% of the adult population in Western countries.
- Overweight and/or obesity represents by far the most important modifiable risk factor for type 2 diabetes mellitus (T2DM). An abdominal type of body fat distribution is also closely associated with T2DM, particularly in the lower body mass index categories.
- Both obesity and T2DM have a strong genetic background. The known susceptibility genes for obesity mainly affect central pathways of food intake, whereas most risk genes for T2DM compromise β-cell function.
- Important environmental factors contributing to the development of obesity include energy-dense diets including large portion sizes and permanent availability of foods, lack of physical activity, and low socioeconomic status.
- An expanded adipose tissue impairs insulin action and causes insulin resistance in muscle, adipose tissue, liver, and possibly other organs.
- Obesity is also characterized by subacute chronic inflammation in adipose tissue because of an impaired paracrine–endocrine function of adipose tissue, but also by mitochondrial dysfunction, local hypoxia, and other still poorly understood disturbances at the cellular level.
- Weight loss in obese individuals is followed by rapid amelioration of all metabolic disturbances including chronic inflammation and insulin resistance. These improvements are brought about by caloric restriction rather than the macronutrient composition of the dietary intervention.
- Bariatric surgery is the most powerful approach to treat morbid obesity and may lead to a marked improvement of the metabolic disturbances if not the resolution of T2DM.

Introduction

Obesity is defined as a common chronic disorder of excessive body fat and has become a global epidemic which is present not only in the industrialized world but also in many developing and even in underdeveloped countries. At present, the prevalence of obesity (defined as body mass index (BMI) ≥30 kg/m^2) is in the range 15% to 35% in the adult populations in Europe, North America, and in many Arabic countries, with an unequivocal trend for further increases [1]. This condition increases the risk of developing a variety of adverse consequences to human health ranging from metabolic disturbances including type 2 diabetes mellitus (T2DM) and cardiovascular complications to disorders of the locomotor system and many types of cancer [2]. In addition, obesity impairs the subjective quality of life in affected people and can reduce life expectancy [3]. Although there is a very specific close relationship between excessive body weight and the risk of diabetes, the presence of obesity may induce many other disturbances that may aggravate the diabetic state.

Definition of obesity and the body fat distribution pattern

The diagnosis and classification of obesity is usually based on the BMI. This simple anthropometric index can be calculated from body weight and height, is independent of body height and correlates reasonably well with body fat mass ($r = 0.4$–0.7). The current classification of body weight according to the World Health Organization (WHO) is presented in Table 16.1. A BMI greater than 30 kg/m^2 is considered to be the central formal criterion for the definition of obesity which is further subdivided into three classes depending on the severity of excessive body fat. The BMI range of 25–29.9 kg/m^2 represents the category of overweight or preobesity which requires additional criteria to assess the concomitant health risks. In Western countries, 30–50% of the population fall into the category of overweight [1].

Not only the extent of excessive body fat mass, but also the anatomic location of the body fat mass determines the risk for metabolic and cardiovascular complications. This is particularly

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

Table 16.1 Classification of human obesity based on body mass index (BMI) (kg/m^2).

Classification	kg/m^2
Underweight	<18.5
Normal weight	18.5–24.9
Overweight	≥25.0
Obesity	
grade I	30–34.9
grade II	35–39.9
grade III	≥40

important for the category of overweight and even in the upper normal range of BMI. At a defined BMI, the pattern of fat distribution can vary substantially. This has been most impressively shown using computed tomography (CT) or magnetic resonance imaging (MRI) scans which are the only imaging techniques to provide a direct assessment of the size of the intra-abdominal visceral adipose tissue. For practical means, waist circumference measured mid-way between the lower rib margin and the upper iliac crest is used as a simple anthropometric measure to assess the fat distribution pattern. This variable has been used in many cross-sectional and longitudinal studies; therefore, the threshold levels demonstrated in Table 16.2 are now well based on human data sets concerning associated health risks. The waist circumference is closely correlated with BMI but cannot discriminate between subcutaneous and intra-abdominal fat depots. Due to this limitation, there is growing clinical interest for more precise imaging methods to obtain a better insight into intra-abdominal and ectopic fat deposition (visceral fat, hepatic fat) in order to improve individual risk assessment.

Obesity is the most potent risk factor for type 2 diabetes

A large body of clinical data consistently demonstrates a close relationship between body fat mass and the risk of diabetes. It is noteworthy that in contrast to other obesity-associated metabolic disturbances, the diabetes risk is already increased in the upper normal range of BMI. This has been shown for both men and women. In the prospective Nurses' Health Study, women in the upper normal range with a BMI of 23.0–24.9 kg/m^2 had a four- to fivefold increased risk of developing diabetes over a 14-year observation period compared with women with a BMI of <22 kg/m^2. In women with a BMI of 29.0–30.9 kg/m^2 the risk of diabetes was 27.6-fold higher than in the lean reference group. Almost two-thirds of women with newly diagnosed T2DM were obese at the time of diagnosis [4]. Similar observations were made for men in the Health Professionals' Study [5]. Moreover, changes in body weight also predicted the risk of diabetes. Weight gain in women after the age of 18 years of 11.0–19.9 kg, which is the average range of weight change between adolescence and menopause in industrialized countries, was found to be associated with a 5.5-fold higher risk of diabetes compared with weight-stable women, whereas weight reduction of the same extent reduced the risk of diabetes by about 80% [4]. Very similar data were reported for men [5]. A recent analysis of the EPIC Potsdam cohort revealed that a weight gain of 1 BMI unit between the age of 25 and 40 years increased the relative risk of T2DM by 25% and had a greater effect than the same weight gain between 40 and 55 years of age [6]. It is also important to note that the duration of obesity has a strong impact on the risk of developing T2DM.

In a recent analysis of the relative contributions of different levels of overweight and obesity to the prevalence of diabetes between 1976–1980 and 2000–2004 in the USA it was found that the increase in total diabetes prevalence from 5.08% to 8.83% was largely caused by the increase in obesity. Of the increased number, 81% was attributed to the different classes of obesity (Figure 16.1). The authors concluded that the increase in diabetes prevalence over recent decades has disproportionately included persons with extreme levels of obesity [7]. Thus, obesity appears to be the main environmental driving force for the manifestation of T2DM.

In addition to the level and the duration of obesity, the risk of developing diabetes is also potently influenced by the fat distribution pattern. In an early study in humans, an abdominal pattern of fat distribution was found to be an independent risk factor for T2DM [8]. Subsequent studies confirmed this observation in many age groups and ethnic populations. Particularly at low degrees of overweight, and even in the upper normal range, the fat distribution pattern strongly predicts the risk for diabetes and the metabolic syndrome. Therefore, waist circumference should be routinely assessed when estimating the risk of diabetes even in normal-weight individuals. In the clinical setting, it is striking to observe that the majority of people with diabetes, particularly those of middle age, show a visible preferential truncal accumulation of excess body fat. It is also interesting to note that similar observations were made for the association between BMI and cardiovascular disease. Among overweight and obese individuals, only those with an abdominal type of fat distribution are at increased risk of coronary heart disease as documented in the INTERHEART study [9].

Table 16.2 Classification of fat distribution pattern, threshold values for the moderately and markedly elevated risk for metabolic and cardiovascular diseases.

	Waist circumference (cm) Elevated metabolic and cardiovascular risk	
	Moderately	Markedly
Men	>94	>102
Women	>80	>88

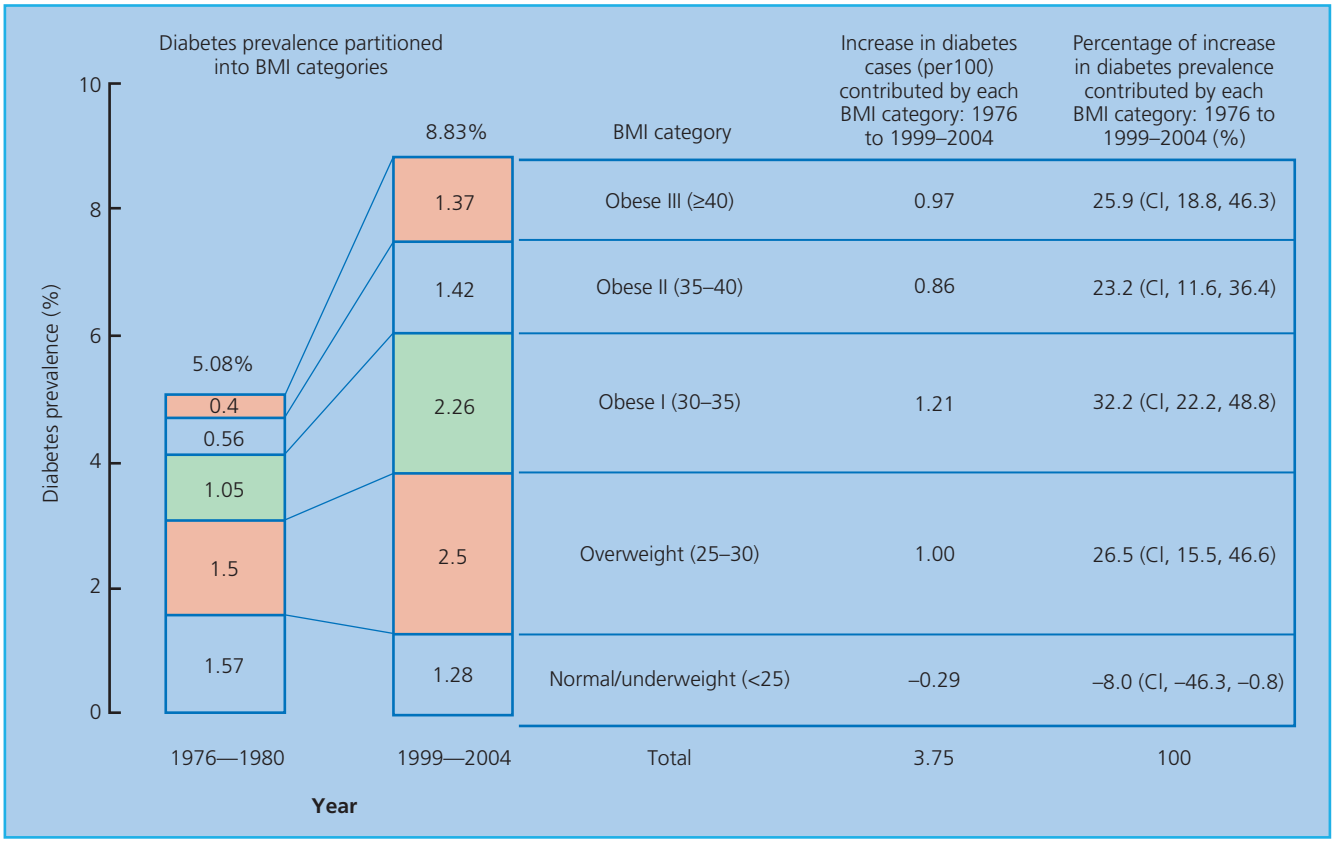

Figure 16.1 Contribution of five body mass index (BMI) categories to the overall prevalence of diabetes. National Health and Nutrition Examination Survey (NHANES) samples of 1976–1980 and 1999–2004 were compared. Source: Gregg et al. 2007 [7]. Copyright 2007 Elsevier.

Genetic predisposition for obesity and type 2 diabetes

It is well known from family, adoption, and twin studies that obesity, like T2DM, has a strong genetic basis. In the classic adoption study by Stunkard et al. [10] there was no resemblance between the adult BMI of adopted Danish children and the BMI of the adopting parents, but a significant correlation to the BMI of the biologic parents, especially to the BMI class of the biologic mother. In a twin study of obesity, concordance rates for different degrees of overweight were twice as high for monozygotic twins as for dizygotic twins. This high heritability for BMI was seen at the age of 20 years and to a similar extent at a 25-year follow-up, suggesting that body fatness is under substantial genetic control [11]. There is also a very close correlation in monozygotic twins who were reared apart, also indicating a high heritability of the BMI trait. In a recent study of 5092 twins living in the London area, the authors estimated the heritability of BMI and waist circumference as 0.77, further supporting the strong effect of the genetic components irrespective of the force of the obesogenic environment [12].

During the last decade, a number of monogenic disorders that result in human obesity have been uncovered. These genetic disorders were only found in rare cases, however, usually children and adolescents with early onset of obesity. At present, a variety of homozygous and compound heterozygous mutations have been described in the leptin–melanocortin signaling pathway, some of them with functional consequences resulting in human obesity. Functional mutations in the melanocortin-4-receptor gene are considered to be the most frequent cause of monogenic obesity in children with a frequency of 2–4% of all obese cases. It is striking that these defects affect mainly genes that are involved in the central control of food intake.

Genome-wide association (GWA) studies in large cohorts with BMI as phenotype reported common genetic variants on various chromosomes. In a recent GWA study, the analysis identified 97 BMI-associated loci. Subsequent pathway analyses provided evidence for a role of the central nervous system, but also pathways related to insulin secretion/action, energy metabolism, lipid biology and adipogenesis [13]. A genome-wide association meta-analysis of traits related to waist and hip circumference reported 49 loci associated with waist/hip ratio adjusted for BMI and an additional 19 loci associated with related waist and hip measures. The identified loci were enriched for genes expressed in adipose tissue. Pathway analyses implicated adipogenesis, angiogenesis, transcriptional regulation, and insulin resistance as processes

affecting fat distribution [14]. Among the gene variants found in GWA studies so far, variants near to the *FTO* and the *MC4R* gene appear to have the strongest effect size on body weight, whereas the effect size of most of the novel "obesity genes" is rather modest. Individuals who are homozygous for the high-risk allele of the *FTO* gene weigh on average 3 kg more than individuals with two low-risk alleles [15]. A recent study elucidated the mechanistic basis of this association and identified a single-nucleotide variant (rs1421085 T-to-C) that shifts the developmental program from energy-dissipating beige adipocytes to energy-storing white adipocytes, thereby reducing mitochondrial thermogenesis in white adipose tissue [16]. Thus, it is apparent from recent work that obesity represents a rather heterogeneous disorder in terms of genetic background and susceptibility to etiologic environmental factors. In addition, the risk for developing comorbidities including T2DM may strongly depend on the individual genetic predisposition towards such diseases. In the case of T2DM, the lifetime risk of developing this disease is about 30–35% in the white North American population and similar in other ethnic groups [17]. It is currently assumed that only those obese individuals who exhibit a genetic failure of the pancreas to compensate for insulin resistance, which is a characteristic consequence of obesity, will develop T2DM [18]; even among the most severely obese (BMI $\geq$40 kg/m^2) only 30–40% will develop diabetes throughout life. Thus, the development of T2DM requires the presence of "diabetes genes" which affect susceptibility via two main mechanisms: (1) through insulin resistance and/or (2) through β-cell dysfunction [19].

Developmental programming of obesity and diabetes

A new component that may have a major role in the development of obesity and T2DM is the modification of gene expression by epigenetic mechanisms during fetal life. Although this is still a poorly defined phenomenon and it is rather unclear which mechanisms may underlie this association, there is some clue that epigenetics may also operate in this context. Observational studies suggest that infants of mothers with gestational diabetes are at increased risk of developing childhood obesity [20]. In another study, siblings born after the mother had developed gestational diabetes (i.e. exposed to diabetes *in utero*) have a much greater risk of T2DM in young adulthood than siblings not exposed to diabetes *in utero* (odds ratio 3.7; $p = 0.02$) [21].

Another interesting clinical observation is that excessive weight gain during pregnancy, independent of initial BMI, may also increase the risk of gestational diabetes in pregnant women [22] as well as early development of obesity in the offspring [23]. It is speculated that both chronic overnutrition and hyperglycemia during pregnancy may cause fetal hyperinsulinemia, hypercortisolemia, and hyperleptinemia. These hormonal changes may result in a persisting malprogramming of hypothalamic centers controlling energy homeostasis and metabolism, thereby increasing the lifetime risk for obesity and T2DM and possibly the risk for other adverse long-term health consequences [24]. The mechanisms mediating these effects are largely elusive, but it is speculated that epigenetic processes such as DNA methylation, histone modification, and changes of the microRNA pattern are involved. Animal experiments suggest that this imprinting process may mainly affect central neuroendocrine pathways which may finally modify appetite regulation [24].

Pathophysiology of obesity

Irrespective of the strong genetic influence on body weight, there is also no doubt that the evolving worldwide epidemic of obesity is primarily a consequence of substantial changes in the environment and lifestyle (see Chapter 9). It is rather new to mankind that food is abundant in many countries and that physical activity is no longer a prerequisite for survival. These dramatic changes in environment and the subsequent changes in lifestyle have occurred within a few decades, a period probably too short to result in adaptations of the genetic background and biologic systems to optimize survival. To date, the relative contributions of the various environmental factors to the epidemic of obesity are hard to quantify in detail and there exist considerable differences between populations.

Humans, like other mammals, are characterized by a tight control of energy homeostasis allowing a stable body weight to be maintained. This setpoint of body weight can vary substantially among individuals and may also vary across lifetime. A complex regulatory system controls energy homeostasis which involves central pathways and peripheral components such as the size of adipose tissue which is sensed to the brain via the secretion of leptin. In addition, gut hormones, signals from the gastrointestinal nervous system and nutrients signal to the brain and induce a complex central integration according to the dietary intake and nutrient requirements of the organism. Central pathways are the anorexigenic leptin–melanocortin link and the orexigenic NPY–AgRP pathway. Many other factors such as insulin modify these signaling processes and thereby influence energy balance [25]. This complex and potent homeostatic system also serves to defend body weight against a critical energy deficiency but also against chronic overnutrition. Several adaptive systems are known to restore the initial body weight under such fluctuations of energy intake and expenditure. This may explain why obese humans exhibit a strong tendency to regain weight after intentional dietary weight reduction. The same tendency to return to initial body weight is observed after experimental overfeeding.

The role of energy homeostasis in the development of obesity has been elaborated by previous studies using indirect calorimetry to investigate the contribution of the resting metabolic rate (RMR) to the risk of obesity. In a study of Pima Indians, RMR was found to be a familial trait and to vary considerably across families [26]. In

prospective studies in Native Americans a reduced rate of energy expenditure assessed in a respiratory chamber turned out to predict body weight gain over a 2-year follow-up period. This finding was confirmed in another group over a 4-year-follow-up period, indicating that a low rate of energy expenditure may contribute to the aggregation of obesity in families [27]. At present, the genetic components for these differences in energy metabolism are still unknown.

Environmental factors promoting obesity and type 2 diabetes

It is now established that a complex gene–environment interaction determines the individual risk to develop obesity (Table 16.3). Even in societies with an abundance of affordable, highly palatable food there is a high variation in body weight across the populations ranging from lean individuals to extremely obese persons. Many other factors such as physical activity, education, and socioeconomic status may also act as strong modifiers of body weight. After two to three decades of modern lifestyle the trend towards obesity appears to reach a plateau, as suggested by recent data from the USA and other Western countries.

Despite the genetic predisposition it is widely accepted that the current worldwide epidemic of obesity is largely a consequence of dramatic changes in lifestyle and environment which emerged over the past 30–50 years. A dramatic change in eating habits and food selection took place, whereas physical activity decreased remarkably because of technologic development concerning transportation and workplaces. Although dietary abundance and sedentary lifestyles have multiple origins, both may equally contribute to a chronic positive energy balance which may result in excess energy storage in adipose tissue.

A rather novel phenomenon is the expansion of the fast-food culture characterized by high-fat, low-starch foods together with a high sugar intake including sugar-sweetened beverages. In addition to having a high energy density, fast-food menus have large portion sizes. This combination has led to the assumption that frequent fast-food consumption is linked to body weight gain and maintenance of overweight and obesity in the population. A recent systematic review of six cross-sectional and seven prospective cohort studies concluded that sufficient evidence exists for this link, at least for the adult population [28]. According to a recent survey, people from the USA obtain one-third of their daily caloric intake from restaurant meals, and one-third of customers of chain restaurants in New York purchased meals containing more than 1000 calories [29]. Thus, there is a growing need to develop new public health policies to limit fast-food consumption and to facilitate a healthier food selection.

Table 16.3 Environmental factors promoting the development of obesity.

Ready availability of food
High palatability of food
High energy density
Relatively low cost of foods
High consumption of sugar-sweetened beverages
Aggressive commercial food promotion
Low physical activity

In addition, a high intake of added sugar in solid foods and sugar-sweetened beverages is another part of the global fast-food culture. A systematic review clearly concluded that among free living people intake of free sugars or sugar-sweetened beverages is a determinant of body weight [30]. In addition, a recent meta-analysis revealed that habitual consumption of sugar-sweetened beverages is associated with a greater incidence of T2DM, even independently of obesity, with an estimated population attributable fraction of 8.7% [31].

Another aspect in the context of high fast-food consumption which may further explain the elevated risk of obesity is the energy density of modern foods. There is convincing evidence that energy density of foods is a key determinant of caloric intake. From an evolutionary point of view, the human regulatory system for energy intake is adapted to starchy foods with low caloric content which require large volumes to obtain sufficient energy. Today, most fast-foods have a high energy density which may favor a passive overconsumption of calories. A recent study showed that the average energy density of fast-food menus is approximately 1100 kJ/100 g, which is 65% higher than the average British diet (approximately 670 kJ/100 g) and more than twice the energy density of recommended healthy diets (approximately 525 kJ/100 g). It is 145% higher than in traditional African diets (approximately 450 kJ/100 g) which represent the levels against which human weight regulatory mechanisms have evolved. The authors concluded that the high energy density of many fast foods challenges human appetite control systems with conditions for which they were never developed [32].

A large cohort study in the USA reported an increase of total daily energy intake by 570 kcal per day between 1977–1978 and 2003–2006, with the largest increase in the last decade. Over this 30-year period, the three components under investigation, that is, energy density, portion size, and eating occasions, contributed to a greater or lesser extent to changes in energy intake, with changes in eating occasions being the largest contributor [33]. Finally, socioeconomic status is a strong determinant of obesity and of T2DM. In most countries there is a gradient between education and household income and the prevalence of obesity. A low socioeconomic status is associated with an unfavorable lifestyle including poor nutrition, low leisure-time physical activity, and low health consciousness. This gradient is usually greater in females than males. Thus, the association between low household income and obesity may be mediated by the low costs of energy-dense foods, whereas prudent healthy diets based on lean meats, fish, vegetables, and fruit may be less affordable for those of lower socioeconomic status [34].

Pathophysiologic links between obesity and type 2 diabetes

T2DM is characterized by an impaired insulin action or a defective secretion of insulin or both. Both defects are thought to be required for the manifestation of the disease and both are present many years before the clinical onset of the disease [35]. To date, the mechanisms by which obesity increases the risk of developing T2DM are only partly understood and the evolving picture is becoming more and more complex. The main adverse effect of obesity is on the action of insulin, particularly in liver, muscle and adipose tissue, but obesity also affects insulin secretion. Substantial advances have been made over recent years in our understanding of how an excessive fat mass, but also chronic overnutrition, may cause metabolic disturbances resulting in overt T2DM in those with a genetic predisposition for the disease.

Lipids and insulin resistance

The earliest hypothesis to explain the relationship between obesity and T2DM is the "glucose–fatty acid cycle" which is based on the observation of a competition between glucose and fatty acid oxidation in the heart muscle and was introduced by Randle et al. [36]. The increased supply of non-esterified fatty acids from expanded adipose tissue depots competes with glucose utilization, particularly in muscle, which represents the organ that oxidizes the largest proportion of glucose. The proposed mechanism is an inhibition of the glycolytic enzymes pyruvate dehydrogenase, phosphofructokinase, and hexokinase. As a consequence, the rate of glucose oxidation is reduced and glucose concentrations rise. The concomitant increased fatty acid turnover is accompanied by an increased release of glycerol from adipose tissue which is reutilized for hepatic glucose production, further augmenting the imbalance of glucose metabolism. Increased hepatic glucose output is another early disturbance contributing to glucose intolerance [37].

In addition, it was reported that elevated free fatty acids can directly impair insulin action. Recent studies suggested that obese individuals and those with T2DM have a high intramyocellular lipid accumulation which is an important feature of the insulin-resistant state. Exposure of skeletal muscle to an excessive lipid supply may lead to intramuscular accumulation, not only of neutral fatty acids, but also of lipid-derived metabolites such as ceramide, diacylglycerol, and fatty acyl coenzyme A (CoA). This lipid accumulation is associated with coincident disturbances in insulin action mediated by an activation of a serine–threonine kinase cascade leading to serine–threonine phosphorylation of insulin receptor substrate 1 (IRS-1) and IRS-2 which may cause an impairment of insulin signaling including an impaired activation of phosphoinositol-3 (PI_3) kinase and other downstream elements [37]. This condition is also caused and exacerbated by chronic overnutrition with a high dietary fat intake. Thus, the increased availability of fatty acids may be the single most critical factor in disturbing insulin action in obesity.

Lipids and β-cell function

Obesity is characterized by an elevated insulin secretion and a decreased hepatic insulin clearance. Human studies suggested that the β-cell volume is increased by about 50% in healthy obese people, probably because of hypertrophy of existing β cells. Insulin release and insulin sensitivity are closely reciprocally related in a non-linear manner (Figure 16.2). Failure of this feedback system is known to result in a progressive decline in β-cell function and to underlie the development of T2DM. In addition to glucose, long-chain fatty acids may also exert a stimulatory effect on insulin secretion from the pancreatic β cells via generation of fatty acyl CoA and activation of protein kinase C [37]. Another effect of fatty acids on insulin secretion is via binding to the G-protein-coupled receptor GPR 40 on the β-cell membrane which may result in a subsequent increase in intracellular calcium and secretory granule exocytosis [38]. Although fatty acids are critical for normal insulin secretion, a chronic exposure of β cells to excessive fatty acids is associated with marked impairment of glucose-stimulated insulin secretion and decrease in insulin biosynthesis [39]. Another mechanism by which elevated fatty acids may impair insulin secretion in response to glucose is via an increased expression of uncoupling protein 2 (UCP-2) in β cells. UCP-2 was found to be upregulated under glucolipotoxic conditions and mitochondrial superoxide has been identified as a post-translational negative regulator of UCP-2 activity in islets [40].

Glucose sensing of the pancreatic β cells requires an intact oxidative mitochondrial metabolism to generate ATP. The resulting high ATP : ADP ratio is a prerequisite for normal insulin secretion. Studies in humans suggest that insulin resistance may also

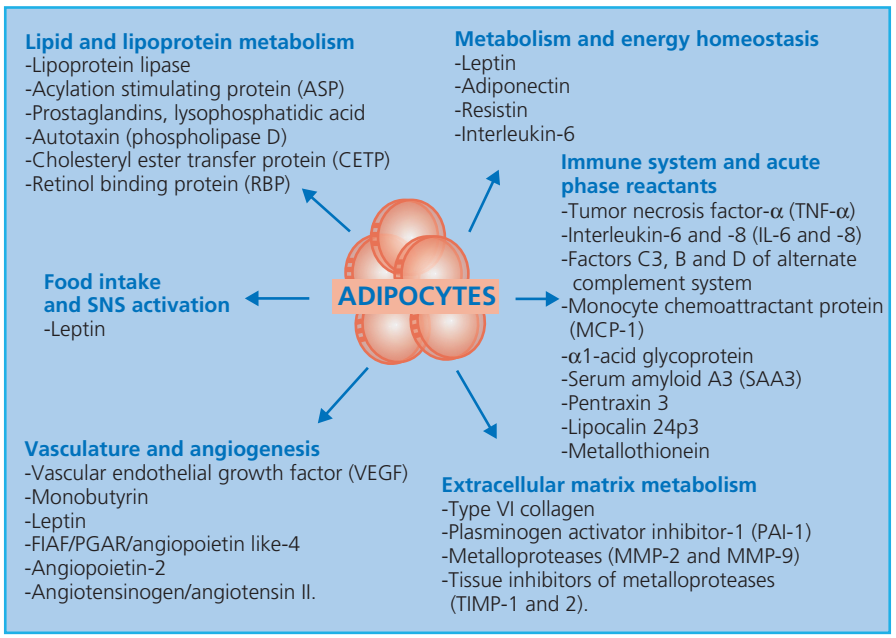

Figure 16.3 Secretory products from adipose tissue and functional relationship. SNS: sympathetic nervous system. Source: Lafontan M. Fat cells: Afferent and efferent messages define new approaches to treat obesity. *Annu Rev Pharmacol Toxicol* 2005; **45**:119–146. Reproduced with permission from Annual Reviews.

arise from defects in mitochondrial fatty acid oxidation which may lead to increased intracellular fatty acid metabolites (fatty acid CoA, diacylglycerol). It was recently shown that young insulin-resistant offspring of parents with T2DM have features of impaired mitochondrial function [41]. Furthermore, it was reported that obese individuals have smaller mitochondria with reduced bioenergetic capacity than lean people [42, 43]. Although studies on this topic are still limited, there is growing evidence that a defective mitochondrial function could be a prominent feature of disturbances in both insulin secretion and action [44].

Adipose tissue as a secretory organ

Another hypothesis that may explain the association between obesity and T2DM is the observation that adipose tissue is a secretory organ that produces and releases a variety of factors that may contribute to the development of insulin resistance and other health risks (Figure 16.3; Table 16.4). Among these factors most data have been collected for a mediator role of tumor necrosis factor α (TNF-α). TNF-α is a multifunctional cytokine which was the first found to be expressed in adipose tissue [45]. It was subsequently shown that TNF-α exerts a variety of catabolic effects in adipose tissue. In addition to TNF-α, it was reported that its two receptor subtypes are overexpressed in adipose tissue from obese individuals [46–48]. The upregulated TNF-α system induces multiple adverse effects at the local organ level such as inhibition of glucose uptake because of an impairment of insulin signaling and suppression of GLUT-4 expression, a reduction of lipoprotein lipase expression and activity, and an increase in lipolysis [49]. Moreover, TNF-α activates the NF-κB pathway in adipose tissue which leads to an increased expression of many proinflammatory proteins such as interleukin 6 (IL-6), IL-8, and monocyte chemotactic protein 1 (MCP-1) among others. Finally, TNF-α was demonstrated to reduce the expression of adiponectin, a protein that is abundantly expressed in fat cells and exerts direct antidiabetic and anti-atherosclerotic actions. A key mechanism by which TNF-α causes insulin resistance may be that this cytokine stimulates the phosphorylation of IRS-1 at the serine residue 307 which inhibits the transduction of the insulin signal to downstream elements [50].

Using an *in vitro* co-culture model of human adipocytes and muscle cells it was recently demonstrated that other fat cell secretory products, in addition to TNF-α, are also involved in the development of muscle insulin resistance [51]. Thus,

Table 16.4 Secretory function of adipose tissue in obesity and potential clinical consequences.

Product	Secretion	Consequence
Free fatty acids	↑	Dyslipidemia (TG ↑), insulin resistance
TNF-α, IL-6, MCP-1 and other cytokines/chemokines	↑	Insulin resistance, type 2 diabetes
Angiotensinogen, angiotensin II and other vasoactive factors	↑	Hypertension
PAI-1	↑	Thromboembolic complications
CETP	↑	Low HDL cholesterol
Adiponectin	↓	Insulin resistance, atherosclerosis
Estrogens	↑	Endometrial and breast cancer

CETP, cholesterol ester transfer protein; HDL, high density lipoprotein; IL, interleukin; MCP, monocyte chemotactic protein; PAI, plasminogen activator inhibitor; TG, triglycerides; TNF, tumor necrosis factor.

it is likely that the negative effect on muscle insulin action is brought about by a combination of adipokines. Although we have currently little information on the nature and the complex interplay of such proinflammatory and anti-inflammatory factors, a few relevant players have been identified. One such element may be MCP-1 [52]. Other potential candidates with a prodiabetes action may include plasminogen activator inhibitor 1 (PAI-1), but also lipid metabolites such as diacylglycerols and ceramides. Retinol-binding protein 4 (RBP-4) was also shown to contribute to insulin resistance via reduced PI_3 kinase signaling and enhanced hepatic expression of the gluconeogenic enzyme phosphoenolpyruvate carboxykinase. An interesting observation in this context is that adiponectin may be able to antagonize the insulin resistance-promoting activity of proinflammatory cytokines released from adipose tissue in an autocrine fashion.

Adipocytes are also able to release products with anti-inflammatory properties including factors such as adiponectin, IL-1 receptor antagonist, and IL-10. By far the most interesting component is adiponectin, which is the most abundantly expressed protein in adipose tissue. It was shown in a number of clinical studies that circulating adiponectin levels are inversely associated with BMI and that low concentrations predict the development of T2DM [53]. Adiponectin is now known to exert a variety of antidiabetic and anti-atherosclerotic effects (e.g. adiponectin stimulates fatty acid oxidation in an AMP-activated protein kinase-dependent manner) [54].

Signaling pathways of inflammation in adipose tissue

Current research has shown that the inflammatory response in human obesity is mediated via activation of the c-Jun N-terminal kinase (JNK) and IKKβ–NF-κB pathways. Both pathways are simultaneously stimulated by cytokines such as TNF-α and IL-6, but also by lipids. It has been convincingly demonstrated in experimental studies that genetic or chemical inhibition of these pathways can reduce inflammation and improve insulin resistance (for review see [55]) (Figure 16.4). In obesity, JNK activity is elevated not only in adipose tissue, but also in liver and muscle. Loss of JNK1 prevents the development of insulin resistance and diabetes in both genetic and dietary mouse models of obesity [56]. IKKβ can act on insulin signaling through at least two pathways. First, it can directly phosphorylate IRS-1 on serine residues and, second, it can phosphorylate the inhibitor of NF-κB (IκB) thus activating NK-κB, a transcription factor that stimulates the production of many proinflammatory mediators including TNF-α and IL-6 [57]. Mice heterozygous for IKKβ are partially protected against insulin resistance caused by lipid infusion, high-fat diet or genetic obesity [58]. Both the JNK and the IKKβ–NF-κB pathways are activated via pattern recognition receptors that function as membrane receptors for a variety of external signals. It is interesting to note that endogenous lipids and lipid conjugates were found to activate toll-like receptors (TLRs) in obesity. It was recently reported that saturated fatty acids bind and activate TLR-4 on adipocytes, thereby suggesting a direct link between exogenous nutrients that are redundant in the obese state and inflammation [59]. Mice with

a loss-of-function mutation of TLR-4 were found to be protected from diet-induced obesity and insulin resistance. These mice also showed a reduced NF-κB and JNK activity under a high-fat diet compared to wild-type control mice [60].

It is noteworthy that most proteins released from adipose tissue are not produced by fat cells but rather by pre-adipocytes and invading immune cells such as activated macrophages. While leptin and adiponectin are true adipokines, which are almost exclusively produced by adipocytes, TNF-α, IL-6, IL-8, MCP-1, visfatin, PAI-1 and others are mainly expressed by pre-adipocytes, macrophages resident in adipose tissue and possibly other cells. The relative contributions of the various cellular components in adipose tissue to the secretion of these products remains unknown and may vary substantially according to depot and model. Nevertheless, all these locally secreted factors appear to participate in the induction and maintenance of the subacute

inflammatory state associated with obesity. It is also important to mention that the invading macrophages release factors that substantially augment adipocyte inflammation and insulin resistance [61]. Another interesting observation in this context is that preadipocytes and macrophages share many common features [57].

The regulation and biologic functions of the secretory products are diverse and only poorly understood. In addition to the direct effects of fatty acids and their intracellular products, other factors may also contribute to the chronic inflammatory state in adipose tissue. It was recently shown that fat cell size may be a critical determinant of the production of pro-inflammatory and anti-inflammatory factors. Enlarged hypertrophic fat cells are characterized by a shift towards a pro-inflammatory state [62], thereby promoting insulin resistance. This is in agreement with clinical data showing that fat cell hypertrophy is associated with an increased risk of developing T2DM [63].

Obesity and endoplasmic reticulum stress

A recent observation suggests that obesity and chronic overnutrition overload the functional capacity of the endoplasmic reticulum (ER) and that the resulting ER stress contributes to the activation of the inflammatory signaling pathways including the JNK pathway. In both high-fat diet induced and genetic obesity models, obesity was shown to cause ER stress with inositol-requiring kinase-1α (IRE-1α) having a crucial role in insulin receptor signaling as a mediator of JNK activation [64]. Subsequent studies further supported the role of ER stress in the pathogenesis of obesity and T2DM. Such studies showed that ES stress is operating in various tissues such as hypothalamus, liver, muscle, and adipose tissue and may induce inflammation, insulin resistance and impaired insulin secretion in a tissue-specific manner [65]. In a mouse model of T2DM, systemic overexpression of 150-kDa oxygen-regulated protein (ORP150), a molecular chaperone located in the ER, improved insulin intolerance and enhanced glucose uptake indicating that this chaperone has an important role in insulin sensitivity and is a potential target for the treatment of T2DM [66].

Obesity and oxidative stress

Increased fat accumulation was reported to be associated with systemic oxidative stress in humans and mice [67]. There was a selective production of reactive oxygen species (ROS) in adipose tissue of obese mice, accompanied by an increased expression of NADPH oxidase and a decreased expression of antioxidative enzymes. The authors also showed that fatty acids increased oxidative stress in cultured adipocytes via NADPH oxidase activation which was followed by dysregulated production of adipokines such as adiponectin, PAI-1, IL-6, and MCP-1. In addition, treatment with an NADPH oxidase inhibitor reduced ROS production, restored the dysregulation of adipokines in adipose tissue and improved diabetes, dyslipidemia, and hepatic steatosis, indicating that the redox status in adipose tissue is a critical factor in the development of the metabolic syndrome [67].

Adipose tissue hypoxia

An expansion of the adipose tissue mass leads to fat cell hypertrophy and subsequent hypoxia of the tissue. A number of mainly animal studies convincingly support the concept that hypoxia has an important if not central role in the development of chronic inflammation, macrophage infiltration, impaired adipokine secretion, ER stress, and mitochondrial dysfunction in white adipose tissue in obesity [68, 69]. These consequences are also accompanied by an inhibition of adipogenesis and triglyceride synthesis and elevated circulating free fatty acid concentrations. Measurement of the interstitial partial oxygen pressure (PO_2) in adipose tissue showed a reduction of up to 70% leading to oxygen levels of about 2% in obese animals compared to lean controls [69]. This observation was further substantiated by the determination of hypoxia response genes such as hypoxia-inducible factor 1α (HIF-1α), vascular endothelial growth factor (VEGF), heme oxygenase 1 (HO-1), and others. The low oxygen pressure may also contribute to a reduced mitochondrial respiration with a consequent increase in lactate production. In humans, HIF-1α was also shown to be increased in white adipose tissue of obese people and its expression was reduced after surgery-induced weight loss [70].

The physiologic basis of adipose tissue hypoxia may be related to a reduction in adipose tissue blood flow and capillary density which has been reported in both obese humans and animals. Although the hypoxic state leads to an increased production and release of pro-angiogenic factors from adipose tissue such as VEGF and others, this compensatory mechanism may not be sufficient to keep the PO_2 at a normal level as the free diffusion of oxygen in the adipose tissue may be limited [69]. Although hypoxia may drive adipose dysfunction in obesity, the functional consequences of altered PO_2 in human adipose tissue are still poorly characterized and await further elucidation [71].

Accumulation of immune cells

Leptin, TNF-α, MCP-1 and other chemokines have an essential role in the recruitment of macrophages to adipose tissue. The secretory profile of both pre-adipocytes and adipocytes includes a variety of chemo-attractants for immune cells. It was recently reported that the attraction of T-lymphocytes possibly caused by stromal cell-derived factor 1 (SDF-1) represents the initial step that subsequently leads to the invasion and activation of circulating monocytes–macrophages resembling the scheme originally described for atherosclerosis [72]. Such accumulation of immune cells and inflammation of adipose tissue has been shown in obese humans [73] and appears to be related to CCR expression of circulating monocytes. As a consequence, a higher migration activity into adipose tissue of obese women was observed which was associated with markers of insulin resistance [74].

Role of body fat distribution pattern

Another important issue in this context is the distribution of body fat. It has long been known from early clinical studies that people with a more abdominal type of body fat distribution are at

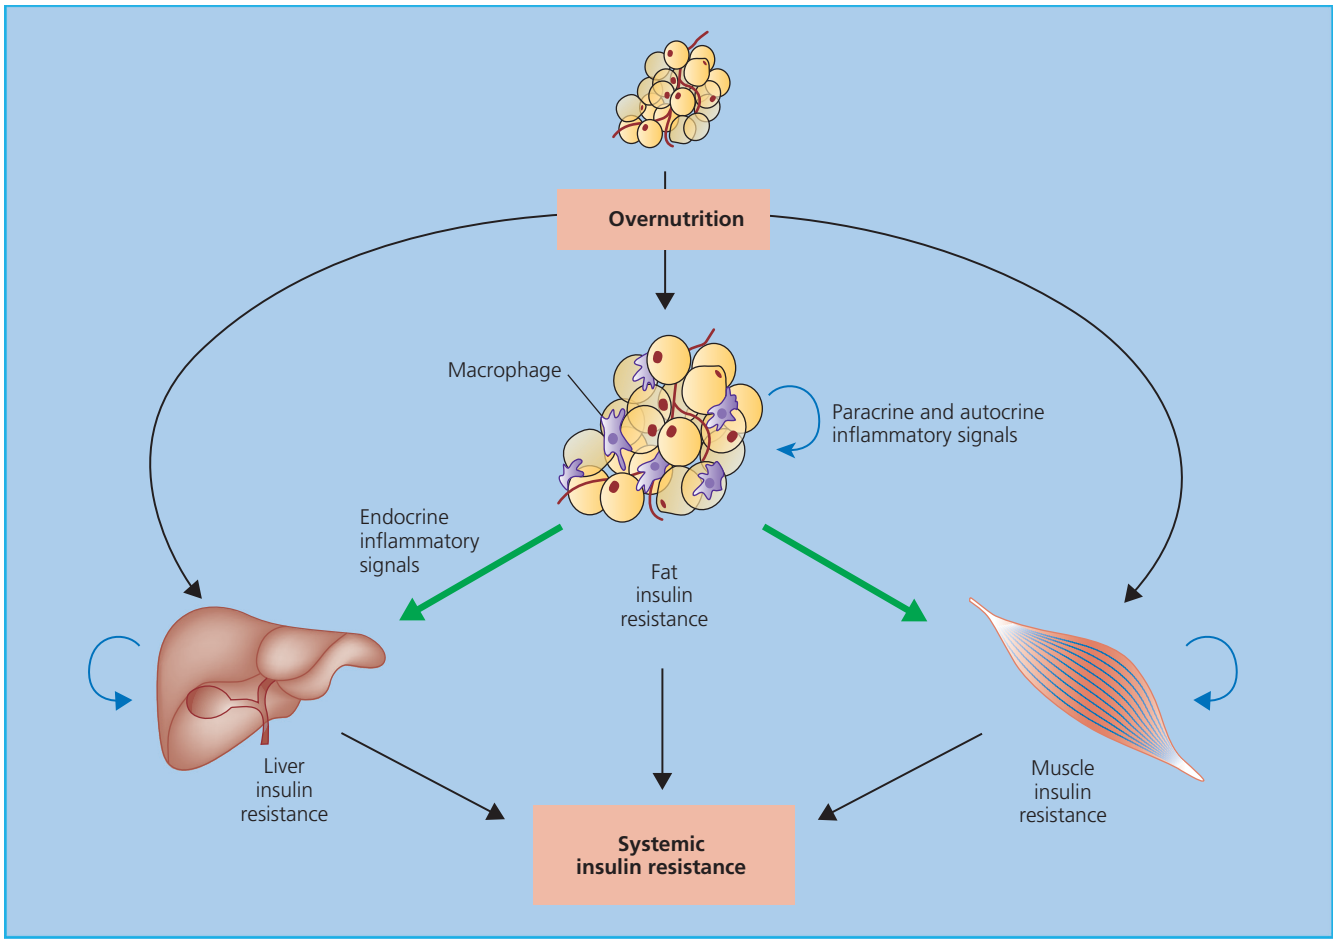

Figure 16.5 Nutrition and obesity-induced inflammation and development of systemic insulin resistance. Source: De Luca C, Olefsky JM. Stressed out about obesity and insulin resistance. *Nat Med* 2006; **12**:41–42. Reproduced with permission from Nature Publishing Group.

increased risk of developing T2DM and other metabolic and cardiovascular complications [75–77]; however, the underlying cause has only recently become evident. Intra-abdominal fat cells exhibit a differing expression profile and are lipolytically more active than subcutaneous adipocytes. Moreover, they show a greater accumulation of lymphocytes and macrophages, indicating greater proinflammatory activity. Visceral adipose tissue also has a much higher blood vessel and nerve density leading to a much greater metabolic activity. Visceral adipose tissue drains into the portal vein and thus the liver is directly exposed to fatty acids and proteins released from this active fat depot promoting insulin resistance in the liver. Thus, the inflammatory process is detected, not only at the level of adipose tissue, but may also affect the liver and possibly other organs. As enlarged visceral fat depots are frequently associated with fat accumulation in the liver, it was also hypothesized that secretory products from the visceral adipose tissue may directly cause hepatic insulin resistance.

In summary, a variety of data suggests that chronic overnutrition with a high-fat, high-sugar diet and as a consequence an accumulation of body fat, particularly in the visceral depots and ectopically in liver, muscle, and other organs, is the primary cause of chronic inflammation in obesity and may promote the development of systemic insulin resistance which affects many tissue including liver, muscle, and the brain (Figure 16.5). It should not be neglected that apart from an unhealthy diet, other lifestyle factors such as lack of physical activity may substantially contribute to these pathologic processes.

Treatment of obesity in the context of the metabolic syndrome and type 2 diabetes

The fact that obesity is the most powerful driving force for the development of T2DM provides the rationale to consider weight management as the most important initial treatment step. Numerous studies have consistently shown that weight loss is not only an effective means to prevent the development of T2DM in those at increased risk, but may also improve the metabolic disturbances and associated risk factors in those with overt T2DM. In addition, weight reduction facilitates reaching the primary treatment goal of a metabolic control close to normal. Interestingly, almost all disturbances mentioned earlier are potentially reversible by weight

loss. This was particularly demonstrated for elevated circulating adipokines. A modest to moderate weight reduction was found to reduce significantly the concentrations of circulating factors such as leptin, C-reactive protein, PAI-1, IL-6, IL-8, MCP-1, and others by 10–50%. By contrast, adiponectin levels are known to rise in relation to weight reduction. In a recent study in surgically treated morbidly obese individuals a significant reduction in macrophage infiltration was documented in adipose tissue samples after a mean weight loss of 22 kg within 3 months [70].

Management of obesity in people with type 2 diabetes

For the reasons outlined, management of obesity should represent a central component in the treatment strategy for T2DM. Although currently available weight reduction programs for people with diabetes have only limited success rates, particularly in the long run, in contrast to common beliefs, recent studies show that obese people with T2DM can achieve clinically significant weight loss. Despite this positive development, treatment of obese individuals with T2DM is usually considered to be more difficult than treating obese people without diabetes for several reasons. People with T2DM are usually older than those without diabetes, which may mean a smaller weight loss as energy expenditure decreases with age. Another reason is that individuals with diabetes focus more on blood glucose control which could result in neglecting other health problems. Finally, the effect of various antidiabetes agents to increase weight or prevent weight loss has to be considered [78]. In the prospective LookAHEAD study, the average weight loss in overweight and obese participants with T2DM in the intensive lifestyle intervention group after 1 year of treatment was 8.6% of the initial body weight and was accompanied by substantial improvements of all weight-associated risk factors despite reductions in the dosage of glucose-lowering agents [79]. However, these effects were not maintained in the following years and were only moderately distinguishable from the control group. After a median follow-up of 9.6 years, the rates of the primary outcome, a composite of death from cardiovascular events, non-fatal myocardial infarction, non-fatal stroke, or hospitalization for angina, did not differ between both groups. Thus, the intensive lifestyle intervention did not reduce the risk of cardiovascular disease in overweight/obese adults with T2DM [80].

Dietary approaches

The cornerstones of a weight reduction program for obese people with diabetes include a moderately hypocaloric diet, an increase in physical activity, and behavior modification, very similar to the recommendations for obese people without diabetes. Numerous studies have applied and examined such concepts and have been critically evaluated in reviews and guidelines [81, 82].

The gold standard in the dietary treatment of obese individuals patients with T2DM is a balanced moderately energy-restricted diet with an energy deficit of at least 500 kcal/day (see Chapter 25). The most important single measure is the reduction in fat intake, particularly in saturated fatty acids. A low-fat, high-carbohydrate diet is generally recommended, but other concepts are equally acceptable. A diet rich in fiber and complex carbohydrates has some beneficial effects on measures of glucose and lipid metabolism but these effects may be small and possibly of limited clinical importance [83]. The concept of a high-carbohydrate, low-fat diet was challenged by clinical studies showing that replacement of saturated fat by monounsaturated fat compared to high-carbohydrate intake is equally favorable or even has advantages with regard to glycemic response and lipids [84]. More importantly, recent studies using a low-carbohydrate, high-protein diet were at least equally effective. In a recent meta-analysis of such studies, HbA_{1c}, fasting glucose and some lipid fractions improved with lower carbohydrate content diets [85]. In a study from Israel, a Mediterranean type of weight loss diet showed small advantages in comparison to the classic low-fat, high-carbohydrate diet in a subgroup of overweight participants with diabetes [86]. Concerning weight loss, a landmark study clearly established that the macronutrient composition of the diet is secondary for weight reduction [87]. A recent systematic review and meta-analysis showed that low-carbohydrate, low glycemic index (GI), Mediterranean, and high-protein diets are effective in improving glycemic control and cardiovascular risk factors in people with T2DM. In comparison to the conventional low-fat diet, these diets produced a slightly greater improvement in glycated hemoglobin and, therefore, should be considered in the overall strategy of diabetes management [88]. From a practical point of view it is extremely important to assess the habitual diet of people with T2DM and to focus counseling on timely changes of their eating habits in order to approach current dietary recommendations [89]. It should be stressed that all efforts for dietary changes should be made as simple as possible as people with diabetes may also be burdened by many requirements to manage their diabetes. For obese individuals with T2DM the frequent recommendation to distribute their allowed calories over 5–6 meals is difficult to meet and may even hinder weight loss without being of any advantage for metabolic control [90]. Therefore, in people without insulin, three meals a day may be more appropriate and advantageous to reach the individual dietary and weight goals.

Another dietary approach is the use of a very-low-calorie diet (VLCD) for initial weight loss. This option may be particularly valuable for those with poor metabolic control or failure of conventional dietary treatments. This mode of dietary restriction is known to be associated with a rapid improvement of insulin resistance and glycemic control after even short periods. To date, the potential benefits and risks of VLCD or (intermittent) fasting concepts in the dietary treatment of obese individuals with T2DM are still poorly studied.

However, there is strong evidence that in addition to the improvement in cardiovascular risk factors the pattern of adipokines and macrophage-associated gene expression changes dramatically under such conditions [91]. Very-low-calorie diets, however, can only be applied for a limited period of time and require intensive medical surveillance. The long-term results of VLCD are moderately better than those of conventional diets, although there is usually considerable weight regain [92, 93].

Therefore, there is need for new sophisticated solutions such as intermittent VLCD in combination with conventional hypocaloric diets to obtain better long-term results. Another possibility is to change the pattern of nutrient intake to modify adipose tissue inflammation. To date, there is little practical information available to indicate whether specific effects of single components in the diet can ameliorate adipose tissue inflammation independent of calorie restriction. In a recent review of dietary components and nutritional strategies for the prevention and treatment of T2DM, the central message was that the quality of dietary carbohydrates and fats consumed is more crucial than the quantity of these macronutrients. The dietary patterns described above were considered to be equivalent and can be tailored to the personal and cultural food preferences including adequate caloric intake for weight management [94].

Antidiabetes drugs and body weight

It has long been recognized that antidiabetes drugs can promote weight gain in people with T2DM (see Chapters 29 and 31). The strongest weight-promoting effect is exerted by insulin. In the Diabetes Control and Complications Trial (DCCT), intensified insulin treatment was associated with substantial weight gain that resulted in unfavorable changes of lipid levels and blood pressure similar to those seen in the insulin resistance syndrome [95]. In the UK Prospective Diabetes Study (UKPDS), insulin treatment caused a mean weight gain of approximately 7 kg over 12 years of treatment in people with newly diagnosed T2DM [96]. In addition, sulfonylureas are known to promote weight gain because of their action to promote insulin secretion. In the UKPDS, the average weight gain under glibenclamide treatment amounted to about 5 kg [96].

Administration of glitazones, PPAR-γ agonists with insulin sensitizing activity, leads to substantial weight gain of 4–5 kg on average. There is growing evidence, however, that weight gain under glitazone treatment occurs mainly in subcutaneous fat, not in the visceral depot, which should have less deleterious metabolic consequences. In contrast, metformin and α-glucosidase inhibitors have a modest weight-lowering potential. The class of DPP-4 inhibitors is rather weight neutral, whereas the administration of GLP-1 receptor agonists, such as exenatide or liraglutide, results in a substantial weight loss [97]. The recently introduced class of SGLT2 inhibitors was found to produce a moderate weight loss of 2–3 kg, due to the urinary loss of glucose [98].

Weight-lowering drugs

Another component in the treatment of obesity is the adjunct administration of weight-lowering drugs. As the efficacy of currently approved drugs is limited, drug treatment is only recommended if the non-pharmacologic treatment program is not sufficiently successful and if the benefit : risk ratio justifies drug administration. At present, only a few compounds are available that have demonstrated efficacy and safety in obese individuals with and without T2DM [99] (Table 16.5). A recently released Clinical Practice Guideline provides information and recommendations for the use of weight-lowering agents, and also on their adverse effects and contraindications [99].

Bariatric surgery

Bariatric surgery is now an established method to reduce body weight in people with extreme obesity (≥40 kg/m^2), but there is growing consensus that this method can also be applied in individuals with T2DM at a BMI ≥ 35 kg/m^2. In this group of people surgery is by far the most effective treatment mode with excellent long-term results compared to all other methods [82]. In the Swedish Obese Subjects study, a large prospective trial comparing bariatric surgery with conventional dietary treatment, sustained weight loss ≥20 kg was achieved in the surgically treated participants with practically no significant weight change in the control group. The surgical intervention not only reduced the incidence of T2DM, but also significantly reduced total mortality [100]. A recent meta-analysis of studies on the effect of bariatric surgery in obese people with T2DM demonstrated that between 70% and 90% had a complete remission of diabetes within the first years after surgery. Weight loss and diabetes resolution was greatest in those undergoing combined restrictive and malabsorptive surgical methods [101]. The majority of insulin-treated patients can stop insulin treatment within a few weeks after surgery and frequently other medications for diabetes and, in addition, for other cardiovascular risk factors can be considerably reduced or discontinued. There are also many studies indicating how rapidly most circulating adipokines are normalized in relation to the degree of weight loss in these individuals.

Conclusions

There is now growing information on how obesity is increasing the risk of developing T2DM. It is apparent that an excess of body fat as well as an unfavorable fat distribution including ectopic fat deposition promotes insulin resistance and impairs insulin secretion. As most people with T2DM are overweight or obese, weight management must be a central component of any treatment strategy, as weight loss has been convincingly shown to provide a marked improvement in metabolic control. In parallel, most if not all underlying disturbances benefit from weight loss or dietary interventions. Conventional concepts combining an energy-reduced diet and an increase in physical activity frequently

have poor long-term results, therefore more effective weight loss strategies should be developed and evaluated.

Key points

- The intestinal microbiome is a diverse collection of over 1000 bacterial species that are increasingly recognized as playing critical roles in host functioning and subsequently health and disease.
- Diet has been shown to influence the composition of the intestinal microbiome and associations between the microbial composition and both body mass and type 2 diabetes have been reported.
- The intestinal microbiome can influence intestinal permeability and thereby play a regulatory role in the development of what is referred to as "metabolic endotoxemia."
- Metabolic endotoxemia has the potential to activate innate immune pathways that interface with insulin signaling pathways and can affect glycemic control.
- Microbial metabolites can act locally at the intestinal mucosal to regulate enteroendocrine cell function, incretin signaling and subsequently glycemic control.
- The intestinal microbiome can modulate the composition of the bile acid pool and downstream intracellular signaling pathways, including FXR and TGR5, to influence glycemic control.
- The intestinal microbiota may also contribute to risk for type 1 diabetes; inappropriate immune education by the microbiota may potentiate autoimmune destruction of pancreatic β cells in genetically susceptible individuals.

The microbiome

The human body is inhabited by a diverse and populous array of microorganisms, termed the microbiome, including bacteria, viruses, fungi, and archaea. The genetic material from this collection of microbes, termed the metagenome, is now estimated to be 150 times larger than that of the human genome [1]. The gastrointestinal tract contains the majority of commensal microbes; however, the urogenital tract, skin, and oral cavity provide niche environments for additional species [2]. Microbes colonize the sterile gastrointestinal tract during birth and from this point are implicated in early life programming of the immune and metabolic systems, protection from infection, and the synthesis of vitamins, minerals, and fatty acids, which continue throughout the lifespan of an individual [3]. Given its size and diversity of function, the microbiome has been considered as an organ in its own right.

Bacterial microbes have received the greatest focus within the intestinal microbiome. Over 1000 bacterial species, numbering as high as 10^{14} in the colon and with a total cell count now estimated at 10 times those of human origin, have been reported [4]. Given the dominance of anaerobic species, early attempts to characterize the diversity of the intestinal microbiome were limited by available sample collection methods and culture techniques [5]. More recently, advances in molecular biology techniques, including use of deep- and next-generation sequencing, have facilitated a number of large-scale projects, including the European MetaHIT Project [6] and the National Institutes of Health Human Microbiome Project [7], which have provided additional insights into the diversity of the commensal species. Initially, these projects classified 90% of gut bacteria as belonging to either one of two phyla, namely Bacteroides or Firmicutes. Within these two divisions, three enterotypes were defined based on variation in either *Bacteroidetes* (enterotype 1), *Prevotella* (enterotype 2), or *Ruminococcus* (enterotype 3) that appeared stable across continents [8, 9]. Classification of stable enterotypes is now considered oversimplified, with the abundance of resident species along the gastrointestinal tract alone displaying up to 90% diversity between individuals in similar geographical locations and thought to be shaped by age, hygiene, medication use, and diet [10].

The microbial species resident in the gastrointestinal tract are increasingly recognized as playing critical roles in host functioning and subsequently health and disease [11–13]. The

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

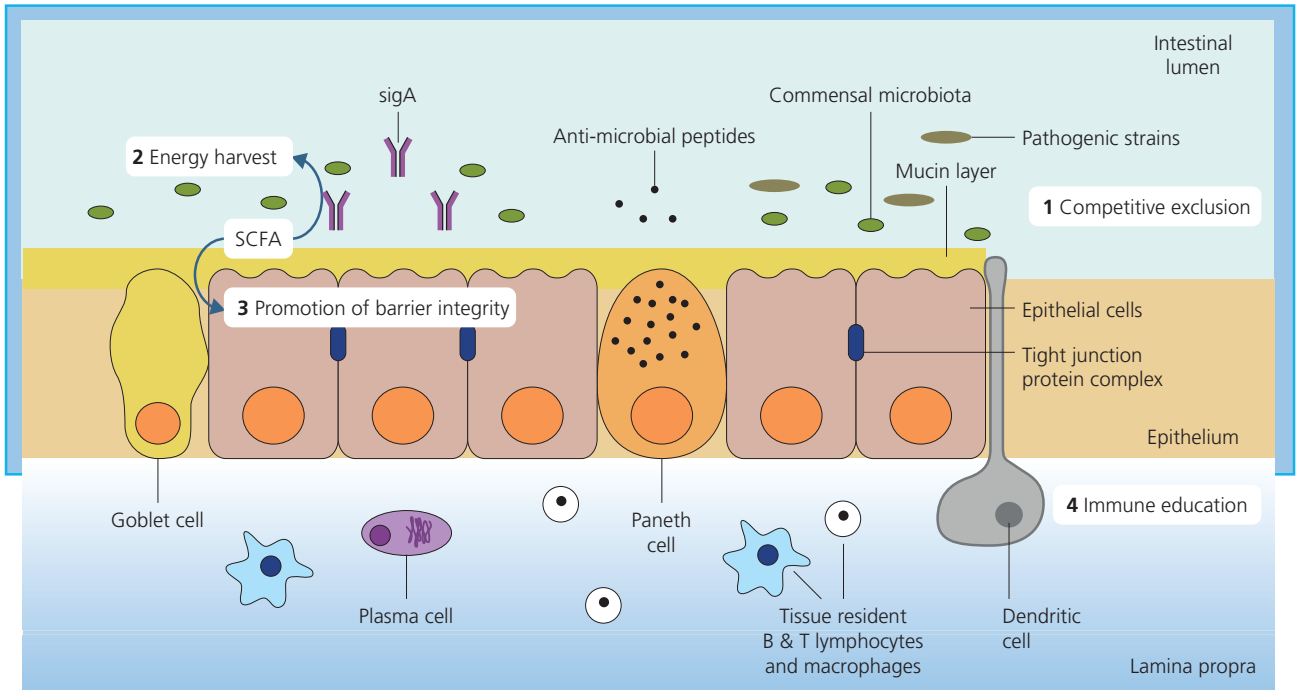

Figure 17.1 A synergistic relationship between the intestinal microbiome and host provides a number of benefits, including (1) competitive exclusion of pathogenic strains, (2) energy harvest, (3) promotion of barrier integrity, and (4) immune education. synergistic relationship between the intestinal microbiota and host provides a number of benefits to host function, including (i) resistance to infection by pathogenic microorganisms through direct competition for nutrients and attachment sites and production of antimicrobial substances; (ii) promotion of epithelial cell proliferation and differentiation to maintain an intact mucosal surface; (iii) promotion of the development of the gut-associated lymphoid tissue via initiation of dendritic cell maturation and B- and T-lymphocyte differentiation; and (iv) energy harvest from non-digestible dietary starches [13–17] (Figure 17.1).

Bacterial fermentation of non-digestible dietary starch occurs predominantly in the colon [18] and produces short-chain fatty acids (SCFAs) (primarily acetate, propionate and butyrate), which have received particular attention as mediating the beneficial effects provided by the intestinal microbiome. Butyrate in particular is recognized as the main energy source for colonic epithelial cells, and is thought to stimulate blood flow and the secretion of gut hormones, enhance fluid and electrolyte uptake, and increase mucin release, all of which contribute to a local tropic effect, epithelial cell proliferation and differentiation, and maintained integrity of the intestinal mucosa [18–20]. The application of -omics technologies has further broadened the knowledge of the roles of the commensal microbial species in health [21], with bacterial communities identified with specific functions in regulating biochemical and metabolic pathways [22, 23].

Greater understanding of the role of the microbiota in metabolic function and immune homeostasis has also led to a growing focus on the role of microbes as a contributing factor for diabetes. The composition of the microbiota is altered in obesity to promote the extraction of energy from food, alter intestinal permeability, and upregulate inflammatory processes in the body. Links between the microbiota and the biochemical processes underpinning the onset and progression of diabetes offer promise that microbial manipulation may be a strategy to reduce the growing burden of associated disease. This chapter explores the way in which the intestinal microbiota contributes to diabetes by promoting the accumulation of adipose tissue and altering metabolic and immune homeostasis.

The intestinal microbiome is associated with body mass

Given the documented relationship between excess body mass and risk for type 2 diabetes mellitus (T2DM), data linking the intestinal microbiome with excess body mass are of interest when considering the role of the microbiome in diabetes pathogenesis. In animal models, lower body mass/body fat in germ-free mice compared with wild-type counterparts [24], even following exposure to a high-fat and sugar-rich Western-style diet [25], suggests that the absence of microbial colonization in the gastrointestinal tract impairs energy harvest. Studies involving transplantation of the intestinal microbiota further implicate the microbiome as a contributor to excess body mass; transplantation of wild-type microbiota to germ-free mice normalizes body weight between groups [24] whereas transplantation of microbiota from obese mice results in an increase in fat mass in germ-free animals [26]. Data such as these suggest a unique microbial composition among

obese animals that favors accumulation of excess body weight, itself a risk factor for T2DM.

In humans, direct comparison of the composition of the intestinal microbiota between overweight and lean individuals has produced mixed findings, likely the result of the small sample sizes examined (groups ranging from two to 70 individuals). A significant decrease in the relative abundance of Bacteroidetes, but an increase in Firmicutes, in obese individuals has been reported [27]. Similarly, reductions in overall bacterial diversity [28, 29] and reductions in the relative abundance of Bacteroidetes, increased relative abundance of Actinobacteria but no significant change in Firmicutes between obese and lean individuals have also been observed [29]. However, others have reported no difference in the dominant phyla [30, 31] and an increased relative abundance of Bacteroidetes in obese compared with lean individuals [32]. Regardless of the discrepant findings, these data suggest that the intestinal microbiota is not static and that the composition of the microbiome can vary within and between populations.

Dietary intervention studies further support the dynamic nature of the intestinal microbiome. Increased caloric content (2400 or 3400 kcal/day at similar macronutrient profiles; 24% protein, 16% fat, and 60% carbohydrates) in otherwise healthy humans for as little as 3 days has been reported to increase the abundance of Firmicutes and decrease the abundance of Bacteroidetes [30]. Even more acute changes have been suggested, with a subsequent study in otherwise healthy adults noting changes in the composition of the intestinal microbiota within 24 h of initiation of a high-fat diet [33]. Changes in the intestinal microbiota in response to weight-reducing diets have also been reported, including reductions in the abundance of some specific Firmicutes species following a 4-week low-carbohydrate weight-reducing diet in obese men [31] and a decreased relative abundance of Bacteroidetes in obese men following a 4-week high-protein, low-carbohydrate diet [34]. It remains to be determined if alterations in the intestinal microbiota that promote energy harvest are a cause or a consequence of Western diets and excess body mass. However, given the functions of the intestinal microbiota beyond energy harvest, additional mechanisms may also contribute to risk for obesity and associated disease.

Composition of the intestinal microbiome is altered in T2DM

To date, few studies have directly compared the intestinal microbial composition between individuals with and without T2DM. However, increased utilization of molecular biology techniques has facilitated this type of analysis. Fecal microbial profiling using 16s RNA characterization has produced conflicting outcomes in terms of overall microbial diversity; some groups reported no difference in overall microbial diversity between people with and without T2DM [35, 36] whereas others suggested a decrease in microbial diversity in those with T2DM [37]. Despite the discrepancies relating to microbial diversity, the majority of studies have reported differences in the relative abundance of specific microbial species between people with and without T2DM [35, 38], including decreased relative abundance of specific Bacteroidetes species, including Bifidobacteria [36] and Bacteroides [37]. An additional study involving microbial characterization of the cecal contents of obese insulin-resistant compared with obese insulin-sensitive individuals reported differing molecular signatures between the groups [39], further supporting a potential relationship between the intestinal microbiota and risk for T2DM.

These early studies were limited by the small sample sizes (groups from eight to 64 individuals) and the degree of species identification possible using pyrosequencing and gel electrophoresis methods. Recently, more extensive metagenome shotgun sequencing has been performed in an ethnic Chinese T2DM case–control cohort ($n = 345$) in a two-stage design [40] and in a cohort of almost 3000 European women classified into T2DM-affected, impaired glucose tolerance, or control groups [41]. Both studies reported differences in the microbial composition between groups, including a decrease in butyrate-producing bacteria in individuals affected with T2DM [40], and support the utility of metagenomic markers to predict disease status. Lastly, a large ($n = 3280$) prospective study quantified the total 16s rDNA concentration present in the circulation at baseline and after 9 years of follow-up and assessed association with T2DM development [42]. Higher baseline concentrations were predictive of T2DM development over follow-up and, although causality was not established, these data suggest that translocation of the intestinal microbiota into the circulation may be an important biological event underpinning the risk for T2DM development.

The intestinal microbiome can influence intestinal permeability

A permeable intestinal mucosa is necessary to facilitate critical absorptive functions, but maintenance of barrier exclusion is essential in isolating the intestinal microbiota within the intestinal lumen. The interaction between various integral membrane proteins and cytoskeletal components provides a structural framework to maintain the integrity of the intestinal mucosa via intercellular tight junctions; however, the intestinal microbiota has been suggested to contribute to the ongoing remodeling of the mucosal surface [13]. *In vitro* experiments demonstrate that exposure of cultured intestinal epithelial cells to both commensal and probiotic microbial species results in upregulation and increased phosphorylation of key tight junction proteins [43, 44]. Likewise, colonization of germ-free mice has been shown to result in the upregulation of key tight junction proteins [45] and normalization of intestinal barrier function in animal models of disease [43, 45]. Further, human clinical studies involving manipulation of the intestinal microbiota via probiotic supplementation reported outcomes that include increased tight junction protein expression in collected duodenal biopsy samples [46], decreased fecal

excretion of the key tight junction protein zonulin [47], and a reduction in intestinal permeability assessed using a dual-sugar absorption test [48], all suggesting preserved integrity of the intestinal mucosa mediated by the intestinal microbiota. Conceivably, altered composition of the intestinal microbiota reported in obesity could impact adversely on intestinal permeability and contribute to translocation of the intestinal microbiota to the circulation and subsequent systemic responses that may contribute to risk for T2DM.

Metabolic endotoxemia

Regardless of the initiating sequence of events, alterations in intestinal permeability have the potential to trigger metabolic endotoxemia (ME). Metabolic endotoxemia is a relatively new concept, coined to describe modest concentrations of circulating bacterial lipopolysaccharide (LPS) in response to non-infectious stimuli [49]. LPS is a cell-wall component of Gram-negative bacterial species and the intestinal microbiota represents a significant reservoir for LPS entry into the circulation. The appearance of LPS in the circulation has been proposed to result from passive diffusion across an intestinal mucosa where tight junction integrity has been compromised and intestinal permeability increased [50], and more recently active transport pathways have also been implicated in metabolic endotoxemia. LPS has been found to be incorporated in chylomicron fractions [51, 52], suggesting that active absorption across the intestinal mucosa as part of normal digestion and absorption may also account for the appearance of LPS in the circulation.

Indeed, diet has been one factor shown to influence LPS translocation across the intestinal mucosa. A dose-dependent relationship between dietary fat content (40–70% total caloric content over 4 weeks) and plasma endotoxin levels has been reported in several murine feeding studies [49, 53]. The same murine model has also shown that antibiotic treatment, resulting in a decreased intestinal microbial load, attenuates the increase in plasma LPS concentrations following the 4-week high-fat feeding [54] and provides further confirmation that the intestinal microbiota is a critical component of metabolic endotoxemia. Likewise, attenuation of the increase in plasma LPS concentrations following a 14-week high-fat (70%) diet has also been reported in a mouse model where the diet was supplemented with a fermentable dietary fiber [55], thought to preserve the integrity of the intestinal mucosa, further implicating intestinal permeability as a determinant of metabolic endotoxemia.

An association between dietary composition and metabolic endotoxemia has also been reported in human studies. Acute increases in plasma LPS have been reported within 1 h [51, 56] to 3 h [57] following consumption of a high-fat meal by otherwise healthy volunteers, with elevations persisting for up to 5 h postprandially [58]. Further, dietary fat content was significantly correlated with plasma LPS concentrations in an epidemiological study of 201 healthy middle-aged men [53], and a small feeding study demonstrated that, even among healthy volunteers ($n = 8$), a month-long Western-style (40% fat) diet was associated with significant (~70%) increases in plasma LPS [59]. These data support the potential for dietary habits associated with risk for obesity and obesity-associated disease to trigger translocation of the intestinal microbial contents to the circulation as well.

Metabolic endotoxemia in T2DM

Whereas the relationships between obesity, diet, and metabolic endotoxemia have received particular attention, few studies have assessed these relationships in individuals with overt T2DM. That said, epidemiological data do implicate circulating endotoxin in the risk for T2DM. Higher plasma LPS concentrations have been reported in a sample of middle-aged individuals affected with T2DM ($n = 25$) compared with a matched control group [60] and in a cohort of treated individuals with T2DM ($n = 346$) [61]. More recently, a larger analysis involving the FINRISK97 cohort ($n \approx 6600$ Finnish adults) found that circulating endotoxin concentrations at baseline were significantly higher in the individuals with T2DM and were predictive of those who developed overt T2DM over the 10-year follow-up period [62]. Given these relationships, understanding the physiological responses to circulating endotoxin may provide further insight into the pathogenesis of T2DM.

Although the impact of sepsis on glucose control and metabolism has been established [63, 64], ethical and logistic challenges mean that few studies have directly manipulated plasma LPS and/or the intestinal microbiota as a way to establish causality for T2DM. However, LPS infusion in a mouse model has been shown to induce changes in insulin sensitivity and glucose control, supporting a causal role for metabolic endotoxemia in T2DM development [49]. Chronic low-dose subcutaneous LPS infusion (300 mg/kg/day) over 4 weeks was shown to elicit increases in fasting glucose and insulin, impaired glucose clearance in response to an oral glucose load, and increased hepatic gluconeogenesis, all suggesting the loss of glycemic control [49]. In healthy humans, the acute effects of intravenous LPS infusion (20 U/kg, ~2 ng/kg total dose) have been assessed during a 10-h euglycemic hyperinsulinemic clamp protocol and significant reductions in glucose utilization were noted [65]. In a subsequent human study, low-dose LPS infusion (3 ng/kg total dose) over a 60-h endotoxemia protocol also resulted in decreased insulin sensitivity (measured as insulin sensitivity index, S_i) and increased insulin resistance (measured as HOMA-IR) at 24 h following LPS infusion [66], further implicating LPS as a causal factor in the development of insulin resistance.

Modulation of the intestinal microbiome is associated with improvements in insulin sensitivity

Beyond these seminal studies implicating bacterial LPS as an initiating factor in impaired glucose control, direct modulation of

the intestinal microbiota has also been show to affect indices of glucose homeostasis. Use of a broad-spectrum antibiotic treatment over 4 weeks in high-fat fed and genetically modified phenotypically obese mice (*ob*/*ob*) has been shown to modulate the intestinal microbial contents, reduce the level of endotoxemia, and elicit reductions in both glucose-induced insulin secretion and insulin resistance index [54]. Subsequent animal models also reported modulation of the intestinal microbial content, reduced endotoxemia, reduced fasting glucose and insulin, and improvements in glucose and insulin tolerance in high-fat fed animals receiving antibiotics [67]. Further, probiotic supplements have also been shown to affect both the intestinal microbial content and indices of glucose control. Single-strain probiotic supplements administered over 14 weeks of high-fructose feeding and over 8 weeks in a diabetic rat model were associated with lower fasting glucose and insulin and improved glucose clearance following a glucose tolerance test [68] and lower fasting insulin and HOMA-IR [69], respectively. Similarly, in high-fat fed mice, improved glucose clearance following glucose tolerance tests was noted following single-strain probiotic supplementation over 5 [70] and 10 weeks [71]. Collectively, these data support the potential for modulation of the intestinal microbiota to mediate improvements in insulin sensitivity.

Although findings from antibiotic studies have yet to be widely replicated in humans in the context of glycemic control, the effects of probiotic supplementation and intestinal microbial transplant have been assessed. Two trials from the same laboratory reported reductions in fasting glucose, fasting insulin, and HOMA-IR in a cohort of overweight adults [72] and reductions in fasting insulin and HOMA-IR in otherwise healthy young adults [73] following 6 weeks of probiotic supplementation. Similarly, 4 weeks of probiotic supplementation was associated with improved insulin sensitivity, assessed via a hyperinsulinemic–euglycemic clamp, in a cohort of overweight adults ($n = 45$) with ranging glucose tolerance [74]. However, not all probiotic trials have been able to demonstrate definitive benefits on glycemic control [75, 76]. Further, in the lone fecal transplant study, men with metabolic syndrome received either an autologous gut microbiota duodenal infusion ($n = 9$) or an allogenic gut microbiota duodenal infusion from healthy lean donors ($n = 9$) with a hyperinsulinemic–euglycemic clamp performed before and 6 weeks following infusion [77]. Gut microbial diversity was significantly increased and improvements in peripheral insulin sensitivity and a trend towards reduced endogenous glucose production were noted 6 weeks following the allogenic infusion only. Although these data further implicate the intestinal microbiota in mediating insulin resistance, they fail to provide insights into the signaling pathways mediating these effects.

The microbiome contributes to T2DM risk via innate immune pathways

As a key component of Gram-negative pathogenic strains, LPS is recognized by pattern recognition receptors that play a critical role in the activation of immune and inflammatory pathways. Immune responses to circulating LPS are well characterized in models of infection and sepsis, but activation of similar signaling pathways would also be anticipated in metabolic endotoxemia and understanding these pathways provides insights into how the intestinal microbiota contribute to risk for T2DM. Regardless of the trigger for LPS translocation, once in the circulation LPS binds to LPS-binding protein (LBP), a constitutively expressed plasma protein, which facilitates the interaction between LPS and various receptors and binding sites. Among these receptors are the toll-like receptor 4 (TLR4) cell surface molecule and its associated co-receptor, cluster of differentiation 14 (CD14). TLR4 activation initiates an extensive intracellular signaling cascade that initially involves recruitment of the MyD88 adaptor protein and activation of IL-1R1-associated protein kinases (IRAKs) [78], which can trigger (i) subsequent phosphorylation of IkB kinase (IKK-B), the degradation of IkB and NF-kB translocation to the nucleus to facilitate transcriptional regulation of inflammatory mediators, including interleukin (IL)-1, tumor necrosis factor (TNF)-α, and IL-6 [79], and (ii) c-Jun N-terminal kinase (JNK) activation [80]. Interestingly, saturated fatty acids also act as ligands for TLR4 [78] and provide an additional stimulus for initiating these same signaling pathways in obesity.

The cross-talk between TLR4 and insulin signaling pathways provide a mechanism linking the intestinal microbiota to insulin resistance (Figure 17.2). Classic insulin signaling pathways involve a complex series of phosphorylation events initiated by the interaction between insulin and its cell surface receptor. Receptor–ligand binding triggers the autophosphorylation of the intracellular domain of the insulin receptor and subsequent phosphorylation (predominately at tyrosine residues) of the intracellular insulin receptor substrate (IRS) family members with additional kinase activity, including Akt involvement, culminating in the exocytosis of glucose transporters to the cell surface to facilitate glucose uptake [81]. Insulin signaling can be regulated by a negative feedback loop where phosphorylation of IRS members (predominately at serine/threonine residues) inhibits further signal transduction, essentially impeding further cellular glucose uptake [82, 83]. Insulin signaling pathways also contribute to the regulation of glycogen synthesis (via glycogen synthase activation [81]) and regulation of metabolic pathways (via transcription factor regulation [82]) and in this way contribute to glycemic control more globally beyond cellular glucose uptake.

Signaling cascades initiated by LPS–TLR4 binding have the potential to regulate the insulin signaling pathways at multiple points. Notably, JNK activation downstream of TLR4 activation can trigger phosphorylation of IRS members at serine/threonine residues, inhibiting further insulin signaling [84, 85]. Additional triggers have been identified for JNK activation and subsequent disruption of insulin signaling, notably ER stress [86, 87]; although these pathways are also relevant in understanding the pathogenesis of T2DM, particularly in the context of obesity and nutrient excess, there is little evidence suggesting direct modulation by the intestinal microbiota. However, inflammatory

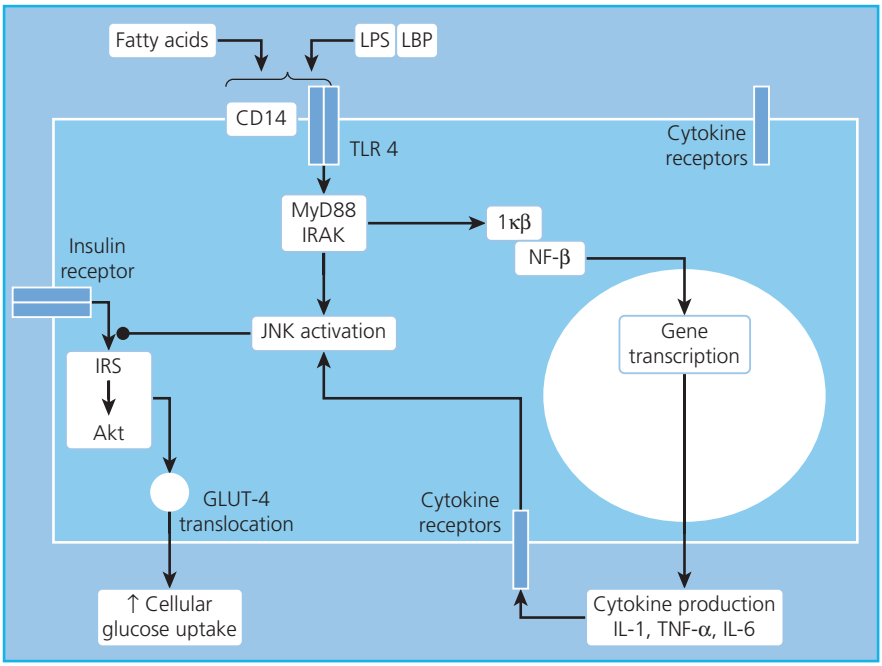

Figure 17.2 Components of the intestinal microbiota (namely lipopolysaccharide, LPS) have the potential to activate innate immune pathways. Cross-talk between TLR4 and insulin signaling pathways provide a mechanism linking the intestinal microbiota to insulin resistance.

cytokines secreted in response to TLR4 signaling and as part of the unfolded protein response can signal back to cells in an autocrine or paracrine fashion and, via their own cell surface receptors, trigger further activation of the JNK pathway, contributing to a cycle of persistent amelioration of insulin signaling [88, 89].

Indeed, studies involving animal knockout models, loss of function mutations, and receptor antagonists provide support for the involvement of the TLR4 and JNK pathways in linking the microbiome and insulin resistance. Animal models involving TLR4 mutants or knockouts [90, 91] and a human clinical trial involving infusion of an anti-CD14 antibody [92, 93] all demonstrate attenuated inflammatory responses to LPS exposure, confirming the role of TLR4/CD14 signaling in mediating the inflammatory response to LPS exposure. Similarly, the murine model mentioned earlier whereby LPS infusion was sufficient to trigger changes in insulin sensitivity and glucose control also demonstrated that this series of responses was attenuated in CD14-deficient mice [49]. These findings are consistent with those from a murine model with a TLR4 loss of function mutation and utilizing a high-fat feeding protocol; the downregulated TLR4/CD14 signaling pathway was protective for metabolic dysregulation and was associated with attenuated IKKB and JNK signaling [94]. Similarly, JNK knockout mice have been shown to be protected from insulin resistance triggered by high-fat feeding [95] and, in an obese diabetic mouse model administered a JNK inhibitory peptide, lower fasting glucose and insulin concentrations and improved glucose control and insulin sensitivity in response to glucose and insulin tolerance tests have been reported [96]. Although these findings are from animal studies only, collectively these data highlight key signaling pathways that link the intestinal microbiome and risk for T2DM.

The microbiome contributes to T2DM risk via modulation of enteroendocrine cell function

Beyond the purported roles of bacterial fermentation products in promoting colonocyte health [20], identification of the signaling pathways via which SCFAs may contribute to metabolic regulation further implicate the intestinal microbiome in the pathogenesis of T2DM. SCFAs have been identified as ligands for a series of G protein-coupled receptors (GPRs) expressed on the intestinal epithelium and also by adipose tissue and immune cells [97]. SCFAs differentially activate various GPRs; propionate shows the highest affinity for GPR41 (also known as free fatty acid receptor 3) and GPR43 (also known as free fatty acid receptor 2), acetate for GPR43, and butyrate for GPR41 and GPR109A [98]. Activated downstream signaling pathways include those implicated in enteroendocrine cell function [99, 100], as discussed below (Figure 17.3), and also the regulation of immunity and inflammation [101], which has the potential to influence insulin signaling pathways.

Potential regulation of enteroendocrine function, particularly glucagon-like peptide (GLP) and polypeptide YY (PYY) secretion, may be especially relevant when considering the role of the intestinal microbiome in T2DM pathogenesis. GLP-1 and PYY are co-secreted from enteroendocrine cells resident in the colonic mucosa in response to nutrient sensing [102, 103]. Some effects of GLP-1 and PYY are similar, including attenuation of gastrointestinal motility and gastric acid secretion [103–105] and induction of satiety, likely via centrally mediated mechanisms [102, 106]. However, GLP-1 and PYY have opposing effects on insulin secretion. GLP-1 acts to increase glucose-stimulated insulin secretion

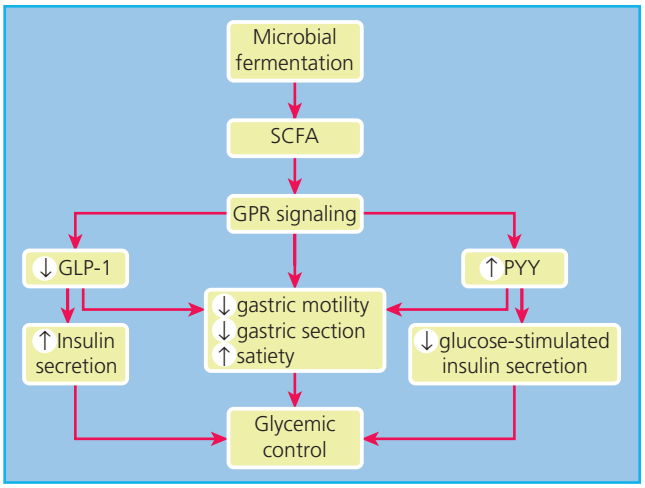

Figure 17.3 Short-chain fatty acids (SCFAs) are produced during microbial fermentation of non-digestible dietary starches. SCFA signaling via G protein-coupled receptors (GPRs) can regulate incretin signaling, namely glucagon-like peptide 1 (GLP-1) and polypeptide YY (PYY), with downstream effects on glycemic control.

by binding to GLP receptors on pancreatic β cells and triggering an intracellular signaling cascade that results in the exocytosis of insulin-containing granules [104, 106]. In contrast, PYY has been shown to inhibit glucose-stimulated insulin release from the pancreas, although the signaling mechanisms underpinning this effect are less well defined [107, 108]. Both GLP-1 and PPY undergo enzymatic cleavage by dipeptidyl peptidase (DPP)-4; for GLP-1 this plays a role in clearance of the active form [109], but for PYY it generates the biologically active form [108]. Given the documented effects of GLP-1 and PPY in the context of glucose control, it is not surprising that both GLP agonists and DPP-4 inhibitors have been developed as T2DM treatments [110].

The potential for the intestinal microbiome, via SCFAs, to modulate GLP-1 and PYY secretion [111] represents a further pathway via which the intestinal microbiome may contribute to insulin resistance and T2DM risk. *In vitro* and animal models and human supplementation studies support this possibility. In primary colonic cultures from wild-type mice, treatment with SCFAs induced GLP-1 secretion, an effect that was attenuated in tissue from GPR41 and GPR43 knock-out mice [100]. Similarly, more pronounced impairments in plasma GLP-1 in response to oral glucose load were noted in the knockout animals [100], further supporting SCFA-induced signaling via GPR41/43 as a key trigger for incretin secretion. A similar study in a rodent model assessing both GLP-1 and PYY responses to SCFAs reported similar outcomes for both primary colonic cultures and systemic responses [112]. Several small-scale human intervention trials in otherwise healthy adults have demonstrated that supplementation with a fermentable prebiotic fiber for 2–12 weeks can result in higher breath-hydrogen excretion (as a surrogate for colonic fermentation) [113] and higher glucose-induced plasma concentrations of PYY [114] and GLP-1 [113, 115]. In a subsequent trial involving hyperinsulinemic adults ($n = 40$), 12 months' supplementation with dietary high-fiber cereal (a form of non-digestible starch and a substrate for the intestinal microbiota) resulted in significant increases in plasma acetate, propionate, and butyrate concentrations, and increases in both basal and postprandial GLP-1 concentrations [116], further supporting an association between SCFAs and GLP-1 and PYY, and highlighting the potential for modulation of the intestinal microbiota to mitigate disrupted incretin signaling in metabolic disease.

The microbiome contributes to T2DM risk via modulation of bile acids

The role of bile acids in lipid digestion and absorption is well established, with bile acid turnover providing a pathway for cholesterol excretion [117]. Beyond these actions, regulatory roles of bile acids in glucose metabolism have also been acknowledged. Bile acid composition has been associated with features of insulin resistance in European adults [118] and altered bile acid composition has also been noted in adults with diabetes [119, 120]. Further, over recent years, clinical trials have demonstrated the effects of bile acid sequestrants on glycemic control. Among these observations are significant reductions in fasting blood glucose in a group of middle-aged men with metabolic syndrome ($n = 20$) after 8 weeks in a placebo-controlled crossover trial [121]; significant reductions in fasting blood glucose and postprandial blood glucose in middle-aged individuals affected with T2DM ($n = 38$) after 12 weeks in a placebo-controlled trial [122]; and significant reductions in glycated hemoglobin, glycated albumin, and postprandial blood glucose in middle-aged individuals affected with T2DM ($n = 59$) after 12 weeks in a placebo-controlled trial [123]. Collectively, these findings all support an association between regulation of the bile acid pool and glucose control.

Although the exact mechanisms linking the bile acid pool and glucose control are yet to be fully defined, two pathways have received particular attention (Figure 17.4). Bile acids are known ligands for the nuclear receptor farnesoid X receptor (FXR), which activates the transcription factor short heterodimer protein (SHP) [124] and regulates the expression of a number of genes involved in bile acid synthesis and metabolism, thereby establishing a feedback loop facilitating bile acid self-regulation [117, 125, 126]. Feedback inhibition of bile acid synthesis has also been reported to involve FXR-independent activation of the JNK signaling pathways [127–129], which, as mentioned above, can inhibit insulin signaling. Beyond this, FXR-mediated signaling has been associated with glucose homeostasis [117]. FXR receptor knockout mice have been shown to have impaired plasma glucose clearance in response to both glucose and insulin tolerance tests [130, 131]. Conversely, administration of FXR agonists in a diabetic mouse model was shown to decrease fasting glucose and insulin [132], suggesting preserved insulin sensitivity. In both settings, intracellular signaling pathways were also examined and either decreased (in the FXR knockouts) or increased (in response to FXR agonist)

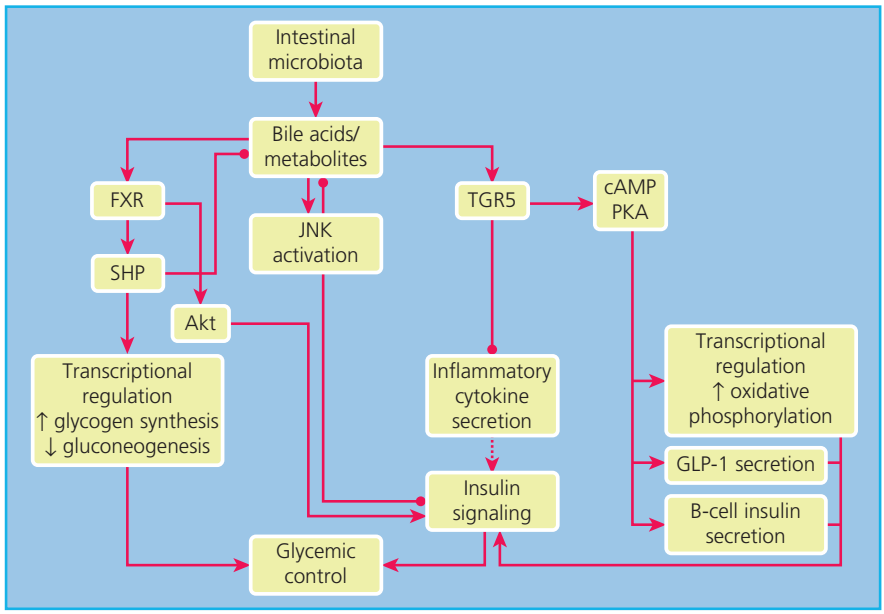

Figure 17.4 The intestinal microbiome influences the composition of the bile acid pool and metabolites. Bile acid signaling through the farnesoid X receptor (FXR) and the G protein-coupled receptor TRG5 pathways can effect transcriptional regulation of various metabolic pathways. Regulation of other signaling pathways can also contribute to alterations in glycemic control.

Akt phosphorylation was reported [130, 132], suggesting that FXR signaling may contribute directly to regulation of insulin signaling pathways. Other studies have implicated FXR in the downregulation of genes involved in hepatic gluconeogenesis [131, 133], and also in glucose-induced insulin secretion from pancreatic β cells [134, 135], providing further mechanisms via which bile acids may contribute to insulin resistance.

In addition to signaling via FXR, bile acids have also been identified as a ligand for the G protein-coupled receptor TGR5 [136, 137]. Activated intracellular signaling pathways are thought to involve protein kinase A and the cyclic AMP response element binding protein, which can regulate gene expression and allows for a range of downstream effects [125]. In the context of insulin resistance, i*n vitro* models have shown that bile acid signaling is able to induce GLP-1 secretion from enteroendocrine and primary intestinal cell cultures, with small interfering RNAs and TGR5 agonists confirming that these responses are mediated via TGR5 [138, 139] activation. Animal models also support a role for TGR5 signaling in mediating glucose homeostasis [140]. Use of selective TGR5 agonists in high-fat fed mice have been shown to decrease plasma glucose and insulin and improve glucose clearance rates in glucose tolerance tests [141, 142]. Further, TGR5 overexpression in a transgenic mouse model resulted in improved glucose clearance rates in a glucose tolerance test and augmented postprandial GLP-1 and insulin secretion, whereas glucose tolerance and GLP-1 secretion were impaired in TGR5 knockout animals [142]. In some human clinical studies involving bile acid sequestrants, GLP-1 responses have been shown to parallel changes in insulin sensitivity [143], further supporting GLP-1 as a link between bile acid signaling and risk for diabetes. Finally, evidence suggesting that TGR5 activation by bile acids may have inhibitory effects on inflammatory cytokine production [137, 144] provides a further mechanism via which bile acid signaling may indirectly contribute to the regulation of insulin signaling pathways.

Given the potential for bile acids to contribute to the regulation of glucose control, modulation of the bile acid pool by the intestinal microbiota provides another interface between the microbiota and risk for diabetes. Although enterohepatic circulation recovers a large proportion of secreted bile acids from the distal ileum, a proportion reach the large bowel where the microbiota catalyze a series of reactions, including deconjugation, dehydrogenation, and dehydroxylation reactions, resulting in the formation of secondary bile acids [145, 146]. Secondary bile acids may themselves contribute to the feedback inhibition of bile acid synthesis and secretion, and other downstream effects via the FXR and TGR5 signaling pathways [147, 148]. Animal models support the involvement of the intestinal microbiota in modulation of the bile acid pool. The composition of the bile acid pool has been shown to differ between germ-free and conventional animals in both rodent [149] and murine models [150]. Further, in several murine experiments, antibiotic treatment has been shown to modulate the composition of the bile acid pool in favor of primary bile acids and upregulation of FXR signaling pathways [151–153], whereas probiotic supplementation appears to favor the production of secondary bile acids and attenuation of FXR signaling [154]. Modulation of the intestinal microbiota in humans has also been show to influence the composition of the bile acid pool. In a study trialing fecal transplantation for recurrent *Clostridium difficile* infection, the composition of the fecal bile acid pool was significantly different following transplantation and tended to favor secondary bile acids [155]. Also of particular interest is a 7-day antibiotic intervention in obese men ($n = 20$) where a reduction in fecal secondary bile acids was noted and alterations in bile

acid composition were correlated with alterations in peripheral insulin sensitivity pre- to post-intervention [156]. Although the bile acid signaling pathways are complex and involve multiple intracellular pathways, effects on glycemic control are plausible and, given the established roles of the intestinal microbiota in regulating the composition of the bile acid pool, further implicate the intestinal microbiota in risk for T2DM.

Type 1 diabetes

It would be remiss to ignore a potential role of the intestinal microbiota in the pathogenesis of type 1 diabetes mellitus (T1DM). Although the precise mechanisms and molecular signaling pathways remain under investigation, support for the interplay between the intestinal microbiota, intestinal permeability, and immune aberrations in initiating the autoimmune destruction of pancreatic β cells continues to grow [157]. Although epidemiological studies are of limited value given the low prevalence of T1DM, reports confirm differences in the composition of the intestinal microbiota between individuals with and without T1DM [158, 159], including decreases in butyrate-producing strains [160, 161], suggesting, at the minimum, an association between the intestinal microbiota and T1DM risk. Studies involving germ-free animal models that report increased T1DM incidence [162] support the importance of a robust intestinal microbiome in mitigating T1DM risk. Similarly, animal models demonstrating that modulation of the intestinal microbiota, using either antibiotics [163] or probiotic supplementation [164], results in delayed onset and reduced incidence of diabetes provide further evidence in support of a potential link between gut microbiome and T1DM risk. Alterations in intestinal permeability have also been noted in both animal models of T1DM [165, 166] and human clinical studies [167–169] and provide insight into the mechanisms that may link the intestinal microbiome and T1DM risk. Given the identified roles of butyrate-producing bacterial strains in promoting the integrity of the intestinal mucosa [43, 45], alterations in the microbial composition may underpin diminished mucosal integrity in T1DM. Increased intestinal permeability and associated translocation of LPS and other antigens across the mucosal surface may trigger aberrations in immune regulation and the development of autoimmune responses in genetically susceptible individuals. Indeed, a role for the activation of innate immune mechanisms in T1DM has been demonstrated in a murine model whereby knockout of the MyD88 intracellular signaling intermediary, activated downstream of TLR receptor–ligand binding, conferred protection against development of T1DM [162].

The role of the microbiota in shaping host immune development also cannot be overlooked in the context of T1DM risk. The increased prevalence of T1DM in developed nations has been interpreted by some to support the hygiene hypothesis, whereby inappropriate immune development in response to limited microbial exposure is considered a risk factor for the development of autoimmunity [170–172]. Immunological aberrations reported previously in T1DM include reduction in FoxP3$^+$ regulatory T cells (Tregs) in the intestinal mucosa of individuals with T1DM [173], reduction in peripheral Tregs [174] and Nk T cells [174, 175], and dysregulated cytokine signaling, suggestive of impaired T-cell function [176, 177]. More recently, Th17 responses have received particular attention for their roles in inflammatory control and autoimmune disease [178–180], and an upregulation of peripheral Th17 cells has been reported in individuals with T1DM [181]. Of further interest are the growing number of reports suggesting a critical role for the intestinal microbiota in regulating Th17 and Treg phenotypes [182–185]; although the precise mechanisms underpinning these effects are yet to be elucidated, these associations do further implicate the intestinal microbiome, via modulation of the immune system, in the risk for T1DM.

Conclusions and perspectives

Given the considerable size of the metagenome and associated metabolic machinery, it is not surprising that the interface between intestinal microbiome and human host has the potential to affect health, including risk for disease. In the context of T1DM, inappropriate immune education by the microbiome may potentiate autoimmune destruction of pancreatic β cells in otherwise susceptible individuals. The potential for cross-talk between the microbiome and immunological and metabolic pathways is also relevant in T2DM; activation of innate immune pathways, modulation of enteroendocrine cell function, and regulation of metabolic signaling pathways by the microbiome all have the potential to disrupt insulin signaling pathways and contribute to loss of glycemic control. Given the increasing prevalence of both T1DM and T2DM, particularly in the developed world, understanding the molecular mechanisms by which the microbiome contributes to risk for diabetes may prove beneficial in the development of additional risk stratification tools. Further, the potential to manipulate the composition of microbiome may enhance existing treatment and management strategies.

4 Other Types of Diabetes

18 Monogenic Causes of Diabetes

Shivani Misra[1] and Andrew T. Hattersley[2]

[1] Diabetes, Endocrinology & Metabolism, Imperial College London, London, UK
[2] Institute of Biomedical & Clinical Sciences, University of Exeter Medical School, Exeter, Devon, UK

Key points

- Monogenic diabetes should be suspected where:
  - presentation is atypical for type 1 or 2 diabetes;
  - there is an autosomal dominant (or maternally inherited in mitochondrial disorders) family history;
  - there are characteristic associated features such as deafness in mitochondrial diabetes or fat loss in lipodystrophy or;
  - diabetes has been diagnosed within the first 6 months of life.
- Mutations in the glucokinase gene, which is important in "sensing" blood glucose levels in the pancreas, result in resetting of fasting glucose to a higher level (5.5–8.0 mmol/L). People with glucokinase mutations have dominantly inherited mild fasting hyperglycemia with only modest changes in glycated hemoglobin. Complications are rare and no treatment is needed.
- Mutations in the transcription factor genes *HNF1A* and *HNF4A* result in dominantly inherited progressive hyperglycemia with symptomatic diabetes in adolescence or young adulthood. People with *HNF1A* or *HNF4A* diabetes are very sensitive to sulfonylurea treatment and may not require insulin until middle or old age.
- Mitochondrial mutations can result in maternally inherited diabetes often with sensorineural hearing loss and a range of other disorders.
- Diabetes diagnosed before 6 months is unlikely to be type 1 diabetes and a genetic cause should be sought even where the patient is now an adult. High-dose sulfonylurea treatment is often more effective than insulin where mutations affecting Kir6.2 and SUR1 subunits of the β-cell potassium channel are identified.
- Acanthosis nigricans is the key feature of insulin resistance and a genetic cause should be considered where there is no concomitant obesity. Partial lipodystrophy results in thin muscular limbs with hypertriglyceridemia and insulin resistance and suggests a mutation in *LMNA* or *PPARG*. In the absence of lipodystrophy an insulin receptor mutation is the commonest cause.

Introduction

Monogenic diabetes results from inheritance of one or more mutations in a single gene and accounts for 1–3% of diabetes cases diagnosed under the age of 30 years. Mutations may be inherited in a dominant or recessive fashion. The majority (90%) of monogenic diabetes cases are initially misdiagnosed as type 1 (T1DM) or type 2 diabetes (T2DM).

Correct genetic diagnosis is important to predict clinical course, explain other associated clinical features, enable genetic counseling, diagnose family members, and most importantly guide appropriate treatment.

Monogenic diabetes where the primary disorder affects the β cell has four main clinical presentations: (1) familial mild fasting hyperglycemia (glucokinase maturity-onset diabetes of the young [MODY]), (2) familial young-onset diabetes (transcription factor MODY), (3) neonatal diabetes, and (4) diabetes with extrapancreatic features. Clinical and biochemical features that help differentiate the common forms of monogenic diabetes that result in β-cell dysfunction from T1DM and T2DM are summarized in Table 18.1. Classification and key features of monogenic diabetes are further summarized in Figure 18.1 and their role in β-cell physiology is depicted in Figure 18.2. Single-gene mutations may also cause diabetes through insulin resistance as occurs in the inherited lipodystrophies and insulin receptor mutations. A number of monogenic multisystem diseases (e.g. hemochromatosis and cystic fibrosis) may cause diabetes; these are beyond the scope of this chapter and are discussed elsewhere (see Chapter 21).

Maturity-onset diabetes of the young

Maturity-onset diabetes of the young (MODY) is autosomal dominantly inherited diabetes that, despite a young age of onset, is not insulin-dependent [1, 2]. It results from β-cell dysfunction rather than insulin resistance [1]. The underlying genetic etiology has now been defined allowing MODY to be subclassified according to the gene involved [3, 4]. Mutations in at least nine genes

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

Table 18.1 Differentiating β-cell monogenic diabetes from type 1 and 2 diabetes. DM, diabetes; GCK, glucokinase; *HNF1A*, hepatocyte nuclear factor 1A (*HNF4A* is similar); MIDD, maternally inherited diabetes and deafness; PNDM, permanent neonatal diabetes; Pop freq, population frequency (frequency of obesity seen in the general population).

Features	Type 1 diabetes	Young type 2	*GCK* MODY	*HNF1A* MODY	MIDD	K_{ATP} PNDM
Insulin dependent	Yes	No	No	No	+/–	Yes
Parent affected	2–4%	Usually	Yes	Yes	Mother	15%
Typical age of onset	6 months – young adult	Adolescent and young adult	Birth (may be diagnosed at any age)	Teens – young adult	Young adult	Under 6 months
Obesity	Pop freq	Yes	Pop freq	Pop freq	Rare	Pop freq
Acanthosis nigricans	No	Yes	No	No	No	No
Glycemia	High	Variable	Mild	High	Variable	High
β-cell autoantibodies	Usually	No	No	No	No	No

have been linked to MODY [5, 6]. These include mutations in the gene encoding the glucose-sensing enzyme glucokinase (*GCK*) and mutations in several transcription factors that affect β-cell development and function, the frequencies of which are summarized in Figure 18.3. Clinical presentation varies greatly depending on the underlying genetic mutation. Table 18.2 summarizes the clinical features of glucokinase and transcription factor diabetes. The strikingly different subtypes of MODY mean it is important to define the underlying genetic etiology. We recommend the use of clinical categories based on underlying genetic cause, e.g. familial mild fasting hyperglycemia resulting from glucokinase gene mutations (*GCK* MODY), familial young-onset progressive diabetes resulting from *HNF1A* and *HNF4A* mutations (transcription factor MODY), and renal cysts and diabetes syndrome (RCAD) resulting from *HNF1B* mutations.

Mutations in the genes associated with MODY should be considered in people with diabetes diagnosed under 25 years of age, who do not fully fit the phenotypes of T1DM or T2DM and who have a strong family history of diabetes (Table 18.1). Differentiating from apparent T1DM is particularly important as these individuals can often be most effectively treated without the use of injected insulin. The differentiation of MODY from other types of diabetes is challenging and attention has turned to strategies that will enable better stratification of those requiring genetic testing,

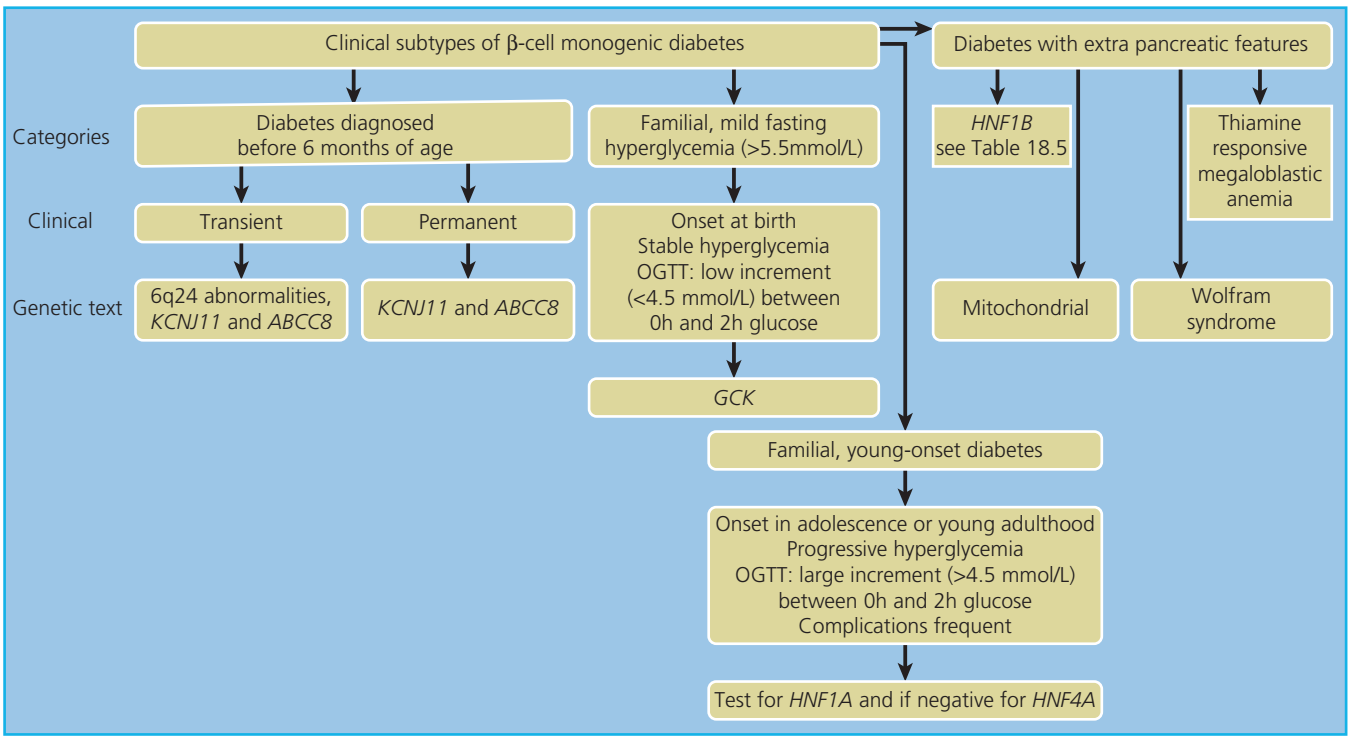

Figure 18.1 Clinical subtypes of monogenic β-cell diabetes. To convert plasma glucose measurements to mg/dL multiply by 18. ABCC8, ATP binding cassette subfamily C; *GCK*, glucokinase gene; HNF, hepatocyte nuclear factor; *KCNJ11*, potassium inwardly rectifying channel, subfamily J, member 11 gene; OGTT, oral glucose tolerance test.

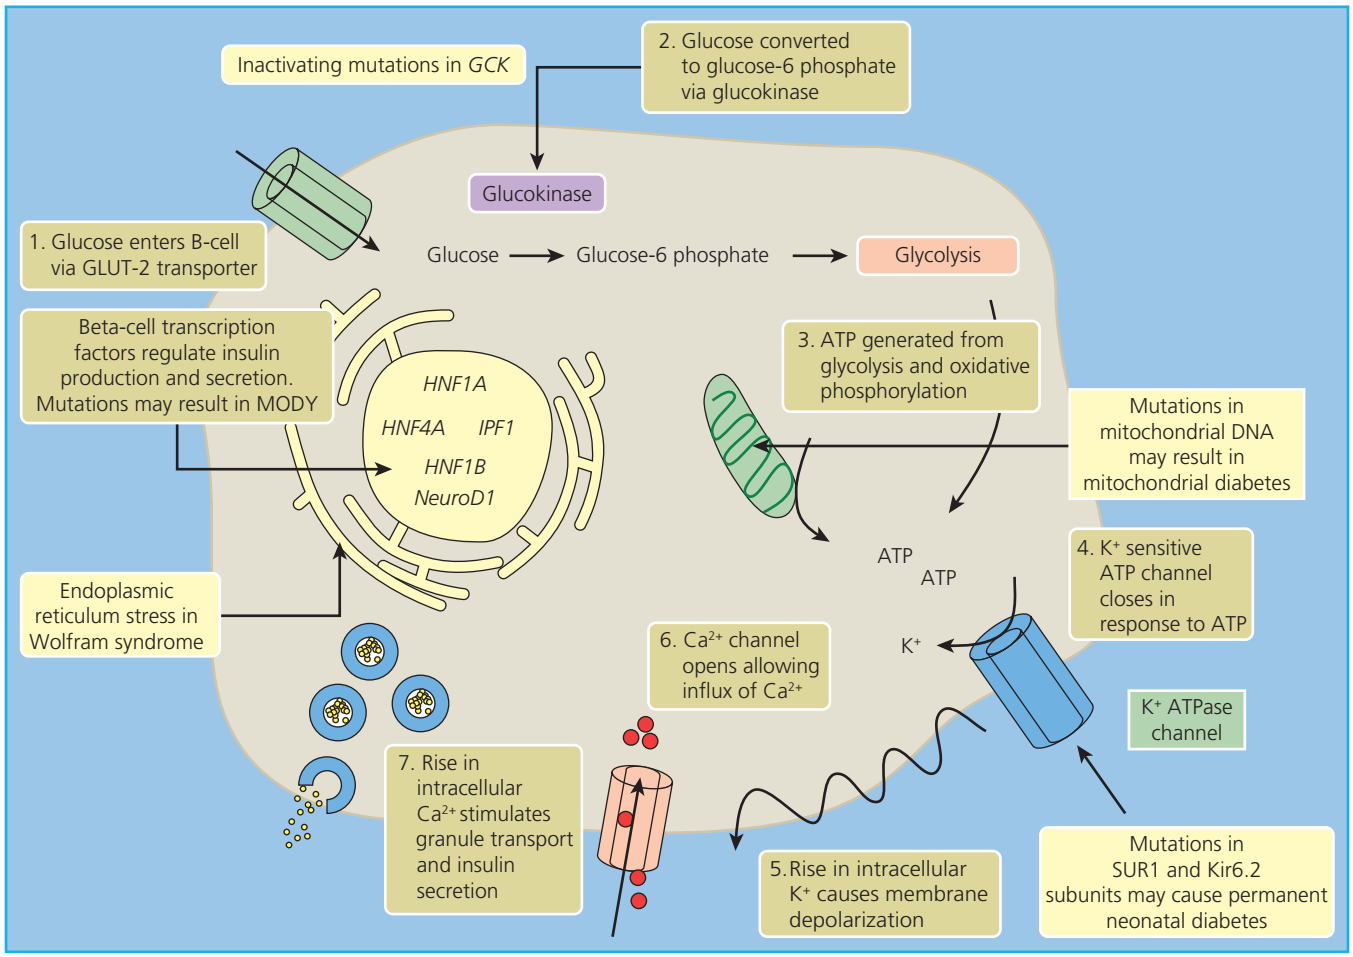

Figure 18.2 Schematic of β cell depicting key steps in glucose sensing and insulin secretion (brown boxes) and transcription factors, enzymes, organelles, and protein channels that may, if mutated, be a cause of monogenic diabetes (pale yellow boxes). Source: Adapted from Fajans et al. [5].

which include the use of a probability calculator, measurement of C-peptide and autoantibodies as well as advances in genetic testing that allow panels of genes to be tested simultaneously.

Prevalence of MODY mutations

MODY has a minimum estimated population prevalence of 108 cases per million, but this is likely to be an underestimate [7]. Prevalence estimates from large systematic surveys are between 1–3% of young-onset diabetes; in the UK UNITED study, 3% of all diabetes diagnosed <30 years of age had MODY (unpublished) while the SEARCH study undertaken in the USA found that 1.2% of all cases diagnosed under 20 years of age had MODY [8]. A population study based on screening pregnant women estimated the glucokinase prevalence to be 1.1 in 1000 population prevalence (or 1100 cases/million population) [9] suggesting most people with glucokinase mutations are not coming to medical attention or are not being diagnosed. Based on current estimates of MODY prevalence, 80–90% of cases are likely to be

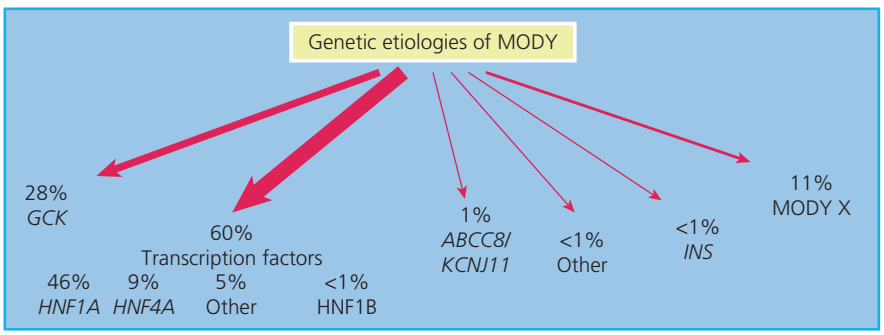

Figure 18.3 The different genetic etiologies in a UK maturity-onset diabetes of the young (MODY) series. MODY X denotes dominantly inherited young-onset non-insulin-dependent diabetes fitting clinical criteria for maturity-onset diabetes of the young where mutations in known MODY genes have not been identified. Source: Adapted from McCarthy and Hattersley [6] and Shields et al. [7].

Table 18.2 Comparison of the clinical characteristics of glucokinase and transcription factor maturity-onset diabetes of the young (MODY). FPG, fasting plasma glucose.

	Glucokinase MODY	Transcription factor MODY
Onset of hyperglycemia	Birth	Adolescence/early adulthood
Presentation	Usually asymptomatic, detected by screening or on routine testing	Usually symptomatic
Nature of hyperglycemia	Minimal increase in glycemia with age Mild (FPG usually 5.4–8.3 mmol/L) HbA_{1c} 40–60 mmol/mol	Progressive deterioration of glycemia with age May be severe (FPG frequently >14 mmol/L off treatment) HbA_{1c} variable depending on age and treatment, may be high
Pattern in an oral glucose tolerance test	FPG >5.5 mmol/L (2 hour – FPG) usually <3.5 mmol/L	FPG often <5.5 mmol/L (2 hour – FPG) usually >3.5 mmol/L
Microvascular complications	Rare	Frequent
Pathophysiology	β-cell defect (glucose sensing defect)	β-cell defect (initially insulin secretion maintained at normal glucose values but not increased in hyperglycemia)
Extrapancreatic manifestations	Altered birth weight	See Table 18.3
Treatment	Pharmacologic treatment rarely needed	Sensitive to sulfonylurea treatment May progress to require insulin

misdiagnosed or unrecognized, highlighting the need for improved case-finding.

Strategies to improve case-finding

The key approach to diagnosing MODY is to consider whether there are clinical features that are unusual for T1DM and T2DM and to undertake genetic testing in these individuals to confirm mutations (Figure 18.4). Though the cost of molecular testing continues to fall, it is still relatively expensive and it is therefore recommended that testing is restricted to those individuals with a moderate to high possibility of a positive result. Traditional clinical features, such as age at onset, a parental history of diabetes, and non-insulin treatment, overlap considerably between MODY and other types of diabetes [7] and therefore independently have poor discriminatory value.

A MODY probability calculator (available at diabetesgenes.org) offers an excellent way to establish if a diagnosis of MODY is likely: it combines clinical information to predict the probability of

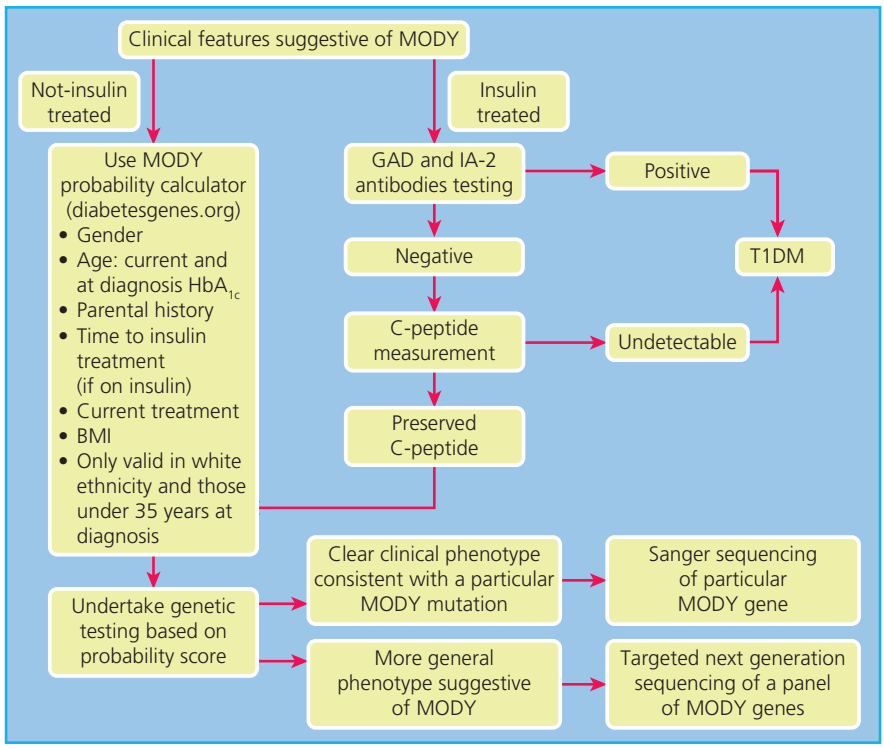

Figure 18.4 An approach to genetic testing in people with suspected MODY mutations. BMI: body mass index. Source: Shields et al. [10] and de Franco et al. [19].

testing positive for MODY [10]. The calculator markedly improved the sensitivity and specificity for identifying MODY compared with standard criteria of diagnosis, age <25 years with an affected parent.

Biomarkers such as C-peptide measurement, pancreatic autoantibodies, lipid profiles, and high-sensitive C-reactive protein (CRP) have all been shown to have some discriminatory value in differentiating cases of MODY from other subtypes; however, they are not without limitation [11–16]. Pancreatic autoantibodies are positive close to diagnosis in 80% of people with T1DM if glutamine acid decarboxylase (GAD) and islet antigen 2 (IA2) antibodies are measured [13]; however, positivity may decrease with duration of diabetes, therefore a negative test does not exclude T1DM. Testing pancreatic autoantibodies in people treated with insulin is therefore of value, if positive, in excluding MODY. The presence of preserved C-peptide secretion in a person with T1DM of long duration may also help stratify those in whom MODY testing should be considered; however, 8% of people with long-term T1DM have stimulated C-peptide levels of >200 pmol/L [17].

Use of diagnostic and predictive molecular testing in monogenic diabetes

Diagnostic testing for the major causes of monogenic diabetes is now widely available. Molecular genetic testing is traditionally guided by the clinical phenotype and also the relative prevalence of mutations within that population. A good example of this approach is in people with a very specific clinical phenotype, where Sanger sequencing of the selected gene alone may be pragmatic, for example, GCK testing in someone with fasting hyperglycemia or *HNF1B* testing in a person with renal cysts and diabetes. However, for other types of monogenic diabetes, for example, transcription factor MODY or neonatal diabetes, it may be difficult to predict the affected gene using clinical features alone. In the past this would result in sequential testing of multiple genes with associated delays in obtaining a diagnosis. However, advances in DNA sequencing technologies now mean panels of genes can be tested simultaneously using next generation sequencing platforms without the considerable costs and time associated with earlier sequencing approaches [18, 19].

Some caution is needed, however, as monogenic diabetes can occur in families that also have T1DM or T2DM. For similar reasons the results of molecular testing should be interpreted in the context of the clinical findings. For example, a person with glucokinase diabetes could also develop T1DM or T2DM.

Where a family member has a confirmed genetic diagnosis, phenotypically unaffected relatives should be tested to assess whether they will be at risk of developing diabetes in the future. Where the main mutation phenotype is diabetes, regular urine or blood testing may be preferable as there is little clear extra benefit from prospective testing. Where families request predictive testing, they should receive full counseling on the potential benefits and disadvantages and be allowed to make their own decisions on this.

Glucokinase MODY

Glucokinase catalyzes the phosphorylation of glucose to glucose-6-phosphate, the first and rate-limiting step in intracellular glucose metabolism in both β cells and hepatocytes (Figure 18.2). Owing to the unique catalytic properties of the enzyme, the rate of glucose phosphorylation is proportional to the glucose concentration, thus allowing β cells and hepatocytes to respond to changes in glycemia. In the β cell, glucokinase acts as a glucose sensor ensuring insulin release is appropriate to the glucose concentration [20]. Heterozygous loss-of-function mutations in *GCK* result in a shift of the dose–response curve to the right [21]. Glycemia is therefore regulated at a higher set point but remains tightly controlled. People with glucokinase mutations are still able to stimulate their β cells maximally [21]. Glucokinase is also present in the liver and as a result these individuals have reduced hepatic glycogen synthesis [22].

Over 200 loss-of-function mutations in *GCK* have been identified, all causing a similar clinical picture. Homozygous loss-of-function glucokinase mutations are a rare cause of insulin-requiring diabetes presenting in the neonatal period [23]. Gain-of-function mutations cause congenital hyperinsulinism [24].

Clinical features

People with *GCK* MODY have mild fasting hyperglycemia from birth, usually 5.4–8.3 mmol/L and HbA_{1c} results range between 40–60 mmol/moL (5.8–7.6%) [25, 26]. There is only a minor increase in HbA_{1c} with age, but this is also seen in older healthy people (Figure 18.5) [25, 27]. People with *GCK* MODY do not have symptoms of hyperglycemia. Post meal glucose values are only mildly raised and there is frequently only a small increase

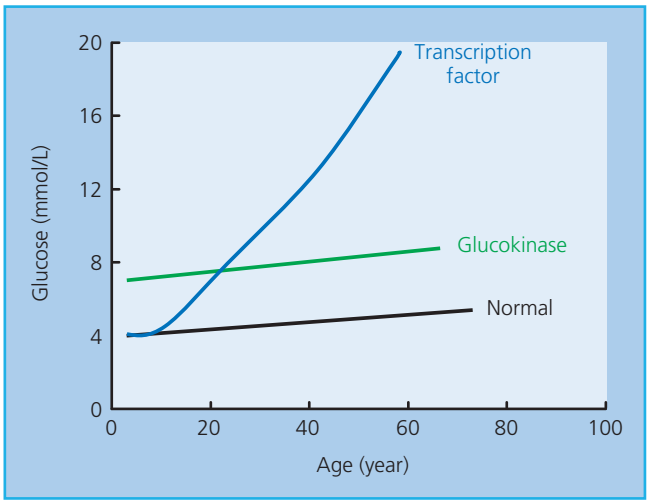

Figure 18.5 Variation of blood glucose concentration with age in people with glucokinase and transcription factor MODY.

(<3 mmol/L in 70% of those with *GCK* MODY) seen at 2 hours on an oral glucose tolerance test [28] which may explain the near normal HbA_{1c} and rarity of complications [29]. Glycated hemoglobin values above 60 mmol/mol (7.6%) would be suggestive of an alternative diagnosis and marked worsening of the glycemia suggests the development of T1DM or T2DM in addition to *GCK* MODY. Microvascular and macrovascular complications are rare even when no treatment is given [30]. As glucokinase MODY is asymptomatic there may be no known family history of diabetes, despite its autosomal dominant inheritance. Testing of apparently unaffected parents can reveal that one parent has mildly raised fasting plasma glucose.

Differentiating from type 1 and 2 diabetes

Diagnosis of glucokinase MODY is most important in young individuals who may otherwise be thought to have T1DM and treated with insulin [31]. Unlike T1DM, hyperglycemia remains mild and β-cell antibodies are usually negative. Fasting C-peptide will remain detectable and the post meal rise in glucose concentration will be far less than in T1DM. Differentiating glucokinase MODY from T2DM can be challenging as both conditions can cause mild hyperglycemia with a strong family history. Lack of obesity and features of insulin resistance, a small increment on oral glucose tolerance testing and non-progression all suggest glucokinase MODY.

Management

Outside of pregnancy, hypoglycemic medication is not recommended as hyperglycemia is mild, complications are rare and medication appears to have minimal effect in lowering glucose because the homeostatic regulation of glycemia is preserved [32, 33]. Once diagnosis is confirmed, treatment can usually be discontinued; however, this should be done with caution as it is possible for T1DM or T2DM to coexist with a *GCK* mutation.

Glucokinase MODY and pregnancy

Clinical features

Women with *GCK* mutations are frequently found to have hyperglycemia during screening in pregnancy and represent 2% of white European women with gestational diabetes [9, 26, 34]. Their identification is important because they have a different clinical course than others with gestational diabetes. The birth weight of the newborn infant will depend on the mutation status of both the mother and the fetus (Figure 18.6). Where only the mother carries the mutation, maternal hyperglycemia may result in increased fetal insulin secretion and growth causing the fetus to be large for gestational age [35]. If the fetus inherits the mutation from the father, however, birth weight is reduced by approximately 500 g as a result of reduced fetal insulin secretion and insulin-mediated fetal growth [35]. If both mother and fetus have the *GCK* mutation the two opposing effects are cancelled out and the newborn infant is of normal weight, providing maternal blood glucose has been left untreated.

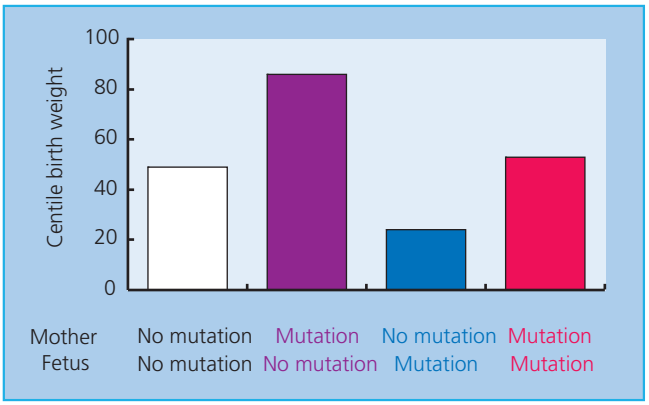

Figure 18.6 The centile birth weight of children in families with glucokinase mutations. The weight is increased by the presence of a maternal mutation and decreased by the presence of a fetal mutation. Source: Data from Hattersley et al. [35].

Genetic testing for *GCK* mutations in pregnancy

We recommend testing for *GCK* mutations when a pregnant woman is found to have persistently raised fasting plasma glucose 5.4–8.3 mmol/L and an increment of <4.6 mmol/L on at least one oral glucose tolerance test (either during or outside pregnancy). An absence of family history should not exclude the diagnosis as asymptomatic hyperglycemia in a parent may not have been detected. Genetic testing of women with a body mass index (BMI) <25 kg/m^2 and a fasting blood glucose >5.5 mmol/L has a sensitivity of 68% and on average 2.7 women will need to be tested to identify one case of *GCK* MODY [9].

Management

Women with hyperglycemia resulting from glucokinase mutations are often treated with insulin during pregnancy in an attempt to correct the fasting hyperglycemia. Fetal genotype, however, is a far greater determinant of fetal birth weight than maternal treatment and insulin appears to have little effect on fetal growth [36]. This probably reflects the difficulty in lowering the blood glucose in women with *GCK* MODY because of increased counter-regulation [37]. Women stop producing their own insulin and produce counter-regulatory hormones if blood glucose is reduced to normal levels, making successful control of blood glucose with insulin difficult. This results in frequent hypoglycemic symptoms at non-hypoglycemic blood glucose concentration and means that large doses of insulin may be required to reduce fasting hyperglycemia to normal levels [37, 38]. In some cases where the fetus has inherited the mutation, intensive insulin treatment has resulted in a low birth weight child [38]. This is to be expected as a small baby is seen when the fetus inherits a mutation from the father and is born to a normoglycemic mother [35, 39]. Testing fetal genotype *in utero* is not without risk and is not recommended unless amniocentesis or chorionic villus sampling is being undertaken for an alternative reason [40]. Assays to detect cell-free fetal DNA in maternal serum are under development and will allow non-invasive fetal genotyping in the future. At present treatment

decisions in glucokinase gestational diabetes are related to fetal growth as shown by scans rather than being made solely on maternal glycemia [38]. If the abdominal circumference is greater than the 75th centile insulin may be used but early delivery is the most successful strategy [26].

HNF1A and *HNF4A* (transcription factor MODY)

Transcription factors are proteins that bind to DNA and form part of a complex regulatory network controlling gene expression. The majority of people with MODY have a heterozygous mutation in a transcription factor gene, by far the commonest being mutations in the hepatic nuclear factors 1A and 4A (*HNF1A* and *HNF4A*). Diabetes resulting from mutations in other transcription factor encoding genes including *HNF1B* and insulin promoter factor 1 (IPF-1) are discussed elsewhere in this chapter.

Transcription factor mutations alter insulin secretion in the mature β cell as well as altering β-cell development, proliferation, and cell death. Mutations in the hepatic nuclear factors appear to alter levels of proteins critical in metabolism including the GLUT-2 glucose transporter and key enzymes in the mitochondrial metabolism of glucose [41–43]. Reduced β-cell proliferation and preserved or increased apoptosis could explain the progressive deterioration in β-cell function seen in these individuals [43–46].

Mutations in *HNF1A* account for up to 70% of cases of MODY with nearly 200 different mutations reported. *HNF4A*, the next most common, accounts for approximately 3% of cases [47].

Clinical features

Heterozygous transcription factor mutations cause autosomal dominant diabetes presenting in adolescence or early adulthood resulting from progressive failure of insulin secretion. While diabetes is similar in *HNF1A* and *HNF4A* mutation carriers as a result of a common pattern of β-cell dysfunction, a number of differences in extrapancreatic features occur (Table 18.3).

Table 18.3 Extrapancreatic features assisting in the differential diagnosis of transcription factor maturity-onset diabetes of the young (MODY). HDL, high density lipoprotein cholesterol; LDL, low density lipoprotein cholesterol.

Transcription factor	Extrapancreatic clinical features
HNF1A	Low renal glucose threshold (glycosuria) Raised HDL Raised cardiovascular risk (in excess of type 2 diabetes)
HNF4A	Increased birth weight/macrosomia Neonatal hypoglycemia Low HDL, low lipoprotein A1 and A2, raised LDL
HNF1B	Renal cysts and renal development disorders and multiple others. See Table 18.5
NeuroD1	None described

Diabetes

People with transcription factor MODY are usually born with normal glucose tolerance and then show progressive β-cell dysfunction until they develop diabetes, usually aged 10–30 years (Figure 18.5). Sixty-three percent of *HNF1A* carriers are diagnosed with diabetes by the age of 25 years and 79% by the age of 35 years; the age of diagnosis is partly related to the location of the underlying mutation within the gene [48–50]. Those show deteriorating glycemia with age require pharmacologic treatment. In the oral glucose tolerance test, in contrast to people with glucokinase mutations, the fasting glucose is often normal initially but there is marked elevation of glycemia at 2 hours and consequently a large 2-hour increment (>5.0 mmol/L) [28]. This occurs because insulin secretion rates in early *HNF1A* MODY remain appropriate, with blood glucose values <8.0 mmol/L but are reduced significantly in comparison to non-diabetic non-mutation carriers above this level [51]. Microvascular complications are frequent particularly when hyperglycemia is inadequately treated [52]. People with transcription factor MODY tend to be lean and insulin-sensitive. Obesity occurs at similar levels to the normal population.

Extrapancreatic clinical features

These are summarized in Table 18.3 and discussed in more detail below.

HNF1A

People with *HNF1A* mutations have elevated levels of high density lipoprotein cholesterol (HDL) which contrasts with the reduced HDL levels seen in T2DM [53]. Despite this they appear to have a greater risk of coronary heart disease than people with T1DM. Frequency of microvascular complications is similar to that seen in T1DM and T2DM and relates to degree of glycemic control [52]. *HNF1A* mutations are associated with a reduced renal threshold for glucose. Mutation carriers without diabetes may develop glycosuria after a glucose challenge even if glycemia remains within normal limits[54].

HNF4A

HNF4A mutations are associated with an 800 g increase in birth weight compared with non-mutation carrying siblings [55]. This means the offspring of *HNF4A* mutation carrying fathers, as well as the offspring of *HNF4A* mothers, are at risk of macrosomia. There is also an increased risk of hypoglycemia in affected neonates. These features appear to relate to increased insulin secretion *in utero* and in early infancy which evolves into reduced insulin secretion and diabetes in later life [55]. *HNF4A* mutation carriers have reduced levels of HDL (and lipoprotein A1 and A2) and frequently have raised LDL, while triglyceride levels are similar to population norms [56].

Differentiating from type 1 diabetes

These individuals are usually diagnosed as having T1DM as they have symptomatic diabetes occurring in adolescence or young

adulthood. We recommend genetic testing for *HNF1A* mutations in any young adult with apparent T1DM, a parent with diabetes, and who is antibody-negative at diagnosis. Evidence of non-insulin dependence increases the likelihood of a positive result; this would include no ketosis in the absence of insulin treatment, good glycemic control on low doses of insulin, or detectable C-peptide with plasma glucose >8 mmol/L 3–5 years after diagnosis (outside the honeymoon period) [57]. While GAD antibodies are usually negative, positive GAD antibodies may be expected in up to 1–2% of people without diabetes, and therefore positive antibodies (particularly at low titer) may not exclude monogenic diabetes; testing should be considered where clinical suspicion is high [58, 59]. *HNF4A* testing should be performed in anyone with a high suspicion of having *HNF1A* who tests negative for *HNF1A* mutations, particularly where there is evidence of increased birth weight and/or neonatal hypoglycemia.

Differentiating from type 2 diabetes

HNF1A should be suspected and mutation screening performed in people otherwise suspected to have T2DM where the following features are present ([57] and www.diabetesgenes.org):

1 Young-onset diabetes: typically before 25 years old in at least one family member;

2 Family history of diabetes: at least two generations and ideally two individuals diagnosed in their twenties or thirties, particularly where affected individuals are non-obese;

3 Absence of obesity, acanthosis nigricans or other evidence of insulin resistance.

In addition, a large increment in the glucose tolerance test (>5 mmol/L), presence of glycosuria with blood glucose <10 mmol/L, marked sensitivity to sulfonylureas (hypoglycemia on low doses), and a lipid profile showing normal or raised HDL and normal or low triglycerides (atypical for T2DM) would all be supportive of a diagnosis of *HNF1A* instead of T2DM [53]. *HNF4A* should be suspected and tested in those who are suspected to have *HNF1A* mutations but test negative on *HNF1A* screening. These individuals have a normal renal glucose threshold and frequently have a personal and/or family history of high birth weights and/or neonatal hypoglycemia.

Management

People with both *HNF1A* and *HNF4A* mutations are sensitive to sulfonylurea therapy which we recommend as first-line treatment [56, 60]. Glycemic control with sulfonylureas is often better than with insulin and the fasting glucose lowering effect is four times greater than that seen in T2DM [60, 61]. Transfer to sulfonylurea treatment is successful in the majority of people although insulin therapy may be required as diabetes progresses [62]. Even very low sulfonylurea doses may cause hypoglycemia. The starting dose should therefore be low; we use a starting dose of 40 mg/day gliclazide or 2.5 mg/day glibenclamide in adults. If there is hypoglycemia with low doses of standard agents, a short-acting agent such as nateglinide may be appropriate [63]. GLP-1 receptor agonists have also been shown to be effective at reducing glycemia [64]. Because of the apparent increased risk of cardiovascular disease in *HNF1A*, statin therapy should be considered for those aged over 40 years.

Management in pregnancy

Evidence to support management strategies for *HNF1A* and *HNF4A* in pregnancy is very limited. Our current practice is to continue sulfonylureas if glycemic control is good before pregnancy on this treatment but otherwise institute treatment with insulin. Consideration should be given to switching other sulfonylureas to glibenclamide in the pre-conception period as this sulfonylurea has the most evidence for safety in pregnancy [65, 66]. However, sulfonylureas have been shown to cross the placenta and increase fetal birth weight independent of maternal glycemia [67]. The risks of placental transfer of sulfonylureas therefore needs to be balanced against a potentially improved control with sulfonylurea use in early pregnancy.

If a fetus carries *HNF4A*, the risk of macrosomia and neonatal hypoglycemia is extremely high whether the mutation comes from the mother or father [55] as it will add >800 g to the birth weight, which may result in considerable obstetric complications.

In women with *HNF4A* there is an additional contribution to fetal birth weight from maternal glycemia and it is very important to avoid adding to this further by glibenclamide use. We therefore recommend switching to insulin towards the end of the second trimester. If either parent is known to carry a *HNF4A* mutation, we recommend:

1 Very tight maternal glucose control to attempt to minimize macrosomia;

2 Serial antenatal ultrasound scans to look for macrosomia with early delivery if this is marked; and

3 Early measurement of neonatal glucose and consideration of diazoxide treatment if hypoglycemia persists.

Other transcription factor MODY

Other transcription factor mutations causing autosomal dominant β-cell diabetes have been identified in the genes *IPF1* and *NEUROD1*, but are very rare; *KLF11* and *PAX4* have been proposed but this work has not been replicated [68–73].

Neonatal diabetes and diabetes diagnosed within 6 months of life

Children diagnosed with diabetes within the first 6 months of life (referred to as neonatal diabetes) are likely to have monogenic diabetes and not T1DM [74–77]. These children commonly present with ketoacidosis and absent C-peptide. Neonatal diabetes is rare, affecting 1 in 100,000–200,000 live births [78]. Approximately half of cases remit spontaneously and are therefore termed

Table 18.4 Causes of neonatal diabetes. Source: De Franco et al. [19].

Pancreatic pathophysiology	Protein, chromosome or gene affected	Prevalence	Inheritance	Features in addition to neonatal diabetes and low birth weight
Reduced β-cell function	K_{ATP} channel (*KCNJ11* and *ABCC8*)	43% of permanent neonatal diabetes, 25% of transient neonatal diabetes	85% spontaneous. Remainder autosomal dominant or recessive	Developmental delay and epilepsy. Sulfonylurea responsive
	Chromosome 6q24	12.8% (70% of transient neonatal diabetes)	Variable	Macroglossia and umbilical hernia
	Glucokinase (homozygous for mutation)	1% (9.6% in consanguineous unions)	Autosomal recessive	Both parents have heterozygous glucokinase associated hyperglycemia
	SLC2A2	<1%	Autosomal dominant	Hypergalactosemia, hepatic failure
	GLIS3	<1%	Autosomal recessive	Congenital hypothyroidism, glaucoma, liver fibrosis, and cystic kidney disease
Reduced pancreatic mass	*PTF1A*	<1% (8.3% in consanguineous unions)	Autosomal recessive	Pancreatic and cerebellar agenesis
	PDX1	<1%	Autosomal recessive	Pancreatic agenesis
	HNF1B	<1%	Autosomal dominant	Exocrine pancreas insufficiency and renal cysts
	GATA6	3.7%	Autosomal dominant	Pancreatic agenesis
Increased β-cell destruction	*EIF2AK3*	2.5% (24.3% in consanguineous unions)	Autosomal recessive	Spondyloepiphyseal dysplasia, renal failure, recurrent hepatitis, and mental retardation
	FOXP3	1.4%	X-linked	Immune dysregulation, intractable diarrhea, eczematous skin rash, and elevated IgE
	STAT3	<1%	Autosomal dominant	Short stature, autoimmune-driven thyroid disease, enteropathy, and eczema
	INS	11% of permanent neonatal diabetes	Autosomal dominant	None

transient neonatal diabetes mellitus (TNDM) as opposed to permanent neonatal diabetes mellitus (PNDM) where diabetes persists. TNDM often recurs in later life [79]. Neonatal diabetes results from mutations of key genes involved in β-cell development or function [19]. Table 18.4 summarizes the known genetic causes of neonatal diabetes.

Permanent neonatal diabetes

Approximately half of PNDM is caused by mutations in the genes *KCNJ11* and *ABCC8* which encode the Kir6.2 and SUR1 subunits, respectively, of the β-cell ATP-sensitive potassium channel (K_{ATP} channel) [80–83]. This channel is constitutively open and regulates insulin secretion by closing in response to the raised intracellular ATP levels that occur as a consequence of hyperglycemia. Channel closure triggers depolarization of the β-cell membrane which leads to insulin secretion. Activating mutations in *KCNJ11* and *ABCC8* prevent closure of the potassium channel in response to increased ATP so the β cell remains hyperpolarized and unable to secrete insulin [84]. Sulfonylureas close the β-cell K_{ATP} channel by an ATP independent route and they have been used successfully in the management of children with neonatal diabetes resulting from *KCNJ11* and *ABCC8* mutations [85]. The K_{ATP} channel is also present in the brain, nerves, and muscles. Reflecting this distribution of channels, 20% of children with *KCNJ11* mutations (and occasionally those with *ABCC8* mutations) have associated neurologic features [77, 80, 81, 84].

Heterozygous mutations in the insulin gene (*INS*) have been identified in 12% of cases of isolated PNDM and insulin treatment is required [86, 87]. A number of other genetic causes have been found which all appear to be relatively rare [78] as outlined in Table 18.4. Parental consanguinity is more likely to result in autosomal recessive inheritance. In children born to consanguineous parents, the commonest cause of PNDM is a homozygous mutation in *EIF2AK3* gene, causing Wolcott–Rallison syndrome [18]. In offspring of unrelated parents the majority (85%) of PNDM resulting from K_{ATP} channel mutations arise spontaneously from *de novo* heterozygous mutations, with the remainder being familial and inherited mainly in an autosomal dominant pattern. About 40% of neonatal diabetes resulting from *ABCC8* mutations, however, are inherited in an autosomal recessive fashion [83].

Clinical features

Diabetes caused by *KCNJ11* mutations typically presents in the first 26 weeks of life (median 4–6 weeks) with marked hyperglycemia often accompanied by ketosis. C-peptide is usually undetectable and pancreatic auto-antibodies negative [80]. As with all neonatal diabetes subtypes, infants are often small for gestational age as a result of reduced fetal insulin secretion with consequent decreased insulin-mediated growth. About 20% of children with PNDM and *KCNJ11* mutations have neurologic features, the commonest being developmental delay, sometimes with muscle weakness and/or epilepsy. The most severe form where neonatal diabetes is accompanied by developmental delay and epilepsy has been named developmental delay, epilepsy and neonatal diabetes (DEND). "Intermediate DEND" refers to neonatal diabetes with less severe developmental delay and no epilepsy. The severity of the clinical condition relates closely to the underlying mutation and its effect on K_{ATP} channel ATP sensitivity [84, 88]. Children without apparent neurological manifestation have been found to have developmental coordination disorders and attention deficits when subjected to in-depth neuropsychiatric testing [89].

Neonatal diabetes caused by *ABCC8* mutation has a similar phenotype but leads to transient neonatal diabetes more commonly than PNDM and rarely has associated neurologic features [81–83]. Children with neonatal diabetes and *INS* mutations present at a median age of 9 weeks and are also often small for gestational age but do not have extrapancreatic features [86].

Management

Although insulin therapy is commonly used in the initial period after diagnosis, the majority of those with *KCNJ11* and *ABCC8* mutations can successfully transfer from insulin to sulfonylurea therapy, usually with significant improvements in glycemic control [82, 85]. Ninety percent of those with *KCNJ11* mutations are able to discontinue insulin, while HbA_{1c} appears to improve in all with a mean drop from 65 to 46 mmol/mol (8.1 to 6.4%) after 12 weeks [85]. Glibenclamide was initially selected as it is nonselective and widely available; it has been used in the majority of cases and may be more effective than other sulfonylurea agents [90]. The doses needed are often higher than those needed for the treatment of T2DM: a median dose of 0.45 mg/kg/day is required with doses up to 1.5 mg/kg/day in some cases [85, 91]. Diarrhea is a possible side effect but this usually only lasts 1–3 days [92]. Sulfonylurea therapy may result in some improvement in neurologic features even where they are commenced in adulthood [90, 93, 94]. Further information on transferring patients from insulin to sulfonylureas can be found at www.diabetesgenes.org. Earlier age at initiation of sulfonylurea therapy appears to correlate with better dose response [95]. Furthermore initiation of sulfonylurea therapy in those with *KNCJ11* or *ABCC8* mutations appears to reverse neuropsychomotor impairments, particularly when started early [96].

Neonatal diabetes resulting from *INS* mutations requires insulin treatment [86]. Affected individuals with a heterozygous *KCNJ11* mutation contemplating parenthood should be counseled that they have a 50% chance of passing on the mutation to their offspring. Where unaffected parents whose child is affected by a heterozygous mutation are planning further pregnancies, the risk of further affected children is low because the possibility of a germline mutation is approximately 5–10% [97]. Where parents have a child with neonatal diabetes caused by a recessive *ABCC8* mutation, there is a 25% chance of each further offspring being affected but the risk is low for subsequent generations.

Transient neonatal diabetes

The genetic etiology of more than 90% of transient neonatal diabetes has been established. The majority (70%) of cases result from abnormalities in the q24 region of chromosome 6 (6q24) affecting imprinted genes [78, 98]. Genetic imprinting occurs when only the maternal or paternally inherited allele of a gene is expressed and this is usually controlled by methylation. In TNDM paternal uniparental disomy, paternal duplication of 6q24 or abnormal methylation of the maternal copy of the chromosome causes overexpression of the paternal copies of the genes *PLAGL1* (also known as *ZAC*) and *HYMAI* [98, 99]. Paternal duplication of 6q24 can be inherited, therefore this abnormality causes the majority of inherited TNDM cases. Uniparental disomy causes sporadic TNDM; cases resulting from abnormal methylation of the maternal copy of chromosome 6 may be sporadic or inherited [98, 99]. The majority (90%) of TNDM not associated with 6q24 abnormalities are caused by mutations in *KCNJ11* and *ABCC8* [77, 79, 82, 100–104].

Clinical features

6q24 diabetes usually presents in the first week of life often with severe hyperglycemia and dehydration but usually without ketosis [98]. Pancreatic auto-antibodies are usually negative and C-peptide is low or negligible. Low birth weight is common (mean birth weight 2.1 kg), and there may be associated macroglossia and/or umbilical hernia. Insulin treatment is required for a median of 12 weeks before the child goes into remission. Diabetes recurs later in life in 50–60% as a result of β-cell dysfunction. The average age of recurrence is 14 years. In some cases hyperglycemia may be intermittent and seen only at times of stress [98, 105]. Where TNDM is caused by *KCNJ11* and *ABCC8* mutations, diabetes tends to present later (median 4 weeks), takes longer to remit and is associated with less intrauterine growth restriction (median birth weight 2.6 kg) [79].

Management

Insulin is required in the neonatal period whereas treatment requirements following relapse vary from diet to oral antidiabetes agents or insulin [105]. In TNDM cases resulting from *KCNJ11* and *ABCC8* mutations, diabetes may be successfully managed with sulfonylureas [79, 82].

Genetic counselling depends on the underlying genetic etiology. Cases caused by uniparental disomy are sporadic and therefore have low risk of occurrence in either siblings or offspring of the affected child. Methylation defects often result from homozygous mutations in the transcription factor gene *ZFP57* and

therefore may be inherited in an autosomal recessive manner [99]. Offspring of men with 6q24 duplication have a 50% chance of developing TNDM whereas if the abnormality is inherited from the mother they will not be affected but the TNDM may occur in the following generation [105].

Genetic testing in neonatal diabetes

At the time of diagnosis of neonatal diabetes it is unknown whether the diabetes will be transient or permanent. We recommend testing for 6q24 abnormalities, *KCNJ11*, *ABCC8*, and *INS* mutations at diagnosis in all diabetes diagnosed before 6 months. Identifying mutations in these genes is important as it will influence treatment. An early diagnosis and very low birth weight make 6q24 most likely. A genetic cause (*KCNJ11* or *INS*) can be established in ~7% of diabetes diagnosed between 6 months and 1 year of age and so consideration should be given to testing this age group, especially where autoantibody tests are negative [76].

Diabetes with extrapancreatic features

A number of monogenic causes of diabetes are associated with distinct features occurring outside the pancreas. In many cases extrapancreatic disease may be the presenting feature, for example in cystic fibrosis and hemochromatosis (see Chapter 21). Clinical subtypes and management of monogenic β-cell diabetes that have extrapancreatic features are summarized in Figure 18.7.

Maternally inherited diabetes and deafness

Maternally inherited diabetes and deafness (MIDD) results from a mutation in mitochondrial DNA and causes maternally inherited diabetes with sensorineural deafness that may be accompanied by a wide range of other features. It affects up to 1% of those with diabetes but is frequently misdiagnosed [106].

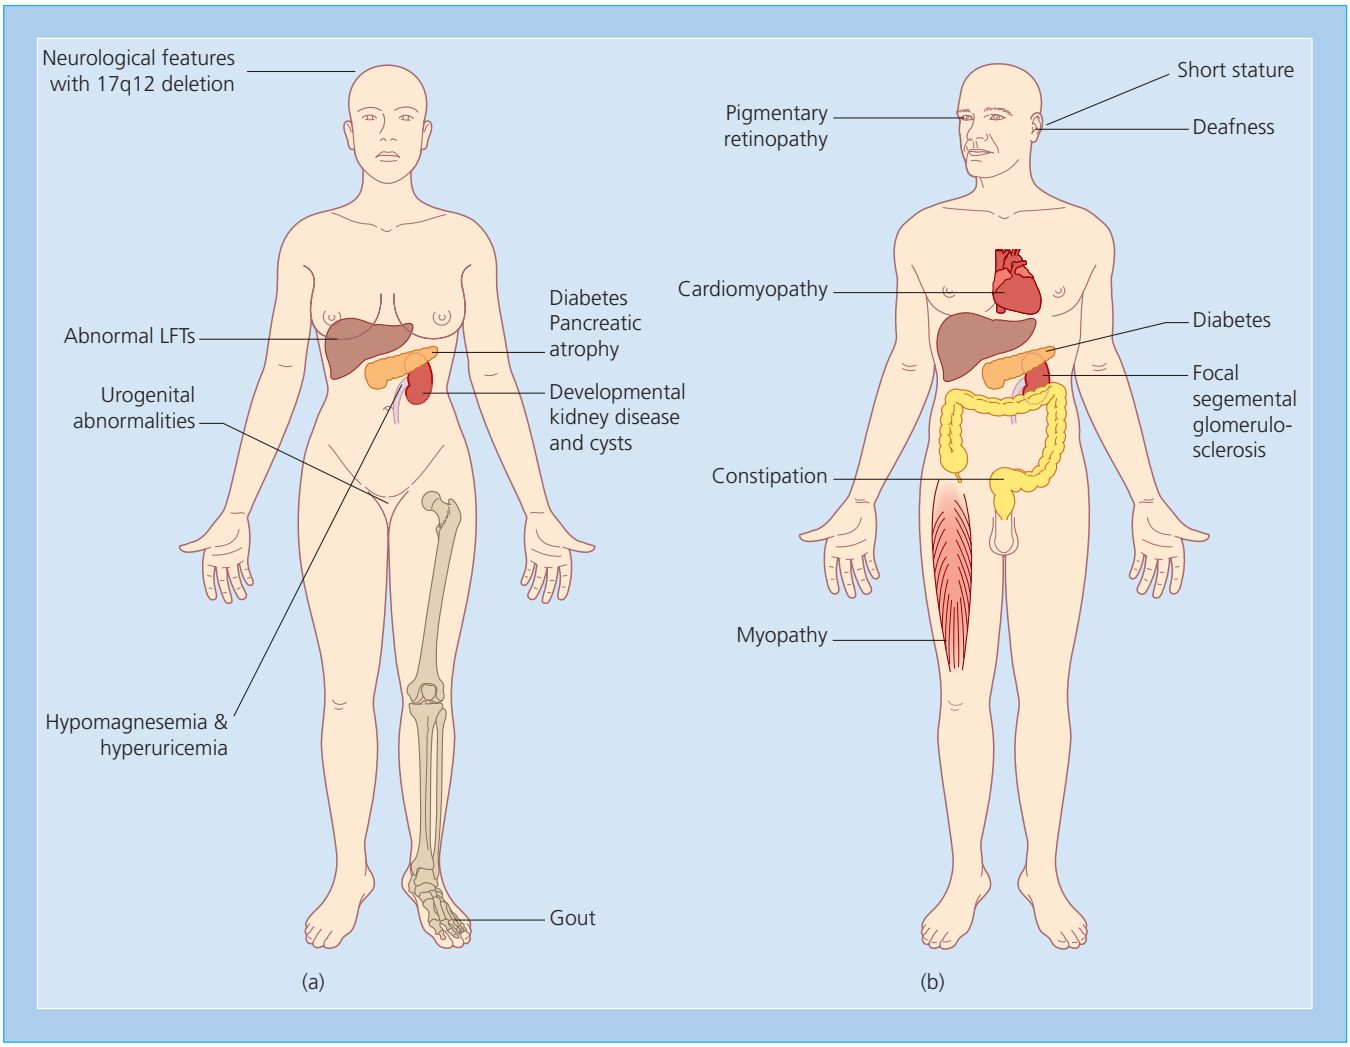

Figure 18.7 Phenotypes of: (a) renal cysts and diabetes syndrome due to *HNF1B* mutation or deletion; (b) maternally inherited diabetes and deafness caused by mitochondrial m.3243A>G mutation. LFTs: liver function tests. Source: Adapted from Murphy et al. [106] and Clissold et al. [129].

Pathogenesis and inheritance

The vast majority of mitochondrial diabetes results from the m.3243A>G point mutation in mitochondrial DNA and other mitochondrial DNA mutations are rare [107].

The m.3243A>G mutation affects the mitochondrial respiratory chain and therefore results in cellular energy deficiency. Organs with high metabolic activity including the endocrine pancreas and cochlea are most affected. Mitochondrial dysfunction in pancreatic islets results in abnormal β-cell function, loss of β-cell mass, and insulin deficiency [106]. As mitochondria are inherited from the mother, only the maternal line in a family is affected, and children of a male patient are not at risk. All children of an affected woman are likely to carry the mutation; however, phenotype varies widely within a family due to heteroplasmy. Offspring inherit a mix of mutant and wild-type mitochondrial DNA and the proportion of mitochondria carrying the mutation will vary as will segregation of mutant and wild-type mitochondria to different tissues [108].

Clinical features

The characteristic clinical features of MIDD are summarized in Figure 18.7. The majority of mutation carriers develop diabetes (over 85%) and sensorineural hearing loss (over 75%) [108–112]. Diabetes is progressive but may present acutely, with ketoacidosis occurring in ~8% of cases [108, 109, 113]. Mean age at diagnosis of diabetes is 37 years but age of diagnosis can range from early adolescence to old age [109, 113, 114].

Hearing loss typically develops in early adulthood [109, 111]. Those with the m.3243A>G mutation have a high prevalence of renal failure with focal segmental glomerular sclerosis found frequently on biopsy [109, 115]. Macular retinal dystrophy is a frequent finding but rarely causes visual symptoms [106, 109, 115]. Cardiac abnormalities include left ventricular hypertrophy, heart failure, and cardiac arrhythmias [116–120]. Other clinical manifestations of the m.3243A>G mutation include short stature, MELAS (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes), psychiatric disorders, proximal myopathy, and gastrointestinal symptoms [106].

Differentiating from type 1 and 2 diabetes

Diabetes caused by the m.3243A>G mutation is difficult to differentiate from T1DM or T2DM. GAD antibodies are usually but not always negative [121–123]. The presence of deafness in the patient or clustering of diabetes and/or deafness in maternal relatives should prompt investigation for the m.3243A>G mutation.

The diagnosis can be confirmed by testing for the m.3243A>G mutation in blood leukocytes or urine. In rare cases the result may be negative on blood-derived DNA because of heteroplasmy loads in leukocytes. Urine or mouthwash samples may therefore be preferable [106].

Management

Diabetes usually requires early insulin treatment [108, 109, 113, 123]. There is a theoretical basis for avoiding metformin in view of the risk of lactic acidosis [106, 108]. Whether there is benefit from use of co-enzyme Q10 supplementation is currently unclear [106, 124, 125]. Monitoring for cardiac manifestations should be considered from a young age. Aggressive blood pressure management and early angiotensin-converting enzyme (ACE) inhibitor treatment may be appropriate in view of the high risk of renal complications. Management of hearing loss involves avoidance of exacerbating factors, prompt treatment of ear infections, hearing aids if necessary, and consideration of cochlear implants where there is profound hearing loss [106, 126, 127].

Maternal relatives of affected individuals and children of female patients should be assumed to carry the m.3243A>G mutation. Therefore, periodic screening for the features and complications of MIDD may be advisable.

Renal cysts and diabetes (*HNF1B* MODY)

HNF1B is a transcription factor with a role in regulating gene expression in a number of tissues including the pancreas, kidneys, liver, genital tract, and gut [128]. Heterozygous deletions or mutations in *HNF1B* can cause developmental abnormalities in all these organs although the commonest phenotypes are renal abnormalities and diabetes. *HNF1B* abnormalities may show autosomal dominant inheritance, although up to 50% of cases arise spontaneously and there is a wide variation in phenotype even with identical mutations [129–134].

Clinical features

The clinical features are summarized in Table 18.5 and Figure 18.7. Developmental renal disease is the most consistent feature with renal cysts being the commonest manifestation [129]. Other possible renal abnormalities include glomerulocystic kidney disease, cystic renal dysplasia, and morphologic abnormalities such as horseshoe kidney. Renal function can range from normal to dialysis-dependent [135, 136]. Half of *HNF1B* mutations carriers have early-onset diabetes caused by both insulin deficiency as a result of reduced β-cell number and increased hepatic insulin resistance. The sensitivity to sulfonylureas found with *HNF1A* and *HNF4A* mutations is absent [137]. Diabetes is usually associated with pancreatic hypoplasia and may be associated with exocrine dysfunction although this is rarely symptomatic [138–140]. Low birth weight is common and transient neonatal diabetes may occur [139]. Other clinical manifestations include non-progressive abnormal liver function tests, genital tract malformations, hypomagnesemia, hyperuricemia, and familial hyperuricemic nephropathy [138, 141]. Learning difficulties and autism are common features particularly in those with a whole gene deletion (17q12). An association with chromophobe renal cell carcinoma has been reported reflecting a probable role for *HNF1B* as a tumor suppressor gene [142, 143].

Differentiating from type 1 and 2 diabetes

Approximately 50% of *HNF1B* mutations and deletions are spontaneous and so there may be no family history. Testing for *HNF1B* abnormalities should be considered where there is unexplained

Renal phenotype		
	Renal cysts	Common
	Renal impairment	Common (15% require dialysis/transplantation)
	Morphologic renal abnormalities	Horseshoe or single kidney
	Renal histology	Glomerulocystic kidney disease, cystic renal dysplasia, oligomeganephronia
	Hypomagnesemia	44%, proximal tubular defect
	Hyperuricemia and gout	20% (clinical gout)
Diabetes		58%. Mean age of diagnosis 26 years, range 10–61 years Insulin treatment common
Other features		
	Liver enzyme derangement	Mild, non-progressive
	Subclinical exocrine pancreatic failure	Reduced fecal elastase
	Genital tract malformations	17%
	Short stature	20% <2 SD below mean height
	Learning difficulties	Neuropsychiatric manifestations particularly associated with 17q12 chromosomal deletion (whole gene deletion)
Uncommon		Joint laxity, hearing loss, prognathism, pyloric stenosis, chromophobe renal cell carcinoma

cystic renal disease, glomerulocystic disease, or other renal developmental abnormalities with or without a past medical or family history of diabetes. It should also be considered in individuals with genital tract abnormalities associated with renal abnormalities. Both simple renal cysts and diabetes are common in the general population and should not lead to testing for *HNF1B* abnormalities. Testing for *HNF1B* should always include dosage analysis to detect gene deletions as these are common and will be missed if the laboratory performs sequencing only [144].

Management

Early insulin therapy is usually required for management of diabetes. The sulfonylurea sensitivity seen in other transcription factor diabetes is not seen in *HNF1B*. Renal management is similar to management of other chronic progressive renal diseases. Our recommendation is to repeat renal ultrasound imaging every 2 years in view of the possible increased risk of chromophobe renal carcinoma and to screen for diabetes yearly in mutation carriers without diabetes.

Other monogenic β-cell diabetes with extrapancreatic features

Wolfram syndrome

Wolfram syndrome (also known as DIDMOAD [diabetes insipidus, diabetes mellitus, optic atrophy, and deafness]) is a rare recessive neurodegenerative disorder characterized by diabetes insipidus, diabetes mellitus, optic atrophy deafness, and a variety of central nervous system abnormalities. Consideration should be given to this diagnosis where there is a combination of diabetes and optic atrophy [145, 146].

Thiamine responsive megaloblastic anemia

Thiamine responsive megaloblastic anemia is a rare autosomal recessive condition characterized by megaloblastic anemia (which may be mild), non-autoimmune diabetes mellitus and sensorineural hearing loss. Treatment with high-dose thiamine can improve some features including diabetes [147].

Wolcott–Rallison syndrome

Wolcott–Rallison syndrome is a rare autosomal recessive condition characterized by early-onset diabetes, spondyloepiphyseal dysplasia, acute hepatic failure, renal impairment, and developmental delay. Diabetes usually presents in infancy and requires insulin treatment [148].

Monogenic diabetes with pancreatic exocrine dysfunction

Mutations in the carboxyl ester lipase (*CEL*) gene have recently been identified as a rare cause of monogenic diabetes with pancreatic exocrine dysfunction [149].

Insulin resistance

Monogenic causes of diabetes resulting from insulin resistance include the inherited lipodystrophies, mutations affecting the insulin receptor or post-receptor signaling and other monogenic syndromes associated with insulin resistance where abnormalities

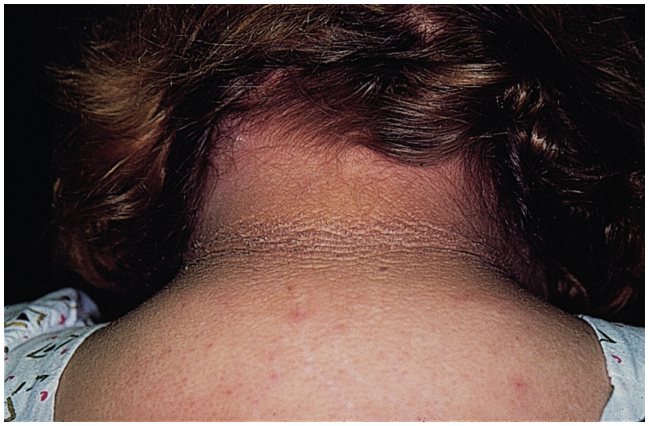

Figure 18.8 Acanthosis nigricans affecting the neck of a 26-year-old woman with severe insulin resistance. Source: Reproduced from Moller and O'Rahilly [207] with permission.

of insulin action are not the primary disorder. There can be considerable clinical overlap in clinical presentation between these conditions [150]. The key features of severe insulin resistance are:

- the presence of acanthosis nigricans (Figure 18.8) particularly in a lean individual;
- ovarian cysts, subfertility, and hyperandrogenism in women; and
- hyperinsulinemia as evidenced by raised endogenous insulin levels, or in those on insulin treatment, very high doses of exogenous insulin.

The presence of some or all of these features should prompt consideration of underlying monogenic causes of insulin resistance. The presence of other clinical features (see Figure 18.9) are related to the underlying cause. Monogenic forms of insulin resistance are comprehensively reviewed in [151, 152].

Insulin receptor gene mutations

Insulin exerts its effects through binding to a transmembrane receptor. Binding of insulin to the alfa subunit of the receptor activates beta subunit tyrosine kinase activity triggering protein activation cascades that lead to insulin's intracellular effects [153, 154]. Mutations in the insulin receptor gene lead to inherited insulin resistance syndromes. The severity of the resulting clinical phenotype depends on the extent of impairment of signal transduction resulting from the underlying mutation [155].

Clinical features

Individuals with severe insulin resistance resulting from insulin receptor mutations may have a number of common features including hyperinsulinemia, acanthosis nigricans, ovarian hyperandrogenism, and disturbances of glucose homeostasis which can include hypoglycemia (classically postprandial) as well as impaired glucose tolerance and diabetes [155]. Three main syndromes resulting from insulin receptor mutations leading to severe insulin resistance have been described: Type A insulin resistance syndrome, Rabson–Mendenhall syndrome, and Leprechaunism (Donohue syndrome). There may be considerable clinical overlap and these syndromes may simply represent varying clinical features from a continuum of severity of receptor dysfunction rather than completely distinct syndromes [155]. Many individuals with insulin receptor defects and severe insulin resistance (men in particular) may not fit into the syndromic descriptions.

Features of the Type A insulin resistance syndrome include severe insulin resistance, acanthosis nigricans, polycystic ovarian disease, hirsutism, and signs of virilization occurring in young females (often termed HAIR-AN syndrome). Those with an underlying insulin receptor mutation are usually slim [156, 157]. The most severe syndrome seen with insulin receptor mutations is

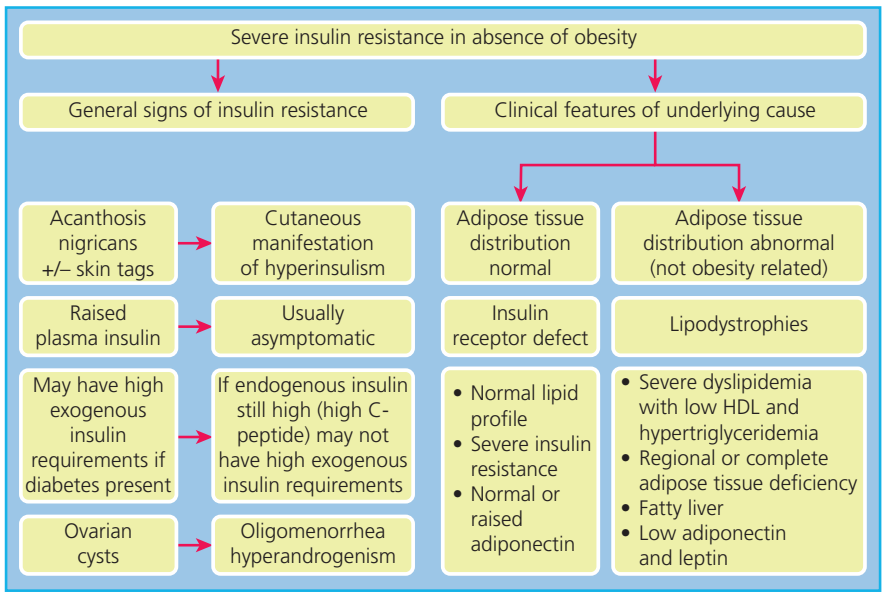

Figure 18.9 Features of monogenic severe insulin resistance.

Leprechaunism (Donohue syndrome), a rare autosomal recessive disorder characterized by low birth weight, growth restriction, disordered glucose homeostasis, characteristic dysmorphic features, and individuals usually do not survive infancy [157, 158].

Rabson–Mendenhall syndrome is an autosomal recessive disorder that is between Leprechaunism and Type A insulin resistance in terms of the severity of insulin resistance. Presentation occurs in childhood with acanthosis nigricans, extreme growth retardation, dysplastic dentition, coarse facial features, lack of subcutaneous fat, and pineal hyperplasia [157, 159, 160]. Reported renal abnormalities include medullary sponge kidney and nephrocalcinosis [159, 160]. There may be paradoxical fasting hypoglycemia at diagnosis but frank diabetes (occasionally with ketoacidosis) develops in later years [161]. Life expectancy is markedly reduced, early death often occurring from complications of diabetes or intractable ketoacidosis.

Differentiating from type 1 and 2 diabetes

The presence of features of insulin resistance in a thin but not an obese individual is suggestive of an underlying insulin receptor gene mutation. Serum adiponectin levels are typically high with insulin receptor mutations whereas they are low in other forms of insulin resistance. It has been suggested that adiponectin levels could be used as a screening test with sequencing of the insulin receptor gene reserved for those cases where adiponectin levels are raised [150, 162, 163].

Unlike T2DM and the lipodystrophies, triglyceride levels with insulin receptor mutations are typically normal [157].

Management

While insulin sensitizers such as metformin and the thiazolidinediones may have a role in management their effect is often limited and insulin therapy is required as β-cell function declines [157]. Glycemic control is often poor despite very high doses of insulin (doses in excess of 500 units/kg/day have been reported). U500 insulin has a role in reducing the insulin volumes required [157, 164]. Insulin-like growth factor I (IGF-I) is capable of stimulating glucose uptake and glycogen storage *in vivo* and has therefore been used in treatment of diabetes caused by insulin receptor mutations. Side effects were frequent in early studies but tolerability may be increased by combining IGF-I with its principal binding protein IGFBP-3 [165].

Inherited lipodystrophies

Lipodystrophies are rare clinically heterogeneous disorders that are characterized by the selective loss of adipose tissue. They are associated with insulin resistance and other features such as diabetes mellitus, acanthosis, dyslipidemia, hepatic steatosis, and (in women) hyperandrogenism, oligomenorrhea, and polycystic ovaries [166]. Lipodystrophies may be inherited or acquired.

Familial partial lipodystrophy

Familial partial lipodystrophies are autosomal dominant disorders associated with the loss of peripheral subcutaneous fat. The two main subtypes result from mutations in *LMNA* and *PPARG*.

Familial partial lipodystrophy associated with *LMNA* mutations (also known as Dunnigan lipodystrophy) results in gradual peripheral subcutaneous fat loss from puberty. This, and the associated muscle hypertrophy, gives a muscular appearance of the arms and legs (Figure 18.10). There may be fat loss from the anterior abdomen and chest and excess fat deposition in the face, neck, and intra-abdominally [167, 168]. Diabetes is common,

Figure 18.10 Familial partial lipodystrophy in a 46-year-old woman. There is truncal and limb lipodystrophy, preserved facial and neck adipose tissue, muscle hypertrophy and acanthosis apparent in the groin regions.

particularly in women [169]. Hypertriglyceridemia may be marked and associated with pancreatitis. Acanthosis and polycystic ovarian syndrome are relatively uncommon. Although hepatic steatosis may develop cirrhosis appears rare [170, 171]. Cardiovascular mortality is high.

Familial partial lipodystrophy associated with *PPARG* mutations appears to be phenotypically similar to that caused by *LMNA* mutations although hypertension is commoner [172–181].

Diagnosis may be obvious in women but more difficult in men where a muscular appearance of limbs is more usual. Early-onset diabetes in a non-obese individual with hypertriglyceridemia should raise suspicion of lipodystrophy particularly if there is marked peripheral fat loss [182].

Congenital generalized lipodystrophy (Berardinelli–Seip syndrome)

This is a rare (estimated prevalence 1 in 10 million) autosomal recessive disorder characterized by a near complete absence of subcutaneous fat from birth, giving a muscular appearance [166]. Because of the absence of functioning adipocytes, lipids are stored in metabolically active tissues. Those affected have features of severe insulin resistance including often widespread acanthosis, hypertriglyceridemia, and low HDL cholesterol [183]. Hepatic steatosis occurs early and may lead to cirrhosis; hepatomegaly is seen frequently [184–186]. Childhood growth is accelerated and bone age advanced. Diabetes commonly develops during adolescence. Other associated features include acromegaloid features, hypertrophic cardiomyopathy, skeletal muscle hypertrophy, bone cysts, and intellectual impairment [186]. Serum leptin and adiponectin levels are markedly reduced [187].

Three molecularly distinct forms have been identified: congenital generalized lipodystrophy types 1, 2 and 3 resulting from mutations in 1-acylglycerol 3-phosphate-O-acyltransferase 2 (*AGPAT2*), Berardinelli–Seip congenital lipodystrophy 2 (*BSCL2*), and Caveolin-1 (*CAV1*). *AGPAT2* and *BSCL2* account for the majority of cases and have some difference in phenotype. Some people with this phenotype do not have mutations in any of these genes and so it is likely there are further genetic etiologies to be discovered [166, 188, 189].

Other inherited forms of lipodystrophy

Rare subtypes of lipodystrophy associated with dysmorphic features include mandibuloacral dysplasia (lipodystrophy with characteristic skeletal abnormalities), SHORT syndrome (short stature, hyperextensibility of joints, ocular depression, Reiger anomaly, teething delay) and neonatal progeroid syndrome [156].

Management of lipodystrophy

Management should address insulin resistance and the main causes of morbidity and mortality in lipodystrophy which include diabetes and its complications, cardiovascular and cerebrovascular disease, recurrent pancreatitis (as a result of severe hypertriglyceridemia), cirrhosis, and psychologic distress related to appearance [166].

Lifestyle changes are important and should include an extremely low-fat diet (<15% total energy from fat) and increased physical activity. Hypertriglyceridemia that does not respond to lifestyle changes and control of hyperglycemia may require treatment with fibrates and high doses of fish oils. Estrogen replacement including contraceptive pills may exacerbate hypertriglyceridemia and is best avoided.

Glycemic control requires a combination of oral treatments and high-dose insulin in the majority. Metformin is commonly used to improve insulin sensitivity although there are no available trial data in inherited lipodystrophies [182]. Response to thiazolidinediones appears to vary with significant improvements in glycemic control and insulin resistance in some but not in all reported cases [181, 190–195]. Where insulin is required dose requirements may be very high and U500 insulin is appropriate. Where proteinuric renal disease develops the threshold for renal biopsy should be low as non-diabetic renal disease (e.g. membranoproliferative glomerulonephritis and focal segmental glomerulosclerosis) appears to be commoner than diabetic nephropathy [196].

Levels of the adipocytokine leptin are markedly reduced in severe lipodystrophies. Leptin replacement has been associated with marked improvements in glycemic control and hypertriglyceridemia in a number of cases of both generalized and partial inherited lipodystrophy [197–203] and may also improve hepatic steatosis [204, 205].

Other monogenic conditions associated with insulin resistance

Other monogenic conditions associated with insulin resistance either have marked obesity (e.g. Alström and Bardet–Biedl syndromes), neurologic disease including myotonic dystrophy and Friedreich ataxia or rapid aging (e.g. Werner syndrome) [206].

Conclusions

Monogenic diabetes results from single gene changes that affect β-cell function or insulin sensitivity. Correct diagnosis can help define prognosis and the best treatment and allow screening of family members. Diagnostic testing is now widely available and should be considered where presentation is atypical for T1DM or T2DM, where there is an autosomal dominant family history, where there are characteristic associated features and in all cases where diabetes has been diagnosed within the first 6 months of life.

[2] University of Connecticut School of Pharmacy, Storrs, CT, USA

Key points

- Many commonly prescribed medications can contribute to hyperglycemia or cause overt diabetes in predisposed individuals.
- The main mechanism by which glucocorticoids cause hyperglycemia is by reducing insulin sensitivity in the liver, skeletal muscle and adipose tissue in a dose-dependent fashion.
- Second-generation antipsychotic use requires scheduled monitoring of glucose, lipids, blood pressure, and body mass index.
- Although combined oral contraceptives are associated with metabolic abnormalities, their use is still recommended for women with type 1 or type 2 diabetes without vascular complications and in women with a history of gestational diabetes.
- Postmenopausal women can safely take menopause hormone therapy without adversely affecting glucose homeostasis or triggering diabetes.
- Menopause hormone therapy has minimal impact upon established type 1 or type 2 diabetes in postmenopausal women. Continued surveillance of glycemic control is prudent in these women and appropriate adjustments should be made to their antidiabetes drug regimens as needed.
- Clinicians need to be aware that the thiazide diuretics can affect glucose homeostasis in a dose-dependent manner but the effect appears to be modest. Maintaining normokalemia is the best defense against this potential metabolic consequence of thiazide use.
- Whether beta-blockers affect glucose homeostasis or contribute to the development of overt diabetes is inconclusive. Beta-blockers with vasodilating properties, such as carvedilol and nebivolol, are the preferred choices for persons with diabetes or those at significant risk for diabetes, unless contraindicated by comorbidities such as asthma.
- Statins appear to increase insulin resistance and decrease insulin secretion, with small increases in HbA_{1c} and fasting glucose.
- Hyperglycemia and diabetes have been reported with the protease inhibitors and some of the nucleoside reverse-transcriptase inhibitors (zidovudine, stavudine, and didanosine). The nucleoside reverse-transcriptase inhibitors can cause insulin resistance, promote lipodystrophy, and pancreatitis.
- Fluoroquinolone-associated dysglycemia appears to be much more common with gatifloxacin compared to levofloxacin. Hyperglycemia tends to occur within 1 to 2 weeks of therapy initiation. Any changes in glycemic control can be managed with careful adjustment of the antidiabetes regimen and continued blood glucose monitoring.
- The calcineurin inhibitors, cyclosporine and tacrolimus, are associated with post-transplant diabetes. Risk factors include older age, obesity, corticosteroid use, non-Caucasian race, hepatitis C, and genetic determinants.
- Diazoxide is a long-known cause of drug-induced hyperglycemia and even diabetic ketoacidosis. Its hyperglycemic effects have been purported to result from impaired insulin secretion, increased glucose production, and decreased peripheral glucose utilization. Evidence suggests that insulin secretagogues (including the incretin mimetics) may be the drugs of choice to manage this condition.
- Whenever possible exposure to drugs that could affect glucose regulation or glycemic control should be limited. If a precipitant drug cannot be avoided, careful monitoring for the occurrence of hyperglycemia is warranted. If a morbid event occurs, the dose should be reduced or the drug discontinued.

Introduction

It has been notably recognized that drugs can do great good but the potential also exists for drugs to do great harm. Drug therapy can worsen an underlying disease state resulting in therapeutic challenges for the clinician. Diabetes is one such example where various drugs can worsen glycemic control and even contribute to hypoglycemic episodes. Importantly, a number of commonly used medications can also predispose the individual to the development of hyperglycemia and even overt diabetes. Corticosteroids, second-generation antipsychotics, diazoxide, statins, oral contraceptives, and niacin are just a few examples of drugs that have been associated with hyperglycemia or drug-induced diabetes. Various mechanisms have been proposed for drug-induced hyperglycemia and include insulin resistance, decreased insulin secretion, decreased glucose uptake, pancreatitis, weight gain, and increased hepatic gluconeogenesis. Whatever

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

Table 19.1 Other medications that can induce hyperglycemia [1–5].

Antidepressants
Gonadotropin-releasing hormone agonists

Megesterol acetate
Niacin
Phenytoin
Rifampin
Ritodrine
Somatostatin analogs—most significant with pasireotide
Terbutaline
Thalidomide

the cause, the clinician should be ever vigilant to the potential for drug-induced dysglycemia taking into consideration patient and drug factors and be prepared to manage its consequences in the appropriate manner.

This chapter will describe selected drug classes and individual drugs that have been associated with hyperglycemia or overt diabetes. Attention will be given to predisposing factors along with the attendant pathophysiologic characteristics utilizing the relevant literature and emerging evidence. The focus will be on medications that are commonly prescribed and those with clear and significant potential for the development of diabetes. Other medications that can induce hyperglycemia are listed in Table 19.1 [1–5]. The chapter will conclude with a discussion of strategies to prevent and manage drug-induced dysglycemia.

Glucocorticoids

Of all the medications that can potentially induce hyperglycemia, glucocorticoids are the drug class that most consistently leads to this effect. Glucocorticoids have been reported to increase blood glucose when administered via numerous routes. They most commonly induce hyperglycemia when administered intravenously or orally, at supraphysiologic doses because of the high bioavailability potential for these routes. They have also been reported to increase blood glucose when administered by the intra-articular and epidural routes [6, 7], and some, but not all, studies found that inhaled corticosteroid led to hyperglycemia [8, 9]. A case-control study of a large primary care registry in the United Kingdom found no association between inhaled, injected, ophthalmic, or topical glucocorticoids with incident diabetes but oral glucocorticoids are associated with up to 2% of cases of new-onset diabetes. The authors acknowledged the limitations of the database which may have provided an underestimation of the risk [10]. Other cohort studies have reported that the odds ratio for glucocorticoids-induced new-onset diabetes ranges from 1.36 to 2.31 [11].

The main mechanism by which glucocorticoids cause hyperglycemia is through reduction of insulin sensitivity in the liver, skeletal muscle and adipocyte, by approximately 50–70%, which appears to be dose-dependent [11–15]. Glucocorticoid administration leads to decreased glucose transport 4 (GLUT-4) expression and migration, decreased glycogen synthesis, and increased hepatic gluconeogenesis [16]. They have also been shown to decrease insulin production and secretion [17, 18].

The most common clinical presentation of glucocorticoid-induced hyperglycemia is a rise in the blood glucose starting in mid-morning and continuing throughout the day until bedtime [19]. Therefore, this adverse drug reaction may not be detected if only the fasting blood glucose is monitored. Oral glucocorticoids are typically administered so that they mimic the physiologic pattern of endogenous cortisol secretion, and once daily glucocorticoids such as prednisone and prednisolone are administered in the morning. Taking into account the peak effect of these medications after a dose (e.g. peak effect of prednisone at 4–6 hours), checking a 1– to 2-hour post-lunch or a pre-dinner blood glucose starting a few days after initiation of treatment will enable detection of any hyperglycemia [11, 18, 19]. An elevation in the fasting blood glucose can occur with higher doses of once-daily glucocorticoids (prednisone 40 mg or equivalent) and with twice-daily administration [19]. People with pre-existing diabetes should monitor their blood glucose more frequently during the course of glucocorticoid treatment and all patients should also be advised to monitor for symptoms of hyperglycemia. As of the time of this writing, there are no published guidelines on the treatment of glucocorticoid-induced hyperglycemia with diabetes medications although a number of strategies have been advocated by various authors [11, 19].

Oral agents that enhance insulin sensitivity (e.g. metformin, thiazolidinediones) or stimulate insulin secretion (e.g. sulfonylureas, non-sulfonylurea secretagogues) address the mechanisms underlying glucocorticoid-induced hyperglycemia. However, concerns about pre-existing renal impairment and other risk factors for lactic acidosis, long duration of action leading to hypoglycemia especially overnight, or slow onset of effect plus weight gain and edema, make the use of metformin, sulfonylureas, and thiazolidinediones, respectively, not an ideal option in some patients [11, 19]. The non-sulfonylurea secretagogues and dipeptidyl peptidase-4 inhibitors may be better choices given their quicker onset of action, effect on postprandial hyperglycemia, and lower potential for hypoglycemia [18]. Insulin therapy offers the flexibility of matching the onset, peak, and duration of action to the pattern and degree of hyperglycemia the individual is experiencing; furthermore the dose can be more easily adjusted when the glucocorticoid dose is changed. Neutral protamine Hagedorn (NPH) insulin or a premixed insulin containing NPH can be the best choice for those taking an intermediate-acting glucocorticoid (e.g. prednisone) in the morning [11, 18, 19]. When given once-daily at breakfast, NPH's peak effect starting at 4 hours after

administration and duration of 10–16 hours closely matches that of the peak effect and duration of prednisone. In individuals on a long-acting glucocorticoid such as dexamethasone, twice-daily dosing of intermediate-acting glucocorticoids, and higher doses (e.g. 40 mg or higher of prednisone or equivalent), fasting hyperglycemia will likely also be seen and a long-acting insulin (insulin glargine or insulin detemir), plus prandial insulin, will likely be needed [18, 19]. Because many courses of treatment with glucocorticoids consist of an initial high dose with a gradual taper to physiologic level and then discontinuation, careful monitoring of blood glucose and subsequent insulin dose adjustments may be necessary to avoid hypoglycemia as the medication is being withdrawn.

Table 19.2 Monitoring schedule for atypical antipsychotics.

Measurement	Baseline	6 weeks	12 weeks	At least annually
Weight and body mass index	X	Measure weekly in first 6 weeks	X	X
Waist circumference	X	X	X	X
Fasting glucose	X	X	X	X
Fasting lipid profile	X	X	X	X
Blood pressure	X	X	X	X

Second-generation antipsychotics

The second-generation antipsychotics (SGA), also known as atypical antipsychotics, are another drug class with well-known hyperglycemic effects (see Chapter 57). Numerous case reports as well as studies of various SGAs worsening of existing diabetes, inducing new-onset diabetes, and hyperglycemic crises exist [20–23]. SGAs can cause blood glucose elevations both acutely and chronically [24–26]. Hyperglycemia has been reported for all currently marketed SGAs in the USA, although the degree of severity varies considerably [25, 27–29]. Olanzapine and clozapine appear to have the highest propensity for this adverse drug reaction [25, 26, 30]. SGAs with the lowest potential for hyperglycemia include the newer SGAs, specifically aripiprazole, ziprasidone, paliperidone, and lurasidone, although data and clinical experience with the newest agents (asenapine, iloperidone, lurasidone) are still limited [27–29, 31]. Quetiapine and risperidone appear to have moderate potential for hyperglycemia relative to the other SGAs [28].

The mechanism of SGA-induced hyperglycemia has yet to be fully elucidated but is likely multifactorial. SGA-induced weight gain is thought to be an important contributor, and SGAs with the highest potential for weight gain (olanzapine and clozapine) are also associated with the most clinically significant hyperglycemia. The binding of SGAs to histamine-1, serotonin, norepinephrine, and dopamine receptors, at different affinities depending on the agent, affects weight gain through regulation of hunger and satiety [28]. However, several studies also demonstrated that hyperglycemia and insulin resistance occur with some SGAs regardless of body weight and food intake [32, 33]. Animal studies also suggest that SGAs may induce hyperglycemia through inhibition of insulin secretion by antagonism of alpha-1 adrenergic, muscarinic (M_3), and serotonergic ($5HT_2$) receptors [34, 35].

Similar to glucocorticoids, SGA administration can lead to not only hyperglycemia but also weight gain and dyslipidemia, which further contribute to cardiovascular risks. These adverse drug reactions, along with the higher prevalence among people with psychiatric illness of being overweight or obese, physically inactive, and smoking, make monitoring and prompt treatment crucial [36]. A large meta-analysis encompassing 25,692 people with schizophrenia found an overall prevalence of 32.5% for metabolic syndrome, and 51.9%, 28.2%, 27.9%, and 20.2% for clozapine, olanzapine, risperidone, and un-medicated patients, respectively [37]. Recommendations for monitoring for the development of hyperglycemia, weight gain, and dyslipidemia were first published in 2004 by the American Diabetes Association, American Psychiatric Association, American Association of Clinical Endocrinologists, and the North American Association for the Study of Obesity [28] but other national and international guidelines have also emphasized the importance of regular screening for glucose and lipid abnormalities [38, 39]. In addition to obtaining personal and family history of diabetes, dyslipidemia, hypertension, obesity, and cardiovascular disease (CVD), these guidelines also recommend obtaining baseline measurement for glucose, lipids, blood pressure, and body mass index with periodic reassessment. A proposed monitoring schedule can be found in Table 19.2 [40]. Specific to fasting plasma glucose, this should be monitored at 12 weeks then annually. In addition, if the person gains 5% or more of their baseline weight during treatment, it is recommended that clinicians consider a switch to another SGA [28]. Several studies have shown an improvement in glucose control after switching from olanzapine to aripiprazole [41]. However, changing to another antipsychotic may not always result in equivalent control of the mental illness and other measures (therapeutic lifestyle changes, diabetes medications) may need to be employed.

Oral contraceptive agents

Combination oral contraceptive (COCs) preparations are used by more than 100 million women worldwide [42]. These products contain one of two estrogens, mestranol or ethinyl estradiol and a variety of progestins (e.g. norethindrone, norgestrel, norgestimate) in monophasic, biphasic, and triphasic formulations. Despite their proven efficacy, a number of adverse events have been ascribed to their use (especially the estrogen component) including metabolic abnormalities such as glucose intolerance

and overt diabetes. The causes of COC-induced dysglycemia have been historically associated with alterations in insulin sensitivity and insulin secretion. However, current evidence does not support a significant effect of COCs on glucose metabolism or homeostasis and the development of clinical diabetes [43]. Interestingly, a recent analysis of data from the Missouri Pregnancy Risk Assessment Monitoring System (PRAMS) in the United States suggested that women with gestational diabetes were nearly 1.5 times more likely to have used hormonal contraception before conception [44]. A recently published Cochrane Database systematic review sought to answer the question of whether COCs adversely affected carbohydrate metabolism in women without diabetes and in those who were overweight. In analyzing 31 trials that met inclusion criteria, there were no significant differences in carbohydrate metabolism among the different preparations. Surrogate endpoints used included fasting and 2-hour postprandial glucose, insulin and glucose area-under-the curve and glycated hemoglobin A_{1C} (HbA_{1c}) levels. Due to various study design deficiencies, the authors were unable to elucidate the metabolic risk of oral contraceptives in obese women [45].

Whereas the risk of dysglycemia from COCs in women without diabetes remains negligible, metabolic effects arising from the use of these drugs in women with type 1 or type 2 diabetes can be consequential. Similarly, unplanned pregnancy in this same population also has significant maternal and fetal consequences especially when glycemic control is poor. Thus contraceptive options must be chosen that do not contribute to an excess metabolic and cardiovascular risk for these women. Based upon the eligibility criteria for contraceptive use published by the World Health Organization (WHO) in 2009 (adapted by the USA in 2010), the use of COCs is favored in women with type 1 or type 2 diabetes without vascular complications and in women with gestational diabetes [43]. A 2013 Cochrane Database systematic review failed to show significant differences between progestin-only, combination hormonal and non-hormonal contraceptives on carbohydrate and lipid metabolism and vascular complications in women with type 1 or type 2 diabetes [46]. These results were ascribed to various methodological deficiencies making interpretation problematic.

Menopause hormone therapy

Menopause hormone therapy (MHT) or hormone replacement therapy (HRT) typically involves the administration of oral estrogens alone or in combination with an oral progestogen for the treatment of postmenopausal symptoms especially hot flashes, vaginal atrophy, and mood instability. Transdermal and intravaginal formulations are also prescribed. Given the potential for COCs to impact glucose homeostasis and glycemic control in women with diabetes, the use of MHT in postmenopausal women can be viewed with similar concerns, especially when the doses are administered by the oral route. The results of two published randomized placebo-controlled trials have dispelled the concern about whether MHT adversely impacts glucose metabolism or precipitates incident diabetes. The Heart and Estrogen/Progestin Replacement Therapy Study (HERS) studied nearly 2800 postmenopausal women with coronary heart disease who took MHT for approximately 4 years [47]. At the completion of the trial, there was no significant difference in the fasting blood glucose levels between women with and without diabetes and those with impaired fasting glucose. Importantly, women taking MHT had a 35% reduction in incident diabetes compared to those in the placebo arm of the trial (NNT = 30 over 4 years). Likewise, women enrolled in the Women's Health Initiative Hormone Trial and receiving conjugated equine estrogens plus medroxyprogesterone were found to have a 21% lower risk of diabetes ($p = 0.03$) at 1-year follow-up compared to placebo controls (NNT = 143 over 5.6 years) [48]. This difference in study results was ascribed to decreases in insulin resistance. The aforementioned findings suggest that postmenopausal women can safely take MHT without adversely affecting glucose homeostasis or triggering diabetes.

Whether women with diabetes can safely take MHT remains more uncertain and untested. A recently published Cochrane Database systematic review showed that glycemic control was not impacted by MHT in women with type 1 diabetes [49]. However, this finding was based upon only one underpowered placebo-controlled randomized clinical trial making the results questionable. Previous studies evaluating the effects of MHT on women with type 2 diabetes suggest improved glycemic control with its use [50, 51]. In a large observational study, investigators evaluated the impact of MHT (opposed and unopposed estrogen therapy) on HbA_{1C} in women with type 2 diabetes. HbA_{1c} was significantly lower in women taking MHT versus those not on MHT (age-adjusted mean ± SE: 7.9% ± 0.03% (63 mmol/mol) vs. 8.5% ± 0.02% (69 mmol/mol), respectively; $p = 0.0001$) [51]. Likewise, an assessment of data from the United States NHANES III (National Health and Nutrition Examination Survey, 1988–1994) indicated that postmenopausal women currently taking MHT had lower fasting blood glucose and HbA_{1c} levels versus women who had never taken MHT 112 versus 154 mg/dL (6.2 mmol/L vs. 8.5 mmol/L) and 6.0% versus 7.1% (42 mmol/mol vs. 54 mmol/mol), respectively. Whereas these aforementioned observational studies cannot support causation, the evidence does promote the notion that MHT has minimal impact upon established type 2 diabetes in postmenopausal women. Continued surveillance of glycemic control is prudent in these women and appropriate adjustments should be made to their antidiabetes drug regimens as needed.

Thiazide diuretics

The thiazide diuretics have been the mainstay for the management of hypertension for over 50 years [52]. Early on it was recognized that this drug class could negatively impact glycemic control in persons with diabetes [53]. Despite their widespread use and clinical utility, questions continue to be raised regarding their potential

effect on glucose homeostasis and glycemic control in those with established diabetes. The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), a very large landmark study in hypertension management, found significantly more new-onset diabetes (FBG $\geq$ 126 mg/dL; 7 mmol/L) with chlorthalidone compared to amlodipine and lisinopril at the 4-year follow-up period (11.6%, 9.8%, and 8.1%, respectively) [54]. In addition, participants with pre-existing diabetes or those who developed diabetes during the original Systolic Hypertension in the Elderly Program (SHEP) were evaluated as part of a long-term follow-up study (14.3 years) [55]. Investigators found that persons with diabetes assigned to chlorthalidone had lower cardiovascular and total mortality rates compared to placebo controls (HR 0.805; 95% CI: 0.680–0.952) [55]. These representative studies, whereas interesting in their findings, provide little resolution to the ongoing debate surrounding thiazide-induced dysglycemia.

Historically, thiazide-induced dysglycemia has been connected to alterations in potassium balance, namely hypokalemia. Since insulin secretion is linked, in part, to an accumulation of intracellular potassium within the pancreatic β cell, potassium loss would impair insulin release resulting in hyperglycemia. In an effort to substantiate this long-held belief, a group of investigators reviewed pertinent intervention trials using thiazides from 1966–2004 that measured serum potassium and glucose levels [56]. Fifty-nine trials met inclusion criteria. Analysis of the trial data supported an inverse relationship between potassium balance and blood glucose levels. However, the effects on blood glucose were modest with an average increase of 7.1 mg/dL ± 7.38; 0.4 mmol/L ± 0.4) [56]. In a subgroup analysis of the above-mentioned SHEP trial, for every 0.5 mEq/L decrease in serum potassium there was a corresponding 45% increase in incident diabetes risk (95% CI: 24–70%; p <0.001) [57]. This association was only evident during the first year of treatment with chlorthalidone. In a more recent subgroup analysis, no correlation was found between fasting serum glucose and serum potassium levels in people with hypertension receiving hydrochlorothiazide alone and when added to atenolol [58].

Clinicians need to be aware that the thiazide diuretics can affect glucose homeostasis in a dose-dependent manner but the effect appears to be modest at best. Maintaining normokalemia is the best defense against this potential metabolic consequence of thiazide use [57]. Any alteration in glycemic control can be managed with careful adjustment of the antidiabetes regimen and continued blood glucose monitoring.

Beta-adrenoceptor antagonists

Beta-blockers are widely used to treat a variety of conditions including hypertension, angina, arrhythmias, and congestive heart failure. Despite their benefits, these drugs can pose problems in persons with pre-established diabetes. Their propensity to mask the adrenergically mediated signs and symptoms of hypoglycemia and delay its recovery is well known. Theoretically, non-selective beta-blockers could also worsen peripheral vascular disease via unopposed alpha receptor stimulation of the vasculature. Whether beta-blockers affect glucose homeostasis or contribute to the development of overt diabetes is less certain. In an older prospective cohort study, the use of beta-blockers was associated with a 28% increased risk of new-onset diabetes (relative hazard, 1.28; 95% CI: 1.04–1.57) [59]. A more recent systematic literature review was undertaken to examine the effects of various beta-blockers on glucose homeostasis, insulin sensitivity, and diabetes risk [60]. Whereas the evidence supporting an association between the administration of selective and non-selective beta-blockers and diabetes-risk is inconclusive, beta-blockers with alpha-blocking properties (e.g. carvedilol) may have a reduced or no risk for diabetes [61]. This discrepancy has been attributed to differences in effects on insulin sensitivity compared to conventional beta-blockers. These findings warrant consideration of a beta-blocker with vasodilating properties, such as carvedilol and nebivolol, as the preferred choice for persons with diabetes or those at high risk for diabetes [60].

HMG CoA reductase inhibitors

The HMG CoA reductase inhibitors, commonly known as statins, have been the mainstay of hyperlipidemia and cardioprotection for over two decades but their hyperglycemic potential has only recently been reported. The FDA changed the product labeling of statin medications to include the findings of elevated fasting glucose and HbA_{1c} in early 2012 [62]. Statins appear to increase insulin resistance and decrease insulin secretion, with small increases in HbA_{1C} and fasting glucose [63]. A meta-analysis reported that the lowest risk for new-onset diabetes is with pravastatin at 40 mg/day (OR 1.07; 95% CI: 0.86–1.3), followed by atorvastatin 80 mg/day (OR 1.15; 95% CI: 0.9–1.5), and highest with rosuvatatin 20 mg/day (OR 1.25; 95% CI: 0.82–1.9) when compared to placebo [64]. Another meta-analysis found that the risk of incident diabetes is 9% (OR 1.09; 95% CI: 1.02–1.17) and that treatment of 255 people for 4 years would result in one additional case of diabetes [65]. The authors also reported that statin therapy would prevent 5.4 major coronary events (coronary heart disease death and non-fatal myocardial infarction) in these 255 individuals and that the potential benefit would be expected to be greater if prevention of strokes and revascularization was also taken into account [65]. The JUPITER trial reported that, for those with one or more diabetes risk factors, rosuvastatin was associated with a 28% increase in diabetes but 134 cardiovascular events or deaths were avoided for every 54 new cases of diabetes [66]. The 2015 American Diabetes Association Standards of Medical Care in Diabetes guideline noted that the absolute risk of rosuvastatin-induced diabetes is small (1.5% with rosuvastatin compared to 1.2% with placebo over 5 years) and recommends statin therapy for most people with diabetes with overt CVD or CVD risk factors [67].

Anti-retroviral therapy for human immunodeficiency virus (HIV)

The pharmacologic treatment of HIV-1 currently includes nucleoside reverse-transcriptase inhibitors (NRTI), non-nucleoside reverse-transcriptase inhibitors (NNRTI), protease inhibitors (PI), integrase strand transfer inhibitors, and entry inhibitors. Hyperglycemia and diabetes have been reported with the PI and some of the NRTIs (zidovudine, stavudine, and didanosine) [68]. These NRTIs can cause insulin resistance, promote lipodystrophy, and pancreatitis [1, 69, 70]. The PIs induce hyperglycemia through increasing insulin resistance and the development of lipodystrophy [71–77]. *In vitro* studies also demonstrated that some PIs can decrease insulin secretion [73, 77]. PI-induced lipodystrophy (Figure 19.1) is characterized by lipohypertrophy (resembling central obesity) with or without lipoatrophy, manifesting as peripheral fat loss (particularly in the extremities, face, and buttocks) [78]. Lipodystrophy, insulin resistance, hyperglycemia, and the dyslipidemia (elevated triglyceride and total cholesterol, reduced high-density lipoprotein cholesterol) associated with PIs can increase the risk of cardiovascular events in treated individuals [79, 80].

Pentamidine

Pentamidine is an antifungal/antiprotozoal agent which is FDA-approved for the treatment and prevention of *Pneumocystis jirovecii* pneumonia commonly associated with HIV-infection and

Figure 19.1 Protease inhibitor-induced lipodystrophy. (a,b) "Buffalo hump" caused by nuchal fat deposition. (c,d) Facial fat atrophy. Source: Courtesy of Professor Munir Pirmohamed, University of Liverpool, UK.

those with immunodeficiency or malignancy. The drug is usually administered intravenously or via inhalation for adults and children alike. Importantly, the drug has the propensity to cause both hypoglycemia and hyperglycemia. Its well-known dysglycemic effects are due to impaired insulin secretion and direct cytotoxicity and β-cell apoptosis. In 128 immunocompromised patients with *P. jirovecii* pneumonia, pentamidine was associated with seven cases of hypoglycemia, 23 cases of overt diabetes, and 18 cases of hypoglycemia followed by diabetes. Seventy-five percent of the patients received the drug parenterally. Hyperglycemia was noted within an average of 52 days (20–90) following pentamidine administration. Insulin was required in 63% of those with diabetes. Risk factors for the development of diabetes included high doses, impaired renal function, and poor clinical status of the patient [81]. In a retrospective chart review of pentamidine-associated adverse drug reactions in 106 HIV-infected persons, 9 persons experienced hyperglycemia with average blood glucose levels of 369 mg/dL (20.4 mmol/L) and a mean time of onset of 14 days [82]. Providers need to be aware of the development of hyperglycemia with pentamidine and monitor patients accordingly for this late-appearing adverse drug reaction.

Fluoroquinolones

The fluoroquinolone class of antimicrobial agents have been available for over 50 years. Despite their clinical utility, a variety of well-known adverse effects have been reported, most noteworthy being arthropathy and QT-prolongation [83]. In retrospective analyses, serious dysglycemia (both hypoglycemia and hyperglycemia) has also been associated with their use culminating in the voluntary removal of gatifloxacin from the US and Canadian markets in 2006 owing to a significant risk of hospitalization for hypoglycemic or hyperglycemic episodes [84, 85]. Although oral gatifloxacin is no longer available from many markets (United States, Canada, Japan, etc.), it is still sold around the world and is available via online distributors.

Whereas many drug adverse effects are a class effect, fluoroquinolone-associated dysglycemia appears to be much more common with gatifloxacin compared to levofloxacin. Ciprofloxacin poses little or no risk [85]. Of the currently available fluoroquinolones in the USA, moxifloxacin appears to have the highest likelihood for causing hyperglycemia compared to levofloxacin or ciprofloxacin [86]. The etiology of fluoroquinolone-induced hyperglycemia is unclear but possible contributing factors include a history of diabetes, failure to adjust doses in renal insufficiency, acute illness, and age. Recent animal studies suggest that hyperglycemia results from increased drug accumulation in the pancreas of individuals with diabetes, histamine-associated release of the counter-regulatory hormone epinephrine, and the prolonged secretion of GLP-1 which inhibits insulin secretion and production [87–89].

The risk of hyperglycemia from fluoroquinolone use (with and without diabetes) warrants careful surveillance by clinicians and patients alike. Hyperglycemia tends to occur within 1–2 weeks of therapy initiation. Any changes in glycemic control can be managed with careful adjustment of the antidiabetes regimen and continued blood glucose monitoring. Likewise, hypoglycemic signs and symptoms must be verified and managed accordingly. Adjustments of oral hypoglycemic and insulin therapy may be required.

Calcineurin inhibitors

There are various classes of drug that are used as immunomodulators to combat rejection following organ transplantation or to manage autoimmune diseases and other inflammatory conditions. One such class is the calcineurin inhibitors. Well-known representative examples include cyclosporine and tacrolimus. Calcineurin is a protein that is involved in the production of the cytokine interleukin-2 (IL-2) by T-helper cells. IL-2 is responsible for T-cell differentiation which is important in the maintenance of cellular immunity.

It had been recognized for many years that transplant recipients suffered from glucose intolerance and also developed type 2 diabetes [90]. At that time several associated risk factors were implicated in the development of post-transplant hyperglycemia or diabetes including the widespread use of corticosteroids in this patient population. In addition to the transplant itself, several immunosuppressant agents administered to counteract rejection were also implicated, namely cyclosporine and tacrolimus [90]. The prevailing belief that cyclosporine is less likely to impair glucose homeostasis versus tacrolimus has been questioned [91]. Alterations in insulin sensitivity and impaired β-cell function are cited as causative factors in the development of glucose intolerance. However, recent evidence corroborates findings that defective insulin secretion is the primary pathologic defect [92]. Whether cyclosporine has any advantages over tacrolimus in managing transplant recipients with pre-existing type 2 diabetes has recently come into question yet remains controversial [93, 94].

Risk factors for post-transplant diabetes (PTDM) include older age, obesity, corticosteroid use, non-Caucasian race, hepatitis C, and genetic determinants [95]. Glucose intolerance or overt diabetes tends to occur within 6 months of immunosuppressant therapy. Clinicians need to be aware of patient risk factors and aggressively manage dysglycemia when it occurs. Inattention to PTDM can result in graft failure and other diabetes-related complications [95]. The optimal therapeutic approach remains to be defined but emerging evidence suggests that insulin secretagogues (including the incretin-mimetics) may be the drugs of choice [95, 96].

Diazoxide

Diazoxide is a thiazide-like drug that had been in clinical use for over 40 years for the management of hypertensive emergencies and hyperinsulinemic hypoglycemia (secondary hypoglycemia). At present, the drug is only available as an oral suspension for

the treatment of secondary hypoglycemia (e.g. insulinoma, islet cell hyperplasias). Importantly, it has been long recognized as a cause of drug-induced hyperglycemia and even diabetic ketoacidosis [97]. Its hyperglycemic effects have been purported to result from impaired insulin secretion, increased glucose production, and decreased peripheral glucose utilization [98, 99]. Diazoxide's ability to inhibit insulin secretion results from "opening" the K_{ATP} channel in the β cell of the pancreas. This ability to inhibit insulin secretion may prove useful in the management of type 1 and type 2 diabetes by preserving β-cell function [100]. Likewise, diazoxide may improve hypoglycemic unawareness via opening SUR1 selective K_{ATP} channels in the central nervous system [100].

Prevention and treatment strategies

The old adage that an ounce of prevention is worth a pound of cure is germane to any discussion involving drug-induced dysglycemia. Clinicians need to be sensitized to the reality that drug therapy may precipitate hyperglycemia in predisposed individuals as well as lead to overt diabetes mellitus. It may be best to avoid precipitant drugs whenever possible and choose more appropriate alternatives. When evaluating a possible case of drug-induced dysglycemia, a careful review of prescription and non-prescription (over-the-counter) medications as well as herbal products and dietary supplements can reveal possible offenders. In addition to a thorough drug history, the clinician should also evaluate the patient's drug regimen and comorbid conditions that may affect the pharmacokinetics or pharmacodynamics of the suspected drug. When drug–drug interactions are suspected, a variety of resources are available to the clinician to facilitate their evaluation. These include various compendia, online references, smart phone applications, professional colleagues, and drug and health information centers. As with any reference tool, it is important to corroborate the information found using a second source. This ensures that the information is accurate and reliable.

Clinicians are often stymied when assessing non-prescription medication by the sheer number of products available for consumption by the patient. One can overcome this fact by employing a review of systems approach akin to asking patients about organ system-based complaints as part of a medical history. In this systematic approach, major product categories are captured and evaluated by asking "head-to-toe" questions. This method has been previously published if more information is needed [101].

Whenever possible limit a patient's exposure to drugs that could affect glucose regulation or glycemic control. Careful attention should be paid to limiting the numbers of drugs, as well as the doses and duration of therapy whenever possible. Baseline data such as weight and fasting blood glucose levels should be obtained when appropriate. This is especially important in people taking more than one medication with the potential for hyperglycemia, prescribed a high dose of the medication, taking concomitant drugs that can increase the concentration or duration of the medication, or those with other risk factors for diabetes (Table 19.3) [1, 67]. Importantly, prospective monitoring of high-risk individuals should be an ongoing process.

Table 19.3 Risk factors for diabetes according to the American Diabetes Association [67].

Age ≥ 45 years
Family history (first-degree relative) of diabetes
Race/ethnicity (e.g. African Americans, Latino, Native Americans, Asian Americans, and Pacific Islanders)
Physical inactivity
Overweight or obese (BMI ≥ 25 kg/m^2 or ≥ 23 kg/m^2 in Asians)
Hypertension (≥140/90 mmHg in adults)
High density lipoprotein cholesterol <35 mg/dL (0.90 mmol/L) and/or a triglyceride level >250 mg/dL (2.82 mmol/L)
History of cardiovascular disease
History of gestational diabetes mellitus or delivery of a baby weighing >9 lbs (>4.1 kg)
Polycystic ovary syndrome
Previously identified prediabetes based on laboratory values
Other clinical conditions associated with insulin resistance (e.g. acanthosis nigricans)

In the event that a precipitant drug cannot be avoided, prudence would dictate careful monitoring for the occurrence of dysglycemia. If a morbid event occurs, the dose of the offending agent can be reduced or the drug can be discontinued if suitable. If necessary, supportive care may be required for a time dependent upon the drug in question and the clinical status of the patient. Most importantly the clinician should learn from the incident and develop strategies to obviate such happenings in the future.

20 Endocrine Disorders that Cause Diabetes

Rachel E. Jennings and Neil A. Hanley

Centre for Endocrinology and Diabetes, University of Manchester, Manchester, UK

Key points

- Endocrine causes of diabetes are mainly a result of an excess of hormones that are counter-regulatory to insulin, and act by inhibiting insulin secretion and/or action.
- Acromegaly is almost always secondary to growth hormone-secreting adenomas of the anterior pituitary somatotrophs and disturbs glucose homeostasis in up to approximately 50% of patients.
- Cushing syndrome is caused by excessive levels of glucocorticoids and disturbs glucose homeostasis to some degree in over 50% of cases.
- Pheochromocytoma is a tumor of the chromaffin cells, which in 90% of cases is located in the adrenal medulla and causes hyperglycemia in approximately 50% of cases.
- Glucagonoma and somatostatinoma are rare islet cell tumors that produce hormones that inhibit the secretion and action of insulin.
- Thyrotoxicosis commonly causes mild glucose intolerance, but overt diabetes only occurs in a tiny minority.
- Other endocrinopathies such as primary aldosteronism and primary hyperparathyroidism can disturb glucose homeostasis.
- Polycystic ovarian syndrome occurs in 5–10% of women of reproductive age and associates with some degree of glucose intolerance or diabetes resulting from insulin resistance in approximately 50% of cases.

Introduction

The primary focus of this chapter is on those endocrine disorders that cause hyperglycemia and where effective treatment of the endocrinopathy can be expected to normalize the blood glucose concentration. These conditions mostly reflect excessive secretion of "counter-regulatory" hormones, the metabolic actions of which oppose those of insulin by inhibiting its secretion, action, or both.

Acromegaly

Etiology, incidence, and clinical features of acromegaly

Acromegaly comprises a constellation of symptoms and signs caused by excessive growth hormone (GH) secretion that leads to bony and soft tissue overgrowth accompanied by cardiovascular and metabolic pathology (Figure 20.1; Table 20.1) [1]. Previous data suggested acromegaly affects approximately 60 people per million [2]; however, current evidence suggests the prevalence is much higher, between 86–240 people per million [1]. In 99% of cases, acromegaly is caused by a pituitary adenoma, most commonly larger than 1 cm in diameter (a "macroadenoma"; Figure 20.1). A tiny minority of cases are caused by excessive secretion of GH-releasing hormone (GHRH) from a hypothalamic gangliocytoma or a carcinoid tumor of the lung or pancreas [3]. A small percentage of acromegaly occurs within the wider endocrine syndrome of multiple endocrine neoplasia type 1 (MEN1) caused by mutations in the tumor suppressor gene, *MENIN* [4]. MEN1 can also include glucagonomas and somatostatinomas, both of which can independently cause secondary diabetes. Acromegaly can also rarely occur within the context of familial isolated pituitary adenomas, with germline mutations in the tumor suppressor gene encoding the aryl hydrocarbon receptor-interacting protein (*AIP*) implicated in the pathogenesis of some cases [5]. Commonly, acromegaly has been present for a decade prior to diagnosis [1]. This long-standing hypersecretion of GH provides the time necessary for the characteristic external features of the disorder to develop (Figure 20.1; Table 20.1). On occasion this timeline can stretch back prior to puberty. GH excess in this circumstance when exaggerated linear growth is still possible causes "gigantism" alongside the post-pubertal features of acromegaly.

Disturbance to glucose tolerance in acromegaly

Glucose intolerance or overt diabetes is common in acromegaly because of the direct hyperglycemic effects of GH excess (Figure 20.2). Diabetes and impaired glucose tolerance occurs in 15–38% of people with acromegaly [6–8]. Diabetes is most frequent in people with higher GH levels [9, 10]. There is also a correlation between serum insulin-like growth factor I (IGF-I) and both fasting and postprandial glucose. In fact, placing age-adjusted IGF-I values into rising quartiles correlated very accurately with

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

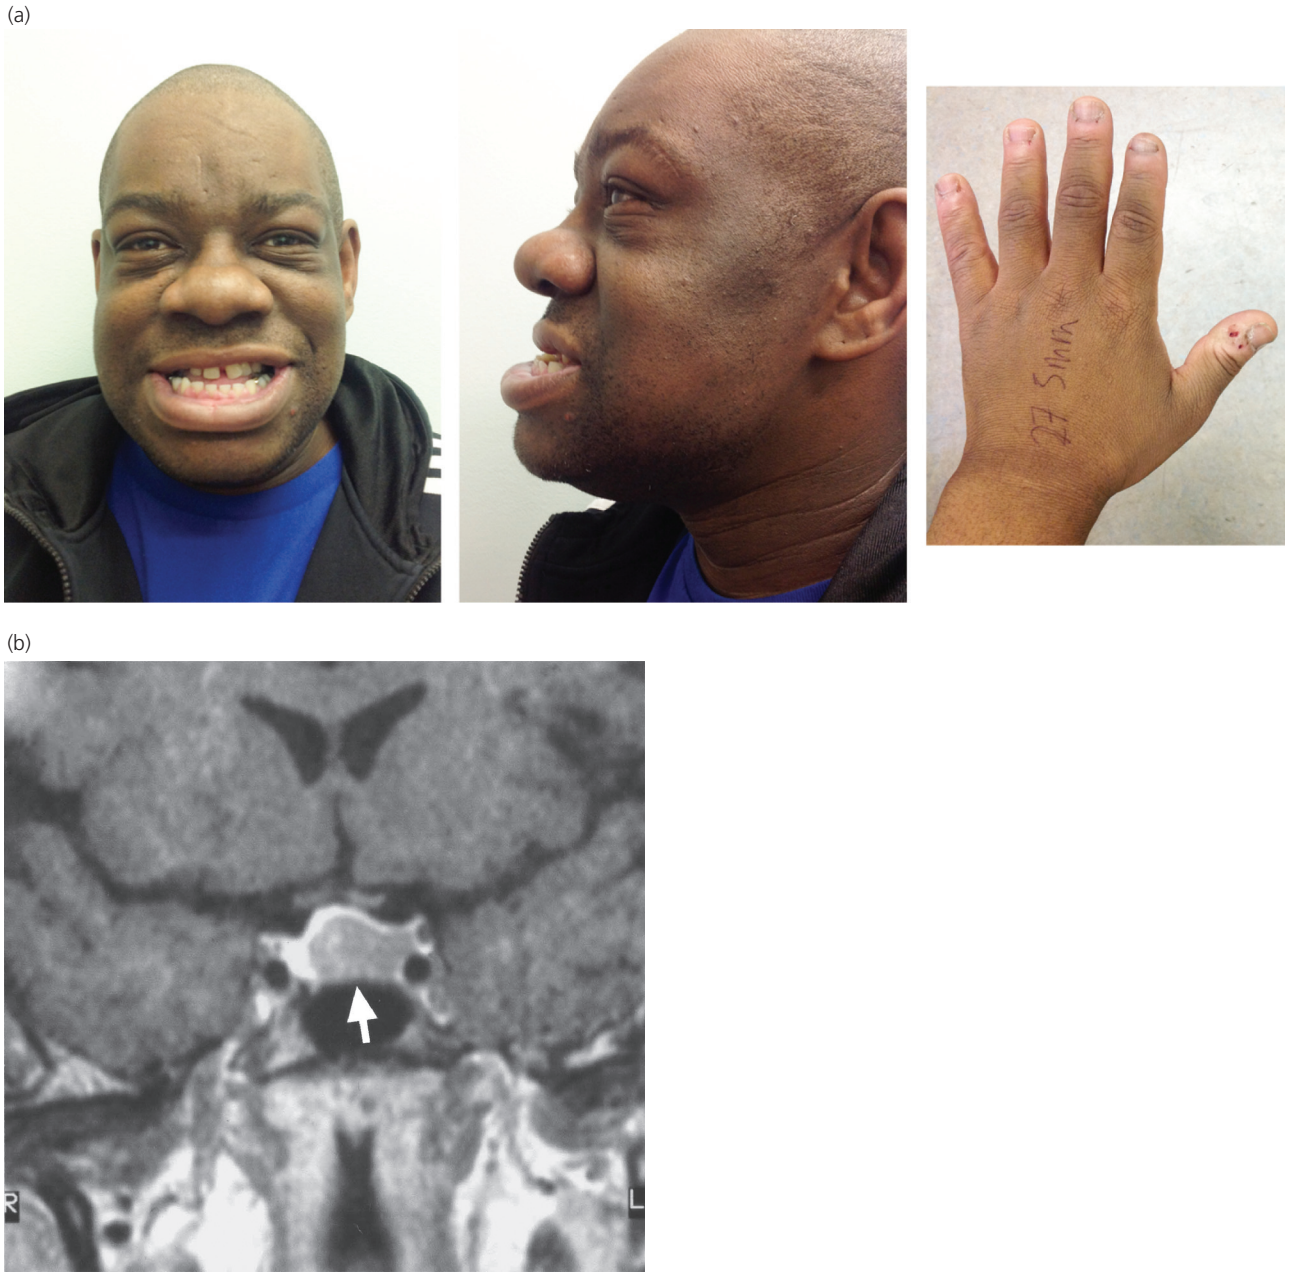

Figure 20.1 (a) Characteristic features of a man with untreated acromegaly. Note the teeth separation, particularly noticeable in the lower jaw and the associated underbite from the mandibular overgrowth. The hand illustrates soft tissue overgrowth and is often described as "spade-like." (b) MR imaging from a patient shows a large adenoma (arrow) in the pituitary extending up to but not in contact with the optic chiasm and also extending out into the left cavernous sinus. R, right; L, left.

decreasing insulin sensitivity such that serum IGF-I levels could predict insulin sensitivity more accurately than either random GH levels or the nadir value following glucose tolerance testing [11].

Clinically, diabetes in acromegaly usually resembles type 2 diabetes (T2DM), with most people not needing insulin therapy but being maintained with oral antidiabetes agents or diet alone [8]. GH can induce insulin resistance when infused into healthy volunteers [12, 13], and insulin resistance is a consistent feature of people with acromegaly [14, 15]. Insulin action is impaired in both the liver and extrahepatic tissues, with diminished suppression of hepatic glucose production and insulin-dependent glucose disposal [13, 15]. For instance, impairment of insulin-mediated activation of glycogen synthase has been demonstrated in skeletal muscle [16–18]. Insulin resistance may also be exacerbated by the lipolytic action of GH, generating non-esterified fatty acids (NEFAs), which act on the liver to increase glucose production and in muscle to inhibit glucose utilization (via the "glucose–fatty acid" cycle) (Figure 20.2). Where pancreatic compensation is

Table 20.1 Clinical features of acromegaly.

Musculoskeletal
Protruding mandible (prognathia) with lower teeth separation
Big tongue (macroglossia)
Enlarged forehead (frontal bossing)
Large hands and feet (carpal tunnel syndrome, tight rings, increasing shoe size)
Osteoarthritis from abnormal joint loading
Increased stature (gigantism; if GH excess occurs prior to epiphyseal closure)
Skin
Irritating, thickened, greasy (increased sebum production)
Excessive sweating
Cardiovascular
Dilated cardiomyopathy causing cardiomegaly and cardiac failure
Hypertension
Metabolic
Impaired glucose tolerance or potentially diabetes
General
Headaches
Tiredness, often very disabling and lowers quality of life and ability to work
Local tumor effects
Compression of the optic chiasm (superior tumor growth) or cranial nerves III, IV, and/ or VI (lateral tumor growth into cavernous sinus)

GH, growth hormone.

adequate, an exaggerated insulin secretory response creating hyperinsulinemia can counterbalance the insulin resistance and maintain euglycemia. Similar to the natural history of deteriorating blood glucose control in T2DM, eventually β-cell compensation fails, the insulin response is impaired and hyperglycemia ensues [14].

Diagnosis and treatment of acromegaly

GH release is normally pulsatile with intervening periods of low level or undetectable hormone, whereas secretion from pituitary adenomas is autonomous. Therefore, the diagnosis can be strongly suspected from a series of random serum measurements where GH is consistently detected. An alternative, better diagnostic test takes advantage of the negative feedback on GH secretion by glucose. A failure of serum GH to suppress to below 2 mU/L (approximately 1 μg/L) within 2 hours of 75 g oral glucose is diagnostic of acromegaly. A further option, particularly suited as the initial screening test for outpatients, is measurement of serum IGF-I, which if raised above sex- and age-matched reference ranges is diagnostic of acromegaly, unless there is a possibility of exogenous GH administration [3]. It is noteworthy that the diagnosis of acromegaly can be difficult in people with type 1 diabetes mellitus (T1DM) where GH hypersecretion is observed. Whereas this might compromise the use of serum GH as a diagnostic biomarker of a somatotroph adenoma, IGF-I values tend to be low in poorly controlled T1DM indicative of a state of GH resistance. Thus, raised serum IGF-I values remain a confident predictor for a diagnosis of acromegaly in people with T1DM. Having diagnosed acromegaly biochemically, magnetic resonance (MR) imaging of the anterior pituitary defines the extent of the adenoma (Figure 20.1).

Based on this investigation, symptoms, patient wishes, comorbidity, and GH levels, treatment can be either surgical, medical, or radiotherapy (Table 20.2) [3]. When the tumor is a macroadenoma, especially if it extends beyond the pituitary fossa, curative surgery becomes unlikely or impossible; however, surgery can be useful for "debulking" and rapid lowering of serum GH levels in patients who are highly symptomatic, or where the tumor has encroached upon the optic chiasm and affected visual fields. The standard approach is transsphenoidal, either via the nostril or from behind the upper lip. Once the sphenoid sinus has been traversed and midline access to the sella turcica gained, tumor is removed from the anteroinferior aspect causing the residual tissue to drop back down into or towards the pituitary fossa. Tumor beyond the fossa, in locations such as the cavernous sinus, cannot be approached directly, hence the reason why surgery for large tumors is not anticipated to be curative [19]. Conversely, cure can be commonly achieved for over 85% of microadenomas (<1 cm diameter) and 40–50% of macroadenomas [20–22]. The reported ranges vary widely according to expertise.

Medical therapy, most commonly using somatostatin analogs, is effective at both lowering GH levels and shrinking the tumor volume [1, 23, 24]. Approximately 60% of patients respond to somatostatin analogs because of the presence of somatostatin

Table 20.2 Treatment of acromegaly.

Advantages	Disadvantages
Transsphenoidal surgery	
Rapid effect	Invasive and requires general anesthetic
Can restore vision in optic nerve compression	Non-curative for large extrasellar tumors
Might be curative if complete resection	
Somatostatin analog drugs	
Non-invasive	Monthly intramuscular injection
May shrink tumor	Expensive
Decreases GH in ~60% of patients	Gastrointestinal side effects (commonly diarrhea)
	Unlikely to be curative (i.e. continuous therapy needed)
Pegvisomant	
Non-invasive	Expensive
Blocks GH action	GH concentrations remain elevated
Radiotherapy	
Non-invasive	Slow to act—may take up to 10 years
Likely to shrink tumor	Standard external three-beam radiotherapy likely to cause hypopituitarism by destroying other pituitary cell types
Likely to reduce GH levels	
Might be curative

receptors (mostly type 2 and type 5) on the tumor cell surface [1, 24]. The analogs can be administered subcutaneously; however, once it is clear that they are tolerated, the most common formulation is month-long intramuscular depot preparations. They can be used either prior to surgery, with the goal of operating on a shrunken tumor, on a long-term basis in place of surgery, or post-surgery where GH levels have not been normalized.

Some GH-secreting adenomas co-express dopamine receptors more characteristic of prolactinomas [24]. Indeed, 25% of cases of acromegaly show raised levels of both prolactin and GH possibly indicating a tumor cell phenotype more consistent with the somatomammotroph from which it is thought that somatotrophs (GH secretion) and lactotrophs (prolactin secretion) terminally differentiate. In these instances, dopamine agonists, as used in hyperprolactinemia, can be useful, especially as they can be administered orally, and allow reduction in dosage of the more expensive intramuscular depot somatostatin analogs. This opportunity to use lower doses of somatostatin analogs may also lessen their side effects, such as gastrointestinal disturbance (most commonly diarrhea) and gallstones. It has been questioned whether commonly used ergot alkaloid-derived dopamine agonists, such as cabergoline, cause fibrotic side effects, especially involving heart valves [25, 26]. Despite concerns from regulatory agencies, the prevailing view from endocrinologists is that the doses of these agents used to treat endocrine disorders (compared with the therapeutic regimens in Parkinson disease) are not problematic. In any case, alternative non-ergot derived agents, such as quinagolide, are available. Bromocriptine is less commonly used because of the almost inevitable side effect of nausea. The role of dopamine in mood disorders and psychosis creates at least a theoretical concern over dopamine agonists in the treatment of endocrine disorders. While the practical significance remains disputed, it is prudent to inquire about mood in the past medical history and systemic inquiry and to encourage the patient to report symptoms if they commence dopamine agonist therapy. At the start of treatment, responsiveness to both dopamine and somatostatin analog therapy can be easily assessed by hourly measurement of serum GH over 8 hours following the administration of a test dose of each agent given sequentially on two consecutive days.

The last two decades has seen the appearance of a new clinical agent that blocks GH action. GH induces signal transduction via binding to its receptor as a dimer. Pegvisomant has been developed as a GH antagonist by preventing this dimerization and blocking downstream GH signaling. This leaves elevated GH levels from the somatotroph adenoma but, nevertheless, pegvisomant is effective at reversing the clinical features of acromegaly, with approximately 60% of patients sustaining normal IGF-I levels after 5 years of treatment [3, 27, 28]. The major problem with its use in many countries has been its prohibitive cost. Concern over tumor growth because of loss of negative feedback (a scenario similar to Nelson syndrome following bilateral adrenalectomy in Cushing disease) seems unfounded [27, 28].

Radiation therapy is most commonly administered as conventional three-field external beam radiotherapy [3]. It is effective at lowering GH and IGF-I levels [29]. This approach delivers approximately 4500 Gy to the pituitary region with the total dose calculated such that the optic chiasm receives less than 8 Gy. An alternative is stereotactic radiotherapy (also known as γ-knife therapy or radiosurgery), which by using more sources can focus a higher concentration of radiation to a defined area of tumor. Whereas the latter modality allows greater preservation of adjacent normal pituitary tissue, the former approach is a more all-encompassing strategy to ensure tumor destruction, albeit with a higher post-therapy incidence of hypopituitarism. The choice is important as there is evidence that pituitary radiotherapy is associated with increased morbidity and mortality from subsequent cerebrovascular disease meaning that repeat therapy is not undertaken lightly [30].

Outcome of acromegaly and the disturbance to glucose tolerance

Unless there are cogent reasons against, attempts should be made to normalize GH excess in acromegaly to decrease the morbidity and mortality associated with the disorder [3, 31]. Curative treatment is best defined by a nadir serum GH of less than 2 mU/L upon 75 g oral glucose challenge. Glucose tolerance improves

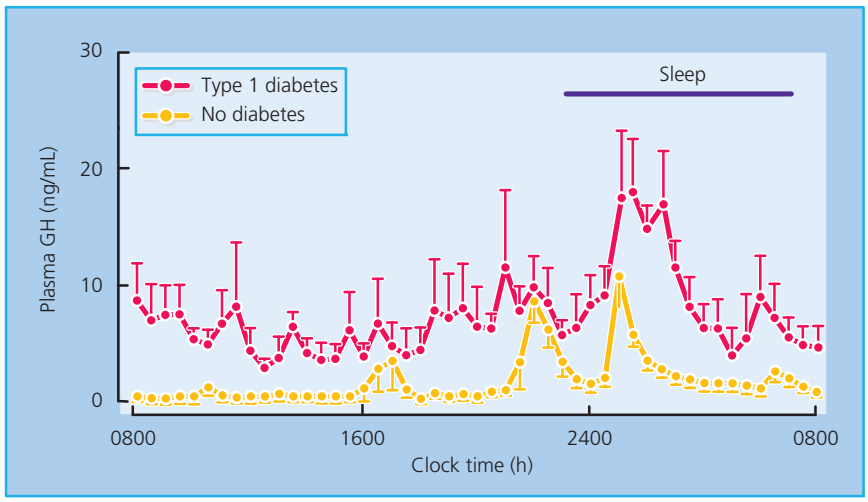

Figure 20.3 Increased growth hormone (GH) secretion in type 1 diabetes. Note the marked hypersecretion during sleep in the early hours of the morning. Source: Hansen et al. 1981 [147]. Reproduced with permission of John Wiley & Sons.

and insulin levels decrease after successful treatment by pituitary surgery and/or irradiation [32, 33]. Hyperglycemia may worsen in a few patients, presumably those with a stronger underlying tendency to T2DM, when GH excess is treated with somatostatin analogs because these drugs suppress insulin secretion [34, 35], similar to the normal effect of somatostatin from the pancreatic islet δ cell upon the adjacent β cell. In the longer term, by virtue of their effect on acromegaly somatostatin analogs tend to improve glucose tolerance [23, 36]. Insulin sensitivity is also improved with pegvisomant therapy in people with both glucose intolerance and diabetes [36–39]. If hyperglycemia persists after serum GH levels have been normalized then the individual should be considered as having T2DM. One caveat to this is the possibility of GH deficiency as part of hypopituitarism post-surgery or radiotherapy [14]. GH deficiency causes centripetal fat deposition, which could itself cause or accentuate insulin resistance and potential loss of euglycemia.

Generally, diabetic complications are rare in acromegaly. Nevertheless, it is worth considering GH action in the context of both macrovascular and microvascular diabetic complications. Untreated GH excess increases cardiovascular morbidity and mortality and, potentially, abnormalities of glucose metabolism occurring in acromegaly could contribute to hypertension which affects over 50% of people with acromegaly [40]. GH has been linked to proliferative diabetic retinopathy ever since resolution of diabetic retinopathy was noted in a woman who developed rapid-onset pan-hypopituitarism [41, 42]; this led to the use of hypophysectomy as a treatment of retinopathy prior to the advent of laser photocoagulation [41]. This view is supported by the observations that people with diabetes who are GH-deficient rarely develop retinopathy [43], and an experimental study in mice demonstrated that inhibition of GH secretion ameliorated diabetic retinopathy [44]. People with diabetes and acromegaly, however, do not show an increased incidence of diabetic retinopathy [45, 46]. Data on the progression of diabetic retinopathy treated with either pegvisomant or somatostatin analogs are contradictory, and the outcome of larger trials are awaited [41].

Effects of diabetes on GH–IGF-I axis

Dysregulation of the GH–IGF-I axis has been well documented in T1DM. The main disturbances include increased GH secretion (Figure 20.3), paradoxically associated with decreased serum IGF-I levels [47]. GH secretory pulses are larger and more frequent and total 24-hour serum and urinary GH levels are elevated. High circulating GH levels are most obvious during periods of poor diabetic control, and return towards normal with improved control. Pulses of GH secretion during sleep in the early hours of the morning lead to insulin resistance, which manifests itself before breakfast and is largely responsible for the "dawn phenomenon" of fasting hyperglycemia [48]. This physiologic effect, along with that caused by exercise and GHRH, is exaggerated in people with T1DM, especially those who have poor glycemic control. GH secretion accounts for much of the decreased insulin sensitivity observed during normal puberty, as well as the deterioration in glycemic control at this time in adolescents with T1DM. Despite GH hypersecretion, levels of IGF-I—the principal mediator of GH activity—are inappropriately low, indicating a state of GH resistance (Figure 20.4). Hepatic resistance to GH has been attributed both to decreased number of GH receptors and to post-receptor defects [47]. Circulating levels of GH-binding protein (GHBP) are also decreased in T1DM. Administration of recombinant human IGF-I (rhIGF-I) as an adjunct to insulin has been demonstrated to reverse GH hypersecretion and improve glycemic control, while reducing insulin requirements. Co-administration of IGF-binding protein 3 (IGFBP-3) with IGF-I has similar beneficial effects on carbohydrate metabolism, and also avoids side effects of IGF-I, notably edema, headache, retinal edema, and jaw pain, as well as reducing the risk of hypoglycemia [49]. Recombinant IGF-I has also been used to treat states of severe insulin resistance in which the insulin receptor is functionally impaired, such as the spectrum from Donohue to Rabson–Mendenhall syndrome (see Chapter 18) [50]. In such individuals, rhIGF-I can be used to treat ketoacidosis, which is the major cause of death and which may fail to respond to massive doses of insulin.

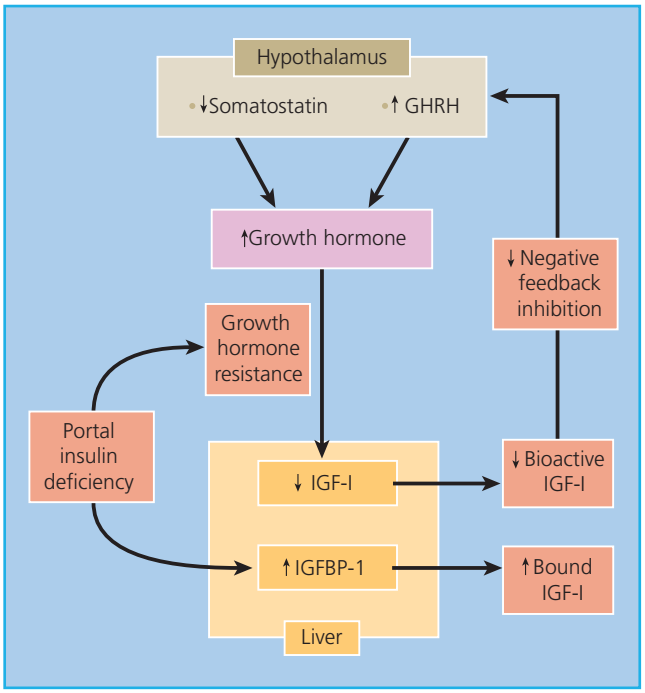

Figure 20.4 Mechanisms of growth hormone (GH) hypersecretion in diabetes. Insulin-like growth factor 1 binding protein 1 (IGFBP-1) binds and reduces the bioavailability of insulin-like growth factor I (IGF-I), which normally decreases GH secretion by negative feedback inhibition on the hypothalamus and pituitary; IGFBP-1 expression is inhibited by insulin.

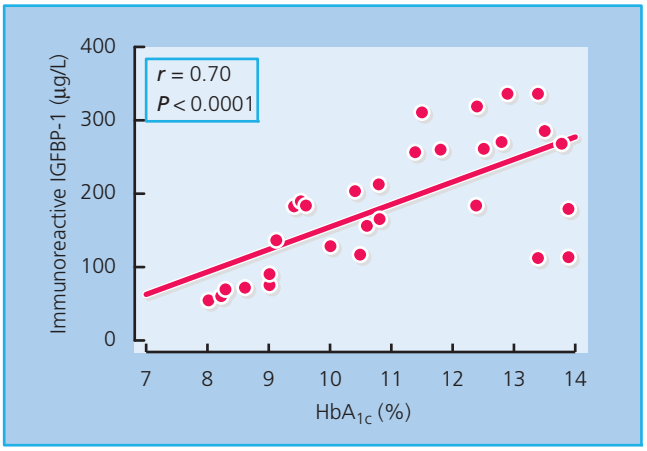

Figure 20.5 Correlation between serum immunoreactive insulin-like growth factor 1 binding protein 1 (IGFBP-1) and glycated hemoglobin (HbA_{1c}) concentrations in 48 people with type 1 diabetes mellitus. Source: Langford and Miell 1993 [148]. Reproduced with permission of John Wiley & Sons.

Abnormalities of IGFBPs may also alter the regulation of the GH–IGF-I axis in diabetes (Figure 20.4). Six IGFBPs have been identified in humans, the two most relevant being IGFBP-1 (molecular weight 25 kDa), whose synthesis by hepatocytes is inhibited by insulin but independently of GH, and IGFBP-3 (molecular weight 44 kDa), which is GH-dependent [51]. IGFBP-1 levels are increased in T1DM as a result of portal and hepatic insulin deficiency (Figure 20.4) [47], and increase with worsening insulin deficiency and rising HbA_{1c} concentrations (Figure 20.5). Increased IGFBP-1 levels have been shown to inhibit IGF-I bioactivity. Portal insulin deficiency in T1DM can thus account for GH resistance, through downregulation of hepatic GH receptors and increased IGFBP-1 levels, both reducing IGF-I production and bioactivity [52]. Decreased IGF-I levels in turn cause GH hypersecretion via reduced negative feedback at the hypothalamus and pituitary, and this exacerbates insulin resistance, thus establishing a vicious circle of raised GH and poor glycemic control (Figures 20.2 and 20.3).

Another consequence of IGF-I deficiency is impaired growth at puberty [52]. Paradoxically, children with new-onset diabetes tend to be taller, especially if the disease develops several years before puberty; increased GH and insulin levels during the preclinical evolution of the disease are a possible explanation. Once diabetes is established, growth may slow, particularly before the age of 10 years and if glycemia is poorly controlled (Figure 20.6). The pubertal growth spurt may be blunted and/or delayed, especially in girls, and this may lead to a reduction in final height [52]. Growth failure in adolescents with T1DM is rare nowadays, possibly because of improved management and monitoring of diabetes. Indeed, intensified insulin treatment has been shown to raise IGF-I levels, in parallel with an increase in growth velocity [52]. Finally, growth failure may be associated with truncal obesity, hepatomegaly (secondary to glycogen and/or triglyceride

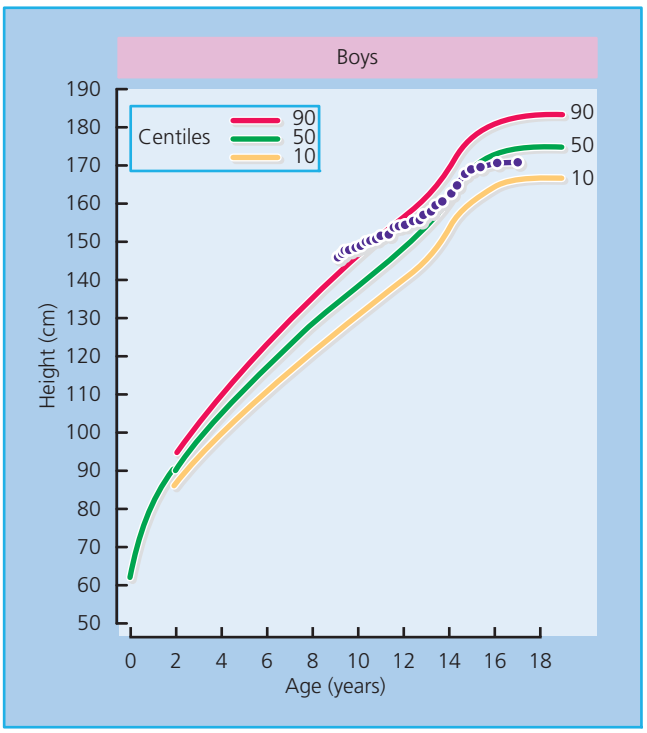

Figure 20.6 Growth failure in a boy with diabetes. Height fell progressively below the centiles (97th centile at diagnosis) and the pubertal growth spurt was delayed, resulting in a lower final height than predicted.

Figure 20.7 Cushing syndrome in a woman presenting with glucose intolerance, hypertension, and altered appearance. The original presentation related to subfertility misattributed as polycystic ovarian syndrome. The cause of the glucocorticoid excess was a small adenoma in the right adrenal gland. Six months following its removal by unilateral adrenalectomy the pronounced changes in physical appearance led to the woman being requested to renew her passport. Blood pressure and glucose homeostasis returned to normal.

deposition) and sexual infantilism in Mauriac syndrome [53]. This condition was reported in children with poor glycemic control and excessively high insulin dosages, but is now rare.

Cushing syndrome

Etiology, incidence, and clinical features of Cushing syndrome

Cushing syndrome comprises a constellation of symptoms and signs caused by excessive levels of glucocorticoid that leads to a characteristic appearance accompanied by metabolic and cardiovascular pathology (Figure 20.7; Table 20.3) [54–56]. It occurs most commonly as a side effect of synthetic glucocorticoids administered for conditions such as rheumatoid arthritis or reversible airways disease. Endogenous Cushing syndrome arises in approximately two-thirds of cases from adrenocorticotropin (ACTH)-secreting corticotroph adenomas of the anterior pituitary which affect 5–10 individuals per million. In one-fifth of cases, the cause is a glucocorticoid-secreting tumor of the adrenal cortex and in one-tenth of cases is secondary to syndromes of ectopic ACTH secretion, most commonly from small cell carcinoma of the lung or, more rarely, carcinoid tumors [54–57]. Cushing syndrome is more common in women than men, with a greater predilection for corticotroph adenomas as the underlying pathology. Prolonged excessive levels of cortisol, the major glucocorticoid in humans, either directly from an adrenocortical tumor or from inappropriate amounts of ACTH causing bilateral hyperfunctional adrenal cortices, cause the characteristic external features of the disorder to develop and results in excess cardiovascular morbidity and mortality (Figure 20.7; Table 20.3) [54–57].

Table 20.3 Clinical features of Cushing syndrome.

Easily bruised, thin skin; poor wound healing
Striae (purple or "violaceous" rather than white)
Thin (osteoporotic) bones that easily fracture
Glucose intolerance/diabetes mellitus
Central obesity, characteristic rounded facies, "buffalo" hump
Susceptibility to infection
Predisposition to gastric ulcer
Hypertension
Disturbance of menstrual cycle; symptoms overlap with PCOS
Mood disturbance (depression, psychosis)

PCOS, polycystic ovarian syndrome.

Disturbance to glucose tolerance in Cushing syndrome

Impairment of glucose tolerance is observed in 30–70% of cases [56, 58, 59]. Overt diabetes occurs in 20–50%, arguably in people predisposed to diabetes (e.g. those with a family history [56, 58, 59]). It resembles T2DM because glucocorticoid excess causes hyperglycemia primarily by inducing insulin resistance, reflected by hyperinsulinemia [58]. Insulin-stimulated glucose uptake and utilization by peripheral tissues are both reduced, while hepatic glucose production is greatly increased through stimulation of gluconeogenesis [56, 60, 61]. This results from the direct activation of hepatic gluconeogenic enzymes such as phosphoenolpyruvate carboxykinase (PEPCK), and an increasing supply of glucogenic substrates (amino acids and glycerol) generated by muscle proteolysis and peripheral adipose tissue lipolysis (Figure 20.8) [61, 62]. Glucocorticoids also have permissive effects on the gluconeogenesis induced by epinephrine (adrenaline) and glucagon. Besides enhancing hepatic gluconeogenesis, glucocorticoids also increase hepatic glycogen storage [62].

With endogenous causes of Cushing syndrome, the hyperglycemia can sometimes be treated effectively with sulfonylureas, but many cases require insulin therapy [61]. For Cushing syndrome caused by exogenous drugs, treatment can be tailored from

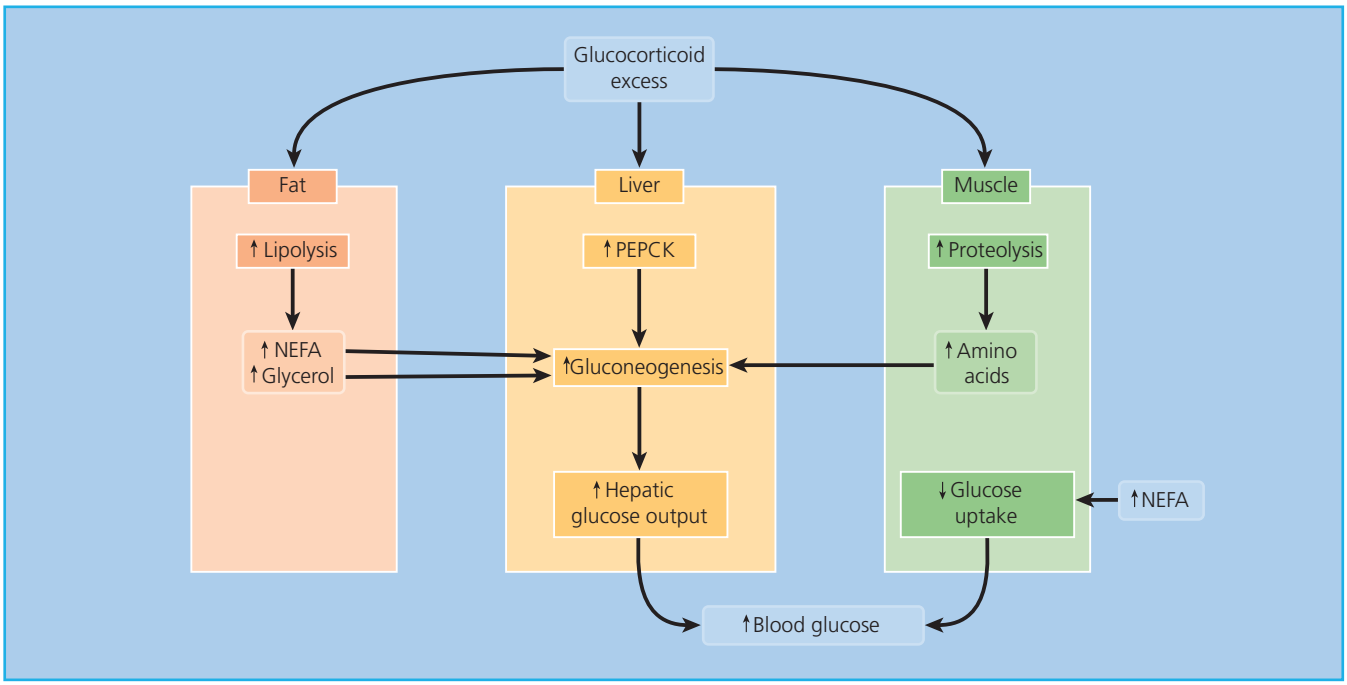

Figure 20.8 Mechanisms of hyperglycemia and diabetes in Cushing syndrome. NEFA, non-esterified fatty acids; PEPCK, phosphoenolpyruvate carboxykinase.

knowledge of the timing and half-life of the glucocorticoid drug as a predictable period of hyperglycemia follows. For instance, prednisolone administered for reversible airways disease at breakfast will generate elevated glucocorticoid levels throughout the remainder of the day with levels falling in the evening. This profile makes the choice of an intermediate-acting insulin administered at breakfast appropriate (see Chapter 19).

Diagnosis and treatment of Cushing syndrome

For exogenously administered glucocorticoids, the diagnosis and treatment of Cushing syndrome are straightforward: wherever possible remove or reduce the offending medication. The major challenge in diagnosing Cushing syndrome resulting from endogenous causes is frequently one of simply considering the condition as the underlying cause of otherwise very common symptoms such as tiredness and weight gain. Avoiding this pitfall is aided by thorough clinical examination when more specific signs may be detected, for instance violaceous stretch marks (called "striae") or proximal myopathy [54–56]. This issue may be particularly pertinent to the diabetes clinic, with some evidence that occult Cushing syndrome may affect up to 2% of people with T2DM [63].

The first goal is to establish the presence of either autonomous secretion or excessive levels of cortisol [54–56]. Several screening tests with high sensitivity have been designed (Table 20.4). Normally, circulating cortisol is relatively high during the day and low at bedtime. Maintained daytime levels at night are abnormal and imply glucocorticoid excess. This can be tested by measuring midnight serum cortisol, although this requires prior acclimatization of inpatients for at least 24 hours and quiet surroundings as cortisol levels rise with minimal stress. Where assays have been validated, bedtime salivary cortisol measurement can now be very useful as patients can post samples to the laboratory from home. Salivary levels are approximately 10% of those in serum and so care must be taken to avoid contamination with blood (e.g. from brushing teeth). The "low dose" dexamethasone suppression tests interrogate the potential loss of physiologic negative feedback at the corticotroph leading to autonomous ACTH secretion. The formal 48-hour test is marginally more specific [54]; however, it is also less convenient to perform in the outpatient setting compared with the overnight 1 mg suppression test. Caution needs to be exercised in patients where dexamethasone metabolism is enhanced (e.g. by antiepileptic medication) as this can lead to false-positive results. In addition, women need to avoid taking the combined oral contraceptive pill for the preceding month or so to avoid elevations in cortisol-binding globulin giving spuriously high total cortisol results. An alternative screening test examines total excretion of cortisol in a 24-hour urine collection, commonly on several occasions, as an integrated assessment of one day's adrenocortical function. It is commonplace for endocrinologists to apply more than one of these various screening tests, which, if failed, provides evidence of glucocorticoid excess and a diagnosis of Cushing syndrome.

Several endocrine tests have been developed to differentiate the various etiologies of endogenous Cushing syndrome (Table 20.4) [54–56]. Undetectable serum ACTH indicates an adrenocortical source of excessive cortisol causing suppression of ACTH secretion by the anterior pituitary. It can be particularly challenging to distinguish between anterior pituitary and ectopic sources of ACTH causing Cushing syndrome. Corticotroph adenomas,

Table 20.4 Diagnosis of Cushing syndrome from endogenous causes.

Test	Interpretation
Screening tests to diagnose Cushing syndrome	
Midnight serum cortisol measurement or bedtime salivary cortisol assay	Maintained daytime levels at night-time indicates autonomous cortisol production of Cushing syndrome
1 mg overnight DST. Oral dexamethasone taken at midnight	Serum cortisol >50 nmol/L at following 9 a.m. consistent with Cushing syndrome
Formal low-dose DST (0.5 mg × 8 doses 6-hourly ending at 3 a.m.)	Serum cortisol >50 nmol/L at following 9 a.m. consistent with Cushing syndrome
24-hour urinary free cortisol measurement	Elevated values support diagnosis of Cushing syndrome
Tests to localize cause of cortisol excess	
Serum ACTH measurement	If suppressed, indicates autonomous adrenocortical overproduction of cortisol (e.g. an adrenocortical adenoma)
If serum ACTH detectable:	
High-dose dexamethasone suppression test (2 mg × 8 doses 6-hourly ending at 3 a.m.)*	>50% suppression of 9 a.m. serum cortisol from pre- to post-test indicates anterior pituitary source; <50% suppression indicates extrapituitary "ectopic" source of ACTH
Bilateral IPSS*	Gradient from IPS to periphery of >2 : 1 supports anterior pituitary source (test can also incorporate CRH administration; see text)
MRI (can include gadolinium enhancement)	Should only be considered once biochemical evidence of pituitary source obtained. Helpful for surgeon in planning transsphenoidal surgery

ACTH, adrenocorticotropic hormone; CRH, corticotropin releasing hormone; DST, dexamethasone suppression test; IPSS, inferior petrosal sinus sampling; MRI, magnetic resonance imaging. *, larger centers commonly tend to progress straight to bilateral IPSS if available and conducted by experienced operators rather than perform high-dose dexamethasone suppression test.

especially intrasellar ones, usually retain a partial capacity for negative feedback. Historically, the "high dose" dexamethasone suppression test, administered as eight 2-mg doses every 6 hours, has exploited this feature with the expectation that cortisol levels reduce pre-test to post-test by at least 50%. As this cause underlies the original description of the disorder by Harvey Cushing in 1912, pituitary-driven glucocorticoid excess is called "Cushing's disease." Extrapituitary tumors secreting ectopic ACTH less commonly display this degree of negative feedback such that ACTH levels and consequently cortisol levels are likely to be higher. Although these tumors may be relatively indolent carcinoids, more commonly they are aggressive carcinomas of the bronchus characterized by a rapid onset of symptoms within a few months, marked hypokalemia, and weight loss. The high level of ACTH also binds to the type 1 melanocortin receptor (MC1R) resulting in skin pigmentation. Clinically, these features are usually obvious. In recent years, the high-dose dexamethasone test has become less prevalent because in settings with appropriate experience and expertise venous sampling of the bilateral inferior petrosal sinuses can distinguish between ectopic or anterior pituitary sources of excessive ACTH with greater sensitivity and specificity. For pituitary sources, a gradient in ACTH levels of at least 2 : 1 (or 3 : 1 after the injection of 100 μg corticotropin-releasing hormone (CRH) intravenously) should be found between central and peripheral samples. However, bilateral inferior petrosal sinus sampling (IPSS) carries the risk of thrombosis in approximately 1% of cases such that some endocrinologists feel the test is not always warranted, especially where preceding biochemical tests have been conclusive and MR imaging shows clear evidence for a tumor. Where biochemistry is supportive of a pituitary source of ACTH excess, but the MR scan is equivocal, even after gadolinium enhancement, IPSS can help to lateralize a corticotroph adenoma by detecting a clear gradient between the right and left sinuses or vice versa. Sources of ectopic ACTH, most commonly in the chest, can be imaged with fine-cut computerized tomography (CT), MRI, or by using isotope-labeled scintigraphy to detect somatostatin receptors present on approximately two-thirds of ectopic ACTH-secreting carcinoid tumors. Autonomous cortisol-secreting tumors of the adrenal cortex can be imaged satisfactorily by CT or MRI when it can be possible to make assessment of functionality according to lipid content. Features of high lipid content imply a tumor with active steroidogenesis.

Wherever possible, curative approaches are undertaken to normalize cortisol secretion as Cushing syndrome carries a high morbidity and markedly increases mortality from cardiovascular causes [54–56, 64]. For adrenocortical sources, unilateral adrenalectomy is performed. For ectopic ACTH-secreting tumors, excision of carcinoids is potentially curative, whereas the natural history of carcinoma of the bronchus with ectopic hormone secretion usually makes palliative care more appropriate. Frontline treatment of corticotroph adenomas is commonly by transsphenoidal surgery. The indications and complications for radiotherapy are largely the same as for those described in the section on acromegaly. The fact that ACTH-secreting adenomas are commonly microadenomas can increase the chances of curative surgery, although this remains heavily operator-dependent. If surgery is delayed, suppressants of adrenocortical steroidogenesis such as ketoconazole or metyrapone can be used temporarily where patients are highly symptomatic and can improve glycemic control [54, 55, 65]. Direct medical therapy against corticotroph adenomas remains suboptimal. Treatment with the somatostatin analog pasireotide takes advantage of the fact that corticotroph adenomas express the somatostatin receptor subtype 5 (in addition to subtypes 1–3). Initial trials demonstrated positive results, with a reduction in urinary free cortisol levels after 12 months of treatment [66]. Approximately three-quarters of patients have

shown a reduction in urinary free cortisol excretion [67]. However, over 70% of patients treated with pasireotide developed glucose intolerance, due to the drug's effects on reducing incretin and insulin secretion [66, 68].

In extremis, bilateral adrenalectomy provides a rapid resolution of excessive cortisol secretion, although the total loss of negative feedback to a corticotroph adenoma can result in dangerous pituitary tumor growth that becomes refractory to further treatment, a scenario called Nelson syndrome. In patients where ACTH levels continue to rise, concomitant radiotherapy to the anterior pituitary can help reduce the risk of this problem arising.

Outcome of Cushing syndrome and the disturbance to glucose tolerance

After successful transsphenoidal surgery, the patient is reliant in the short term on external glucocorticoid administered as oral hydrocortisone. However, a return of cortisol secretion from the adrenal gland(s) can be anticipated over ensuing weeks or months. Commonly, a physiologic return of diurnal rhythm is never achieved postoperatively [69]. For some, the extensiveness of anterior pituitary surgery, or the long-term suppression either of normal corticotrophs (pituitary or ectopic ACTH-secreting tumors) or normal adrenocortical cells (cortisol-secreting tumors) causes a permanent state of hypocortisolism because of inadequacy of the remaining tissue. This can require continued hydrocortisone administration as for those with Addison disease, except that mineralocorticoid replacement should not be required.

With successful treatment of Cushing syndrome (Figure 20.7), glucose intolerance may resolve. In such instances, when the patient might be entirely dependent on replacement doses of hydrocortisone, care needs to be taken not to cause hypoglycemia by continued antidiabetes medication. By contrast, persisting abnormalities are relatively common, most likely associated with persistent visceral obesity and metabolic syndrome [7, 61]. On close analysis in one case series, there was a marked persistence of visceral obesity and glucose intolerance in approximately 60% of those who fulfilled criteria for remission of Cushing syndrome [70].

Effects of diabetes on hypothalamic–anterior pituitary–adrenal cortex axis

Evidence of overactivity of the hypothalamic–pituitary–adrenal (HPA) axis has been reported in children, adolescents, and adults with diabetes, including moderate increases in urinary free cortisol excretion, plasma cortisol and ACTH concentrations [71–74]. These abnormalities have been related to the duration of diabetes [72, 73] and to the presence of diabetic neuropathy [74]. Serum cortisol levels fall as metabolic control improves [75].

The role of 11βHSD1 in diabetes

The similarities between Cushing syndrome and the metabolic syndrome have led researchers into investigating a potential role for the HPA axis and cortisol metabolism in obesity and its metabolic complications. The inactive form of cortisol, cortisone, can be converted back into active cortisol via catalysis by the enzyme 11β-hydroxysteroid dehydrogenase type 1 (11βHSD1), present in the liver as well as peripheral tissues, including adipose tissue [76]. The activity of 11βHSD1 is potentially dysregulated in obese people, with increased activity in adipose tissue and reduced hepatic activity [77]. Whilst circulating cortisol levels are not increased in obese people, the local adipose-generated cortisol may contribute to some metabolic complications of obesity, such as impaired glucose tolerance. In addition, levels of 11βHSD1 seem increased in those with obesity and T2DM [78]. These findings have resulted in 11βHSD1 becoming a potential therapeutic target for diabetes, with pharmacological inhibitors in development [76].

Pheochromocytoma and paraganglioma

Etiology, incidence, and clinical features of pheochromocytoma and paragangliomas

Catecholamine-secreting pheochromocytomas and paragangliomas are tumors arising from the neural crest-derived chromaffin cells of the adrenal medulla (pheochromocytoma, 80–85%) (Figure 20.9) [79, 80] or the paravertebral sympathetic chains in the chest, abdomen, or pelvis (paragangliomas). Approximately, 10% of pheochromocytomas are bilateral. They can secrete epinephrine, norepinephrine, dopamine, or various combinations thereof. Although most pheochromocytomas are sporadic, advances in molecular genetics have demonstrated a hereditary basis underlying approximately one-third of diagnoses, not just in well-known syndromes, such as MEN2, von Recklinghausen neurofibromatosis, and von Hippel–Lindau disease [81]. In fact, there are now at least 10 genes associated with pheochromocytomas and paragangliomas linked to particular tumor phenotypes [79] (Table 20.5). For instance, succinate dehydrogenase subunit B (*SDHB*) and succinate dehydrogenase subunit D (*SDHD*) mutations are more frequent in extra-adrenal tumors [81]. Mutations in *SDHB* are more commonly associated with a malignant phenotype [81]. The risk of malignancy also increases with tumor size [81].

The clinical symptoms of catecholamine-secreting pheochromocytomas and paragangliomas are classically described as a triad: headaches, sweating, and tachycardia [82]. Hypertension is the most common clinical finding and occurs in 80–90% of cases. It can be paroxysmal or sustained, the latter occurring especially in children and in norepinephrine-secreting tumors [83]. Other symptoms may be secondary to the co-secretion of various other peptide hormones such as vasoactive intestinal peptide (VIP), substance P, atrial natriuretic factor, endothelin-1, CRH, and GHRH [84]. The normal adrenal medulla predominantly secretes epinephrine, converted from norepinephrine by methylation. This reaction is governed by the enzyme phenylethanolamine-*N*-methyltransferase (PNMT), the expression of which is dependent on high concentrations of cortisol draining centripetally from the

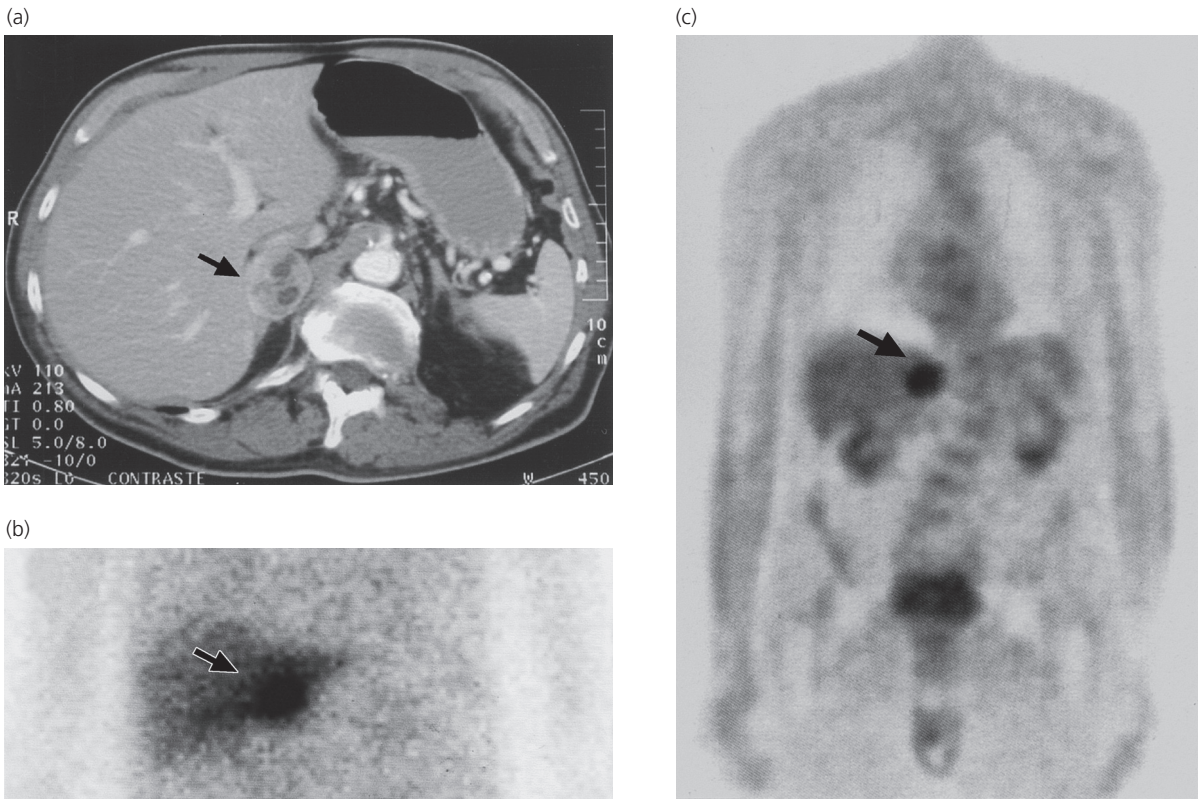

Figure 20.9 Pheochromocytoma in a 75-year-old man with recent-onset type 2 diabetes treated with a sulfonylurea, who was admitted on an emergency basis with severe chest pain and hypertension (blood pressure 240/130 mmHg). Blood glucose on admission was 27 mmol/L. Urinary catecholamine excretion was greatly increased, and a pheochromocytoma of the right adrenal was demonstrated by: (a) computed tomography; (b) scanning with ^{131}I-metaiodobenzylguanidine, which is taken up by catecholamine-synthesizing tissues; and (c) positron emission tomography with ^{18}F-fluorodeoxyglucose. After laparoscopic removal of the tumor, diabetes and hypertension both resolved.

Table 20.5 Genes associated with catecholamine-secreting pheochromocytomas and paragangliomas.

Gene	Germline mutation rate (% detected in all PPGL)	Key characteristics and associations
SDHB	10.3	Extra-adrenal tumors; malignant phenotype
SDHD	8.9	Extra-adrenal tumors; paternal inheritance
SDHC	*1*	Head and neck PGL
SDHA	<2	Extra-adrenal tumors
SDHAF2	*ND*	Head and neck PGL
VHL	7.3	von Hippel-Lindau disease
RET	6.3	Multiple endocrine neoplasia type 2
NF1	*3.3*	Neurofibromatosis type 1
TMEM127	<2	Adrenal tumors
MAX	<2	Malignant phenotype

PPGL, pheochromocytoma and paraganglioma.

outer adrenal cortex towards the adrenal vein [82]. For this reason, larger tumors with more marked disturbance of the normal anatomy or paragangliomas along the sympathetic chain are notable for predominantly secreting norepinephrine as conversion to epinephrine is compromised.

Disturbance to glucose tolerance in pheochromocytomas and paragangliomas

Hyperglycemia occurs in up to approximately 50% of people with pheochromocytomas and paragangliomas, mostly pheochromocytomas. The prevalence of diabetes is approximately 35% [85]. Its presence in a young hypertensive person of normal body weight should raise suspicion of pheochromocytomas and paragangliomas. The predominant mechanism is catecholamine-mediated reduction in insulin sensitivity and insulin secretion, predominantly caused by epinephrine rather than norepinephrine (Figure 20.10) [86–88]. Epinephrine inhibits β-cell insulin secretion via stimulation of α_2-adrenergic receptors [89]. In the liver, epinephrine activates β_2-adrenoceptors to enhance glycogenolysis transiently and gluconeogenesis in a more sustained fashion [90–92]. This hepatic gluconeogenesis is fueled by the precursors,

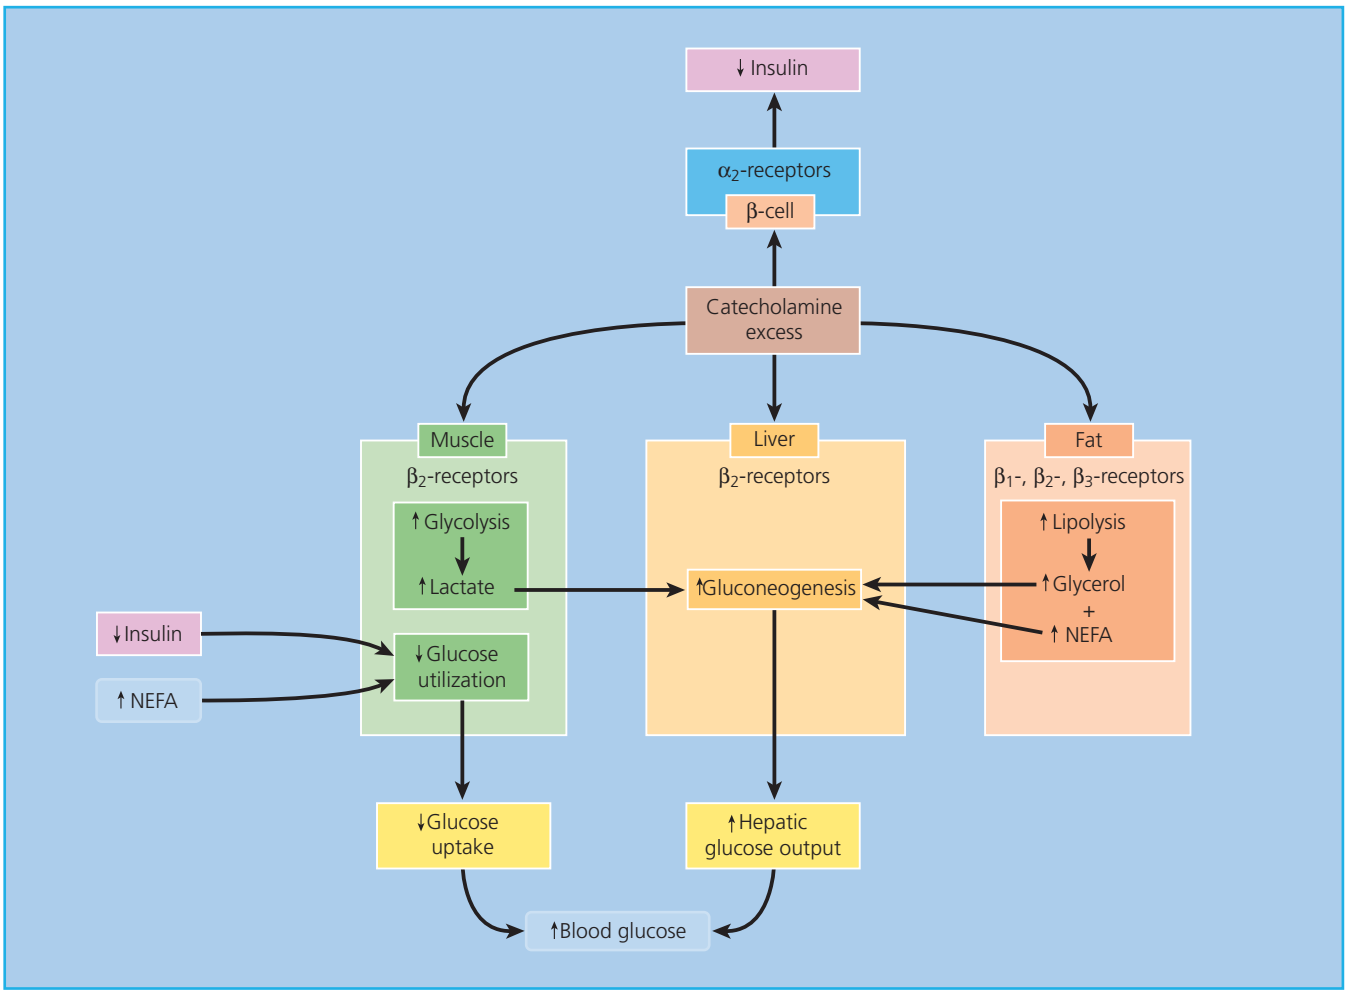

Figure 20.10 Mechanisms of hyperglycemia in pheochromocytoma. NEFA, non-esterified fatty acid.

lactate, alanine, and glycerol, generated by β_2-adrenergic stimulation of muscle glycolysis and adipose tissue lipolysis. Lipolysis in adipose tissue is also stimulated via the β_1- and β_3-adrenoceptors. In addition, epinephrine can impair glucose utilization in muscle through direct β_2-adrenergic effects. The predominance of these β_2-adrenergic effects probably explains why epinephrine, with its higher affinity for β_2-receptors, is more potent than norepinephrine in producing hyperglycemia [90–92]. All these effects are potent mechanisms that raise blood glucose, explaining why epinephrine release is an important component in correcting hypoglycemia after inhibition of insulin and increased glucagon secretion in the hierarchy of counter-regulatory responses (see Chapter 35).

Diagnosis and treatment of pheochromocytomas and paragangliomas

Pheochromocytomas and paragangliomas are diagnosed by demonstrating an excess of circulating catecholamines. This is most accurately achieved by measuring their metabolites, metanephrines, derived by the enzymatic action of catechol-O-methyl transferase in the urine over 24 h and in the plasma [79]. These measures are superior to historical measurement of the metabolite, vanylmandelic acid, and the catecholamines themselves in terms of sensitivity and specificity [79]. Imaging the tumor can be performed by either MRI or CT. Treatment is surgical removal of the tumor as an adrenalectomy, increasingly performed laparoscopically unless malignancy is suspected [79]. Preoperative preparation must be meticulous to prevent both a hypertensive crisis during manipulation of the tumor and cardiovascular collapse after its removal. This is achieved by initial α-receptor blockade, most commonly using the irreversible agent phenoxybenzamine, followed by a beta-blocker if needed. The order of implementation is important to prevent a hypertensive crisis from unopposed α-adrenoceptor stimulation. The preoperative α-adrenergic blockade often controls hypertension, but has less effect on glucose intolerance [90, 93]. In malignant pheochromocytoma where surgery is not possible, adrenolytic drugs, such as mitotane, can be used palliatively.

Outcome of pheochromocytomas and paragangliomas and the disturbance to glucose tolerance

Removal of the tumor corrects the metabolic abnormalities. If presentation, diagnosis, and treatment have occurred without undue delay, it also resolves the hypertension [90, 93–95]. Greater understanding of the molecular genetics of pheochromocytomas and paragangliomas makes clinical genetics input very important which can direct the order of genetic testing, even in seemingly isolated tumors [79, 81]. It is also straightforward to exclude hyperparathyroidism by measuring serum calcium as this simple test, if normal, goes a long way to excluding MEN1. Annual follow-up to exclude recurrent pheochromocytomas and paragangliomas is by measurement of plasma metanephrines. People with pheochromocytomas and paragangliomas due to identified genetic disorders should be followed up at least annually in dedicated services combining the skills of endocrinology and clinical genetics.

Effects of diabetes on adrenal medulla function

Function of the adrenal medulla may be selectively impaired in people with long-standing diabetes and hypoglycemia unawareness; attenuation of the epinephrine response to hypoglycemia can delay the restoration of normal serum glucose levels. Epinephrine responses can remain normal to other stimuli, indicating failure of sympathetic activation at a specific, possibly hypothalamic level (see Chapter 35).

Other endocrine conditions causing disturbance of glucose tolerance

Three tumor types derived from the gastroenteropancreatic endocrine system can cause disturbance of glucose tolerance: glucagonoma, somatostatinoma, and tumors secreting vasoactive intestinal polypeptide (VIPoma). While these tumors are still referred to as "neuroendocrine tumors (NETs)" the term is misleading as their embryological origin is from the gut endoderm; they are not related to neural development.

Glucagonoma

Glucagonoma is a rare tumor of the α cell of the pancreatic islet. The first clear-cut case was reported in 1942, but the "glucagonoma syndrome" (in a series of nine patients with similar symptoms) was not described until 1974 [96, 97]. It may form part of MEN1 caused by mutations in the tumor suppressor gene, *MENIN* [98]. In a series of 21 patients, the syndrome's most striking clinical features were weight loss (71%), necrolytic migratory erythema (67%) (Figure 20.11a), diabetes (38%), cheilosis or stomatitis (29%), and diarrhea (29%) [99]. In this report, patients with the combination of necrolytic migratory erythema and diabetes mellitus were diagnosed more rapidly (after a mean of 7 months), but some cases remain undetected for years. Glucagonoma should be considered particularly in people with diabetes and unexplained weight loss or a chronic blistering skin rash.

Necrolytic migratory erythema (Figure 20.11a) is described in full in Chapter 52. It usually involves the buttocks, groin, thighs, and distal extremities, and characteristically remits and relapses [96, 97]. Hyperglucagonemia may contribute to the rash, as also may hypoaminoacidemia through glucagon's enhancement of amino acid uptake by the liver and zinc deficiency [97]. The glucagonoma syndrome is also characterized by a normochromic normocytic anemia, a tendency to thrombosis (pulmonary embolism is a common cause of death) and neuropsychiatric disturbances [96]. Reporting of the prevalence of diabetes in glucagonoma has been variable but it probably affects approximately three-quarters of individuals [96]. In cohorts with this detection rate, the hyperglycemia has most commonly been mild and may respond to oral antidiabetes agents. In studies with lower rates of diagnosis, 75% of people required insulin [96]. The hyperglycemia is largely brought about by the effects of glucagon on stimulating hepatic gluconeogenesis and, in adequately fed individuals, glycogenolysis [97].

The diagnosis is suggested by finding a pancreatic mass and high fasting plasma glucagon concentration in the absence of other causes of hyperglucagonemia (e.g. severe stress, hepatic and renal failure, poorly controlled diabetes, small-bowel malabsorption, and synthetic androgenic drugs) [96, 97, 100]. Surgical removal of the tumor is the treatment of choice, but 50% of tumors have metastasized to the liver by the time of diagnosis (Figure 20.11b) [99]. Treatment can then be completed by hepatic artery embolization and/or chemotherapy; somatostatin analogs can also suppress glucagon secretion. The rash may respond to normalization of glucagon levels following removal of the tumor or by the use of somatostatin analogs. The administration of zinc, a high-protein diet and control of the diabetes with insulin may also help [96, 97, 99, 100].

Somatostatinoma

Somatostatinomas are extremely rare tumors arising in 1 in 40 million individuals from δ-cells of the pancreatic islet or enteroendocrine cells of the duodenum and ampulla of Vater [101]. They may be sporadic or as part of genetic syndromes, such as MEN1 [101]. The first two somatostatinomas were found incidentally during cholecystectomy [102, 103], but a subsequent case was diagnosed preoperatively and extensively investigated [104]. The diagnosis was suggested by the triad of diabetes, steatorrhea and gallstones, associated with a tumor of the duodenum [104]. These features, together with hypochlorhydria, are attributable to the widespread inhibitory effects of somatostatin on endocrine and exocrine secretions [101]. Consistent with inhibition of both insulin and glucagon by somatostatin, hyperglycemia is mild, non-ketotic and satisfactorily controlled without insulin [104].

Diagnosis is made by clinical presentation, measuring elevated fasting levels of circulating somatostatin and imaging by CT or MRI. Octreotide scintigraphy can also be used to localize

the tumor. Surgical resection is the treatment of choice and can be curative. Where tumors are large and malignant with metastases at the time of diagnosis, debulking, embolization, and chemotherapy (including radiolabeled somatostatin analogs) are appropriate [101].

Vasoactive intestinal peptide-producing tumor (VIPoma)

The first VIP-secreting tumor was recognized by Verner and Morrison in 1958 [105]. Classic features are caused by elevated circulating VIP levels and include watery diarrhea (pancreatic cholera), hypokalemia, and achlorhydria [100, 106]. Hypercalcemia and glucose intolerance occur in half of the patients, but overt diabetes is unusual; hyperglycemia is probably secondary to the glycogenolytic effect of VIP and/or to hypokalemia, which can impair both insulin secretion and insulin sensitivity. Diagnosis is aided by serum assay for fasting VIP levels. The tumors are usually large and have metastasized from the pancreatic tail by the time of diagnosis. Debulking surgery forms the mainstay of treatment and 10-year survival is approximately 40% [106].

Hyperthyroidism

Hyperthyroidism is defined by overproduction of thyroid hormones. Hyperthyroidism leads to thyrotoxicosis, the manifestations of increased circulating thyroid hormones (Table 20.6) [107]. Ignoring the association of autoimmune hyperthyroidism (Graves' disease) with T1DM, thyrotoxicosis per se can disturb glucose tolerance in approximately one-third of individuals, with diabetes occurring in a further 8% of patients [108]. There is evidence for insulin resistance as the primary defect [107, 108], especially in those who are overweight [109], although insulin secretion may also be impaired [108, 110]. Glucose production and expression of the hepatocyte glucose transporter 2 (GLUT-2) protein are enhanced by thyroid hormone excess [111–113]. The insulin resistance is improved with restoration of euthyroidism even if body mass index (BMI) rises [108]. When hyperthyroidism develops in people with insulin-treated diabetes, glucose control deteriorates and insulin requirements increase in approximately half the patients; these changes are reversed following treatment of hyperthyroidism [114]. In addition to these alterations in insulin secretion and

Table 20.6 Clinical features of thyrotoxicosis plus features associated with Graves' disease.

Clinical features of thyrotoxicosis
Weight loss despite full, possibly increased, appetite
Tremor
Heat intolerance and sweating
Agitation and nervousness
Palpitations, shortness of breath/tachycardia ± atrial fibrillation
Glucose intolerance
Amenorrhea/oligomenorrhea and consequent subfertility
Diarrhea
Hair loss
Easy fatigability, muscle weakness and loss of muscle mass
Rapid growth rate and accelerated bone maturation (children)
Specific features associated with Graves' disease
Bruit in a diffuse, firm goiter
Thyroid eye disease, also called Graves' orbitopathy
Pretibial myxedema—thickened skin over the lower tibia
Thyroid acropachy (clubbing of the fingers)
Other autoimmune features (e.g. vitiligo)

action, the response to oral glucose tolerance testing is also altered in hyperthyroidism because of faster intestinal absorption [88].

Hypothyroidism

Hypothyroidism is defined by insufficient production of thyroid hormones. Similar to hyperthyroidism, hypothyroidism (both overt and subclinical) is associated with impaired glucose tolerance. Although the underlying mechanism is less well characterized compared with hyperthyroidism, raised insulin levels suggest insulin resistance as the metabolic disturbance in hypothyroidism [113]. Glucose transport and uptake into myocytes via GLUT-5 transporters is decreased, potentially due to reduced blood flow to muscle tissue [115]. Insulin clearance is also reduced [113]. Together these physiological changes result in increased circulating glucose levels [113].

Primary hyperaldosteronism

Primary hyperaldosteronism was originally described by Conn in 1955 in a patient with hypertension, hypokalemia, and neuromuscular symptoms associated with an adrenocortical adenoma secreting aldosterone [82]. A benign adenoma is the most common primary cause (65%) with bilateral hyperplasia accounting for 30% of cases. A handful of cases are brought about by a genetic recombination event between the genes encoding two closely related steroidogenic enzymes (cytochrome P450 11β-hydroxylase and aldosterone synthase) called familial type 1 hyperaldosteronism or glucocorticoid-remediable hyperaldosteronism. This causes aldosterone secretion under the regulation of ACTH, which is suppressible by glucocorticoids [82]. Although debate is active over the extent to which more subtle normokalemic aldosterone excess causes hypertension, the relevance of primary hyperaldosteronism to glucose tolerance relates largely to the hypokalemia that is part of the classic Conn syndrome. Low serum potassium impairs insulin secretion [94]. Others have questioned whether aldosterone might exert other diabetogenic effects on glucose metabolism, although this remains unclear [116]. Glucose intolerance has been reported in approximately 50% of patients [117]. This is generally mild and overt diabetes is unusual. Defective insulin release has been implicated with delayed or reduced insulin responses following oral glucose challenge. Removal of the adenoma or potassium loading can correct these defects [117].

Primary hyperparathyroidism

Primary hyperparathyroidism is secondary to hypersecretion of parathyroid hormone, usually by a parathyroid adenoma and less commonly by parathyroid hyperplasia [118]. The prevalence of diabetes in primary hyperparathyroidism is approximately threefold higher than in the general population [119–121], with some people requiring insulin therapy. Insulin resistance with hyperinsulinemia is generally held responsible, with raised intracellular calcium limiting cellular glucose uptake [121]. It has been debated whether treatment by parathyroidectomy improves glucose homeostasis; some reports argue that it is beneficial for both diabetes and impaired glucose tolerance [122, 123] while others find less effect [124, 125]. Possibly this relates to duration and severity of the calcium disturbance. With the widespread availability of serum biochemistry, hyperparathyroidism is shifting from a symptomatic disorder to an asymptomatic one where serum calcium tends to be only marginally elevated. In the latter scenario, glucose tolerance appears less affected [126].

Hypopituitarism with growth hormone deficiency

In children, lack of GH increases insulin sensitivity such that young children with GH-deficiency tend to develop fasting and readily provoked hypoglycemia [127, 128]. Using insulin tolerance tests, children with GH-deficiency were more insulin-sensitive than short children with normal GH secretion [127]. This exaggerated insulin sensitivity attenuates with age and puberty, possibly following increased gonadal steroid production [127] and changes in body composition, characterized by increased abdominal fat, such that adults with GH deficiency demonstrate insulin resistance [12]. Given that GH excess is diabetogenic and acute GH administration raises fasting glucose and fasting insulin levels, and reduces insulin sensitivity [14, 17], the value of GH replacement to improve glucose tolerance is likely to be related to whether it can be administered physiologically.

Given this challenge, it is not surprising that the long-term results of GH replacement are somewhat conflicting [12]: a 30-month study showed a deterioration in glucose tolerance and insulin sensitivity despite an increase in lean body tissue and a reduction of fat mass [129]; another study of 6 months' duration found rises in fasting glucose and HbA_{1c} without effects on peripheral or hepatic sensitivity [130]; however, a 5-year trial concluded that GH replacement decreased HbA_{1c} levels [131]. Another study, evaluating the impact of GH therapy in people with GH-deficiency during transition from childhood to adulthood, showed that the beneficial effects of chronic treatment on body

composition did not overcome the direct antagonistic effects on insulin action [132]. Insulin secretion may also deteriorate during GH administration [129]. Thus, the replacement of GH in hypopituitary patients with diabetes is contentious: long-term treatment with GH may improve insulin sensitivity via improvements in body composition; however, such individuals need to be monitored regularly and overtreatment that might lead to the development of diabetes should be avoided [12, 133].

Endocrine disorders that associate with diabetes

Several endocrine disorders are associated with T1DM because of a common etiology and similar pathology (e.g. autoimmune adrenalitis [Addison disease] or autoimmune thyroid disease). Attention for the onset of new autoimmune pathologies is warranted in people with these disorders. In people with T1DM, screening can be justified to exclude hyperthyroidism or hypothyroidism by measuring serum thyroid stimulating hormone (TSH) annually. The development of Addison disease in people with T1DM markedly increases sensitivity to insulin such that unanticipated hypoglycemic reactions occur as dose requirements fall. Even in the absence of diabetes and insulin therapy, Addison disease can cause hypoglycemia, especially in children. Rare conditions resembling T1DM with associated endocrinopathies, such as the autoimmune polyglandular syndromes or POEMS syndrome may occur. Monogenic causes of diabetes that affect other endocrine organs are covered in Chapter 18. Examples (and their respective endocrine disorder) include the various types of hemochromatosis (primary hypogonadism, Chapter 21), Wolfram syndrome (diabetes insipidus) and Kearns–Sayre syndrome (hypoparathyroidism, hypogonadism, and hypopituitarism). Here, polycystic ovarian syndrome (PCOS) is addressed as a complex endocrine disorder that includes insulin resistance. The hormonal alterations in PCOS share relevance with some of the mechanisms underlying glucose homeostasis in pregnancy and obesity, covered in Chapters 61 and 16, respectively.

Polycystic ovarian syndrome

PCOS is defined as clinical or biochemical hyperandrogenism with oligo- or anovulation where other definable causes have been excluded [134–139]. Some definitions incorporate the detection of multiple ovarian cysts into the diagnosis [138, 139], although these occur in approximately half of women with Cushing syndrome and are non-discriminatory (Figure 20.12) [140, 141]. PCOS occurs in 5–10% of women of reproductive age and is characterized primarily by insulin resistance although there is also evidence of β-cell dysfunction [136, 142]. Impaired glucose tolerance and T2DM are present in nearly 40% and 7.5–10%, respectively, of women with PCOS, with the former having a tendency to progress to T2DM and being associated with an approximate threefold higher risk of gestational diabetes [142]. These data are confounded to some degree by the effect of obesity, but the incidence of PCOS remains increased across ethnicities whereas obesity rates vary [136]. Indeed, it can be argued that PCOS in women with normal BMI represents the most severe form of the disorder where genetic screening programs are most likely to identify PCOS susceptibility genes.

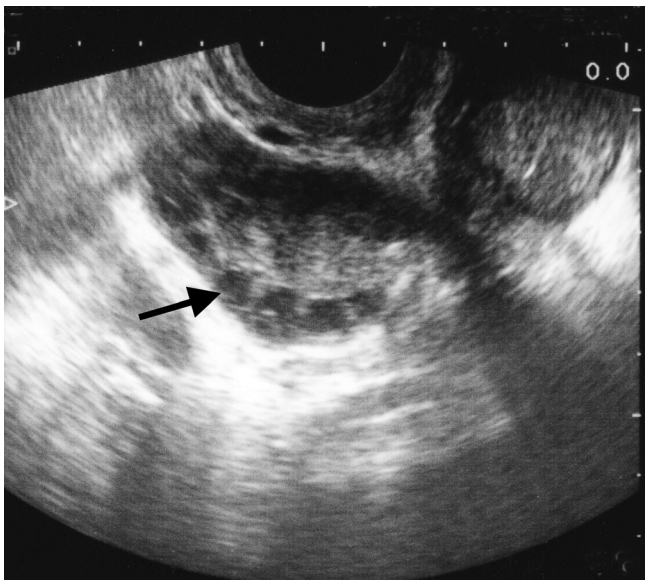

Figure 20.12 Polycystic ovary syndrome, showing characteristic ultrasonographic appearance of large, mainly peripheral cysts (arrow).

The source of the androgens is both the adrenal cortex and the ovary [143]. The raised insulin levels can stimulate androgen production by the ovary and interfere with other aspects of ovarian function. Within the adrenal cortex, where insulin receptors are expressed in the zona fasciculata of the adrenal cortex [144], there is some evidence that insulin can influence glucocorticoid versus sex steroid precursor production [143].

The diagnosis of PCOS is one of exclusion, meaning that clinical and biochemical findings are only supportive of the condition [145]. Serum estradiol is detectable and usually >200 pmol/L. Endocrine abnormalities include increases in serum luteinizing hormone (LH) leading to a raised LH : FSH (follicle stimulating hormone) ratio, androstenedione and testosterone concentrations. Serum sex hormone-binding globulin (SHBG) levels are commonly low. Ovarian ultrasound is useful to help exclude the presence of a tumor underlying the androgen excess [145].

Further evidence that the condition is caused by insulin resistance comes from its amelioration with exercise and agents that improve insulin sensitivity such as metformin or thiazolidinediones [146]. As well as lowering blood glucose, these agents improve menstrual regularity and increase the chance of ovulatory cycles [146].

21 Pancreatic Diseases and Diabetes

Ranjit Unnikrishnan and Viswanathan Mohan
Dr. Mohan's Diabetes Specialities Centre, Madras Diabetes Research Foundation, WHO Collaborating Centre for Non Communicable Diseases Prevention and Control, Chennai, India

Key points

- Pancreatic disease is a rare cause of diabetes.
- Acute pancreatitis is associated with transient hyperglycemia which rarely persists.
- Chronic pancreatitis secondary to any cause can lead to permanent diabetes which is typically difficult to control; imaging studies reveal dilated ducts and pancreatic calculi.
- Tropical calcific pancreatitis is a disease of unknown etiology found in low- and middle-income countries associated with large pancreatic calculi and diabetes (fibrocalculous pancreatic diabetes).
- Hereditary hemochromatosis is an inherited disorder that produces diabetes secondary to iron deposition in the pancreatic islets and subsequent islet cell damage.
- Pancreatic carcinoma may complicate type 2 diabetes, diabetes secondary to chronic pancreatitis and, most commonly, fibrocalculous pancreatic diabetes. It is important to suspect malignancy in any patient who complains of back pain, jaundice, or weight loss in spite of good glycemic control.
- Pancreatic surgery can lead to diabetes that is insulin-requiring and often difficult to control.
- Cystic fibrosis is a relatively common genetic disorder affecting the lung, pancreas, and other organs. Up to 75% of adults with cystic fibrosis have some degree of glucose intolerance.

Introduction

The pancreas plays an important role in carbohydrate metabolism and is a key player in the pathophysiology of different types of diabetes. It is therefore surprising that pancreatic disease is a rare cause of diabetes, accounting for less than 0.5% of all cases of diabetes. The prevalence of undiagnosed disease, however, may be much higher [1]. The rarity of diabetes in pancreatic disease may be explained, in part, by the presence of considerable β-cell reserve in most individuals. It has been estimated that nearly 80–90% of the pancreas has to be destroyed or removed for diabetes to develop in otherwise healthy individuals.

A number of disease processes affecting the pancreas can lead to diabetes; some of these are listed in Table 21.1. Most of these conditions damage the exocrine as well as endocrine components of the pancreas. The exocrine parenchyma and islet tissue lie in intimate contact with each other and are functionally related. This may explain why parenchymal disease can impair β-cell function [2].

Acute pancreatitis

Acute pancreatitis varies considerably in its impact on the gland and its metabolism. Pathologic findings vary from mild edema to hemorrhagic necrosis, and the clinical presentation spans a wide spectrum from mild to fulminating or fatal illness.

The most common causes of acute pancreatitis are alcoholism and gallstone disease. Table 21.2 sets out the causes of acute pancreatitis. It is of interest that diabetes, in itself, is a risk factor for acute pancreatitis, and that use of certain classes of oral antidiabetes agents (particularly the glucagon-like peptide-1 receptor agonists and the dipeptidyl peptidase-4 inhibitors) has been reported to be associated with acute pancreatitis [3, 4]. A recent review by the U.S. Food and Drug Administration and the European Medicines Agency has concluded. However, that the currently available data do not support a causal relationship between incretin-based drugs and pancreatitis [5].

Classically, the disease presents with sudden onset of epigastric pain, associated with nausea and vomiting, aggravated by

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

Table 21.1 Pancreatic diseases associated with glucose intolerance and diabetes.

Inflammatory
Acute
Chronic, including fibrocalculous pancreatic diabetes
Infiltration
Hereditary hemochromatosis
Secondary hemochromatosis
Very rare causes: sarcoidosis, amyloidosis, cystinosis
Neoplasia
Adenocarcinoma of the pancreas
Glucagonoma
Surgical resection or trauma
Cystic fibrosis

food and partially relieved by sitting up and leaning forward. Physical examination reveals low-grade fever, tachycardia, and hypotension. Jaundice may also be found infrequently. Cullen sign (periumbilical discoloration) and Grey Turner sign (flank discoloration) indicate severe necrotizing pancreatitis.

Commonly found metabolic abnormalities include hyperglycemia, hypocalcemia, hyperlipidemia, hypoalbuminemia, and coagulation disorders [6]. Serum levels of amylase and lipase are elevated, but these are neither sensitive nor specific. Computed tomography (CT) or magnetic resonance imaging (MRI) shows edema of the pancreas. Loss of the normal enhancement on dynamic CT scanning indicates pancreatic necrosis.

Most patients with acute pancreatitis develop transient hyperglycemia, which mostly results from a rise in glucagon levels rather than from β-cell injury [7]. Hyperglycemia is usually mild and resolves within days to weeks without needing insulin treatment. Permanent diabetes is rare and occurs mostly in cases with fulminant disease and multiorgan failure, in whom the incidence approaches 25% [8]. Blood glucose levels exceeding 11.1 mmol/L (200 mg/dL) during the first 24 hours indicate a poor prognosis [9].

Non-specific elevations of serum amylase and lipase may also be found in diabetic ketoacidosis [10]. Acute pancreatitis, however, may affect up to 11% of patients with ketoacidosis, usually with mild or even no abdominal pain [9].

Chronic pancreatitis

This condition is characterized by progressive and irreversible destruction of the exocrine pancreatic tissue, leading to exocrine pancreatic insufficiency and varying degrees of glucose intolerance which often require insulin. The causes of chronic pancreatitis vary according to the geographic location (Table 21.3).

Alcohol abuse accounts for most of the cases (>85%) in European and North American populations. Alcohol alters the composition of pancreatic secretions, leading to the formation of proteinaceous plugs that block the ducts and act as foci for calculi formation. Tropical chronic pancreatitis is a distinct form of the disease that is not associated with excessive alcohol intake and is prevalent in low- and middle-income countries [11].

Hereditary chronic pancreatitis is a rare entity, inherited in an autosomal dominant fashion. Mutations in a number of genes have been implicated including *PRSS1* (encoding cationic trypsinogen), *SPINK1* (serine protease inhibitor, Kazal type 1), and *CFTR* (cystic fibrosis transmembrane conductance regulator) [12–15].

Obstructive chronic pancreatitis is a rare condition that follows occlusion of pancreatic ducts by tumors, scarring, pseudocysts, or congenital anomalies. Stones are not seen. Surgery or endoscopic dilatation may occasionally be curative.

Idiopathic pancreatitis, which accounts for 10–20% of all cases, affects two distinct age groups, one with onset at 15–25 years and the other at 55–65 years [16]. Cigarette smoking is a risk factor and mutations in specific genes have also been postulated [15, 17, 18].

Common (90% of cases)	Rare
Alcohol abuse	Hereditary relapsing pancreatitis
Idiopathic	Obstructive chronic pancreatitis
Tropical chronic pancreatitis	

Epidemiology

Chronic pancreatitis is prevalent worldwide. In Europe and North America, the incidence is about four cases per year per 100,000 population [19, 20]. Tropical chronic pancreatitis is confined to tropical and subtropical regions of the world, with the highest prevalence rates reported in southern India.

Pathologic features

The term chronic calcific pancreatitis accurately describes the pathologic changes in over 95% of cases of chronic pancreatitis in European and North American countries. The ductal and acinar lumina are filled with proteinaceous plugs which later calcify, forming small stones composed chiefly of calcium carbonate or calcite. Huge stones can occur but these are more characteristic of tropical pancreatitis. The stones are found diffusely throughout the affected organ. Microscopically, there is atrophy of the ductal epithelium and stenosis of the ducts, associated with patchy fibrosis. There may also be foci of necrosis, with infiltration by lymphocytes, plasma cells, and histiocytes [21]. Ultimately, the pancreas shrivels and develops an opaque capsule that may adhere to surrounding organs.

As fibrosis progresses, the acini atrophy and eventually disappear, leaving clusters of islets surrounded by sclerosed parenchyma. Neoformation of islet cells from ductal tissue can occur (nesidioblastosis) (Figure 21.1). Immunohistochemistry studies reveal generalized decrease in the number of islets, accompanied by overall reduction in β-cell density and insulin immunoreactivity which correspond to disease duration and C-peptide levels (Figure 21.2; Table 21.4) [22, 23].

Clinical features and diagnosis

Abdominal pain is the predominant symptom and the usual reason for seeking medical care. The pain is usually steady, boring and agonizing, and located in the epigastrium or left hypochondrium with radiation to the dorsal spine or the left

Table 21.4 Islet cell changes in chronic pancreatitis [28].

Cell type	Changes observed
β cells	Decreased numbers (40% below controls)
α cells	Increased numbers
β-cell : α-cell ratio	0.6–2.5 (controls, 3.0–3.5)
PP cells	Increased numbers
δ (D) cells	Unchanged

shoulder. Bending forward or assuming the knee–chest position relieves the pain. The cause of the pain is unknown, but may relate to increased intrapancreatic or intraductal pressure, or to ischemia of the pancreas. It tends to remit and relapse and follows an unpredictable course. The development of end-stage pancreatic disease is associated with disappearance of the pain in many cases.

Exocrine pancreatic insufficiency may manifest with steatorrhea and features of fat-soluble vitamin deficiency, although steatorrhea may not be apparent on a low-fat diet. The combination of oily and greasy stools with diabetes should raise the suspicion of chronic pancreatitis.

Investigations

Demonstration of pancreatic calculi on a plain X-ray of the abdomen is diagnostic (Figure 21.3). In cases where obvious calculi cannot be found, ultrasonography, CT scanning or endoscopic retrograde cholangiopancreatography (ERCP) will help to confirm the diagnosis. ERCP is considered the gold standard and usually reveals irregular dilatation of the pancreatic ducts with filling defects caused by stones (Figure 21.4). CT scanning shows patchy increases in parenchymal density and, ultimately, atrophy of the gland.

Exocrine pancreatic function can be assessed by measuring the urinary excretion of compounds that are liberated in the gut by pancreatic enzyme action on orally ingested precursors such as NBT-PABA (para-aminobenzoic acid) or fluorescein dilaurate (pancreolauryl). Screening tests of pancreatic enzymes (fecal chymotrypsin, fecal elastase) are also used as they are simpler to perform but are less specific. Measurement of pancreatic output (via a tube placed in the duodenum) following ingestion of the Lundh test meal may also be helpful. Serum amylase is usually normal, except during acute attacks.

Diabetes in chronic pancreatitis

Abnormal glucose tolerance and diabetes complicate around 40–50% of cases of chronic pancreatitis. Unlike acute pancreatitis, the cause here is damage to the β cells, owing to loss of trophic signals from the exocrine tissue [2, 24]. The diabetes is of insidious onset and usually occurs several years after the onset of pain. The prevalence has been assessed at 60% after 20 years [25]. Half or more of patients require insulin for optimal glycemic control [26, 27], but ketoacidosis is rare, even if insulin is withdrawn. Possible explanations include better preservation of β-cell function (compared with type 1 diabetes [T1DM]) [28], reduced glucagon secretion and lower body stores of triglyceride, the major substrate for ketogenesis [28, 29]. On account of the lower glucagon reserve, these people are also prone to severe and prolonged hypoglycemia, and often diabetes is difficult to control with wide fluctuations of blood glucose levels.

Chronic diabetic complications

It was originally thought that people with pancreatic diabetes were not at increased risk of microvascular complications; however, it has now been shown that retinopathy [30], nephropathy [31], and neuropathy [32] occur in these individuals at frequencies similar to those with type 2 diabetes (T2DM). The risks of macrovascular complications, however, are relatively low. This may partly be explained by the favorable blood lipid profile that often accompanies the malnutrition commonly seen in these people [33].

Management of diabetes in chronic pancreatitis

Removal of obvious causes, such as alcohol and hypertriglyceridemia, will help to prevent progression of the damage to the gland.

Pain can be very difficult to manage. Measures include total abstinence from alcohol, dietary modification (small frequent

meals with low fat content), analgesics, and the somatostatin analog, octreotide, which suppresses pancreatic exocrine secretion. In a subgroup of patients, massive doses of non-enteric-coated preparations of pancreatic enzymes have been shown to reduce pain. Surgical interventions include sphincterotomy, internal drainage of pancreatic cysts, endoscopic removal of calculi (via ERCP), insertion of duct stents, and denervation procedures. Total resection of the pancreas followed by whole pancreas or islet cell transplantation may be an option for intractable cases.

Malabsorption can be effectively treated with a low-fat diet with pancreatic enzyme supplements (along with histamine H_2 blocker or proton pump inhibitor to block gastric acid secretion) taken at meal times.

Diabetes can be managed along conventional lines, with a few caveats. High carbohydrate and protein intakes are encouraged along with fat restriction in order to prevent steatorrhea whilst preventing weight loss. Over 80% of patients require insulin; however, the required doses are typically low, around 30–40 units/day [26, 27]. Diabetic control is often difficult to achieve, with frequent and severe hypoglycemia; reduced glucagon secretion may be responsible.

It is of interest that individuals with T2DM also exhibit evidence of reduced exocrine pancreatic function, albeit not to the

degree found in "pancreatic" diabetes. In a study from India, it was found that the prevalence of exocrine pancreatic insufficiency (measured by the fecal chymotrypsin assay) was 4.5% in T2DM, as compared to 87.5% and 23.5% in fibrocalculous pancreatic diabetes and T1DM, respectively [34]. Pancreatic insufficiency has been postulated to occur as a result of loss of trophic action of insulin on the exocrine tissue; however, some authors also contend that autonomic neuropathy affecting the enteropancreatic reflexes plays a role in the pathogenesis [35]. However, routine screening of people with T2DM for exocrine pancreatic insufficiency in the absence of symptoms is not recommended.

Tropical chronic pancreatitis

This is a distinct variety of chronic pancreatitis seen predominantly in low- and middle-income countries in the tropical and subtropical regions of the world [36, 37]. This entity was first reported in 1959 by Zuidema [37] in people from Indonesia but the disease was subsequently reported in several countries in Africa and Asia. The highest prevalence appears to be in southern India, particularly in the states of Kerala and Tamil Nadu [38]; however, the prevalence seems to be declining even in these areas.

The disease usually starts in childhood with recurrent abdominal pain and during adolescence progresses to large pancreatic calculi and ductal dilatation (Figures 21.3 and 21.5). By adulthood, frank diabetes is found in more than 90% of patients [39]. Nevertheless, it remains a rare cause of diabetes, constituting less than 1% of all cases of diabetes even in regions where it is most prevalent [40]. A recent study in urban southern India reported a prevalence of 0.36% among people with self-reported diabetes and 0.019% among the general population [41].

The term "tropical chronic pancreatitis" is used to denote the prediabetes stage of the disease whereas the term fibrocalculous pancreatic diabetes is used to describe the clinical picture once diabetes has supervened (Figure 21.6).

The etiology of this condition remains unknown. Poor nutrition has been implicated as a possible factor; however, this may be the consequence rather than a cause of the pancreatopathy. The condition can also affect well-nourished individuals [42]. In the past, attention was also focused on the role of dietary toxins such as cyanogens (found in cassava), but this link has not been substantiated. Cases have been found to cluster in families, which may suggest a genetic etiology for the disease [43–46]. A number of studies have reported an association between the *SPINK1* gene and tropical chronic pancreatitis [47–53]. A role has also been suggested for oxidant stress and free radical-mediated injury but this has not been proven conclusively [54].

Figure 21.5 Calcite stones of various sizes removed from the pancreas of a person with fibrocalculous pancreatic diabetes.

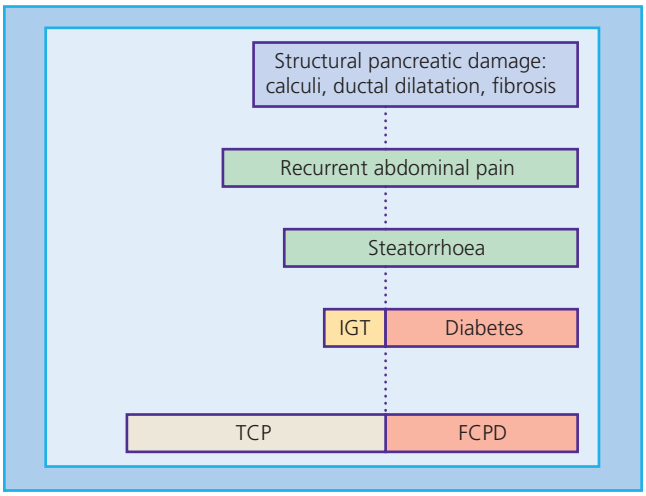

Figure 21.6 Natural history of tropical calcific pancreatitis (TCP) and fibrocalculous pancreatic diabetes (FCPD). IGT: impaired glucose tolerance.

Salient differences between alcoholic chronic pancreatitis and tropical chronic pancreatitis are summarized in Table 21.5. The classic clinical triad of tropical chronic pancreatitis consists of abdominal pain, steatorrhea, and eventually diabetes. The disease often progresses steadily from euglycemia through impaired glucose tolerance to frank diabetes. Most patients require insulin but

Table 21.5 Differences between tropical chronic pancreatitis and alcoholic chronic pancreatitis.

	Tropical chronic pancreatitis	Alcoholic chronic pancreatitis
Demographic features		
Male : female	70 : 30	90 : 10
Peak age at onset (years)	20–30	30–50
Socioeconomic status	Poor > affluent	All groups
Alcohol abuse	Absent	Present
Pancreatic morphology		
Prevalence of calculi	>90%	50–60%
Features of calculi	Large; in large ducts	Small, speckled; in small ducts
Ductal dilatation	Usually marked	Usually moderate
Fibrosis	Heavy	Variable
Risk of pancreatic cancer	Markedly increased	Increased
Diabetes		
Prevalence	>90%	50%
Time course	Faster evolution	Slower evolution

are generally not prone to ketosis; some can be managed with oral antidiabetes agents (Figure 21.7). Studies have shown that the risk of developing pancreatic carcinoma in tropical chronic pancreatitis is 100-fold greater than in those without the disease and is much higher than in other forms of chronic pancreatitis [55]. Pancreatic malignancy should be suspected in individuals with tropical chronic pancreatitis if they complain of intractable pain or significant weight loss even after attaining good glycemic control.

Management of tropical chronic pancreatitis and fibrocalculous pancreatic diabetes is similar to that outlined for chronic pancreatitis.

Hereditary hemochromatosis

This condition, also called idiopathic or primary hemochromatosis, is the most common autosomal recessive genetic disorder in people of Northern European ancestry, with a prevalence of 4–5 per 1000 [56, 57]. The classic triad of diabetes, cirrhosis, and bronzed hyperpigmentation of the skin was first described by Trousseau in 1865 and called "hemochromatosis" by von Recklinghausen in 1889 [58].

Etiology and pathology

Genetic basis

Most cases of primary hemochromatosis arise from mutations in the hemochromatosis gene (*HFE*), located on the short arm of chromosome 6, close to the major histocompatibility complex (MHC), which explains the linkage with HLA A3 [59]. The HFE protein encoded by this gene is expressed on the cell surface of various tissues, including the enterocytes of the duodenal brush border, where iron is chiefly absorbed. The *HFE* gene modulates iron absorption by binding to the transferrin receptor. In two-thirds of cases, a C282Y mutation (substitution of cysteine by tyrosine at position 282) in the *HFE* gene is responsible [56]. Another mutation, H63D, seems to act synergistically with C282Y [60]. These mutations inhibit the binding of HFE to transferrin, leading to an excessive and inappropriate increase in intestinal iron absorption and greatly increased body iron stores. Non-*HFE* mutations are also rarely found to be responsible in some cases.

Pathophysiology

The primary defect is excessive iron absorption across the mucosa of the proximal small intestine, which continues even in the setting of greatly increased total body iron stores (often 15–20 g: cf. normal adult iron stores of 1–2 g). Excess iron is deposited preferentially in the liver, pancreas (exocrine tissue as well as islets), pituitary, heart, and parathyroids (Figure 21.8). Tissue injury is postulated to occur as a result of rupture of iron-laden lysosomes, generation of free radicals (by decomposition of hydrogen peroxide catalyzed by the ferrous and ferric ions—the Fenton reaction) and by the stimulation of collagen synthesis by activated stellate cells.

Clinical features

The classic clinical features are hepatic cirrhosis, diabetes, and skin hyperpigmentation ("bronzed diabetes") (Figure 21.9). Hepatic fibrosis and cirrhosis usually only develop in those aged over 40 years, unless other factors such as alcoholism are present. Portal hypertension, hepatic failure, and hepatocellular carcinoma (in 15% of cases) are late sequelae [61]. Bronzing of the skin, which occurs in 70% of cases but may be less evident in darker-skinned races, is caused by both iron deposition in the subcutaneous tissue and increased melanin in the basal dermis. Hypopituitarism, hypogonadism, hypoparathyroidism, and chondrocalcinosis with pseudogout are less common features.

Presenting symptoms include weakness, weight loss, diabetic symptoms, arthralgia, erectile dysfunction, and skin pigmentation. Signs include hepatosplenomegaly, heart failure, skin pigmentation, testicular atrophy, arthropathy, hypogonadism, and occasionally hypothyroidism. Many people with hemochromatosis, however, are asymptomatic and may be detected during investigation for unrelated reasons or through genetic screening of family members of those with hemochromatosis.

Diabetes in primary hemochromatosis

The prevalence of diabetes depends on the severity of iron overload and presence of cirrhosis [62]. Up to 50% of patients have glucose intolerance and 25% have overt diabetes [63], although the disease is an extremely rare cause of diabetes in the general population. The prevalence is steadily declining as the diagnosis is being made earlier, before significant pancreatic damage has occurred. Both insulin resistance and β-cell failure contribute to the development of diabetes, and most people eventually require insulin. These individuals are prone to both microvascular and macrovascular complications [64], the risk of nephropathy being particularly high in those carrying the H63D mutation [65].

Investigations and diagnosis

The diagnosis should be suspected in any person with diabetes, hepatomegaly or liver disease, skin pigmentation, arthritis, and hypogonadism. A high index of suspicion is required to make an early diagnosis, because significant iron overload can exist with few or none of these clinical manifestations.

The total-body iron stores can be assessed using measurement of serum ferritin and percent saturation of transferrin. Serum ferritin is a useful screening test for relatives of affected individuals, but because ferritin is an acute phase reactant, the levels of which can be elevated in inflammatory states, abnormally high results should be confirmed by other tests (Table 21.6) [66]. Serum iron and percent saturation of transferrin are elevated early in the

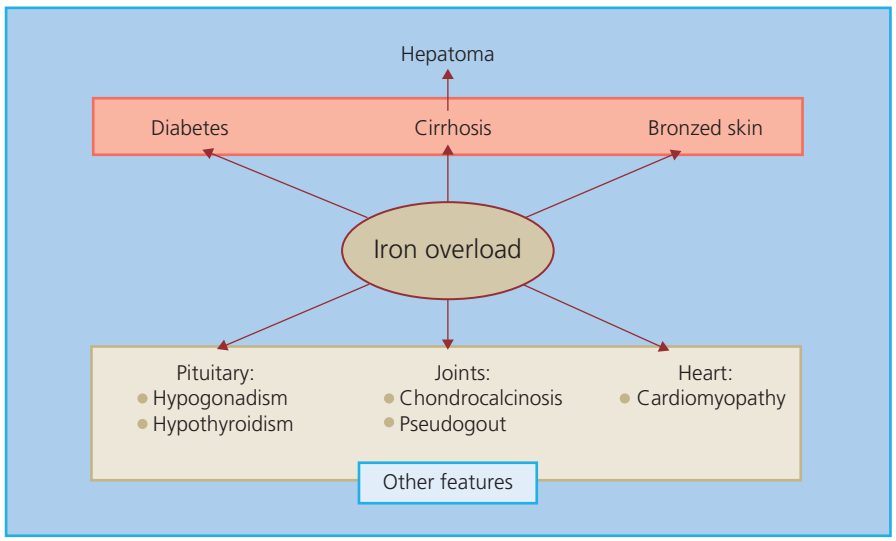

Figure 21.9 Clinical features of hereditary hemochromatosis. The classic triad comprises diabetes, cirrhosis, and hyperpigmentation of the skin ("bronzed diabetes").

Table 21.6 Diagnostic tests in hereditary hemochromatosis [63].

	Hemochromatosis	Normal
Serum iron (μg/dL)	180–300	50–150
Transferrin saturation (%)	80–100	20–50
Total iron-binding capacity (μg/dL)	200–300	250–370
Serum ferritin (μg/dL)		
Men	500–6000	20–300
Women	500–6000	15–250
Hepatic iron concentration (μg/g dry weight)	10,000–30,000	300–1800

course of the disease, but lack specificity. A combined measurement of the percent transferrin saturation and serum ferritin levels provide a simple and reliable screening test for hemochromatosis. A positive test mandates genetic testing.

The role of liver biopsy in diagnosis and management of hemochromatosis has significantly diminished following the development of genetic testing for the C282Y mutation. The major role of liver biopsy at the present time is in excluding the presence of cirrhosis, which is a major risk factor in the development of hepatocellular carcinoma. Hepatic iron overload can also be detected using imaging techniques such as CT or MRI scanning.

All first-degree adult relatives of individuals with hemochromatosis should be tested for C282Y and H63D mutations, in an attempt to detect disease in the early precirrhotic phase at which stage treatment can prevent further progression.

Treatment

Treatment of hereditary hemochromatosis is by repeated venesection, which must be started as early as possible. Removal of excess iron by venesection prevents diabetes and cirrhosis and prolongs survival [61]. Chelating agents such as desferrioxamine are more expensive, less safe, and less effective than venesection. Diabetes may be improved by venesection, but usually requires insulin treatment. Management is often complicated by hypoglycemia caused by concomitant α-cell damage and glucagon deficiency. Hepatic transplantation for hereditary hemochromatosis was previously associated with a poor prognosis, but survival rates have improved of late. Diabetes tends to worsen after transplantation because of the use of immunosuppressant drugs [67]. Hepatocellular carcinoma is a late complication and may be an indication for transplantation if the disease remains localized.

Secondary hemochromatosis

Iron overload can also occur as a consequence of repeated blood transfusion and disorders of erythropoiesis such as thalassemia and sickle cell anemia, in which case the condition is termed secondary hemochromatosis or hemosiderosis. Pancreatic damage and diabetes frequently result. The duration of disease and number of transfusions correlate well with the degree of glucose intolerance. It has been postulated that iron overload may induce an autoimmune attack against the β cells, thereby contributing to development of diabetes [68].

Pancreatic neoplasia

Adenocarcinoma of the pancreas is the fifth most common cause of cancer death and is increasing in its incidence [69]. It has a poor prognosis, with a 5-year survival rate of less than 3%.

Although diabetes has long been associated with pancreatic adenocarcinoma, the nature and strength of the association remain controversial. A meta-analysis of 20 epidemiologic studies showed a twofold increased risk of pancreatic cancer among people with diabetes of more than 5 years' duration [70], suggesting that diabetes is a risk factor for the neoplasm. Other studies, however, have concluded that the cancer preceded and caused the diabetes [71], a view supported by observations that diabetes may improve after resection of the tumor. Some studies have even suggested that diabetes protects against pancreatic cancer [72]. Tropical chronic pancreatitis is associated with a 100-fold increase in the risk of developing pancreatic carcinoma [56]. The association of incretin-based therapies with pancreatic carcinoma remains controversial [73, 74]; the U.S. Food and Drug Administration and the European Medicines Agency have recently concluded in a review that assertions regarding a causal association between incretin-based diabetes therapies and pancreatitis or pancreatic cancer are inconsistent with the current data [5].

The diagnosis of pancreatic carcinoma must be suspected in any person with T2DM who complains of unexplained weight loss (despite insulin therapy and apparently good control of diabetes), back pain, or jaundice.

Pancreatic surgery and diabetes

Diabetes is a frequent complication of pancreatic resection performed for various indications. The incidence and severity of diabetes depends on the extent of resection of the distal segment, where the islets are most abundant. In one study, diabetes developed in 56% of cases following distal resection [75].

Diabetes is more likely to follow subtotal pancreatectomy than procedures such as lateral pancreaticojejunostomy and pancreaticoduodenoctomy (Whipple procedure). Diabetes is obviously inevitable following total pancreatectomy.

Management of diabetes caused by pancreatic surgery

The diabetes is usually difficult to control, with wide excursions in blood glucose levels. Patients are exquisitely insulin-sensitive and prone to hypoglycemia as a result of the loss of glucagon function. Frequent small meals and multiple small doses of insulin can minimize these problems to an extent. Use of a subcutaneous insulin infusion pump may be beneficial in some cases. People with diabetes following pancreatectomy are ideal candidates for whole pancreas or islet cell transplantation.

Associated exocrine pancreatic insufficiency should also be addressed. Meals should be low in fat and high in carbohydrate and protein. Pancreatic enzyme therapy will help in controlling steatorrhea and stabilizing blood glucose [76].

Cystic fibrosis

Cystic fibrosis is a multisystem disease characterized by recurrent airway infection leading to bronchiectasis, pancreatic insufficiency, abnormal sweat gland function, and urogenital dysfunction. It is an autosomal recessive disorder caused by mutations in the *CFTR* gene located on chromosome 7q22. This gene encodes a protein, cystic fibrosis transmembrane conductance regulator (CFTR), which regulates the chloride secretion across epithelial surfaces. Various mutations have been described of which deletion of the phenylalanine residue at position 508 (Δ508) is the most common [77]. The defect produces unusually viscid secretions which lead to pancreatic ductular obstruction, dilatation, and pancreatic insufficiency. The incidence is 1 in 2500 live births in white European populations, but the disease is much less common in Africans and Asians [78].

The most common clinical features are steatorrhea, failure to thrive and growth retardation, recurrent lung infections, hepatobiliary complications, osteoporosis, and symptoms of fat-soluble vitamin deficiency such as night blindness. The diagnosis is confirmed by the presence of an elevated sweat chloride concentration in excess of 60 mmol/L.

Diabetes in cystic fibrosis

The incidence of diabetes in children with cystic fibrosis is 2–3% (about 20 times higher than in the general population). The incidence rises steadily through adolescence, with up to 25% of individuals in their twenties developing diabetes and a further 50% having glucose intolerance [79]. Occasionally, diabetes is the first manifestation of cystic fibrosis.

As the treatment of the lung disease in cystic fibrosis has improved, more and more people are surviving into adulthood, leading to an increase in the prevalence of diabetes in cystic fibrosis.

The major factor in the pathogenesis of diabetes is damage to the pancreatic β cells secondary to exocrine pancreatic degeneration. Other postulated mechanisms include enhanced absorption of glucose [80] and autoimmune attack against the β cell, which may explain why T1DM is more common in relatives of people with cystic fibrosis [81]. The physiologic insulin resistance of normal puberty may also contribute. Interestingly, diabetes develops more commonly in people homozygous for Δ508 than in heterozygotes [82].

Diabetes is usually insidious in onset and characterized by a delayed, flattened, and prolonged insulin secretory response to glucose [83]. Ketoacidosis is rare, although insulin treatment is usually required. As patients now survive longer [77], chronic microvascular complications are also frequently seen, although macrovascular disease is virtually unknown. Hyperglycemia predisposes to chest infections in these individuals and may be an important, often overlooked, cause of weight loss.

Management

The International Society for Pediatric and Adolescent Diabetes (ISPAD) recommends that all children with cystic fibrosis be screened for diabetes with an oral glucose tolerance test (OGTT), starting from 10 years of age [84]. Although there is debate about the optimal glucose needed to prevent pulmonary exacerbations, current guidance recommend the diagnostic criteria are the same as for other forms of diabetes. The OGTT should not be performed during acute exacerbations of pulmonary disease, particularly if the treatment includes glucocorticoids. Although some patients initially respond to sulfonylureas, most ultimately need insulin and this is reflected in the guidelines for treatment which recommend insulin as the treatment of choice [85]. In addition to controlling diabetes, insulin also improves body weight and pulmonary and pancreatic function [79, 86, 87]. Annual monitoring for complications of diabetes is recommended, starting 5 years after the diagnosis of diabetes [88, 89].

Dietary modification in people with cystic fibrosis who also have diabetes presents much the same difficulties as in people with chronic pancreatitis. A diet rich in carbohydrates and protein but restricted in fat is recommended. Oral pancreatic enzyme therapy helps to improve nutrient digestion and absorption. Enteric-coated preparations of lipase can control steatorrhea. Fibrosing colonopathy is a concern in patients receiving higher strengths of lipase [84].

Conclusions

Although rare, diabetes secondary to pancreatic disease is potentially important. The underlying pancreatic disease may need treatment in its own right, while disorders with a genetic basis must be identified so that other family members can be screened. Diagnosis of pancreatic diabetes requires a high index of suspicion. Suggestive symptoms include features of pancreatic disease (steatorrhea, unexplained weight loss, or back pain) and severe and brittle diabetes in the absence of a family history of diabetes.

5 Managing the Patient with Diabetes

22 Clinical Presentations of Diabetes

Ee Lin Lim[1] and Roy Taylor[2]

[1] University Hospital Southampton NHS Foundation Trust, Southampton, UK
[2] Diabetes Research Group, Institute of Cellular Medicine, Newcastle University, Newcastle upon Tyne, UK

Key points

- People with type 1 diabetes (T1DM) usually present with classic symptoms and occasionally diabetic ketoacidosis.
- People with type 2 diabetes mellitus (T2DM) may be asymptomatic or present with classic symptoms.
- In the context of thirst, polydipsia, and polyuria, the presence or absence of weight loss is an important diagnostic feature
- The mode of presentation of slow onset T1DM, monogenic, and pancreatic diabetes is helpful in diagnosis.
- With advancing age, the renal threshold for glucose increases and thirst perception diminishes.
- Consideration of the impact of the initial consultation upon the individual is important.
- T2DM may present with complications of diabetes which may be either microvascular or macrovascular.
- Initial diagnosis of T2DM during acute myocardial infarction or stroke is common.
- Presentation may be asymptomatic and discovered on routine examination or laboratory test.
- Diabetes of onset in pregnancy is important and ideally detected by an effective screening program.

Introduction

Diabetes has long since taken over from syphilis as the great imitator, and nowhere is this more apparent than in the wide variation of possible modes of initial presentation. The classic triad of thirst, polydipsia, and polyuria accounts for only a modest proportion of new diagnoses of diabetes. The relatively acute onset of such symptoms associated with loss of weight is the hallmark of type 1 diabetes mellitus (T1DM). Ketoacidosis or hyperosmolar hyperglycemic syndrome may precipitate a dramatic presentation of T1DM or type 2 diabetes mellitus (T2DM) to emergency services. Non-specific symptoms including tiredness, general malaise, and repeated or persistent skin infections may lead to a biochemical diagnosis of diabetes. Screening of at-risk groups or individuals allows early diagnosis. Regrettably, the nature of the condition is such as to allow it to remain asymptomatic for years, allowing the clinical presentation to be a long-term complication of diabetes. This could be in the form of macrovascular disease (myocardial infarction, stroke, black toe) or in the form of microvascular disease (loss of visual acuity, neuropathy). Pregnancy may cause gestational diabetes (GDM), which, although it may remit after delivery, does indicate a high risk for future T2DM.

Clinical considerations at presentation

At the heart of any consultation involving the presentation of diabetes there is a patient. Depending upon prior knowledge, "diabetes" may be associated in their mind with blindness and amputation, disability and premature death. Alternatively, it may be associated with vague concepts of malaise along with lumbago or fibrositis. The patient's beliefs and thoughts on diabetes need to be established if the diagnostic consultation is to be a therapeutic consultation. In an era of medicine by numbers, often traduced as "evidence-based medicine," it is easy to overlook the impact of the consultation itself upon the person who will live with diabetes. "Where were you when JFK was shot?" "What was it like when you were told you have diabetes?" The moment is likely to be memorable and influential.

The therapeutic consultation will involve listening, a process that need not be unduly time-consuming. "Do you know of anyone with diabetes?" "What do you know of diabetes just now?" The information received will allow the patient's likely type of diabetes and immediate prognosis to be put into perspective. Together with other aspects of sound clinical history-taking, it will also transform that person's view of the consultation. Patients list

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

"listening" as the most valued attribute of a doctor. Although others may listen too, this cannot be delegated to the healthcare team.

At what stage of diabetes is the person in front of you? The implications for the individual who was identified on routine screening are quite different from those for the person presenting with a black toe. The former is likely to be at an early stage of a long process with a good chance of modifying disease progression, whereas the latter is likely to have other tissue complications already established. Clearly, genetic susceptibility to develop complications plays a part as well as natural history time course. The former patient may never develop more than microaneurysms in the eye and be resistant to diabetic nephropathy. Even if they are to be susceptible to complications, these are amenable to intervention over a period of many years. The latter patient, however, requires clear explanation of what can be done and how future trouble can be avoided. Hippocrates summed it up nicely: "Cure sometimes, relieve often, comfort always."

The possibility of cure should not be overlooked. Diabetes has long been regarded as incurable. However, this is not always true. At the beginning of the 21st century and with further advances in our understanding, the number of circumstances where diabetes can be cured will increase. Look out for the slatey grey person with large liver and hemoglobin level of 19 gm/dL. Hemochromatosis is rare as a cause of diabetes but it is treatable and therefore important (Chapter 21). The person taking a combination of thiazide diuretic and beta-blocker will be pleased to have hyperglycemia at least ameliorated by use of alternative agents (see Chapter 19). Cushing syndrome may include curable diabetes (see Chapter 20). Few people on systemic steroid therapy can be taken off treatment just because of the development of diabetes, but knowledge is cheering that the diabetes will go away or become much more easily controllable when the steroid course finishes. Cure of short-duration T2DM by substantial and sustained weight loss is possible for those who have the determination and willpower to change long-standing behavior patterns [1]. For such people, this knowledge is life-changing and normoglycemia continues as long as weight regain is avoided [2, 3]. Only 50% of individuals with diabetes of duration longer than 8 years can reverse their diabetes, compared with around 90% of those with diabetes for less than 4 years [4]. Bariatric surgery produces dramatic and long-term cure of T2DM in the early years of the condition by enforced calorie restriction [5, 6].

Types of diabetes

The classification of diabetes will remain the cause of much debate until the exact etiology of each subtype has been established. Currently, the paradigm is to group together those people who appear to have primary β-cell destruction as T1DM, and those who are not slim and who can be controlled at least in the early years with diet and oral agents as T2DM. The monogenic causes of diabetes are capable of precise genetic description and are clearly separate (see Chapter 18). Similarly, pancreatic disease such as chronic pancreatitis, pancreatic carcinoma, and hemochromatosis is capable of precise diagnosis (see Chapter 21). T2DM, however, is a term used to describe conditions that do not fit into the other, more easily defined categories. It is clear that more subtypes will be identified in due course.

The important practical question at the initial presentation of a person with diabetes is whether insulin therapy is necessary. In some circumstances there is no doubt, such as diabetic ketoacidosis or severe weight loss with ketonuria and glycosuria in a child (Figure 22.1). More usually in adult practice the question must be asked. Table 22.1 lays out the common and distinguishing features from the clinical history, examination and urinalysis to help the clinician come to the answer. The subsequent sections consider the separate features in context.

Thirst, polydipsia, and polyuria

These symptoms result from an osmotic diuresis as a consequence of hyperglycemia. The symptoms are common to all types of diabetes although the time course is likely to be shorter and the symptoms more severe in T1DM. Not infrequently, sugar-containing carbonated drinks are selected to slake thirst with resulting worsening of symptoms. A careful history documenting the time course of symptoms and any change in intake of specific drinks is important. Remembering how many times per day urine is passed is not easy, but nocturia is more clear-cut and the number of times urine is passed at night should be quantified. "Do you need to drink water when you get up at night?" is a reasonably objective measure of thirst.

For glucose to escape into the urine, plasma glucose concentration must exceed the renal threshold for tubular reabsorption of glucose and the absolute amount of glucose delivered to the renal tubules must exceed the maximum absorptive capacity. The renal threshold averages 11 mmol/L but displays a wide individual variation of around 6–14 mmol/L [7]. Additionally, the maximum absorptive capacity varies with age such that older people exhibit glycosuria at higher plasma glucose levels [8].

The rise in maximum renal tubular absorptive capacity with increasing age is clinically significant as older people will only develop osmotic symptoms at higher plasma glucose levels. Conversely, a negative urine test is even less likely to exclude a diagnosis of diabetes than in younger people. In addition to the need for higher plasma glucose levels in older people to produce osmotic symptoms, the threshold for triggering the sensation of thirst rises with advancing years [9]. This is important because, once the maximum renal absorptive capacity has been exceeded, dehydration will become considerably more advanced before thirst is sensed. These age-related changes are highly relevant to development of severe hyperosmolar states.

The presence of chronic hyperglycemia itself changes the renal sensitivity to vasopressin such that thirst is not appreciated despite rising plasma osmolarity [10]. Hence, the combination of undiagnosed diabetes and advanced age is particularly potent in

Figure 22.1 A 3-year-old boy before and after 3 months of insulin therapy (1922). The severe wasting of muscle and adipose tissue due to the insulin deficiency of type 1 diabetes is painfully evident in the left-hand panel. There is no more dramatic reminder of weight loss as a prominent presenting feature of type 1 diabetes especially if presentation is delayed. The speed of restoration of body mass on replacing insulin (right-hand panel) is impressive. Source: Eli Lilly & Co. Reproduced with permission.

Table 22.1 Clinical features at presentation of type 1, type 2, and monogenic diabetes. This is a diagnostic guide with exceptions because of specific circumstances. It is not exhaustive and does not include rarer forms of diabetes, including syndromic diabetes.

	Type 1	Type 2	Monogenic	Pancreatic
Weight loss	Yes (not essential e.g. in slow onset T1DM)	Usually, no	No	Possible. If marked consider pancreatic carcinoma
Ketonuria	Yes (not essential in slow onset T1DM)	No unless recent fasting	No unless recent fasting	Yes, but not necessary for diagnosis
Time course of symptoms	Weeks or days	Months	Months	Weeks or months
Severity of symptoms (e.g. nocturia >3)	Can be marked	Variable but not usually extreme unless fueled by sugary drinks to assuage thirst	Not usually severe	Depends on clinical situation
Family history	Possibly of insulin dependence at a young age	Present in 30% with onset in adult life	Present in almost all with onset in childhood or adult life	Only by chance except in association with hemochromatosis
Age	Peak age in preschool and teenage years but can present at any age	Typically after the age of 20 years	Childhood, adolescence or adult	Usually middle aged and older

delaying appropriate action to increase oral fluid intake as dehydration progresses. The clinical features identified from the history at presentation will vary in relation to the above factors. In older people, thirst may not be experienced despite an osmotic diuresis and polydipsia will be absent. The most reliably quantitated feature of an osmotic presentation is therefore frequency of nocturia, and specifically an increase from habitual levels.

In children, enuresis may be the first symptom of polyuria. Sudden onset of enuresis should always prompt testing of urine for glucose. It must be noted that a urine test is entirely appropriate as an initial screen in this situation, as the absence of glucose from the urine absolutely excludes hyperglycemia as a potential cause of polyuria.

Weight loss

Establishing whether significant weight loss has occurred is the most important aspect of history-taking in those with newly presenting diabetes. Unless secondary to concurrent disease, the symptom strongly suggests insulin deficiency and hence newly presenting T1DM. Its absence does not exclude T1DM as the speed of onset of insulin deficiency and the presence of intercurrent illness, which may have exacerbated osmotic symptoms, may mean that weight loss has not yet commenced.

Weight loss at presentation of T2DM may occur as a result of dietary restriction often undertaken because of suspicion of impending health problems. Such deliberate changes in eating habit are readily established from the history. Typically, weight does not change, or even continues to rise, prior to the symptomatic onset of T2DM.

The weight loss reflects mainly the relative loss of the anabolic actions of insulin. Muscle wasting may be prominent, especially in young men. Associated loss of muscle strength may be reported. As an anabolic hormone, insulin acts principally to inhibit protein degradation [11]. Its relative absence allows the balance between continuous protein synthesis and breakdown to be disturbed. There is an additional effect of insulin deficiency in the failure of normal promotion of lipogenesis and inhibition of lipolysis. Excess non-esterified fatty acids accumulate in plasma, forming substrate for ketogenesis. If the clinical presentation of diabetes is acute, a component of the weight loss will reflect the loss of both intracellular and extracellular water.

Blurred vision

Major changes in plasma glucose will be followed over a period of days and weeks by blurring of vision. The symptom is typically present after a relatively acute change, usually in the context of presentation of T1DM or in the specific circumstance of a hyperosmolar presentation of T2DM. It is most important to explain to the patient that the visual blurring will become worse following the relatively rapid correction of gross hyperglycemia. This explanation is vital to avoid the supposition that diabetic blindness is already progressing with consequent unnecessary worry. It is also important to prevent the unnecessary purchase of spectacles that will be redundant after the hyperglycemia is treated.

It is reasonably assumed that shifts in osmotic pressure between plasma and inside the eyeball accounts for the visual change. Certainly, this provides a practical and immediately understandable explanation. Detailed tests, however, have not to date tied down any identifiable refractive change [12].

Infections

Exposure of leukocytes to glucose concentrations above 11 mmol/L produces paralysis of phagocytic and other functions [13]. This effect, together with other possible effects upon immune function, explains the impaired ability to fight off bacterial and fungal infections. Susceptibility to viral infections appears to be little changed although clear data are lacking.

Recurrent or refractory yeast infections may draw attention to previously undiagnosed diabetes. Most frequently this involves vaginal candidiasis in women or balanitis in men. Initial control of blood glucose levels will permit clearance of the infection with continued antifungal application. Staphylococcal pustules, boils, and carbuncles may be present at the diagnosis of diabetes, especially T1DM. This clinical observation was supported by a prospective study of 482 people with skin or mucous membrane sepsis presenting to an accident and emergency department who were found to have over a threefold increased incidence of capillary blood glucose >7.8 mmol/L compared with a background population [14].

Very rare but serious infective presentations of diabetes must be considered. Necrotizing fasciitis is considerably more common in people with diagnosed and undiagnosed diabetes [15]. Fournier gangrene (gangrene of the perineum and genitalia) is associated with diabetes in almost 50% of cases [16]. The rare and often fatal facial and/or maxillary sinus fungal infection mucormycosis is most often associated with diabetes [17].

Diabetic ketoacidosis

Diabetic ketoacidosis (DKA) occurs as a result of marked insulin deficiency associated with an increase in circulating levels of counter-regulatory hormones. It is characterized by hyperglycemia, acidosis, and ketonuria. It mainly occurs in people with T1DM, but it is not uncommon in some people with T2DM. There is a wide geographic variation in the reported incidence of DKA. For example, EURODIAB, a cross-sectional survey of 3250 people with T1DM in 29 centers in Europe, reported that 8.6% of participants had been admitted with a diagnosis of DKA in the previous 12 months [18]. In 25% of cases, DKA is the presenting feature of

T1DM [19]. The overall mortality rate from DKA ranges 2–5%, but is higher in the elderly.

DKA typically presents with the symptoms of hyperglycemia (i.e. thirst, polyuria, and polydipsia). Patients may also complain of malaise or lethargy and muscle cramps. Abdominal pain and vomiting may be sufficiently severe as to mimic an acute surgical problem. It is critically important to recognize this, as the administration of an anesthetic is almost invariably fatal. All doctors dealing with emergencies should be aware of the potential pitfall of missing this tell-tale sign of DKA.

Clinical signs include dehydration, deep, sighing respirations (air hunger or Kussmaul respiration), and a sweet-smelling fetor (like nail varnish remover) caused by the ketones on the breath. As the ability to detect the smell of ketones is genetically determined, and approximately one-third of people are unable to do this, it is important that individual doctors are aware if they are not equipped with this additional diagnostic tool. Consciousness may be clouded. If the condition has progressed to the stage of coma, the associated signs of dehydration must lead to urgent checking of blood glucose and ketones and arterial blood pH in order to expedite definitive treatment. If bedside blood ketone testing is not available then the semi-quantitative urine test to detect ketonuria is entirely satisfactory.

The marked deficiency or absence of insulin in this condition means that insulin-mediated glucose uptake into tissues such as muscle, fat, and liver cannot occur and hepatic glucose output is unrestrained. In the meantime, the dysregulated secretion of counter-regulatory hormones (glucagon, growth hormone, and catecholamines) enhances the breakdown of triglyceride into free fatty acids and increases the rate of gluconeogenesis, which is the main cause for the high blood glucose level in diabetic ketoacidosis. Beta-oxidation of these free fatty acids leads to formation of ketone bodies (β-hydroxybutyrate, acetoacetate, and acetone). Acetone is volatile and is released from the lungs, giving the characteristic sweet smell to the breath. Metabolic acidosis ensues when the ketone bodies are released into circulation and deplete the acid buffers.

The hyperglycemia-induced osmotic diuresis further depletes sodium, potassium, phosphates, and water. Patients are often profoundly dehydrated and have a significantly depleted total body potassium at presentation. Sometimes, a normal or even elevated serum potassium level is seen as a result of the extracellular shift of potassium with severe acidosis. Great care must be taken to monitor serum potassium levels repeatedly once insulin treatment is started as the concentration can drop precipitously (see Chapter 36).

Hyperosmolar hyperglycemic syndrome

Hyperosmolar hyperglycemic syndrome (HSS) occurs exclusively in people with T2DM. Often there is a history of several days of ill health. The principal clinical feature is profound dehydration. Confusion is usual, and focal neurologic symptoms such as weakness on one side or hemi-sensory abnormalities may develop and be easily confused with stroke. HSS was previously termed hyperosmolar non-ketotic coma. This terminology has been changed as coma is a relatively rare feature (<10%) and mild ketosis may be present at diagnosis.

HSS shares many features in common with DKA, the major exception being the absence of significant ketoacidosis. This is likely because of the residual low-level insulin secretion, which suppresses lipolysis sufficiently to avert ketogenesis but not sufficient to prevent hyperglycemia. Additionally, hyperosmolarity itself may decrease lipolysis, limiting the amount of free fatty acids available for ketogenesis. HSS accounts for 10–30% of hyperglycemic emergencies. As the prevalence of T2DM rises inexorably, it is becoming an increasingly common hospital admission. Up to two-thirds of those affected have not previously been diagnosed as having diabetes.

Macrovascular presentations

Acute myocardial infarction

As the risk of ischemic heart disease is linearly related to fasting and postprandial blood glucose concentrations, it is not surprising that both impaired glucose tolerance (IGT) and diabetes are over-represented in populations presenting with acute myocardial infarction (MI) [20]. Consequently, T2DM frequently presents for the first time at hospitalization for MI.

This presentation is complicated by stress hyperglycemia resulting from the catecholamine and cortisol elevations. Although this may cause problems for the purist wishing to evaluate an effect of diabetes per se, from the perspective of the patient with a life-threatening condition exacerbated by dysglycemia, exact definitions of diabetes are not relevant. Stress hyperglycemia and established diabetes have similarly increased mortality from MI. In a New York municipal hospital cohort of patients with MI, 3-year mortality was 52% in those with stress hyperglycemia (defined as admission blood glucose >7.0 mmol/L) compared with 42% in those with diabetes [21]. The 3-year death rate in those with normal glucose levels was 24% in the same study. A meta-analysis has confirmed this effect, with a 3.9-fold increased risk of death associated with stress hyperglycemia compared with a 1.7-fold increased risk of death associated with established diabetes [22]. In this context, one of the most important findings of the Diabetes mellitus, Insulin Glucose infusion in Acute Myocardial Infarction (DIGAMI) study is often overlooked. The effect of reasonable glycemic management (blood glucose <10 mmol/L) for those with no prior insulin therapy and stratified as having low coronary risk factors produced a 52% improvement in mortality [23]. This group would have included those with stress hyperglycemia. In contrast, the DIGAMI study showed no significant benefit of acute blood glucose control for individuals previously treated with insulin.

Estimates of the incidence of stress hyperglycemia at presentation of MI range 10–16% [24, 25]. This compares with

estimates of prevalence of diabetes at presentation of MI of 25–32% [24, 26, 27]. Variation in these figures is likely to reflect the background prevalence of IGT and T2DM in the population, as well as increased awareness and effective screening processes to identify previously undiagnosed T2DM.

Good clinical practice demands measurement of plasma glucose on diagnosis of an acute coronary syndrome. If plasma glucose is raised (7 mmol/L may be quoted, but in the individual, case interpretation depends upon time since last meal), then both fasting plasma glucose and HbA_{1c} should be measured. Raised plasma glucose should indicate a need for particular attention to adequate glucose control during the acute event. Given that the HbA_{1c} result is unlikely to be available immediately, hyperglycemia indicates a need for rapid control in the acute situation when the first few hours are critical. A fasting plasma glucose of >5.6 mmol/L during the acute admission and/or admission plasma glucose of >7.8 mmol/L yielded a sensitivity of almost 90% and a positive predictive value of 44% for detecting diabetes [28].

Where there is diagnostic uncertainty, targeted screening in the post-acute setting with a standard 75 g oral glucose tolerance test (OGTT) is acceptable. But when is the optimal time to perform this test? In a group of people with MI but no previous diagnosis of diabetes, both pre-discharge and 6 weeks post-discharge OGTTs were performed and correlation with pre-discharge OGTT was good [29]. There was 49% concordance between classifications to which each participant was assigned in both OGTTs. The best predictor of abnormal glucose handling (IGT or diabetes) being diagnosed at 3 months was observed to be the 60-minute blood glucose level during the pre-discharge OGTT. However, for all admitted with MI it is essential that HbA_{1c} is measured and that the result is acted upon.

Acute stroke

The prevalence of previously diagnosed diabetes in people with acute stroke is 8–28% but an additional 6–42% have unrecognized pre-existing dysglycemia [30]. Plasma glucose at presentation is a major prognostic factor. One series of 86 people with acute stroke demonstrated that full functional recovery at 4 weeks was restricted to those with presenting blood glucose levels <8 mmol/L [31]. None of the individuals with a raised presenting plasma glucose regained full function by 4 weeks. The extent to which this reflects the metabolic stress response in proportion to the severity of the cerebrovascular insult as opposed to hyperglycemia itself impairing subsequent recovery from ischemic damage cannot be ascertained from these observational data.

The observations on poorer outcome in those who had stress hyperglycemia following MI have been reproduced in respect of acute stroke disease. In a systematic review of observational studies examining the prognostic significance of hyperglycemia in acute stroke, the unadjusted relative risk of in-hospital or 30-day mortality was 3.07 (95% CI: 2.50–3.79) in people without diabetes but with admission plasma glucose level >6–8 mmol/L and 1.30 (95% CI: 0.49–3.43) in those with known diabetes [32]. The relative risk of poor functional outcome in hyperglycemic patients without diabetes was 1.41 (95% CI: 1.16–1.73). It appears that a sudden increase in plasma glucose levels impairs tissue function more in those individuals who have not been habituated to hyperglycemia.

Persistent hyperglycemia (defined as blood glucose >7.0 mmol/L) in the 72 hours after acute stroke was found to be associated with an increase in infarct size, measured using magnetic resonance imaging, and worse stroke outcome [33]. Nonetheless, there are currently no satisfactory outcome studies of control of plasma glucose upon the outcome of stroke [34]. The largest study to date, which included 993 participants, failed to achieve control of plasma glucose at 24 hours [35]. Importantly, no assessment has yet been conducted of plasma glucose control during the first few hours after presentation with acute stroke, and it is likely that it is in this window of time that this particular presentation of hyperglycemia may most beneficially be managed.

Microvascular presentations

Eye presentations

Symptomatic loss of vision may occasionally be the presenting feature of T2DM, where hyperglycemia has been present for an uncertain number of years, silently causing tissue damage and retinopathy. Loss of vision as a diagnostic event is most often a consequence of macula edema but may also be secondary to vitreous hemorrhage. Central or branch retinal vein occlusion is more common in diabetes and may also cause symptomatic presentation of the condition.

Around the time of diagnosis of T2DM, marked retinopathy with cotton wool spots or intraretinal microvascular abnormalities was found to be present in 8% of men and 4% of women in the UK Prospective Diabetes Study (UKPDS) [36]. The critical importance of arranging full retinal examination, preferably by digital retinal imaging, is illustrated in Figure 22.2. Approximately 1% of individuals presenting with symptomatic T2DM have sight-threatening retinopathy at that time. Very early recognition is essential as the initial treatment of the diabetes will decrease blood glucose levels, cause retinal blood flow to return acutely to normal levels and may result in marked worsening of the retinopathy.

In the UKPDS, the severity of retinopathy was found to be related to higher fasting plasma glucose levels. In addition, in men, increased alcohol consumption was related to increased severity of retinopathy, while leaner women had more severe eye lesions. Visual acuity was normal in most patients, but in men there was a trend for those with more severe retinal lesions to have worse visual acuity.

The potential severity of diabetic retinopathy at the time of diagnosis of T2DM is illustrated by the observation that 15% of those with moderate background retinopathy progress to require photocoagulation therapy within 3 years [37]. The specific reason for photocoagulation therapy was maculopathy alone in 72% and proliferative retinopathy in 11% in this group of individuals

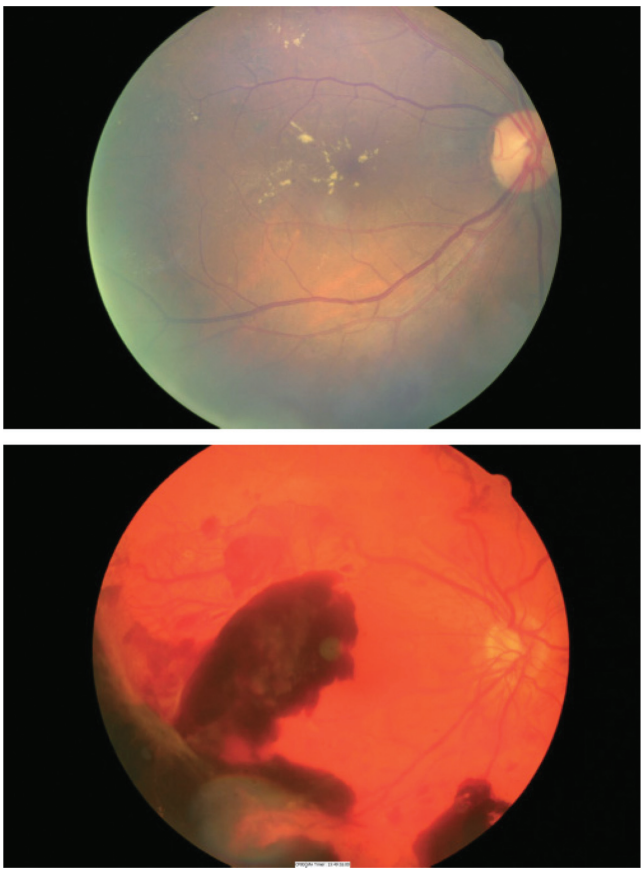

Figure 22.2 Upper panel: immediate laser therapy was required for the macular edema associated with the severe exudative maculopathy present at the time of diagnosis. Lower panel: new vessels are present both arising from the optic disk and from the peripheral retina. Bleeding from the latter caused the prominent pre-retinal hemorrhages which obscure the fovea and in this case caused presentation because of loss of visual acuity.

with T2DM. Although it is likely that the prevalence of retinopathy of all grades of severity is lower if T2DM is diagnosed at routine screening rather than symptomatic presentation, this has yet to be quantified.

Neuropathic syndromes

Although any of the neuropathic syndromes of diabetes may precipitate the initial presentation, symmetrical distal sensory neuropathy, mononeuropathies, and amyotrophy are the most likely candidates. The possibility of diabetes underlying most presentations of neurologic symptoms must be considered.

Diffuse symmetrical sensory neuropathy is the most common neuropathy. A precise estimate of the true prevalence of this neuropathy has been difficult to ascertain, and reports vary from 7 to 60% in people with diabetes, depending on the criteria and methods used to define the neuropathy [38, 39]. The prevalence increases with both age and duration of diabetes. At 12-year follow-up in the UKPDS, 64% of men and 44% of women who were free of neuropathy at baseline developed at least one neuropathic abnormality [40].

Any nerve may be affected by an acute diabetic mononeuropathy, but palsy of cranial nerves III, IV, VI, and VII present most often. It is a rare mode of presentation of T2DM, but not T1DM.

Diabetic amyotrophy may present as weight loss, and unless pain in the thighs is prominent the clinical picture may resemble that of malignant disease. Weakness of quadriceps, with visible wasting and absence of the knee tendon reflex, should allow recognition and lead to the measurement of plasma glucose. Such presentation is likely to be associated with T2DM but again is rare.

A foot lesion can be a presenting sign of diabetes, and it is estimated that the lifetime risk of developing a foot ulcer in people with diabetes may be as high as 25% [41]. Presentation with a black toe is associated with T2DM particularly. Peripheral neuropathy leads to sensory motor and autonomic dysfunction, with loss of the protective pain sensation, dry skin, and callus formation. Loss of pain sensation in the feet is usually unnoticed and subsequent trauma does not come to attention until obvious injury is apparent. In approximately half of those with foot ulcers, concomitant peripheral arterial disease is present [42]. In the EURODIALE study, foot ulcers with presence of peripheral arterial disease were associated with considerably lower healing rates, and higher major amputation and mortality rates [43].

Pregnancy

The time course of presentation of GDM may be predicted from knowledge of its pathogenesis. The key variable is the physiologic insulin resistance that develops during pregnancy. Although several necessarily small studies have quantitated this, it is most clearly illustrated by an observation of the change in exogenous insulin requirements during pregnancy in T1DM. During steady glycemic control and food intake, insulin requirements do not change until around 18 weeks' gestation, whereafter there is a linear increase until around 28 weeks' gestation [44]. The extent of change varies in individual pregnancies from none to over threefold increase, with an average increase in daily insulin dose of 40% [45]. The range is assumed to be a function of the placenta (fetal-derived tissue) as considerable variation is exhibited between successive pregnancies in the same woman.

In the light of this information, it can be understood why the elevated blood glucose levels of GDM are not seen in the first half of pregnancy. Screening for GDM will be most sensitive later in pregnancy but this sensitivity must be balanced with the opportunities to intervene. Current guidelines therefore recommend testing at 24–28 weeks' gestation. Predisposed women cannot mount an adequate β-cell response if the degree of insulin resistance becomes too great. Following one pregnancy complicated by GDM, although increased, the risk of recurrence in a subsequent pregnancy is far from certain, reflecting the variation in

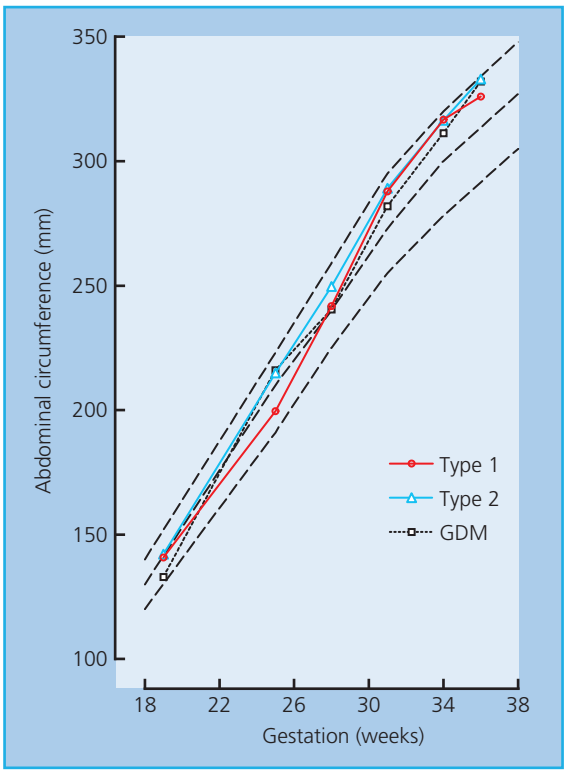

Figure 22.3 Similar rates of increase in fetal abdominal circumference in gestational diabetes (GDM) and pre-gestational diabetes as measured by ultrasound. Source: Lim et al. 2009 [47]. Copyright 2009 SAGE Publications.

insulin resistance in successive pregnancies as the latter is determined by the placenta, tissue which is derived from the individual fetus. Higher rates have been reported in South Asian and Hispanic populations, as would be expected from the higher background prevalence of T2DM (52–69%) [46]. The importance of detection and treatment of GDM is reflected by the data shown in Figure 22.3. The rate of intrauterine growth is as rapid in GDM as it is in T1DM and T2DM [47]. Early diagnosis of GDM carries major advantages for mother and child. The risk of developing subsequent diabetes in those with GDM ranges from 2.6 to 70% over periods from 6 weeks to 28 years [48]. Current NICE guidelines (March 2015) for "Diabetes in pregnancy" recommend that blood glucose should be tested prior to discharge, then fasting plasma glucose should be performed at 6–13 weeks (or HbA_{1c} after 13 weeks) as well as repeated annually for those women with GDM. This will miss a proportion of women with normal fasting plasma glucose and IGT, but it should be noted that the occurrence of GDM should itself be the trigger to advise vigorous lifestyle change and weight loss in particular.

Mild degrees of elevation of plasma glucose may be sufficient to be deleterious to the fetus, and these are far less than those that could produce osmotic symptoms [49]. Screening for GDM is therefore essential. Symptomatic presentation of GDM is unusual in the context of a healthcare system that provides universal screening for GDM. Where osmotic symptoms and superficial fungal infections are part of the clinical presentation, however, it is important to ask whether this is new onset T1DM or T2DM. The former tends to be associated with higher plasma glucose levels and ketonuria. Both are associated with clearly elevated HbA_{1c} levels as the hyperglycemia has been present for several weeks or months. If the presentation is in the first half of pregnancy, it is likely that it will not remit after delivery. If the presentation is in the first half of pregnancy and is associated with raised HbA_{1c}, then a diagnosis of pre-existing diabetes may confidently be made and discussed with the woman [47].

Screening

It has been estimated from the 2002 National Health and Nutrition Examination Survey (NHANES) that one-third of the 13.3 million US adults with diabetes remained undiagnosed [50]. A similar estimate has been made for the UK [51]. Figures based on AHPO diabetes prevalence model (http://bit.ly/aphodiabetes) estimated that 3.2 million people were diagnosed in UK but 634,000 had undiagnosed diabetes in 2013. Universal screening has not been implemented in the UK, however, as criteria for cost-effective and clinically effective screening are not met. The 2012 NICE Guidelines recommend that individuals at high risk due to ethnicity (non-white European), obesity, or family history of diabetes should have fasting plasma glucose or HbA_{1c} tested, and also that a validated risk assessment tool or self-assessment questionnaire should be used in all over the age of 40 years with testing of individuals with a high-risk score [52]. Fasting plasma glucose >7.0 mmol/L (126 mg/dL) or HbA_{1c} >48 mmol/mol (>6.5%) indicates need for a second test to diagnose T2DM. Fasting plasma glucose of 5.5–6.9 mmol/L (99–125 mg/dL) or HbA_{1c} 42–47 mmol/L (6.0–6.4%) is recommended to be managed as pre-diabetes with an intensive lifestyle program.

Fasting glucose, 2-hour post-challenge glucose and HbA_{1c} all equally well predict the future microvascular complications of diabetes and can be considered diagnostic as well as screening tests [53]. The use of the concept of "impaired fasting glucose" with a cutoff of 5.5 mmol/L offers a simple way of excluding or demonstrating dysglycemia [54]. Urinalysis for glycosuria has a high specificity (96–100%) but a low sensitivity (16–43%). Testing random blood glucose is specific but insensitive [55].

The population of individuals with early T2DM who are identified by any screening procedure differs considerably from those who present symptomatically. They are less likely to have established microvascular or macrovascular complications of diabetes. Attitudes to health may differ. The diagnosis will be less welcome as it does not point the way to relief of discomfort and may not be accepted as important for future health. Adherence to therapeutic advice concerning weight, diet, and physical activity may not be as good as following a symptomatic presentation. For these reasons, a more careful approach to discussing the need for future action is required with appropriately sensitive follow-up by the diabetes team.

Other presentations

Ants clustering around urine is a classic description of diabetes, although it is not clear how often this comprises the presenting complaint today. Periodontal disease, especially aggressive periodontitis, is more common in those with diabetes and may occasionally be the presenting complaint [56]. Cataracts typically develop 10 years earlier in people with diabetes [57]. Altered taste or excess production of saliva has been reported as presenting features of diabetes [58].

Conclusions

The mode of presentation of diabetes is enormously varied. Especially as the incidence of diabetes is rising in all age groups, both in the UK and worldwide [59], the onus is upon healthcare professionals to diagnose the condition effectively. Failure to recognize presenting features of diabetes can be costly for the patient.

Key points

- People with diabetes are individuals who have a condition that has medical, personal, and social consequences. They are not passive recipients of healthcare and are not defined by their disease state.
- Optimal diabetes management occurs when the multidisciplinary diabetes care team and person with diabetes actively work together as equal partners to achieve diabetes-related goals.
- Life-threatening diabetes emergencies, such as diabetic ketoacidosis, must be effectively managed, and attention paid to their prevention.
- Acute symptoms of hyperglycemia need to be addressed by careful pharmacological management and lifestyle modification support.
- Diabetes management is a balance between supporting short-term optimal glycemic control and quality of life whilst at the same time reducing the risk of long-term complications. This is achieved through effective medical treatment of glycemic control and cardiovascular risk factor management and appropriate psychosocial support and education.
- The time of diagnosis can be traumatic and is a key milestone in the management of diabetes when effective education, support, and treatment are needed.
- Regular lifelong contact between the person with diabetes and their healthcare team is essential in order to support the person with diabetes to cope with the demands of a complex condition that changes throughout a person's life.
- Diabetic complications should be managed effectively if and when they present to reduce the morbidity associated with them.

Introduction

Diabetes is a lifelong condition that for the majority is currently incurable. It is associated with premature mortality and morbidity, from an increased prevalence of cardiovascular disease and microvascular complications affecting the kidney, nerve, and eye [1, 2]. High-quality randomized trials have shown that improving glycemic control is associated with a reduction in microvascular complications [3–5] while a multifaceted approach to cardiovascular risk factors will reduce cardiovascular morbidity and mortality [6]. Addressing the psychosocial challenges faced by people with diabetes has been shown to be effective in terms of reducing psychological distress and improving self-management behaviors [7]. Supporting the person with diabetes in making choices based on the best evidence available, and providing them with autonomy in consultations leads to greater self-care and improved metabolic control [8].

The person living with diabetes will spend the vast majority of their time managing their own diabetes and only an estimated 1% of their time in contact with healthcare professionals. Therefore it is crucial to provide individuals with appropriate medical and psychosocial support to help them optimally self-manage their diabetes. Given the central role of the person with diabetes and the relatively little contact with healthcare professionals, it is important that the purposes of the consultation or other contacts with the diabetes healthcare team are well defined and their aims are made clear. To ensure that the individual derives the maximum benefit from the time spent with their diabetes healthcare team, whether this is in a hospital or primary care setting, the consultation should be collaborative, patient-centered, and goal-focused. As well as the clinic visit, diabetes care may also be provided through phone or email contact or through educational sessions outside a traditional clinic setting.

This chapter provides an overview of the aims and philosophy of diabetes care. Separate aspects of care will be covered in greater detail in subsequent chapters. The aims of diabetes care and management to improve the quality of life of the person with diabetes are fourfold. Life-threatening diabetes emergencies, such as diabetic ketoacidosis or severe hypoglycemia, should be managed effectively including preventative measures. The acute manifestations of hyperglycemia, such as polyuria and polydipsia, need to be addressed. In practice, these occupy only a minority of the work undertaken by diabetes healthcare professionals. Much of the focus of care is therefore directed towards minimizing the long-term complications through screening and working together

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

with the person with diabetes to support improved glycemic control and cardiovascular risk factor management. This provides a challenge for the diabetes team because people with type 2 diabetes often have no symptoms at the time of care, yet are asked to make lifestyle changes and take medications that may place a considerable burden upon them. It is also important that clinicians bear in mind the fourth aim of care which is to avoid iatrogenic side effects, such as hypoglycemia. Involvement of the person with diabetes in this care planning is paramount to success.

St. Vincent's Declaration

During the 1980s, there was a transformation in the widely held perceptions of the roles of people with diabetes and philosophy of care. Instead of being viewed as passive recipients of health care, there was an increasing recognition that people with diabetes were individuals with a condition that has medical, personal, and social consequences. During this time there was an increasing awareness and acceptance of the concept that each person with diabetes should accept part of the responsibility for their treatment and act as equal partners with healthcare professionals. In response to this paradigm shift, representatives of Government Health Departments and organizations for people with diabetes from all European countries met with diabetes experts under the auspices of the Regional Offices of the World Health Organization and the International Diabetes Federation in the hillside town of St. Vincent, Italy on October 10–12, 1989. They unanimously agreed upon a series of recommendations for diabetes care and urged that action should be taken in all countries throughout Europe to implement them (Box 23.1) [9]. Since this time this philosophy of partnership working between people with diabetes and healthcare professionals has been adopted within individual nations' strategies to improve the quality of diabetes care.

The diabetes care team

The diabetes care team involves a multidisciplinary group of healthcare professionals who are available to support the person with diabetes (Figure 23.1). A key component of diabetes care is to ensure that the individual with diabetes is at the center of the provision of care. This means that they should be an equal member of the diabetes care team working together with the healthcare professionals. This relationship should provide the information, advice, education, and support of the individual with diabetes to enable them to feel sufficiently empowered to manage their condition themselves whilst ensuring that the care offered is tailored appropriately for the individual and their circumstances.

The large number of health professionals involved in the diabetes care team means that the roles and responsibilities of all must be clearly presented and agreed upon. It is often helpful for the person with diabetes if the key members of the diabetes care team

Box 23.1 St. Vincent's Declaration [7]

- Elaborate, initiate and evaluate comprehensive programs for detection and control of diabetes and of its complications with self-care and community support as major components.
- Raise awareness in the population and among healthcare professionals of the present opportunities and the future needs for prevention of the complications of diabetes and of diabetes itself.
- Organize training and teaching in diabetes management and care for people of all ages with diabetes, for their families, friends, and working associates and for the healthcare team.
- Ensure that care for children with diabetes is provided by individuals and teams specialized both in the management of diabetes and of children, and that families with a child with diabetes get the necessary social, economic, and emotional support.
- Reinforce existing centers of excellence in diabetes care, education, and research.
- Create new centers where the need and potential exist.
- Promote independence, equity and self-sufficiency for all people with diabetes, children, adolescents, those in the working years of life, and the elderly.
- Remove hindrances to the fullest possible integration of people with diabetes into society.
- Implement effective measures for the prevention of costly complications:
  - Reduce new blindness due to diabetes by one third or more.
  - Reduce numbers of people entering end-stage renal failure by at least one third.
  - Reduce by one half the rate of limb amputations.
  - Cut morbidity and mortality from coronary heart disease by vigorous programs of risk factor reduction.
  - Achieve pregnancy outcomes in women with diabetes that approximate that of women without diabetes.
- Establish monitoring and control systems using state-of-the-art information technology for quality assurance of diabetes healthcare provision and for laboratory and technical procedures in diabetes diagnosis, treatment, and self-management.
- Promote European and international collaboration in programs of diabetes research and development through national, regional, and WHO agencies and in active partnership with diabetes person with diabetes organization.
- Take urgent action in the spirit of the WHO program, "Health for All," to establish joint machinery between WHO and IDF European Region, to initiate, accelerate, and facilitate the implementation of these recommendations.

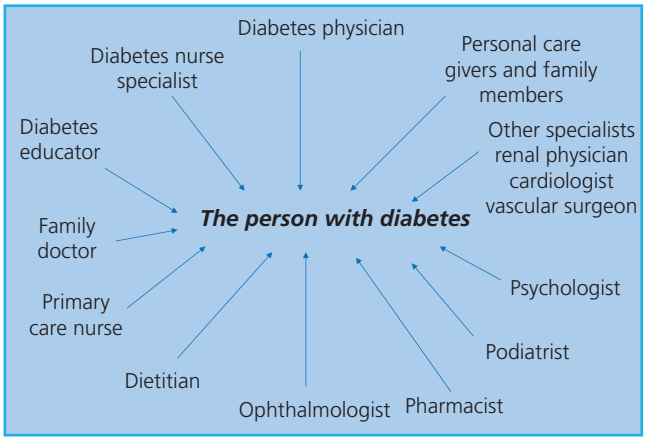

Figure 23.1 The multidisciplinary group of healthcare professionals who are available to support the person with diabetes.

are identified, as they will have more contact with some healthcare staff than others.

The majority of routine diabetes care takes place in a primary care setting but some people with diabetes with complications or complex medical or psychological needs will require management and support in a specialist setting for some or all of their care [10]. The diabetes physician usually takes overall responsibility for the diabetes medical care but other specialists may be involved, for example an ophthalmologist may be needed to examine the eyes carefully and treat diabetic retinopathy, if present. Diabetes care is multidisciplinary involving doctors, nurses, and many allied healthcare professionals whose responsibility is to support the person living with diabetes in the management of their condition. A close collaboration between primary and secondary healthcare professionals and among specialists is needed to ensure that all involved are aware of the issues that are relevant to the individual with diabetes and that care is integrated and coordinated across the wide range of disciplines involved. Placing the person with diabetes at the center of care is likely to facilitate the collaboration.

Given the chronic nature of diabetes, continuity of care is essential. Ideally this should be provided by the same doctors and nurses from visit to visit but where this is not possible, the healthcare team should have access to previous records so that they are fully aware of the medical history and background of the person with diabetes. In some developing countries, this is particularly challenging where medical records are often focused around single episodes of acute care of infectious diseases [11].

With the involvement of the person with diabetes in the diabetes team, that individual assumes a number of responsibilities. The task of implementing the day-to-day management plan of the diabetes lies with the individual; it may sometimes be difficult for healthcare professionals to accept this. It is important to understand that diabetes self-management is challenging and so the diabetes care team should be available to support the person through their experiences with their condition. Adolescence can be a particularly challenging time as this period of the person's life coincides with a time of rapid change, transition to adulthood and increasing independence. Risk-taking, experimentation and increasing responsibility along the path to diabetes self-management by the adolescent are to be expected (Chapter 60).

Improving the outcome of the consultation

The time that a person with diabetes spends with a healthcare professional is limited and should be used as effectively as possible. Clinicians often give conflicting advice, both within the team and from one consultation to the next [8]. Goals are often not followed up, leaving the person with diabetes feeling frustrated. Studies have shown that typically physicians interrupt their patients 18 seconds after the patient starts to describe their problems, approximately half of patients' concerns are not discussed, and in 50% of consultations, the patient and physician disagree on the central problem presented [8]. Such disagreement and inconsistency are associated with poorer outcomes. Greater self-care and metabolic control are achieved through supporting the person with diabetes to make choices based on the best evidence available and providing autonomy in consultations. In the UK, the Department of Health has produced literature entitled "Questions to ask" (Table 23.1) which provides guidance about the questions a person with diabetes might want to ask during a consultation to maximize the benefits from the visit to their healthcare team [12].

The consultation or education program should help the person with diabetes gain a clearer understanding of their condition. This can only be achieved effectively when professionals and people with diabetes are enabled to work together. Taking a holistic approach, such as embodied in the Kaleidoscope model of care [13] (Figure 23.2), can facilitate this collaborative, patient-centered joint goal-setting approach.

The Kaleidoscope model of care presents a novel, holistic, tailored, and individualized approach to healthcare delivery for people with diabetes through an assessment of an individual's current regimen, barriers and motivation, and available support resources. It is flexible and applicable in different health settings, fundamentally promoting the specific needs of the individual with diabetes. These needs are dynamic, taking a different shape at different points in time, whilst recognizing and adapting to the range of care needed.

It is good practice to provide the person with diabetes with copies of any letters written about them [14, 15]. Questions about their treatment should be encouraged and people should be aware of what will happen next, including any requirement for further investigation. Regular review of management plans through joint dialogue, listening, discussion, and decision-making between the individual and the healthcare professional, sometimes known as care planning, is the key to enhancing relationships and partnership working [16]. Contact details should be made available to enable the individual with diabetes to seek help if further questions arise.

Table 23.1 Checklist of questions to ask your doctor at your appointment [10].

Tests, such as blood tests or scans
What are the tests for?
How and when will I get the results?
Who do I contact if I don't get the results?

Before your appointment
Write down your two or three most important questions.
List or bring all your medicines and pills—including vitamins and supplements.
Write down details of your symptoms, including when they started and what makes them better or worse.
Ask your hospital or surgery for an interpreter or communication support if needed.
Ask a friend or family member to come with you, if you like.

During your appointment
Don't be afraid to ask if you don't understand. For example, "Can you say that again? I still don't understand."
If you don't understand any words, ask for them to be written down and explained.
Write things down, or ask a family member or friend to take notes.

Before you leave your appointment
Check that:
You've covered everything on your list
You understand, for example "Can I just check I understood what you said?"
You know what should happen next—and when. Write it down.

Ask:
Who to contact if you have any more problems or questions
About support groups and where to go for reliable information, and
For copies of letters written about you—you are entitled to see these.

After your appointment, don't forget to
Write down what you discussed and what happens next. Keep your notes.
Book any tests that you can and put the dates in your diary.

- **Ask:**
"What's happening if I'm not sent my appointment details," and
"Can I have the results of any tests?" (If you don't get the results when you expect—ask for them.) Ask what the results mean.

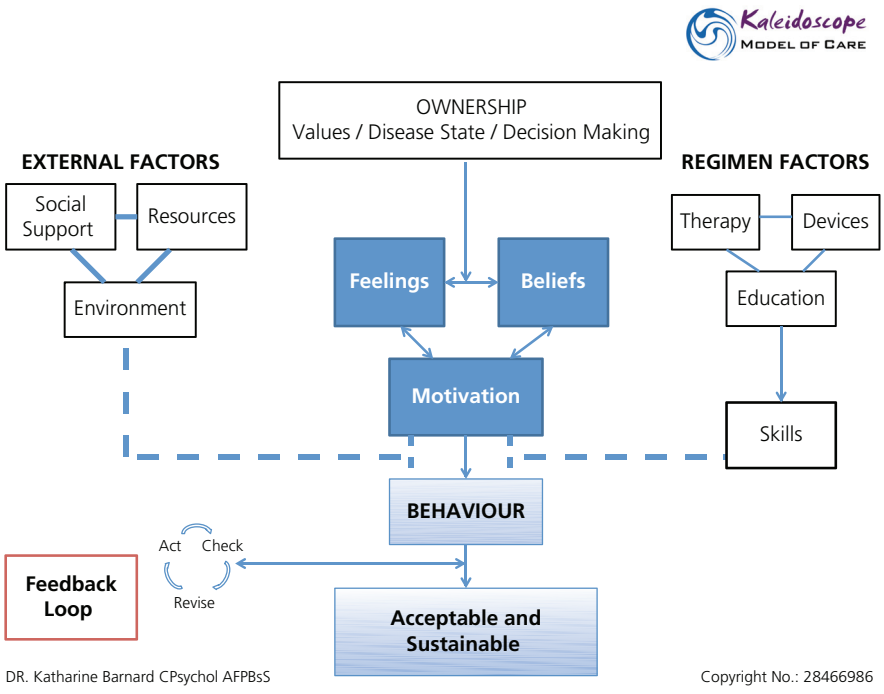

Figure 23.2 The Kaleidoscope model of care [13].

Following diagnosis

The period following the diagnosis of diabetes is crucial for the long-term management of diabetes. A huge amount of information and skills need to be assimilated by the person with diabetes at a time when they may be least able to do so, perhaps because of denial of or anger with the diagnosis [17]. Empathy and considerable skill are therefore needed to support the person with diabetes at this time. The diabetes team should perform a medical examination (usually the physician) and work with the individual to develop a program of care that is individualized and includes treatment-oriented goals.

Issues relating to diagnosis

The diagnosis of diabetes is based on the finding of one or more glucose values above internationally agreed values [18, 19] (Chapter 2). Usually a diagnosis has been made prior to referral to the diabetes clinic but this is not always the case. In the absence of symptoms, individuals require two glucose or glycated hemoglobin values above the diagnostic criteria to fulfil the diagnosis of diabetes.

Advice may be required to determine the type of diabetes as the distinction is not always as clear as may be expected. When a young pre-school child develops weight loss, polyuria, polydipsia, and ketoacidosis over a short period of time, the diagnosis is obviously type 1 diabetes (T1DM). In contrast if an asymptomatic elderly overweight individual is found to be hyperglycemic, the diagnosis is type 2 diabetes (T2DM) (Chapter 22). These presentations lie at two ends of a spectrum, and the diagnosis of the type of diabetes may be less clear when the onset occurs in an overweight adult in their 30s who is found to have islet cell antibodies. Diabetes healthcare professionals should also be alert to the possibility of monogenic causes of diabetes (Chapter 18).

Although a precise diagnosis may not be needed from the outset, an early decision should be made about the necessity for insulin therapy (Chapter 22). While there may be clinical features that suggest the type of diabetes, time is often a useful diagnostic tool to determine whether the person with diabetes requires insulin.

Diabetes education

A key component of the empowerment of the person with diabetes is the provision of diabetes education [20] (Chapter 24). This information should be provided in a patient-centered manner as it is retained more effectively when delivered in this way. Education may be provided individually or in a group setting.

It is essential that the person with diabetes understands their diabetes and develops the skills and competencies required to self-manage the condition as well as possible. People with newly diagnosed diabetes should have the chance to speak with a diabetes specialist nurse (or practice nurse) who can fully explain what diabetes is [21]. This will provide an opportunity to discuss the treatment and goals as well as providing a practical demonstration of any equipment required to support self-management, for example, blood glucose meters or insulin devices. The importance of ketones testing for those with T1DM should be explained. Where self-monitoring has been advocated, it is essential that the individual knows how to interpret the results and how to act appropriately in response to that information.

A qualified dietitian should provide advice about how to manage the relationships between food, activity, and treatment (Chapter 25). Where necessary, they should explain the links between diabetes and diet and the benefits of a healthy diet, exercise, and optimal diabetes control. As an essential member of an effective clinical care team, a diabetes specialist nurse or practice nurse also has a role in providing dietary advice together with relevant literature [21].

The social effects of diabetes should be discussed, as they may relate to employment, insurance or driving (Chapter 58). Some countries require individuals with diabetes to inform the appropriate licensing authorities. Advice about diabetes and foot care should also be given (Chapter 48).

Although education is essential following diagnosis, it is important to appreciate that this is a lifelong process that should take into account recent advances in medical science and changes in circumstances of the person with diabetes [20].

The best measure of successful education is not simply that someone knows more, but rather that they use the new knowledge to enhance diabetes self-management. The simple provision of knowledge by itself is often insufficient to influence behavioral change. High demands are placed on the person with diabetes regardless of the type of diabetes, especially when the benefits are not immediate, may only accrue with time and even then may not be appreciated. The individual with diabetes needs to gain an understanding that improved glycemic control can help in preventing the long-term complications of diabetes, such as a myocardial infarction or proliferative retinopathy, even though they may have never experienced these conditions.

The diagnosis of diabetes may provoke a grief reaction and support is needed from the diabetes team to help the person with diabetes work through this (Box 23.2). Engagement is needed to help the individual adapt to living with diabetes and engage in optimal self-management rather than being left feeling overwhelmed by diabetes or that their healthcare team can take control for them. For some it may take a very long time to accept their diabetes and the demands this places on their life. Therefore emotional and psychological support and techniques need to be available in the long term.

People with newly diagnosed diabetes often want to speak with others who have diabetes who have had similar experiences while developing diabetes. Many countries have diabetes-related charities that can provide this support and it is important that information about what help is available, including local centers or patient support groups, is provided in a timely fashion.

Box 23.2 Case study

Dave is 25 years old and recently diagnosed with type 1 diabetes. The diagnosis was made following an acute admission to hospital with diabetic ketoacidosis and insulin therapy was initiated.

Initially appearing to accept the diagnosis, Dave quickly became very angry about his perceived loss of control over his life and the reduction in his quality of life because of the new demands placed by diabetes and its treatment. Feeling guilty about whether he could have prevented it, and despairing about the lifelong condition, Dave found it increasingly difficult to keep up with the daily tasks of self-management, which in turn contributed to his feelings of despair and loss of control.

The healthcare team helped Dave identify some short-term goals for diabetes self-management and sign-posted social media support online including Twitter, as well as a local support group. Dave and his healthcare team worked together on problem-solving techniques to help make some of the diabetes tasks more achievable in his daily routine.

Ongoing clinic visits

The diabetes team needs to work to together with the person with diabetes to review the program of care including the management goals and targets at each visit [22]. It is important that the individual shares equally in all treatment decisions as this improves the chances of jointly agreed goals being adopted following the consultation. A family member, friend, or carer should be encouraged to attend the clinic to help support the person with diabetes, and to stay abreast of developments in diabetes care [23].

An important goal of management is to prevent the microvascular and macrovascular complications of diabetes without inducing iatrogenic side effects. This involves active management of hyperglycemia together with a multifaceted approach targeting other cardiovascular risk factors.

Glycemic management

It is important to enquire about and discuss hyperglycemic symptoms and problems with medications, including issues relating to injections, hypoglycemia, and self-monitoring of blood glucose.

Hyperglycemic symptoms

Symptoms relating to hyperglycemia usually occur when the blood glucose rises above the renal threshold leading to an osmotic diuresis. Polyuria, particularly at night, polydipsia, and tiredness may ensue. General malaise may also occur and is not always ascribed to the hyperglycemia.

Medications

The diabetes care team is responsible for ensuring that the person with diabetes has access to the medication and equipment necessary for diabetes control. In many, but not all, countries this is available for free or at a reduced rate; many people with diabetes may be unaware of this and timely advice may alleviate some of the anxieties about the cost of diabetes.

Oral glucose-lowering drugs

Each of the oral glucose-lowering drugs has its strengths and profile of side effects (Chapter 31) and these should be discussed. Strategies may be devised to maximize the tolerability of diabetes medications. For example, the timing of metformin in relationship to meals, or the use of long-acting preparations may reduce the risk of gastrointestinal upset. Where treatments are not being tolerated, these should be changed, in order to facilitate improved concordance with the regimen. Another example is the need to discuss the risks of hypoglycemia with sulfonylureas.

Insulin

Insulin therapy is complex: it must be given by self-injection or pump and there is considerable variation in the doses, regimens, and devices available to people with diabetes. It is important that during the clinic visit, the individual has an opportunity to discuss injection technique and any difficulties with injection sites, which should be examined at least annually. Information about the appropriate storage of insulin and safe disposal of sharps (needles) is needed.

The commonest side effects of insulin are hypoglycemia and weight gain (Chapter 29). In addition to these, there are a number of other issues that should be addressed including injection site problems, such as lipohypertrophy, and device and needle problems.

Assessment of glucose control

Supporting the person with diabetes to achieve optimal glycemic control is a vital component of diabetes care. The methods of assessing glucose control essentially involve short-term measures, such as self-monitoring of blood glucose, and long-term measures, such as glycated hemoglobin (HbA_{1c}) (Chapter 27). Not all people with diabetes will need to undertake self-monitoring of blood glucose but where they do, it is incumbent on the healthcare professional to discuss with them the findings and how these will affect future management. The glycated hemoglobin provides a measure of the longer term adequacy of glycemic control and sometimes there may be a discrepancy between this measure and self-monitored blood glucose. It is important to explore the reasons that underlie the differences, which may range from biological issues, such as genetically determined rates of glycation, through inappropriately timed glucose readings to fabricated results. A pristine sheet (with no blood stains from finger-sticks) and with the use of a single pen color may be a clue to the latter. It is important to explore in a non-judgmental way why the individual might engage in such a practice. The

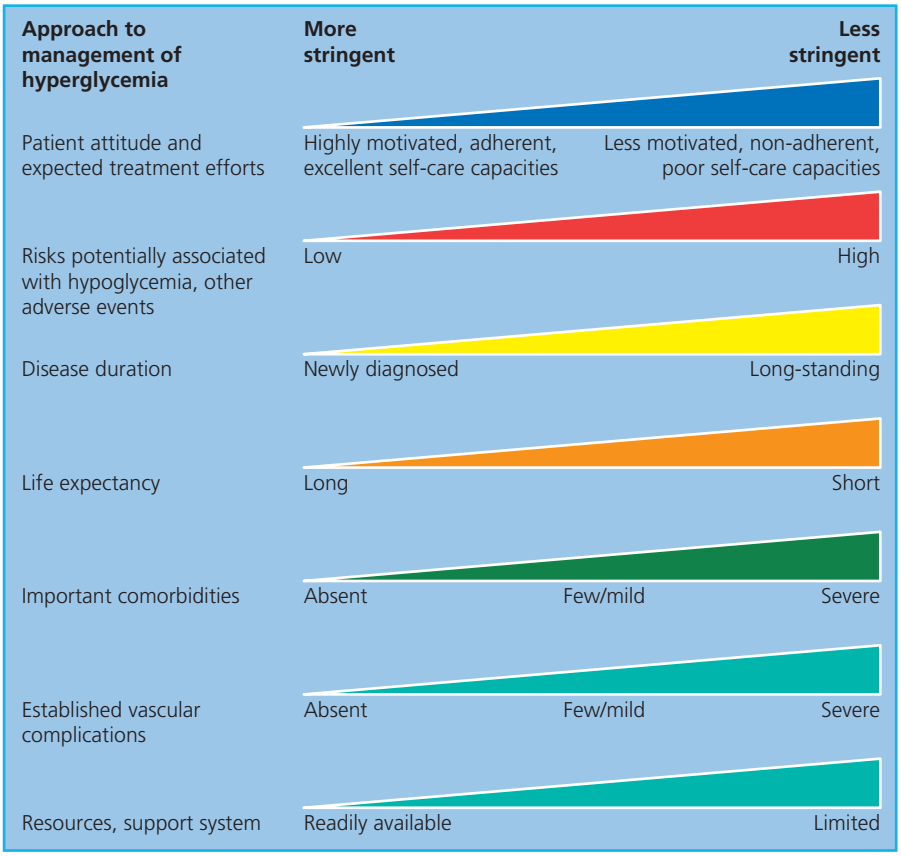

Figure 23.3 EASD/ADA Approach to management of hyperglycemia [24].

use of computers and the ability to download results may help to observe patterns of hyperglycemia although it is important to make sure that the meter has not been shared. Increasingly it is possible to use the Internet to review glucose remotely.

People with diabetes need to be supported in an open and non-judgmental way. Sometimes clinicians can appear to show the opposite, which is unhelpful and counter-productive to joint goal-setting, and collaborative consultation. Feeling reprimanded or misunderstood can be frustrating and upsetting, and it is understandable why someone would not choose to put themselves through the experience if they did not have to. It is better to build a relationship whereby the person with diabetes feels that the healthcare professional is there to support and work together to find solutions and overcome barriers to optimal self-management.

The Diabetes Control and Complications Trial and the United Kingdom Prospective Diabetes Study (UKPDS) have clearly established that lower levels of glycemia are associated with reduced risk of long-term microvascular complications in T1DM and T2DM, respectively [3–5]. For this reason, learned societies such as the American Diabetes Association and European Association for the Study of Diabetes and government bodies such as the National Institute for Health and Care Excellence have set tight glycemic targets to minimize the risk of complications for individuals with diabetes [24–26]. Furthermore in the UK, general practitioners are incentivized financially to achieve tight glycemic control for their patients. However, there has been an increasing awareness of the need to individualize targets for the person with diabetes, depending on factors such as life expectancy, duration of diabetes, comorbidity including cardiovascular disease, resources, and availability of support (Figure 23.3).

The natural history of the development of complications is long and in some situations may be longer than the life expectancy of the person with diabetes. It would be a poor trade to insist on switching a frail complication-free 90-year-old person to insulin if they subsequently fell and broke their hip and died as a result of insulin-induced hypoglycemia. Less melodramatic but still important is the consideration about dietary and lifestyle change in people with low risk of disabling complications: is it really necessary to deny an elderly person with diabetes a piece of birthday cake if this is one of the few food pleasures in their life? A more sensible approach would be to advise a limit to portion size, rather than insist on severe dietary restriction.

Although there is an appropriate clinical emphasis on glycemic targets, the results of The Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial [27], the Action in Diabetes and Vascular disease: Preteraz and diamicron MR controlled evaluation (ADVANCE) trial [28], and the Veterans Affairs Diabetes

Trial (VA-DT) have led to a note of caution [29]. These trials have shown that tight glycemic control in people with a longer duration of diabetes did not prolong life. In the case of the ACCORD trial increased cardiovascular mortality was seen in those receiving intensive glycemic control [27]. Again these findings highlight the need for individualized targets.

Despite clinical guidance and the availability of effective treatments, many people with diabetes are unable to achieve the desired level of glycemic control. It is important for the healthcare professional to explore the reasons why this might be together with the individual. Advice about adjustment of treatment or further education or psychological support may be needed.

A common limiting factor in the ability to achieve optimal control is hypoglycemia which is one of the most unpleasant, socially aversive, inconvenient, and feared side effects of diabetes medication (Chapter 35). The frequency and severity of hypoglycemic episodes should be discussed. An exploration of the underlying causes and advice about prevention is required for the future.

When a person with diabetes is treated with insulin, it is important to ensure that they carry a readily accessible source of fast-acting glucose, such as glucose tablets. Concentrated glucose solution and glucagon should also be made available for use in more severe hypoglycemia. As these treatments may only be used infrequently, it is worth regularly checking whether they are in date. Furthermore as they need to be administered by a third party, it is important to ensure that the friends and relatives of the person with diabetes know how to administer them and are confident in doing so before they are needed.

In some instances, the only way of avoiding disabling hypoglycemia is to accept a lesser degree of glycemic control. This recalibration of glycemic goals should be decided with the individual and a target appropriate for the circumstances should be agreed. As well as the risk of hypoglycemia, other factors should be considered when discussing the target including the overall clinical situation and risk of complications affecting the individual.

Assessment of cardiovascular risk

The commonest cause of death in people with diabetes is cardiovascular disease and much effort has been expended to develop strategies that will reduce its morbidity and mortality [30].

Cardiovascular risk should be assessed at least once a year for people with diabetes. This should include a history of cardiovascular risk factors, such as family history and smoking, an examination to include weight, waist circumference, and blood pressure as well as investigations such as a lipid profile. The results of this assessment can be used to calculate cardiovascular risk using the various risk engines available. Some, such as the UKPDS risk engines for coronary heart disease and stroke, were designed specifically for use in people with diabetes and are readily available on the Internet [31, 32].

Since the risk of myocardial infarction is almost as high in people with diabetes as in those without but with pre-existing cardiovascular disease, the diabetes itself is widely considered to be a major risk factor for cardiovascular disease [33]. This has influenced prescribing guidelines which now recommend that specific pharmacological interventions are required to reduce the incidence of cardiovascular disease in people with diabetes regardless of risk assessment. Large randomized controlled trials have shown the effectiveness of these interventions and are discussed in greater detail in Part 8 [34].

Although physicians may appreciate the close connection between diabetes and cardiovascular disease, many people with diabetes have never been told about this increased risk, and the importance of blood pressure and lipid control. Thus, many individuals are not taking appropriate drugs for cardiovascular prevention, or if they are the doses may be inadequate to achieve recommended targets. When working with someone with diabetes, it is important that strategies to reduce cardiovascular disease and the need for preventative drugs are discussed. In addition, the increased vascular damage promoted by smoking in the setting of diabetes may not be appreciated.

The main classes of drugs used are lipid-lowering drugs, predominantly statins, and antihypertensives, particularly drugs acting on the renin-angiotensin system. Antihypertensives are also important in the prevention of microvascular complications as discussed in the following section.

While each individual intervention for the various risk factors is important in the prevention of macrovascular disease, the Steno 2 study has demonstrated that a coordinated approach to the management of cardiovascular risk can be successful [6]. In this study, the clinic setting and protocol-driven approach to overall cardiovascular risk led to significantly improved mortality compared with routine care.

Microvascular complications

Around 80% of individuals will have developed microvascular complications by the time they have had diabetes for 20 years [35]. Many complications will remain asymptomatic until they have catastrophic consequences. The management of microvascular complications involves measures to prevent, detect, and treat. General measures, such as optimal glycemic and blood pressure control, lead to a reduction in the incidence and progression of microvascular complications but specific preventative measures are also needed and are discussed below [3–5, 36].

Eyes

Diabetic retinopathy remains a common cause of blindness in people of working age (Chapter 38). It is almost invariably asymptomatic until there is a catastrophic sight-threatening hemorrhage. For this reason it is important to screen regularly for retinopathy to allow treatment before hemorrhage and visual loss occur. Traditionally this has been performed by examination of the visual acuity and fundoscopy within the diabetes clinic at least on an annual basis. Alternatively in many countries, dilated ophthalmological examinations are regularly performed by a specialist.

The gold standard for screening now, however, is digital retinal photography, which may be undertaken in several different

settings. When this is performed outside the traditional diabetes clinic, communication between the screener and diabetes team is essential if other aspects of diabetes care are to take account of the development of retinopathy.

Where retinopathy is detected within the clinic, it is the responsibility of the clinic to ensure that the individual is referred for specialist ophthalmological attention in a timely fashion.

Neuropathy

Distal symmetrical polyneuropathy is the commonest form of neuropathy seen in diabetes and is addressed in the following section on the diabetic foot. Autonomic neuropathy may affect the person with diabetes in a number of ways, for example gustatory sweating, postural hypotension, or bloating (Chapter 39). Healthcare professionals should be alert to this possibility if symptoms suggestive of these conditions are raised.

Foot problems

Diabetes is the commonest cause of non-traumatic lower limb amputation in the developed world (Chapter 48). Around 10–15% of people with diabetes develop a foot ulcer as a result of the combination of peripheral neuropathy and vascular insufficiency to the foot.

Prevention of ulceration is an important goal and requires educating the person with diabetes so that they are aware of this possibility. It is important to inform people that they should not delay in obtaining professional help if problems ensue.

An assessment of the risk of foot ulceration is needed at least annually and more frequently when neuropathy or vascular disease is present. The assessment should include a history of previous ulceration, trauma as well as an examination of the skin, vascular supply, and sensation. Opportunistic foot screening should also be performed if an individual with diabetes is admitted to hospital.

In patients with numbness, close attention to discovering unsuspected foot lesions, including examination of the sole of the foot using a small mirror, must be performed by the individual on a regular basis. This can lead to rapid intervention and prevent an early infection from progressing, potentially averting such devastating consequences as osteomyelitis and gangrene.

Prompt referral to the podiatrist and foot clinic should be arranged by the diabetes clinic if needed.

Kidneys

Diabetic nephropathy is characterized by a progressive increase in urinary albumin excretion which is accompanied by increasing blood pressure and decline in glomerular filtration rate ultimately culminating in end-stage renal disease. It is also associated with a marked increase in the rate of cardiovascular disease.

Microalbuminuria, the earliest stage of nephropathy, affects around 50% of people with diabetes after 30 years while frank proteinuria affects a quarter of people with T1DM after 25 years. Diabetic nephropathy is a common reason for the initiation of renal replacement therapy. Although it appears that with modern treatments of diabetes, the percentage of people with diabetes developing end-stage renal disease appears to be falling, the absolute numbers requiring renal replacement therapy is increasing in line with the increased prevalence of diabetes worldwide.

Diabetic nephropathy is asymptomatic and so screening is required annually. This is usually achieved by measurement of urinary albumin excretion. The commonest method is a single urinary albumin to creatinine ratio (ACR) measurement which should be repeated two to three times if abnormal. An estimation of glomerular filtration rate should be obtained annually.

The primary prevention of nephropathy relies on excellent glycemic control as well as tight blood pressure control. Once nephropathy is present, blood pressure management is the mainstay as there is little evidence that glycemic control at this stage slows the rate of progression. The antihypertensive drugs of choice are angiotensin-converting enzyme (ACE) inhibitors or angiotensin-2 receptor antagonists as they have specific effects on renal blood flow [37, 38].

There has been some debate about the value of undertaking urinary ACR measurements in people with T2DM, the argument being that tight blood pressure control (often including an ACE inhibitor or angiotensin-2 receptor antagonist) together with good glycemic control should form part of the general management of cardiovascular risk reduction, regardless of the presence of microalbuminuria.

It is important that the person with diabetes understands the need for screening followed by treatment if nephropathy develops. Timely referral to the nephrology team is needed to ensure that the management of renal disease is managed promptly in those with abnormal renal function.

Diabetes emergencies

Diabetic ketoacidosis and hyperosmolar hyperglycemic syndrome

Diabetic ketoacidosis and hyperosmolar hyperglycemic syndrome are potentially life-threatening emergencies (Chapter 36). The person with diabetes needs to be educated about the risk of these and strategies to prevent them from happening should be discussed. If a person with diabetes has been admitted with diabetic ketoacidosis or hyperosmolar hyperglycemic syndrome, the opportunity should be taken to explore the reasons why this episode occurred and to identify what might be changed to prevent this from happening in future. The commonest causes of hyperglycemic emergencies in those with pre-existing diabetes are infections and insulin omission and errors. It is particularly important that people with diabetes understand the "sick-day" rules where insulin should never be discontinued and indeed doses may need to be increased even when appetite is diminished.

Hypoglycemia

Hypoglycemia is a common diabetic emergency affecting most people with T1DM and ~60% of insulin-treated people with T2DM (Chapter 35). Hypoglycemia may have a major adverse

Table 23.2 Causes of hypoglycemia.

- Excessive insulin administration
  - Person with diabetes, doctor or pharmacist error
  - Deliberate overdose during a suicide or parasuicide attempt
- Excessive sulfonylurea administration
- Unpredictable insulin absorption
  - Insulin is absorbed more rapidly from the abdomen
  - Lipohypertophy
- Altered clearance of insulin
  - Decreased insulin clearance in renal failure
- Decreased insulin requirement
  - Missed, small, or delayed meals
  - Alcohol
    - Inhibits hepatic glucose output
  - Vomiting
    - May occur with gastroparesis, a long-term complication of diabetes
  - Exercise
    - Promotes glucose uptake into muscle
    - Increases rate of insulin absorption
- Recurrent hypoglycemia and unawareness

effect on quality of life and fear of hypoglycemia is the most important limiting factor in the achievement of optimal glycemic control.

It is important that the person with diabetes is educated about the symptoms of hypoglycemia and the actions to be taken to prevent and treat it. As noted earlier, friends and family members should be invited to learn about hypoglycemia and its management in order to intervene when necessary, for example, providing glucagon treatment if the person with diabetes is unconscious. If hypoglycemia becomes disabling or recurrent, it is important to explore underlying causes (Table 23.2).

Lifestyle issues

Diabetes has a number of social, psychological, and medical consequences and an important aspect of diabetes care is to discuss how diabetes may be affecting social issues such as driving, education, and employment (Chapter 58). The healthcare professional may need to act as an advocate for the person experiencing discrimination. Some aspects of lifestyle also affect diabetes care, such as diet, exercise, smoking, and alcohol. These issues should be discussed sensitively in order help the person with diabetes understand how their lifestyle affects their diabetes and general health. Support should be given to help and encourage the individual to make changes to their lifestyle where these are appropriate.

Psychological issues

Both the diagnosis of diabetes and the chronicity of the condition can provoke a number of psychological reactions, such as anger and sadness in the individual which may be akin to a bereavement reaction or a chronic sorrow response (Chapter 56). More serious mental health problems, such as depression, are common in people with diabetes and these can impede the person's ability to achieve optimal glycemic control [39] (Chapter 57).

It is important for those working in diabetes care to explore with the individual whether they are experiencing psychological problems as they may be reluctant to raise this in the consultation. While all members of the diabetes team should be able to recognize and address basic psychological problems, an essential team member is a psychologist who can address more complex needs. Despite the importance of psychological issues, this need is frequently unmet because of a lack of trained healthcare professionals.

The Diabetes Attitudes Wishes and Needs (DAWN™) study, a global survey of people with diabetes and healthcare professionals involved in their care, substantiated the association of diabetes with multiple psychological challenges and the close interrelationship between emotional well-being and diabetes outcome [40]. It also pointed to important deficiencies in the emotional care of and support for people with diabetes, which became the basis for the DAWN Call to Action with the goal of implementing person-centered diabetes care.

In 2012, the second global DAWN™ study (DAWN2™) was conducted to re-evaluate the state of diabetes care, both globally and within each of the 17 participating countries, including the UK. In the global DAWN2 study, nearly half of the surveyed people with diabetes reported diabetes-related distress, 12% rated their overall quality of life "poor" or "very poor," and approximately 14% had likely depression [41]. Notably, family members were also considerably impacted by having a person with diabetes in their household, with 35% experiencing the care for the person with diabetes as a burden [23]. In 45% of family members, diabetes care had its most negative impact on emotional well-being [23].

Sexual health

Sexual dysfunction

Sexual dysfunction is more common in both men and women with diabetes than in the general population. This can affect the person's quality of life considerably. Many people are reluctant to discuss this aspect of their lives because of embarrassment and so it is the responsibility of the healthcare professional to enquire about this. There are now effective treatments for erectile dysfunction and failure to ask about this can deny the person with diabetes the opportunity to receive this treatment.

Pregnancy planning

Starting a family is an important milestone for many and the presence of diabetes can make this decision more difficult for the woman with diabetes (Chapter 61). Women are often worried about the effects that diabetes will have on their pregnancy and vice versa. The implications for the long-term risk of diabetes in the offspring are also of concern.

Planning for a pregnancy by a woman with diabetes can dramatically improve the outcome, reducing the risk of miscarriage, congenital malformations and macrosomia, with its attendant risks of shoulder dystocia, and neonatal hypoglycemia [42]. Most oral medications should not be used in pregnancy and the treatment regimen may need to be altered as part of the planning process.

Despite this, many women enter pregnancy without adequate preparation or pre-conception care. It is therefore incumbent on the healthcare professional to discuss pregnancy with all women of child-bearing age, including adolescents, to ascertain their plans regarding pregnancy. The answers are often not black and white; women may not actively be planning to become pregnant but are sexually active and not using effective contraception. Contraceptive advice is needed and where a pregnancy is being planned, women should be referred to a dedicated pre-conception clinic as these have been shown to improve the outcomes of diabetic pregnancies.

With an increasing number of women with T2DM of child-bearing age, it is important that pre-conception advice is not solely focused on those with T1DM. This is particularly relevant as many women with T2DM are not seen in specialist centers.

Prompt referral to a joint diabetes antenatal clinic is necessary once a woman becomes pregnant.

Men may also have concerns about embarking on a family because of the increased risks of diabetes in their offspring and these anxieties need to be discussed sensitively.

Inpatient diabetes care

It is estimated that around 10–15% of people in hospital have diabetes (Chapter 34). In many instances the diabetes is coincidental to the admission and the individual remains capable of managing their own diabetes, often with greater skill than the healthcare professional around them. Optimal diabetes control remains an important goal as this improves the rate of recovery and may lead to an earlier discharge.

Admission to hospital is a worrying time but much of the fear can be alleviated if a full explanation of the treatment in hospital is given along with an opportunity to discuss any particular concerns. Being given the opportunity to discuss the management of diabetes can be reassuring. Where possible, the person with diabetes should be allowed to continue to self-manage their diabetes. The individual should be encouraged to bring in their own insulin supplies where admissions are planned. There should be access to their regular diabetes healthcare team where possible as the admission may provide an occasion to check techniques and results. Ready access to carbohydrate and appropriate coordination of mealtimes, snacks, and medication should obviate the need for more dramatic treatment of hypoglycemia.

There will be times when the person with diabetes is unable to manage their diabetes themselves. In these instances, the responsibility will fall entirely on the healthcare team, for example, during surgery when the person with diabetes is unconscious and requires intravenous insulin and dextrose.

Following discharge, clear communication with the primary care and hospital diabetes teams is essential so that any changes in management or medication are made known to those involved in the individual's care.

Involving people with diabetes in the planning of healthcare and service development

Involving people with diabetes and their carers in the planning and decision-making of local health services enables these to be built around the needs of those who use the service, rather than the needs of the system [43]. An open dialogue is needed and service users should feel that their views are listened to. This will improve the accountability and legitimacy for any decisions made and is likely to improve clinical and care outcomes. People with diabetes should be encouraged to express their views and concerns about their services as better feedback about service provision should help to improve and shape future provision of care.

Conclusion

The aim of diabetes care is to improve the lives of those with diabetes. This can only be achieved through a partnership between the person with diabetes and a multifunctional healthcare team that should be in place to support the person with diabetes.

Key points

- Diabetes education and psychosocial support are critical elements of care for all people with diabetes and their family members.
- Being able to self-manage diabetes requires substantial knowledge, motivation, and behavioral competencies by people with diabetes and their family members.
- Diabetes education needs to be implemented in a sufficiently flexible manner to be incorporated into multiple settings, not just formal and structured diabetes education.
- People with diabetes must be placed at the center at all times in diabetes education. Active involvement in their own healthcare must be prioritized over educator-dominated involvement.
- Diabetes education programs are more effective if they are based on participant- and empowerment-oriented principles and principles of adult learning.
- Group-based diabetes education has a positive effect on clinical, lifestyle and psychosocial outcomes, including glycated hemoglobin (HbA_{1c}), fasting blood glucose concentration, diabetes knowledge, self-management, empowerment, and self-efficacy.
- The provision of appropriate training of diabetes educators, including the management of psychosocial issues, cannot be overestimated.
- Group processes and active participation during diabetes education appear more important for improving coping skills than the didactic content of the program.
- People with diabetes should be supported to work specifically and realistically with setting goals and to think about potential obstacles and facilitators to achieving them.
- Family-based diabetes education interventions seem a potentially important supplement to enhance diabetes management in everyday life
- Evaluation of diabetes education should focus on understanding how, for whom, and under what conditions specific programs will work.
- The main limiting factor of diabetes education is that it almost always does not include ongoing care and education.

Introduction

There is broad consensus in the global diabetes community that diabetes education and psychosocial support are critical elements of care for all people with diabetes and their family members [1]. The aim of providing diabetes education and psychosocial support is to promote behaviors that will lead to the prevention or delay of the complications of diabetes and to enhance good quality of life [1]. The ultimate outcome of diabetes education is effective self-management; hence the preferred term is *diabetes self-management education*.

Diabetes is primarily managed on a daily basis by people with diabetes, who are often supported by the active participation of their family members. As such, self-management requires substantial knowledge, motivation, and behavioral competencies by people with diabetes and their family members [2, 3].

The recent second Diabetes, Attitudes, Wishes and Needs (DAWN2) study, conducted in 17 countries across four continents, revealed that, on average, only 49% of people with diabetes reported having ever participated in a diabetes education program. Of those who participated, 81% found the diabetes education helpful [4] and participation was associated with more positive quality of life and well-being outcomes. For family members, participation in diabetes educational programs was lower (average 23%) but helpfulness was comparable (72%) [5]. These results indicate that diabetes education services are valued but there is insufficient exposure to those who might benefit. Diabetes education services therefore need to be implemented in a sufficiently flexible manner to be incorporated into multiple settings, not just formal and structured diabetes education. Consideration of novel means of providing diabetes self-management education should be strongly encouraged and supported.

Diabetes self-management education is defined in the American Diabetes Association Guidelines as an ongoing process of facilitating the knowledge, skill, and ability necessary for diabetes self-management behaviors. Diabetes self-management

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

education is intended to support informed decision-making, self-care behaviors which often involve changing behavior, problem-solving, and active collaboration with the healthcare team to improve clinical outcomes, health status, and quality of life. The process of education must be based on the needs, goals, and life experiences of the person with diabetes and is preferably guided by evidence-based standards. Diabetes self-management support and psychosocial support more broadly include:

> *"Activities that assist the person with diabetes in implementing and sustaining the behaviors needed to manage his or her condition on an ongoing basis beyond or outside of formal self-management training. The type of support provided can be behavioral, educational, psychosocial, or clinical" [1]*

An important recent development, and one that serves as the basis for this chapter, is the combination of self-management education and psychosocial support. Organizing the activities of the educator around the concept of supporting the person with diabetes to engage in the relevant self-management behaviors represents a major shift to being a collaborator as well as an educator.

In this chapter, we will present a framework to guide the diabetes educator. Given that at least one-half of people with diabetes do not participate in formal diabetes education services, this framework needs to be adapted to multiple settings, for example, formal diabetes education services, primary and specialty care services, and public health.

To achieve maximal effectiveness, self-management education and psychosocial support must be integrated. Persons with diabetes must be placed at the center and active involvement in their own healthcare must be prioritized over educator-dominated involvement [3, 6]. This is referred to as patient-centered or person-centered care. Person-centered care can be a challenge for many diabetes educators, who are often more comfortable with providing recommendations and teaching management skills than in addressing the psychosocial context of a person's life as the foundation of supporting self-management [7]. In diabetes education person-centered care composes an essential paradigm shift compared to more traditional didactic diabetes education which communicates disease-specific knowledge [8]. It raises a stressful situation for the educator whereby issues not directly related to diabetes may be overriding priorities for the person with diabetes, thereby limiting the goals and expectations of the educator at any moment in time.

The self-management education process is brought to life through the active involvement of people with diabetes and their family members, using recognized pedagogic processes and educator skills. The educational content follows from an effective partnership between people with diabetes, their family members, and educators, employing a broad concept of health and an individual tailoring in group-based as well as one-to-one education sessions. Thus, diabetes education should be standardized by function, not by content.

This paradigm shift requires a new approach, which presents a substantial challenge when considering the traditional skills of educators providing diabetes education. Educators experience numerous barriers regarding the facilitation of person-centered and participant-involving education [8, 9]. Many agree with the philosophy of this paradigm shift, but its implementation remains a huge challenge [8, 9].

Currently there are many programs available for diabetes education and support with more or less evidence of effect (10–12). However, the focus in this chapter will not be on specific programs or models but rather on the educational and psychosocial principles and methods that guide enhancement of self-management education and support. The rationale for this is that given the varied contexts in which diabetes self-management education is administered and the varying supports available to an educator any chosen method must be fluid and contextual. What works for one person in one context may not work for another.

Theory underlying diabetes education

Person-centered diabetes self-management education has the intention of empowering people with diabetes to engage in the challenging behaviors associated with glycemic, lipid and blood pressure control and complication prevention, for example, foot care. For the healthcare professional, this requires shifting from being an educator to being an educator *and* a collaborator [8, 9, 13, 14]. Adolfsson et al. [9] conclude that educators are entrenched in their roles in traditional didactic patient education, but are challenged to change from an exclusive role as medical expert to include roles as facilitator and catalyst of motivation. A review by Barlow concluded that many educators fail to support patients because of a lack of basic adult educational skills despite the fact that educators may be the main source of support for people with diabetes [15]. The potential of self-management education and support can be realized when guided by two health education principles: dialogue and participation.

Dialogue is to be understood in a broad sense as a way of conducting diabetes education [16, 17]. The traditional one-way didactic model, in which the educator provides information to persons with diabetes in a traditional teacher–student relationship (i.e. monologue, not dialogue), may be successful in conveying information, but is less useful when it comes to encouraging, enabling, and supporting people with diabetes to take responsibility for control and management of their condition [18]. Behavior change theory indicates that educators must instead engage participants in a dialogue to identify challenges, set goals, increase self-efficacy, and address barriers to change [19, 20]. It is useful to take the position that behavior change is hard, and sustained behavior change is even harder. This perspective acknowledges that once behavioral habits become entrenched, much behavior is cued by the environment as well as natural preferences. For example, a 55-year-old man with type 2 diabetes who has never liked exercise and dislikes the idea of medication and illness, and has developed unhealthy eating and drinking habits as part of a stable and supportive friendship circle, is unlikely to change behavior as a result

of listening to lectures on the benefits of healthy eating, medication adherence, and physical activity.

Participation likewise implies a shift in perspective from a disease-centered and paternalistic approach towards care centered on the needs of the person. Effective and meaningful diabetes education requires that people with diabetes are actively involved and that teaching is tailored to the needs and preferences of the individual; in other words, it does not rely exclusively on educator assumptions of needs and preferences [16, 21, 22].

Educator knowledge must take second place to the decisional processes of the person with diabetes. The profile of expert knowledge and teaching is changed in the way the educator engages with those living with diabetes. Consider the same 55-year-old man with diabetes who dislikes exercise, has never been physically active, and has many individual, social and financial barriers to increasing activity. What are the conditions under which this individual will choose to do all of the work necessary to add a disliked behavior to his routine? Overcoming the personal barriers to change is less likely to arise from teaching and telling than it would from effective understanding and supportive negotiation of health behavior choices. In this example, the educator could communicate understanding and respect of the challenges to the recommended behavior, and explicitly acknowledge that the person is in charge of the decision, while seeking permission to discuss ways to overcome barriers, be they informational, motivational, emotional, relational, or practical. This is reflected in the recent promotion by the American Association of Diabetes Educators of the AADE7 Self-Care Behaviors [23]. Within this framework professional services are oriented around the behaviors of healthy eating, being active, glucose monitoring, medication adherence, problem-solving, reducing risk, and healthy coping. However, many educators will need to change their approach in order for self-management support to be effectively implemented. Imagine how an educator might feel and behave if they needed to become comfortable supporting a person with type 1 diabetes who chooses not to take bolus insulin, only basal, out of a fear of weight gain. Several specific aspects of change can be identified as necessary in promoting the educator in the role of self-management support. Specifically, self-management support has significant implications for the diabetes–educator relationship and for the acceptance of complexity as well as for the need for principles to guide method.

Many educators believe that the essence of their professional role is to recommend specific actions based on evidence and to educate persons with diabetes based on their knowledge. It is no surprise that educators often do most of the talking in clinical encounters, that they make frequent recommendations in the form of statements, and that they commonly interrupt people with diabetes if they stray from the agenda of the educator. These relational dynamics place the educator in the dominant position as expert. In some situations this might be acceptable, but unless the person with diabetes is receptive to this type of guidance it could be problematic and result in the person with diabetes feeling judged, or developing learned helplessness [24]. One way of understanding a change-based relationship is to describe the typical approach to intervention as based on the constructs of assessment and diagnosis, treatment and intervention, and finally outcome. From this perspective it follows that competency is based on the skill of the educator. In contrast, a more collaborative, change-based relationship could be described using the constructs of description, prediction, and choice. Here the role of the educator is not to be an expert exclusively but to collaborate in understanding how the current situation has evolved (describe), what the implications of the current situation are (predict), and to explore the potential alternative outcomes if the person with diabetes were to make a different choice (choose) [7].

A second shift that will support effective self-management education is the issue of complexity [25]. Most medical research, and approaches to clinical care, are influenced by reductionism: the intent to find THE solution to problems. This method might have relevance to medications but does not describe behavior. An alternative to the reductionist approach is to consider complexity theory, with the intent of matching the approach to the situation. In situations where complexity is appropriate, interventions are not so much guided by procedure but by principle. Different procedures may be equally appropriate if they impact on the principle in similar ways, for example if self-efficacy is the principle that predicts sustained behavior, then whatever procedure used by an educator that increases self-efficacy is acceptable. Reductionism and complexity, even chaos, can be considered as they relate to two constructs; understanding and agreement [25]. When the degree of understanding about a phenomenon is high and the degree of agreement on how to address the phenomenon is high, this is an indication of a simple system and a situation where reductionist protocols are required. When the degree of understanding and agreement is very low, this is an indication of a chaotic system where there is no precise guidance available. When degree of understanding and agreement are partial, this is a complex system and principles are the approach to take. Consider, for example, a procedure such as regular weighing of those with type 2 diabetes and obesity. Should regular weighing be advised? Although we understand some of the mechanisms that can help control weight, it is not highly under behavioral control. Given the complexity of weight management, it might be better therefore to look for the principle of empowerment or self-efficacy. Thus, if one explores with a patient the impact of weighing on empowerment or self-efficacy, this will guide the healthcare professional to advise either weighing in the case of the person who finds weighing helpful or not weighing in the case of the person who finds it demoralizing.

The third shift associated with self-management support picks up on the distinction between method (what one does) and principle (the guiding rationale for what one does). Given that self-management necessarily places the responsibility on the person with diabetes it becomes necessary to respect the choices made by any given person. If the educator focuses on the principle then they can negotiate the method with the person with diabetes without threatening their personal choice.

Identification and use of theory to guide method

One of the learnings from the behavioral science field is the importance of theory-driven interventions. This is important because many healthcare educators look to the behavioral sciences for tools to implement in their practice. By contrast, the use of tools, without theory, might be misguided. Some understanding of the underlying theory is crucial when an educator decides which tool to choose. Otherwise the implementation might be confusing and limiting. For instance, if one were to use a goal-setting tool based on behavior modification principles with a person who was not ready to change then creating a goal might occur as a way of the patient pleasing the educator. There are a number of theories of behavior available and currently these appear like a shopping list. This makes it difficult for diabetes educators to be guided by these theories. The risk is that different groups will adopt different theories for no reason other than familiarity or fiat. Another choice is to organize these theories in a coherent model that will guide the diabetes educator.

Theoretical models are categorized in reference to the person with diabetes being the decision maker, in reference to drivers of behavior, and in reference to how the educator can influence behavioral choices through counselling methods.

At the center, the person with diabetes can be seen as an individual who will make specific behavioral choices (person as decision maker). The dominant theoretical model describing how people make behavioral choices is the Self-Regulation model, which can be assessed using the Illness Perception Questionnaire [26]. This scale identifies five dimensions of illness beliefs: consequences (e.g. perceived seriousness), personal control, treatment control, timeline, and emotional representation. Understanding these beliefs can be a valuable guide to the diabetes educator and, for instance, when applied to a person newly diagnosed with type 2 diabetes, they can be a helpful guide. Consider the person who perceives the consequences of their diagnosis as minor or someone who does not believe that treatment will reduce complications, perhaps based on a family history of early, devastating complications. Or consider the person who reports overwhelmingly distressing emotions following diagnosis. Understanding these common-sense beliefs will guide the educator to potential solutions.

Also, theoretical models explaining the drivers of behavior can be useful. The Social Cognitive Theory [27], the Theory of Planned Behavior [28], and the Transtheoretical model [29] help to explain what determines a person's behavior and can help the educator identify important motivational constructs that are associated with change. For instance, the constructs of self-efficacy, readiness to change (stages of change) and the influence of the beliefs of important others are explained in these theories.

Perhaps most important are the models that guide the educator on how to counsel a person with diabetes to help them develop the motivation to change. Here the principles of patient centeredness [30], empowerment [31], and motivational interviewing [32] provide specific knowledge and pathways to guide people toward change. Finally, it is also important to consider the person with diabetes as they exist within the immediate social world. The role of the family and the social network is important to incorporate into an understanding of the person and how change can occur. Consider two people; one with positive support from partner and friend and a second who lives without a partner and is socially isolated. Diabetes self-management is likely to be influenced by these factors. Broader social factors, such as the social determinants of health [33], for example, income, socioeconomic status, literacy, and employment, will all play a role, as do cultural factors.

It is not the job of the educator to be an expert in all of these areas; however, it is the job of the educator, from a self-management support perspective, to be aware of these issues in order to incorporate them into any diabetes self-management plan. An educator who is aware that there are many helpful theories that will guide them in effectively collaborating with the person with diabetes can use various theoretical perspectives as general guidance to appropriate methods. An overview of relevant theories is shown in Table 24.1.

Health education methods

Many issues that impair self-management efforts of diabetes educators are grounded in communication challenges [14]. Educators who restrict patient participation through time constraints and pre-planned topics, and use persuasive recommendations that exclude the patients from taking part in the planning of their own care [37] operate counter to strong evidence that goals generated by people with diabetes produce better outcomes than goals produced by healthcare professionals [37]. It only makes sense that a person will be more committed to pursuing goals that are their own than goals that are "given" to them by another person. A Health Technology Assessment of patient education programs concluded that education programs for people with diabetes are more effective if they are based on participant- and empowerment-oriented principles and principles of adult learning [18]. The best outcomes of patient education seem to be produced with an empowerment approach, which is problem-based, individually and culturally tailored to address psychosocial, behavioral, and clinical issues relevant to people's needs and readiness to learn [39]. In reality, educators are responsible for translating abstract concepts and theories to concrete programs tailored to the needs of very different patients [40].

Modalities of education

Most studies of the effects of diabetes education show that group-based diabetes education has a positive effect on clinical, lifestyle and psychosocial outcomes, such as HbA_{1c}, fasting blood glucose, diabetes knowledge, self-management, empowerment, and

Table 24.1 Health education theories.

	Guiding theoretical perspective	Model	Example constructs
Person with diabetes			
Faces the personal responsibility to make behavioral choices	Health beliefs	Self-regulation model [34]	Perceived consequences, personal control, treatment control, timeline, and emotional impact
	Motivation	Social cognitive theory [27] Theory of planned behavior [28] Transtheoretical model [29]	Self-efficacy, perceived social norms, readiness to change/intentions
	Emotion	Diabetes distress scale [35]	Emotional burden, regimen-related distress, physician-related distress, interpersonal distress
Person with diabetes–educator relationship			
The patient–educator relationship can provide a context to consider new behavioral options	Patient centeredness	Patient-centered clinical method [30]	Understand the whole person, explore the person's illness experience, find common ground and cultivate the relationship to overcome barriers
	Motivational communication	Motivational interviewing [36]	Non-judgmental curiosity, effective use of questioning and listening, working with ambivalence and supporting self-efficacy
	Empowerment	Patient empowerment [13]	Appreciating the process of respecting the autonomy of the person with diabetes

self-efficacy [41]. Group-based education can be cost-effective, person-centered and provide interactive learning with a high level of patient satisfaction compatible with individual education [39, 42, 43]. Group-based education is fundamentally based on social learning processes in which people with a chronic illness undergo a process of change via observational learning and modeling [44]. Participants learn to benefit from the possibilities that arise in the meeting with other people with diabetes, as well as educators [45]. Group processes and active participation during diabetes education appear more important for improving coping skills than the didactic content of the program [46].

There are many curricula that utilize evidence-based approaches available for diabetes education. The National Institute for Health and Care Excellence (NICE) in the UK defines structured diabetes patient education as "a planned and graded program that is comprehensive in scope, flexible in content, responsive to an individual's clinical and psychological needs, and adaptable to his or her educational and cultural background" [47]. In its review of the evidence, NICE identifies some principles of good practice including that: "education should be provided by an appropriately trained multidisciplinary team to groups of people with diabetes, unless group work is considered unsuitable for an individual." In more detail NICE underlines the use of established principles of adult education and "a variety of techniques to promote active learning to meet the different needs, personal choices and learning styles of people with diabetes in the formal, regular assessment of individuals' learning needs." The provision of appropriate training of educators is underlined as well as the provision of educational opportunities that are broadly accessible for people with diabetes and taking into account culture, ethnicity, disability, and geographical issues.

Educator skills in group-based diabetes education

Group-based education has become a widespread method of support, yet only a handful of studies have actually sought to show the kind of professional roles and competencies that are needed in participatory, group-based patient education [48, 49]. The educators continually have to manage different roles and the shifting between roles is necessary to provide person-centered education; however, the juggling of roles is challenging. Educators can benefit from understanding each of the roles and be able to perform all of them in order to juggle them successfully. Juggling is thus the ability to master the switching between the different roles to meet the needs of the individuals as well as the group as a whole and to challenge the participants appropriately as regards content and learning styles [17].

Some well-recognized juggler attributes are:

- ***humility*** – the ability to be approachable without projecting one's self and beliefs onto the group;
- ***flexibility*** – openness to try new process approaches, willingness to change, or stretch outside one's boundaries in the facilitator role; and
- ***professionalism*** – being ready to deal professionally with feelings in the group [50].

The roles that are juggled include the embracer, the facilitator, the translator, and the initiator [17, 51].

The **embracing** role is based on empathy [52, 53]. Empathy plays a major role in the treatment of people with diabetes as it encompasses both the desire and the ability to understand them on their own terms [52]. Morse et al. [54] propose a descriptive model of clinical empathy with affective, moral, cognitive and behavioral dimensions. Norfolk et al. [52] propose a new model about the empathic journey towards therapeutic rapport in consultations focusing on the doctor's behavior, motivation, and required skills. The factors mentioned in the Morse and Norfolk studies are important competencies for educators' ability to act in the embracer role in group-based diabetes education; however, it might be more complicated in groups than in one-to-one encounters, since educators need to spread their focus among multiple persons with different needs.

The **facilitator** role is rarely described in the literature. Notable exceptions are guidelines for facilitating patient empowerment programs [55] and a study about speech practices facilitating patient participation in health counselling, in which concrete facilitation skills are suggested [37]. However, other professional fields, such as business and organization, provide more extensive literature on facilitation [56]. The facilitation literature divides facilitator competencies into higher and lower levels of competence, where higher competencies are about developing a participatory environment and lower order competencies relate to specific skills, such as listening and questioning [50].

The **translator** role, in which the educator translates medical concepts into relevant and understandable information, implies a change of the typical health educator roles. In traditional medical and disease-specific patient education, educators give information and advice, handle acute situations and perform problem-solving [53]. In the 1980s, however, following patient demands for a more active role in healthcare, the Ottawa Charter emphasized the need of the individual to be seen as a "whole person" [57]. This implies that educators have to move away from unidirectional teaching to an approach in which they become translators: they are experts in medical knowledge and patients are experts on their lives. Patient experiences must be central to education and professionals have to "unlearn" being in control of the process [58].

The **initiator** role closely links to principles of motivational interviewing [36] and empowerment interventions [59]. The initiator faces the challenge of avoiding confrontation or authority traps such as "knowing best." In general, facilitation and participatory methods are rarely part of the curriculum or the educational experiences of health professional educators [53], which may explain the challenges they experience when delivering participatory, group-based diabetes education.

Dialogue and participation in diabetes education—practical examples

The principles of dialogue and participation have recently been translated into the development of flexible tools to be used in group-based or individual diabetes education. Figures 24.1, 24.2, and 24.3 show how the tools make use of pictures, quotes, and statements to engage and give voice to people with diabetes. The tools and their participatory and person-centered approach thus support the call for flexible and dynamic approaches to diabetes education [60, 61].

Using cultural probes is a new and promising method in diabetes education. It is a research method deriving from the design world [62] and also used as an explorative method in ethnographic studies [63, 64]. Methods include the use of postcards with questions concerning participants' attitudes to their lives, maps where participants can highlight areas of importance to their lives, and cameras with instructions asking participants to take photos of important objects. Visual methods similar to cultural probes such as photos, videos, and drawings are often used as a method for data collection [65, 66]. Cultural probes can be seen as a medium through which participants express themselves, and the method is characterized by a high level of interaction and involvement of participants. Cultural probes have demonstrated positive properties with regard to gaining profound insights into a person's life and strengthening active involvement among participants. Recently the use of cultural probes in diabetes education has been shown as a promising method of translating the theoretical concepts of person-centeredness and of putting active involvement into practice to support both educators and people with diabetes. One example of the use of probes is the Conversation Map tool which successfully facilitates interactive dialogue among people with diabetes through relationship building, trust, and confidence as well as the sharing of personal stories and experiences [67]. Further examples are the DESMOND program [10], and the NEED and EMMA programs [68, 69] shown in Figures 24.1 to 24.3.

"Who am I?" consists of 50 picture cards. The aim of the exercise is to give participants the opportunity to introduce themselves to each other by selecting picture cards that give different associations. The exercise can enable participants to talk about themselves and give the diabetes educator insight into their lives more than their disease.

"Balance Cards" consists of 27 cards with pictures and quotes. The aim of the exercise is to assist participants in talking about the imbalances, challenges, and possibilities they experience in their daily lives with diabetes. The exercise can make it easier for participants to express difficult topics and facilitates dialogue among participants.

The aim of the "My Day" exercise is to establish close contact between the person with diabetes and the educator to gain shared insight into daily life and identify relevant details and challenges related to diabetes behaviors to form the strategy for subsequent actions.

The aim of the exercise "Postcard" is to get people with diabetes to reflect on their own concerns.

The aim of the exercise "Goal and plan" is to assist people with diabetes in working specifically and realistically in setting goals and thinking about potential obstacles and facilitators to achieving them.

"Who am I?" consists of 50 picture cards. The aim of the exercise is to give participants the opportunity to introduce themselves to each other by selecting picture cards that give different associations. The exercise can enable participants to talk about themselves and give the diabetes educator insight into their lives more than their disease.

Figure 24.1 Examples of picture cards from the exercise "Who am I"? [68, 70, 71].

Psychosocial support in diabetes education

One of the most challenging aspects of diabetes education is that diabetes is both a biomedical disease and a behavioral challenge [19, 73]. In order for positive diabetes outcomes to be realized the person with diabetes must engage in intentional, effortful, and sustained behaviors. However, the importance of outcomes to the educator (e.g. $HbA_{1c} < 7.0\%$ (53 mmol/mol)) cannot supersede the importance of outcomes for the person with diabetes (e.g. living life as normally as possible) and things go well only when the two are in synchrony.

There is an association between psychosocial problems and poor diabetes outcomes such as risk of hypoglycemia and frequent omission of prescribed medicine [74, 75]. At the same time, poor diabetes outcomes can cause psychosocial problems, such as fear of hypoglycemia, diabetes distress, and functional or occupational interference. Depressive phenomena have been shown to be common in those with diabetes, particularly diabetes distress. Diabetes distress has been found to be distinct from and more prevalent than depression among adults with diabetes [76, 77]. Further, compared to depression, diabetes distress is independently and more strongly associated with poor diabetes self-management and poor glycemic control [77]. It has been suggested that people with diabetes distress may be incorrectly diagnosed as having depression and thus experience an ineffective approach to treatment [78]. A recently published paper by Fisher et al. emphasizes that emotional distress is best considered as a "continuous psychological characteristic," rather than a distinct "comorbid clinical condition" [79]. In this way, diabetes distress is distinct from mental health disorders and thus is a characteristic to be aware of in diabetes education.

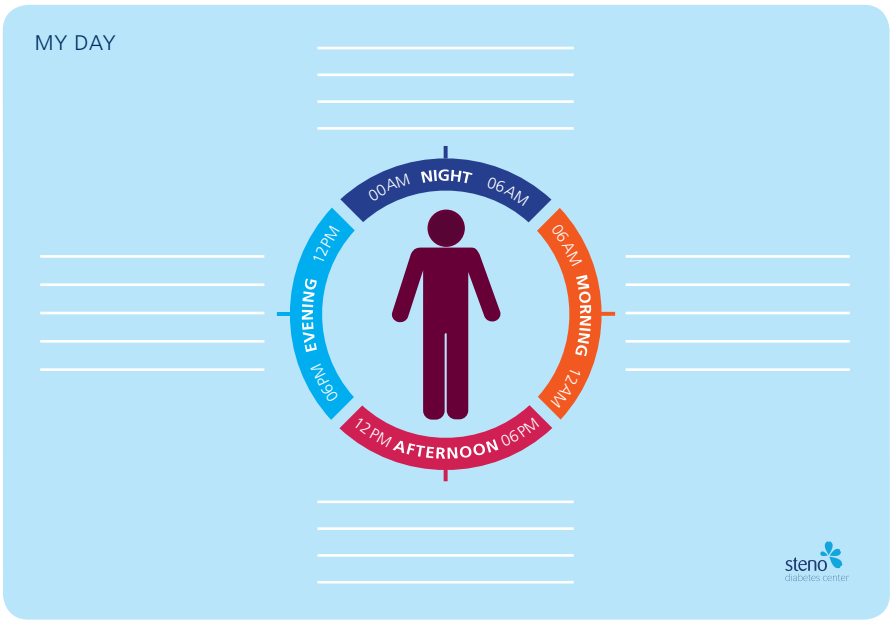
Figure 24.4 illustrates that quality of life is a combination of sources of distress as well as sources of well-being. That is, not only is it important to understand how unhappy a person with diabetes is, it is also important to understand issues of resilience, happiness, meaning, and positive engagement in life [80]. If an educator is able to identify a person with diabetes who reports distress this can be followed by an understanding of the drivers of this distress. Understanding the contribution of living with diabetes, the contribution of non-diabetes-related problems of living, and signs of psychopathology as drivers of this distress can be very helpful. One way this can be of help is to guide the diabetes educator about how to address the uncovered distress. In the

"Balance Cards" consists of 27 cards with pictures and quotes. The aim of the exercise is to assist participants in talking about the imbalances, challenges, and possibilities they experience in their daily lives with diabetes. The exercise can make it easier for participants to express difficult topics and facilitates dialogue among participants.

Figure 24.2 Examples of picture cards from the exercise "Balance Cards" [68, 70].

situation where there is significant diabetes-specific distress it is likely that the diabetes service is the best place for these issues to be addressed. This puts the responsibility of care on the diabetes educator, perhaps with the assistance of a mental health provider. In the situation where there is significant distress associated with problems of living, sensitive advice and support from the diabetes educator would be helpful. In the situation where there is suspicion of psychopathology interfacing the diabetes, referral to mental health services would be recommended. This perspective is in keeping with the work by Fisher on the distinction between diabetes distress and depression [35, 79].

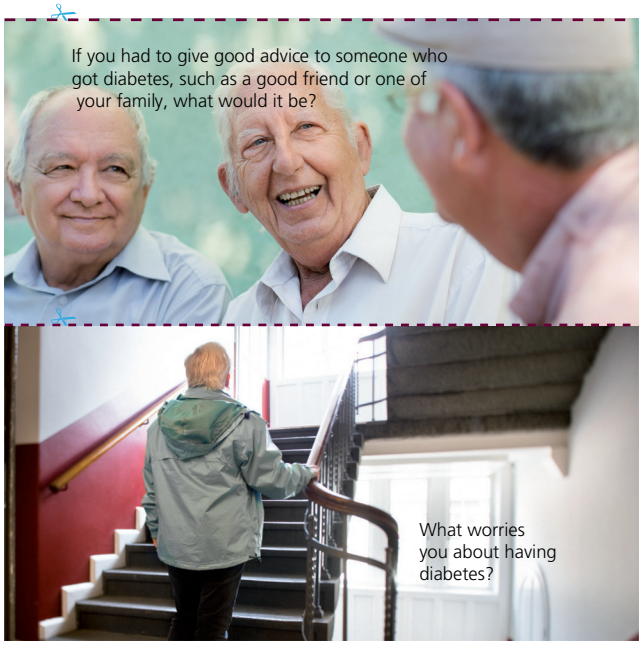
While it can be stressful for diabetes educators without a background in psychology to address psychosocial issues within their scope of practice, it can be helpful to know that often the



(a) The aim of the "My Day" exercise is to establish close contact between the person with diabetes and the educator to gain shared insight into daily life and identify relevant details and challenges related to diabetes behaviors to form the strategy for subsequent actions

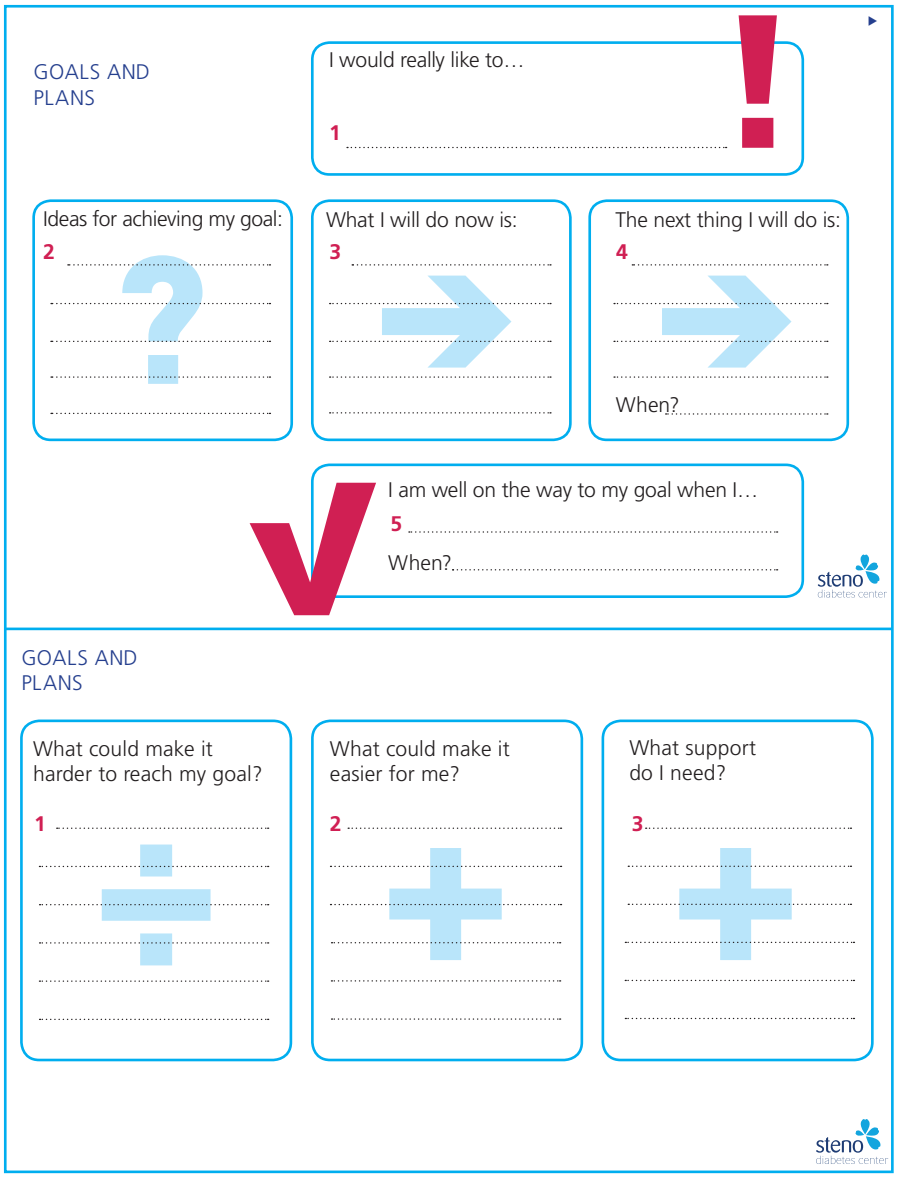
POSTCARD

There is a question on each of the two postcards. The idea of the questions is that you should think about them a little before next time. On the back of the cards, you can jot down your thoughts and answers, either as a short story or as bullet points. If you do not wish to write anything, you can tell me about your thoughts on your next visit.



(b) The aim of the exercise "Postcard" is to get people with diabetes to reflect on their own concerns.

Figure 24.3 (a–c) Examples of exercises from the patient education program EMMA (Empowerment, Motivation and Medical Adherence) [69, 72].



(c) The aim of the exercise "Goal and plan" is to assist people with diabetes in working specifically and realistically in setting goals and thinking about potential obstacles and facilitators to achieving them.

Figure 24.3 (*Continued*)

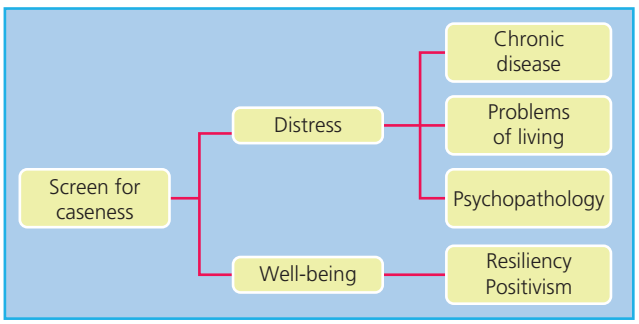


Figure 24.4 Determinants of quality of life.

ability to communicate one's distress (i.e. to be heard) is often experienced as very beneficial. If the educator takes the position that they are not the expert and that it is not their responsibility to "fix" the potential problems, then supportive communication can be easier. For instance, it would not be inappropriate for a provider to declare "I'd be interested in hearing about what you are going through and possibly make any recommendations that I think might be helpful." Research indicates a positive association between the presence of physician empathy and better diabetes outcomes [81].

The Diabetes Distress Scale is a useful guide for the diabetes educator as it involves four very understandable dimensions of

distress: emotional burden, regimen-related distress, physician-related distress, and interpersonal distress. Table 24.2 adapts these self-report scales into easy to use questions that would support the educator in addressing these dimensions. For instance, if the person with diabetes indicates feeling judged by healthcare providers the educator could address this in a direct and supportive manner.

It is also useful for the diabetes educator to be mindful of how diabetes fits into the social world of an individual. The idea of diabetes-specific as well as general social support is important here [82, 83]. Individuals with diabetes can experience benefit from having sensitive discussions with their diabetes educator about the presence or absence of support from others regarding diabetes self-management. The potential of engaging peers in supporting diabetes outcomes should also be noted [84].

Family perspectives in diabetes education

The second Diabetes, Attitudes, Wishes and Needs (DAWN2) study included a survey of 2057 adult family members of adults with diabetes. According to this study, supporting a relative with diabetes was perceived as a considerable burden by 35% of family members. The study also revealed that 40% of family members experienced high levels of distress related to concerns about their relative with diabetes, and 61% stated they were very worried about hypoglycemia in their family member with diabetes [5, 85].

Persons with diabetes generally engage in self-management of their diabetes within a family setting. Family members play a role in the everyday tasks such as meal preparation and time management and often provide moral, emotional, and practical support. Thus, struggles with self-management and blood glucose control, poor well-being, and psychological distress are relevant not only to the individual adult with diabetes. To the contrary, these problems affect—and are affected by—the entire family. Unfortunately, the majority of education programs exclusively target individuals with diabetes [86–89]. Furthermore, research targeting the interface between adults with chronic disease and their families is relatively scarce and family factors have until recently been virtually ignored in relation to adults with diabetes. Shields et al. [90] reviewed chronic health interventions involving couples and families and were unable to identify any studies pertaining to adults with diabetes.

Family-based diabetes education interventions seem a potentially important supplement to enhance diabetes management in everyday life. However, considering the emerging state of research in this area it is unclear how to educate and support family members of people with diabetes most effectively [88, 91]. The inclusion of family members in information and education processes may be useful. However, there is an urgent need for educational interventions for family members to enable translation of knowledge about diabetes into positive and constructive support of the person with diabetes. The family is an under-utilized resource with potential for benefitting diabetes management.

Evaluation of diabetes education

Given the literature on the potential positive role that diabetes education can have on persons living with diabetes and their family, perhaps the most important indicator in the evaluation of diabetes education is the availability of and access to diabetes education. Biological outcome measures have for a long time dominated the evaluation of diabetes education, which is unsurprising as they make up essential outcomes in diabetes. In reviews and meta-analyses of diabetes education the most commonly used outcome measures can be divided into four categories: biological, behavioral, knowledge, and psychosocial outcomes. Most attention has been paid to biological outcomes, particularly, HbA_{1c}, and knowledge-based outcomes. Less attention has been placed on behavioral outcomes and least on psychosocial outcomes [92].

An interesting and useful perspective, which is consistent with the complexity of diabetes education, is to examine the mechanisms by which an education program works [91, 93]. If an education program is found to have effect, how do we know what to replicate and what to change when we implement the program somewhere else? Why do some programs work in one place for one group of participants, and not for another? How do we identify what it is about the context that makes a difference? Focusing on mechanisms of effects is complicated as the education process typically involves multiple interacting components. It is thus difficult to identify the precise mechanisms leading to effects of the various components [15, 94]. Further, outcomes depend on the competencies of educators and the preconditions and motivation of participants as well as organizational conditions, all of which may be difficult to capture in a randomized controlled trial [94]. In response to this, theory-driven forms of evaluation have gained attention as they can generate knowledge about the effectiveness of an education program as well as knowledge about the underlying mechanisms of effects [95]. Simultaneously important information is generated about elements of importance for the replication and improvement of an education program [96, 97].

Theory-driven evaluation consists of "an explicit theory or model of how the program causes the intended or observed outcomes and an evaluation that is at least partly guided by this model" [96]. Thus, a core element of theory-driven forms of evaluation is the development and use of theory in the evaluation process. The theory, often referred to as program theory, specifies relationships between intervention actions and intended outcomes [95].

An education program is an incarnated theory of change; a theory about how to change problematic conditions or behavior. However, this theory is often unrecognized or poorly articulated perhaps due to the fact that a program is an active open system which:

- is apt to change over time as the program unfolds;
- works through the ideas and intentions of those implicated in them;
- works differently among different subgroups.

Table 24.2 Exploring diabetes distress in diabetes education and support.*

Components of diabetes distress	Diabetes distress scale	Suggested probes (questions)
	Scale items	
Emotional burden	- feeling that diabetes is taking too much mental and physical energy; - feeling angry, scared, or depressed when I think about living with diabetes; - feeling that diabetes controls my life; - feeling that I will end up with long-term complications no matter what I do; - feeling overwhelmed by the demands of diabetes.	If diabetes were a weight that you carried in a knapsack on your back, how heavy would it be? (Not at all… A little… Moderately… Very… Overwhelming) To what extent does living with diabetes upset you? (Not at all… A little… Moderately… Very… Overwhelming) Problematic emotional reactions to living with diabetes occur for some people. Would you say yes to any of the following emotions as being problematic for you because of your diabetes?: - sad/down - anxious/worried - frustrated/angry
Regimen-related distress	- feeling that I am not testing my blood sugars frequently enough; - feeling that I am failing with my diabetes regimen; - not feeling confident in my day-to-day ability to manage diabetes; - feeling that I am not sticking closely enough to a good meal plan; - not feeling motivated to keep up with diabetes self-management.	To what extent do you feel burdened by the activities required to manage your diabetes? (Not at all… A little… Moderately… Very… Overwhelming) Are there aspects of managing your blood sugars that you find particularly stressful? Do you ever think that you are not doing a good job following the guidelines for diabetes? To what extent do you find the tasks of diabetes upsetting (frustrating, overwhelming, worrying)?
Interpersonal distress	- feeling that friends or family are not supportive of my self-care efforts; - feeling that family or friends don't appreciate how difficult diabetes can be; - feeling that friends or family don't give me the emotional support I would like.	To what extent do you find it stressful dealing with other people because of your diabetes? (Not at all… A little… Moderately… Very… Overwhelming) To what extent do family, friends or other people make it harder for you to live with diabetes? (Not at all… A little… Moderately… Very… Overwhelming) Do you find that there are people in your life who make your experience of diabetes stressful to you? When you think about people in your life who are either supportive or not supportive of your diabetes would you say that there are more unsupportive people than supportive? Which of the following social situations do you find stressful regarding diabetes?: - family - friends - work
Educator-related distress* *This concept is adapted to include all healthcare educators	- feeling that my doctor doesn't know enough about diabetes; - feeling that my doctor doesn't give me clear enough directions; - feeling that my doctor doesn't take my concerns seriously enough; - feeling that I don't have a doctor who I can see regularly about diabetes.	To what extent do you find it stressful dealing with your healthcare educators? (Not at all… A little… Moderately… Very… Overwhelming) When you think of healthcare educators who you find either unhelpful or helpful regarding your diabetes would you say that there are more unsupportive healthcare educators than supportive? Do you find any of the following healthcare educators that are stressful to deal with?: - family doctor - diabetes specialist - diabetes educator

*Scale questions developed with the permission of Drs. Lawrence Fischer and William Polonsky (January 2015) [35].

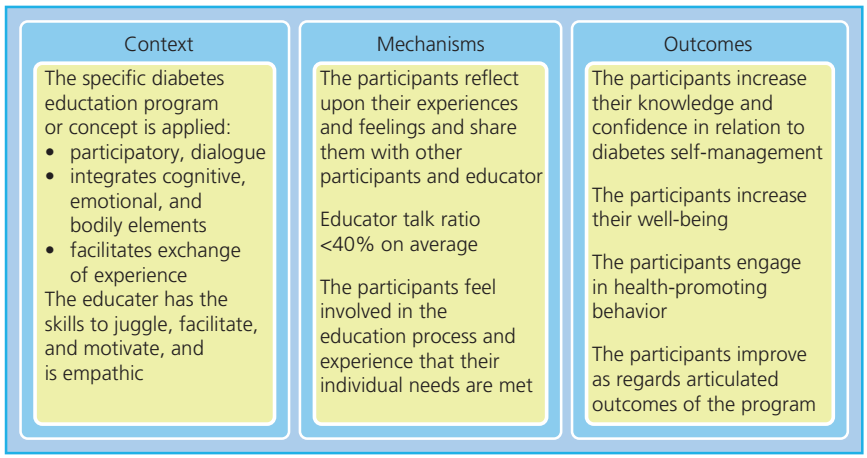

Figure 24.5 Program theory [97].

Pawson and Tilley [98] described "realistic evaluation," which focuses on three key concepts for understanding how, for whom, and under what conditions programs will work: *outcomes* that are likely to be the most effective, *mechanisms* through which outcomes occur, and *contexts* where the outcomes potentially will be replicable. Mechanisms refer to the process of how people interpret and act upon the intervention to produce outcomes. Mechanisms are not assumed to be fixed, but contingent on particular contexts. Thus the program theory can be expressed as context-mechanism-outcome (C-M-O) configurations. The evaluation implies the development of a theory about how outcomes, mechanisms and contexts operate and use of this theory to direct empirical work. The evaluation focuses on exploring whether the theory can explain the observational data [98]. In a recent review regarding use of "realistic evaluation" the use of C-M-O configurations were found to provide clarity in complex evaluation environments and rich information about what type of interventions work for whom in what context [99].

Figure 24.5 shows a program theory: If a person with diabetes is recruited to the program and completes it, and if the program takes a specific educational approach, then the person will attain improved knowledge and skills related to the management of diabetes and increased autonomy and quality of life. Working with program theory, ideally a second level of data collection and analysis is needed in order to evaluate whether (a) the theory is right but not properly implemented; (b) the theory should be refined; or (c) the theory is wrong. (See also Box 24.1.)

Box 24.1 Key points in program theory

- Realist evaluation is about theory testing and refinement
- Realist evaluation develops and tests C-M-O configurations (hypotheses) empirically
- Realist evaluation applies any approaches, tools, and methods that are appropriate to test a program theory
- Realist evaluation is potentially time-consuming as there are no independent criteria for closure

Conclusion

The main limiting factor of diabetes education is that it almost always does not include ongoing care and education. Once people with diabetes complete the program in its entirety, they do not have a component of ongoing support to allow tailoring of the education to their continued diabetes care needs. The provided education becomes education for life and therefore conclusive, without any opportunity for an information refresher or support mechanism needed to adjust to changes in perceived needs and preferences of people with diabetes. The lifelong process of diabetes self management requires continued adjustments in knowledge, skills, motivation, and support. Education and support should be a lifelong process, starting at the point of diagnosis and remaining as an essential component of diabetes care.

25 Lifestyle Issues: Diet

Nicola Guess
Diabetes and Nutritional Sciences Division, Kings College London;
Nutrition and Dietetics Research Group, Department of Medicine, Imperial College London, UK

Key points

- Weight loss is primary mediator of diabetes risk reduction and management of type 2 diabetes in those overweight or obese.
- Calorie content of and adherence to the diet is more important than macronutrient content for successful weight loss maintenance.
- The type and quality of dietary fat and carbohydrate, respectively, are more important than amounts of these macronutrients for prevention and management of diabetes and its complications.
- A number of dietary patterns are effective for weight loss, and diabetes and cardiovascular risk, and should take into account individual preferences.
- Matching carbohydrate to insulin dose, either as part of multiple daily insulin or continuous subcutaneous insulin injections, is the most effective approach for the management of glycemia in type 1 diabetes.
- Women with diabetes planning to become pregnant should take 5 mg of folic acid per day to prevent neural tube defects.
- Calorie restriction to lose weight should not be recommended during pregnancy, but limiting weight gain can improve pregnancy outcomes.
- Low glycemic index foods may help control blood glucose concentrations during pregnancy.

Introduction

Diet plays an important role in the effective management of type 1 diabetes (T1DM) and type 2 diabetes (T2DM) and is fundamental to the prevention of T2DM.

The aim of nutritional management of diabetes is to optimize glycemic control and blood pressure, correct any lipid abnormalities, and, in doing so, reduce the risk of long-term complications [1–3]. Dietary advice must be evidence-based and individualized, taking into account personal and cultural preferences, and ensuring the diet is appropriate and compatible with the person's lifestyle, existing treatment regimen, other comorbidities, and willingness to change [1–3].

Individuals with diabetes are up to four times more likely to develop cardiovascular disease (CVD) [4, 5], with an elevated risk also seen in impaired glucose tolerance [5] compared to individuals with normoglycemia. Therefore, evidence-based nutritional recommendations for individuals with diabetes are based on the glucose management of the diabetes, reducing the risk of developing CVD and the complications of diabetes and CVD [1, 2, 6]. The strength of evidence for the different nutritional recommendations for both management of diabetes and prevention of CVD is graded according to the type and quality of published studies as well as by statements from expert committees [1]. The gold standard for evidence-based guidelines are meta-analyses of large well-controlled trials with long follow-up periods that include fatal or non-fatal clinical endpoints. However, this information is often not available and instead surrogate endpoints, such as glycemia, body composition, lipoprotein profile, blood pressure, insulin sensitivity, and renal function are used to determine the potential of dietary modification to influence glycemic control and risk of acute and chronic complications of diabetes [1, 2].

While nutritional science illuminates the underlying mechanisms of diet on disease risk, in practice, nutrients are consumed as foods and as part of dietary patterns. Therefore, throughout this chapter, while reference will be made to the impact of individual macro- and micronutrients on clinical outcomes, the reader is referred to how these nutrients form part of an overall healthful dietary pattern for diabetes prevention and management. Tables 25.1 and 25.2 summarize such dietary approaches.

Energy balance and body weight

Weight management is now understood to be the primary strategy for prevention of diabetes and glycemic control in people with T2DM who are overweight or obese [1, 2]. Weight gain is associated with increased diabetes incidence [7] and insulin

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

Table 25.1 Table showing the association of particular dietary components on risk or management of type 2 diabetes, and their inclusion or exclusion in established dietary patterns or guidelines. Orange indicates components with a protective association; blue indicates components with a deleterious association.

Dietary components	Mediterranean	DASH	Diabetes UK	NICE	Effect on diabetes management/risk
Fruit	*	*	*	*	Dietary fiber associated with reduction of risk.
Vegetables	*	*	*	*	Dietary fiber associated with reduction of risk.
Nuts/seeds	*	*	*	*	↑ PUFA/MUFA:SFA ratio associated with reduction in FPG, HbA_{1c} and insulin resistance. Insoluble fibers associated with reduction in risk of diabetes. Magnesium associated with reduction of risk of diabetes.
Pulses	*	*	*	*	Soluble fibers reduce postprandial glucose in randomized control trials.Low GI associated with reduction of risk, and reduces HbA_{1c} by 0.5%.
Fish and seafood	*		*	*	No known effects of omega-3 on diabetes management or risk
Increased white:red meat ratio			*	*	↑ PUFA/MUFA:SFA ratio associated with reduction in FPG, HbA_{1c} and insulin resistance.
Wholegrains/cereal fiber	*	*	*	*	Insoluble fibers associated with reduction in risk of diabetes. Magnesium associated with reduction of risk of diabetes.
Low glycemic index			*	*	Associated with reduction of risk, and reduces HbA_{1c} by 0.5%.
Olive oil	*				↑ PUFA/MUFA:SFA ratio associated with reduction in FPG, HbA_{1c} and insulin resistance.
Vegetable oil (sunflower, rapeseed oil)			To replace butter and SFA spreads	To replace butter and SFA spreads	↑ PUFA/MUFA:SFA ratio associated with reduction in FPG, HbA_{1c} and insulin resistance.
Low-fat dairy		*	*	*	Dairy intake associated with reduction of risk; milk proteins may leads to reduced glucose concentrations and increased insulin secretion. Vitamin D and calcium associated with reduction of risk.
Alcohol	Moderate	↑			Moderate intake associated with reduction of risk.
Decreased red or processed meat					Diets high in red, especially processed meat associated with increased risk of diabetes.
Butter	Limited		Replaced with non-SFA spreads	Replaced with non-SFA spreads	↓PUFA/MUFA:SFA associated with increased risk of diabetes, FPG, HbA_{1c} and insulin resistance.
Sweetened beverages		*	Limit	Limit	Sugar-sweetened beverages associated with increased BMI, leading to increased risk of diabetes.
Sodium					No known effects of omega-3 on diabetes management or risk

* = included in dietary pattern.

resistance [8], while weight loss reduces insulin resistance and glucose handling in people with and without diabetes [9]. A series of large-scale lifestyle-based randomized control trials [10, 11] have conclusively shown that a 5–7% weight loss in people at risk of diabetes reduces risk by up to 66% (Figure 25.1) [10]. While these programs also included other components such as increasing fiber, decreasing total and saturated fat and increasing physical activity, weight loss was the primary driver of the reduction in risk [12]. Interestingly, there also appears to be a legacy effect of weight loss on diabetes prevention, such that even 3 years after the intervention stopped, there was still a 48% risk reduction in the intervention group [13].

Weight loss also reduces important risk factors for CVD including circulating triglycerides and blood pressure [1]. A systematic review of studies with at least 2 years' follow-up showed that intentional weight loss in people with T2DM can reduce their mortality risk by 25%, with a higher risk reduction with greater weight loss [14]. The recent LookAHEAD study found that an intensive lifestyle for primary prevention of CVD did not significantly reduce CVD-related morbidity or mortality after nearly 10 years of follow-up [15]. However, this may reflect the limitations of dietary improvements in long-term mortality in people treated aggressively with antihypertensive and dyslipidemic medications [16], and does not discount the role for weight

Table 25.2 Table showing the association of particular dietary components on risk of cardiovascular disease, and their inclusion or exclusion in established dietary patterns or guidelines. Orange indicates components with a protective association; blue indicates components with a deleterious association.

Dietary components	Mediterranean	DASH	Diabetes UK	NICE	Effect on CVD risk

loss and dietary change in improving quality of life [16], reducing intensification of medical treatment of diabetes and CVD, and greater physical functioning [15, 16]. Reductions of 5–10% are effective at reducing CVD risk factors and are achievable and feasible, although larger weight loss may reduce risk further [17].

Weight management has also been considered for people with T1DM as the prevalence of overweight and obesity is increasing in T1DM [18], and the co-presentation of insulin resistance is associated with poorer glycemic control [19]. However, there is little evidence that body weight or weight loss influences glycemic control in people with T1DM [18]. Furthermore, in both T1 and T2DM, caution should be applied to intentional versus unintentional weight loss as unintended weight loss in people with diabetes may also be an indication of a suboptimal medical management or poor concordance with medications leading to poor glycemic control [20].

Therefore national [2, 21] and international [5] guidelines recommend initial weight loss of 5–10% in overweight or obese people for the purposes of T2DM management and prevention of T2DM and CVD.

Currently there is no consensus on the optimal diet to achieve and maintain the recommended weight loss [1]; however, the overall energy content of the diet is more important than macronutrient composition [1, 22–26]. Effective strategies for which there is evidence in people with diabetes include low-carbohydrate [27], low-glycemic index [28], low-fat [10, 11], very-low-calorie-diet [29], and meal replacement [30]. There has been particular interest in low-carbohydrate diets [31] which appear to be most effective at promoting weight loss over the short term, and may also have beneficial effects on glycemia independent of body weight [32–34]. While there is little evidence for their added benefit over the long term [35–37], practitioners should be open to this approach and individual preference. The primary factor in achieving and maintaining weight loss remains adherence, and the best approach is therefore one that fits with a person's lifestyle, habits, and goals [1, 2, 35].

Carbohydrate and diabetes

The carbohydrate content of diets for the prevention and management of T2DM is of secondary importance to the overall energy content of the diet but remains the primary determinant of glycemic control in people with T1DM [1].

Quantity

There is no evidence for a specific quantity of carbohydrate in the diet for the management of T2DM [1], although as little as 20% of calories from carbohydrate has been used in T2DM over 2 years and appears safe [37]. Currently there are no randomized control trials investigating eucaloric carbohydrate restriction on risk of diabetes, but epidemiological data suggest there is no relationship between total carbohydrate intake and risk of diabetes [1, 38–41). In both prevention and management of diabetes, quality and source of carbohydrate are more important than total amount (see carbohydrate quality).

In contrast, carbohydrate counting forms the basis of management of T1DM, where recommended carbohydrate intake should take into account energy requirements, blood glucose concentrations and insulin dosing [1,42–45]. Carbohydrate counting is a meal planning approach which involves matching 10 g or 15 g carbohydrate portions to a particular bolus insulin dose [43, 44], and is based on the premise that carbohydrate is the primary driver of postprandial glucose concentrations [45]. As a concept, carbohydrate counting has been around since the 1920s [46], but has been widely employed since its use in the Diabetes Control and Complications Trial [47]. It is now the dietary strategy of choice in T1DM. Approaches to carbohydrate counting can vary immensely between country, region, institution, and individual practitioner but may include:

- carbohydrate awareness;
- basic carbohydrate counting and label reading;
- development of the patient's skills in monitoring and recording blood glucose levels in relation to food intake, medications, and physical activity;
- sophisticated matching of carbohydrate to insulin dose
  - this may include the use of wizard bolus meters or apps to aid in the estimation of carbohydrate intake and insulin requirement.

These techniques should enable the person with T1DM to add or subtract short- or rapid-acting insulin at meals and snacks to control and correct blood glucose levels [43, 44, 48, 49]. The heterogeneity in these approaches must be taken into account when interpreting the evidence for carbohydrate counting [48].

Adjustment of insulin to carbohydrate intake

In people with T1DM treated with multiple daily insulin or continuous subcutaneous insulin infusion (CSII), carbohydrate counting with insulin dose adjustment is an effective approach to lower HbA_{1c}, reduce the occurrence of hypoglycemic episodes, and improve quality of life and other clinical markers such as body mass index (BMI) and waist circumference [3, 50–55]. However, there is a need for good quality education, and appropriate clinical support is necessary to ensure accurate and consistent insulin dose adjustments [3, 48]. Inaccuracy in carbohydrate counting or dose adjustment is common, and is associated with poorer clinical outcomes [48, 56–58]. Care must be taken to ensure that carbohydrate

counting and dietary advice is not detrimental to an individual's weight management goal. Additional snacks are not automatically required and should be tailored to the individual's needs. Referral to a structured education program of proven benefit, such as the DAFNE (dose-adjustment for normal eating) program, ideally 6–12 months after diagnosis, is recommended [3]. In individuals with fixed or biphasic insulin regimens, consistency in carbohydrate intake is recommended and is associated with reductions in HbA_{1c} [1, 59, 60].

A small number of recent studies have suggested that the fat and protein content of the meal should also be taken into account when planning an insulin regimen [61, 62]. However, any potential physiological benefits of these approaches need to be balanced with the complexity and burden for the person with diabetes.

Carbohydrate in the treatment of mild to moderate hypoglycemia

Mild or moderate hypoglycemia is a common occurrence with insulin treatment in both T1DM and T2DM. Glucose is the most effective treatment and should be given immediately [3]. National and international guidelines recommend 15–20 g should be given immediately (Box 25.1), followed by another 15 g if blood glucose does not rise by 4 mmol after 15 minutes [44]. A follow-up carbohydrate snack (15–20 g) may be necessary to reduce the risk of further hypoglycemia, particularly in circumstances where blood glucose is likely to continue to decrease, such as following alcohol consumption or physical activity [44].

Carbohydrate quality

Dietary carbohydrates represent a heterogeneous group of compounds which include glucose, cellulose, fructose, lactose, starch, resistant starch, sucrose, oligosaccharides, and lignin. The diverse effects of these different structures on diabetes and metabolic risk factors [63] are too numerous to expand on in this chapter, but these factors emphasize the limitations of such terms as a high or low carbohydrate diet. Nevertheless, the "quality" of these different carbohydrates can be imperfectly but usefully captured by use of the glycemic index.

The glycemic index (GI) is an indication of the glucose-raising potential of the carbohydrate, and is defined by the incremental area under the blood glucose curve (iAUC) as a percentage of each person's average iAUC for a standard food, usually 50 g glucose or white bread [64, 65]. The glycemic load, which is the product of the dietary glycemic index and total dietary carbohydrate, may also be used to express the overall quality of carbohydrate in the diet [65].

Box 25.1 Foods containing 15–20 g of fast-acting carbohydrate

- Small glass of sugary (non-diet) drink
- At least three glucose tablets
- Five sweets, e.g. jelly babies
- Small carton of pure fruit juice
- Glucose gel

In people with T2DM, a Cochrane review of randomized controlled trials suggests adoption of a low GI diet can lead to HbA_{1c} reductions of 0.5% [65]. While data from epidemiological studies suggest low GI diets are associated with a lower BMI [66, 67], the data from randomized control trials have demonstrated a reduction in HbA_{1c} independent of changes in body weight [68, 69]. Low GI diets are associated with a lower risk of T2DM [70], but there are currently no controlled trials examining the effect of the glycemic index on T2DM incidence as a primary outcome.

The evidence of effectiveness of low-GI diets in management of glycemia of T1DM is unclear [1] and the latest National Institute for Health and Care Excellence (NICE) guidelines do not recommend their use in people with T1DM [3].

Glycemic index may also reduce CVD risk by lowering triglyceride and low-density lipoprotein (LDL) cholesterol levels and increasing high-density lipoprotein (HDL) cholesterol [71]. However, current guidelines do not make specific recommendations regarding glycemic index and CVD risk.

Dietary fiber

The indigestible nature of dietary fibers renders them low or non-glycemic [72, 73]. However, dietary fibers themselves and foods high in fiber appear to influence glucose homeostasis beyond their glycemic index [74–76]. Increasing dietary fiber by approximately 18 g/day up to total intake of 50 g/day leads to a reduction in fasting plasma glucose of 0.7–0.9 mmol/L [75, 76] and of HbA_{1c} of 0.3% [75]. According to the American Diabetes Association, there is currently insufficient evidence to recommend people with diabetes consume fiber in amounts exceeding the current recommended daily allowances (RDA) [77]. Furthermore, the majority of people in Western populations do not meet the minimum recommendations, and targeting this should be a dietary priority.

Dietary fiber is inversely associated with diabetes risk in cohort studies [78]. In the Finnish Diabetes Prevention Study, participants were advised to consume 15 g/1000 kcal of fiber [79], which appeared to reduce diabetes risk, an effect partly independent of its effects on body weight [80]. Current guidelines for diabetes prevention recommend increasing fiber intake to reduce diabetes risk [1, 77].

Epidemiological data support a protective role of dietary fiber against CVD, with the data most consistent for wholegrains [81–83]. There are currently insufficient data from randomized control trials, and current guidelines do not make specific recommendations for the role of fiber on CVD risk.

Dietary mono- and disaccharides

Sucrose

Despite controversy about the role of sugar in diabetes management, moderate intake of sucrose (10–15% total energy) or other

added sugars can be included in the diet of people with diabetes without worsening glycemic control or insulin sensitivity [1, 60, 84–87]; however, care must be taken not to exceed energy requirements [1, 2, 77, 88]. In a randomized controlled trial, there was no difference in insulin resistance after 6 weeks' of 25% versus 10% of energy from sucrose in healthy people [86]. In contrast, 1 liter per day of a sucrose-containing beverage increases hepatic lipid deposition compared to isocaloric quantities of milk, water, or aspartame-sweetened beverages [89]. The effect of sucrose on glucose excursions is no different from other sources of sugars or starch, provided the total amount of carbohydrate is equal [1, 60, 84–87]. There is no definitive evidence that sucrose per se influences CVD risk. Therefore recommendations for sucrose intake for people with or at risk of diabetes are based on those for the general population, namely limiting the consumption of energy-dense, nutrient-depleted sucrose.

Fructose

Fructose is a low-glycemic monosaccharide and isocaloric exchange of fructose for other carbohydrate improves glycemic control in people with T2DM over the short term, even when consumed up to 160 g/day [90]. However, the metabolism of fructose leads to processes detrimental to human metabolism including increased *de novo* lipogenesis, ectopic lipid accumulation, elevated triglycerides and uric acid, leading to non-alcoholic fatty liver disease and increased cardiovascular risk [91]. While there is a need to identify the optimal quantity of fructose which improves glycemia without deleterious cardiometabolic effects [92], a variety of fruits and vegetables are to be encouraged as part of an overall dietary pattern [1, 2, 86] (Tables 25.1 and 25.2).

Non-nutritive sweeteners

The non-nutritive sweeteners approved for use in the UK and Europe include aspartame, saccharin, asulfame potassium, cyclamate, and sucralose [93]. The increased sweetness of these compounds means they are consumed in miniscule amounts in the diet, and recommendations for people at risk of or with diabetes are the same as the general population [94]. These sweeteners do not contribute to energy intake or influence glucose levels [94]. Other sweeteners commonly used are sugar alcohols. While moderately glycemic, sugar alcohols are consumed in such minor amounts that their consumption does not require alterations in insulin adjustment [1].

Dietary fat

The role of dietary fat in diabetes management has been of interest for decades following observations that dietary fat can modify insulin signaling in the 1950s [95] and the association between saturated fat and CVD [1, 96]. However, there appears to be little association between total fat in the diet and risk of diabetes [95]. Although diabetes prevention programs have limited total fat [10, 11], weight reduction per se and not macronutrient composition of the diet was the primary driver of risk reduction [12]. Similarly, there is no consensus on percent calories from fat in relation to diabetes management [1, 77, 95]. Instead, the types and sources of fat consumed and total quality of the diet appear to be more important.

Saturated fat

Replacement of saturated fat (SFA) with polyunsaturated fat (PUFA) is associated with a reduction in diabetes risk in multiple cohort studies [95, 97]. The evidence is currently stronger for replacement with PUFAs than monounsaturated fatty acids (MUFAs) but this may reflect the close association of MUFAs with SFAs in Western diets and the availability of biomarkers for PUFA intake in prospective studies [95]. Data from randomized controlled trials do not consistently demonstrate a detrimental effect of saturated fat on insulin sensitivity [98–100], but methodological differences in these studies, such as sample size, duration, and the macronutrient which replaces saturated fat may explain these inconsistencies [95, 98–100].

The proposed relationship between saturated fat and CVD largely arose based on early population studies [101]. However, several updated meta-analyses have questioned the conclusion that simply reducing SFA intake will necessarily reduce CVD prevalence [102, 103]. Instead, replacing macronutrient appears to be important: replacement of saturated fat with refined, but not high-quality carbohydrate or unsaturated fat has been linked to worsening of atherosclerotic risk factors including elevated triglycerides, reduced HDL cholesterol, and increased concentrations of small, dense LDL particles [102–106], emphasizing the need to consider the quality of the diet as a whole.

Similarly, recent studies have also drawn attention to the heterogenic nature of dietary fat classes, with short-chain, long-chain, and odd-chain saturated fats associated with diabetes risk reduction, and medium-chain saturated fats associated with increased risk [107, 108]. Odd-chain fatty acids are predominantly found in dairy products, but whether or not these fatty acids have beneficial effects per se or whether these associations reflect other nutrient components found in dairy is currently unclear.

Similarly, saturated fats come from a variety of food sources, including red and processed meats, dairy products, nuts and oils, and a prudent approach is therefore to promote foods associated with healthful dietary patterns such as nuts, seeds, oils, low-fat dairy, fish, and fruit and vegetables, and to limit red (particularly processed) meat and butter (Tables 25.1 and 25.2).

In summary, current guidelines recommend limiting saturated fat to 7% of energy intake, but careful consideration should be given to the replacing macronutrient and overall dietary pattern (Tables 25.1 and 25.2).

Polyunsaturated fat

The most abundant PUFA in the diet is linoleic acid, which is inversely associated with diabetes incidence and CVD in prospective cohort studies [95, 97]. The use of long-chain PUFAs as

biomarkers for intake strengthens the subjective nature of cohort studies, which typically rely on self-reported dietary intake [95, 109]. Clinical trials evaluating the effect of PUFA on insulin sensitivity or surrogate markers for diabetes risk have not been consistent [110, 111]. The short duration of some of these studies may be important as PUFAs are believed to act partly via altering membrane fluidity, which may take up to 3 months [95].

As stated above, replacement of saturated fat with PUFAs reduces CVD risk, and surrogate risk markers [105–107, 112, 113], and sources of PUFAs such as nuts, seeds, and vegetables oils should be encouraged as part of a healthy diet (Tables 25.1 and 25.2).

Omega-3 fatty acids

There is little evidence from observational and experimental studies that omega-3 fats improve glycemia in healthy individuals and people with T2DM [95, 114–117] or reduce risk of developing diabetes [116]. Of concern, high doses of fish oil have been shown to impair glucose homeostasis [115].

In contrast, the cardioprotective effects of omega-3 fats such as reducing serum triglycerides, and modifying platelet aggregation and thrombogenicity [117] have led to recommendations to include oily fish twice a week to reduce CVD [1–3, 21, 118]. Importantly, "more" is not better, and previous support for omega-3 supplementation for prevention of CVD in people with diabetes was withdrawn by NICE [21].

Monounsaturated fat

Recent evidence from the PREDIMED and earlier KANWU trials suggests MUFAs may improve insulin sensitivity and reduce diabetes risk independent of energy restriction, particularly where MUFAs replace SFAs [99, 119]. There is also good evidence from randomized controlled trials that diets high in monounsaturated fat can reduce glucose concentrations in people with T2DM [120–122], and can be used to replace carbohydrate without detrimental effects [1, 123]. There are few studies that have specifically examined the effect of MUFAs on glycemic control in individuals with T1DM, and there is insufficient evidence to make firm recommendations.

Replacing saturated fat with monounsaturated fat can reduce risk of CVD [124, 125], and controlled trials demonstrate high-MUFA diets can increase HDL cholesterol, lower blood pressure, and other surrogate markers of CVD risk [105–107, 111, 113, 126–128].

Monounsaturated fat is a significant component of a Mediterranean diet [129], and it is important to consider the confounding effects of other aspects of this dietary pattern including fish, fruits and vegetables, and moderate alcohol on clinical risk factors. For example, in the PREDIMED trial, extra virgin olive oil had a greater effect on CVD risk reduction than olive oil, despite identical proportions of monounsaturated fat, indicating nutritive and non-nutritive components are also important [130]. Therefore, while monounsaturated fats appear to have independent effects on glucose homeostasis and CVD risk, greater risk reduction is likely achieved by following a diet rich in wholegrains, fruit, vegetables, fish, and limited saturated fat [1, 129, 130].

Trans fats

Trans fats occur naturally in foods such as milk or other dairy products as a bi-product of rumination or are produced industrially (partially hydrogenated vegetable oils). There is little evidence that total trans fat in the diet influences glucose homeostasis [131]; however, prospective studies using the dairy fat trans-palmitoleic acid as a biomarker have shown this naturally occurring trans fat is inversely related to diabetes risk [132]. However, it is unclear whether the fat per se has beneficial effects on glucose homeostasis, or whether the erstwhile nutrients of dairy mediate this risk reduction. Naturally occurring trans fats are found in minute amounts in dairy foods, whereas industrially produced trans fat can contribute up to 4 g a day in US diets [133].

There is compelling evidence from clinical and epidemiological studies that industrially produced trans fats have a deleterious effect on CVD risk [133–135], and national and international guidelines have recommended their reduction or complete elimination in the diet [1, 20, 133, 136].

In practice, these observations support and inform recommendations for a healthy dietary pattern (Table 25.2), with dairy products forming a part of approaches, such as the well-researched Dietary Approaches to Stop Hypertension (DASH) diet, and minimizing foods high in hydrogenated vegetable oil, which typically include biscuits, cakes and other sweet, high-fat goods.

Dietary cholesterol

There is little evidence that dietary cholesterol increases diabetes risk [137]. Instead, recommendations to limit cholesterol intake come from some clinical studies, which have demonstrated that dietary cholesterol can raise LDL cholesterol [138]. This contention has been a subject of considerable debate for many years. A recent meta-analysis of prospective studies examining whether dietary cholesterol ultimately influences risk of CVD were inconclusive [139] and the American Heart Association/American College of Cardiology have raised concerns about the heterogeneity of the data available [140].

However, given the potential impact of dietary cholesterol on LDL cholesterol, the possible increased absorption of dietary cholesterol in people with diabetes [141], and the elevated risk of CVD in people with diabetes, any changes to current guidelines to limit dietary cholesterol to 200–300 mg per day are premature [142].

Protein

Given the primary role of weight loss in prevention and management of T2DM and prevention of CVD, numerous studies have evaluated the effect of higher protein intakes on satiety and weight management in amounts of up to 40% energy from protein [23, 143–145]. However, the concomitant changes in the amount

and quality of carbohydrate and fat in these studies make it difficult to draw any firm conclusions, and the long-term effects of consuming more than 20% of calories from protein on diabetes management and complications are unknown [77]. Guidelines therefore reiterate that the most effective weight-loss diet is one that takes into account an individual's preferences, beliefs, cultural values, and practical considerations [1, 2, 22, 77].

Protein is also a macronutrient of interest due to its capacity to increase insulin secretion acutely [146]. However, whether high dietary proteins impair, improve or have a neutral effect on glycemia is not clear [46, 146–149] while long-term studies up to 12 weeks' length do not show any chronic effects of high-protein diets on insulin secretion [148, 149].

There is therefore insufficient evidence to suggest current guidelines for the general population, which recommend 15–20% of calories should come from protein, should be modified for individuals with T1DM or T2DM who have normal renal function [1, 78]. Suggestions that dietary protein may be modestly linked to increased risk of diabetes [150] may reflect sources of protein such as red or processed meats; dietary patterns that provide vegetable sources of protein alongside low-fat meat represent a prudent approach (Table 25.1).

Micronutrients

A number of micronutrients have been specifically linked to diabetes risk in cohort studies; however, very few randomized controlled trials have confirmed these associations. Such micronutrients include magnesium [151], vitamin D [152–154], calcium [153, 154], and chromium [155]. Similarly, epidemiological trials and *in vitro* data have suggested that antioxidant vitamins and folate (Vitamins A, C, E, and beta-carotene) could play a role in modifying CVD risk. However, well-designed randomized control trials to confirm these associations are lacking [156], and NICE do not recommend such supplementation [157].

Therefore current guidelines recommend regular consumption of a variety of vegetables, fresh fruit, legumes, dairy products, vegetable oils, nuts, wholegrain breads, and oily fish to ensure that recommended vitamin and mineral requirements are met [1] (Tables 25.1 and 25.2). This message should be reinforced alongside clarification that there is no proven benefit of vitamin or mineral supplements for management of diabetes.

Salt or sodium

Reduced sodium intake can lower blood pressure, and sodium intake should be limited across the population including individuals at higher risk of CVD [158, 159]. A reduction in mean salt intake of 3 g per day for adults (to achieve a target of 6 g per day) would lead to around 14–20,000 fewer deaths/year from CVD [21]. Dietary patterns, such as the DASH diet, which are low in sodium and high in potassium, magnesium, and calcium form an effective approach to control hypertension and are appropriate in people with diabetes (Table 25.2).

Sterols and stanols

Plant sterols and stanols have no known effect on glucose homeostasis but have been shown to reduce LDL and total cholesterol in people with and without diabetes [160]. Dietary guidelines have recommended 2–3 g per day of fortified foods to lower LDL and total cholesterol irrespective of whether the individual is taking statins [1], but they are not included in the updated NICE guidelines for lipid modification in the prevention of CVD in people with diabetes [21].

Alcohol

In cross-sectional and prospective studies, a modest alcohol intake is associated with a reduced risk of diabetes and CVD, while excessive (>30–60 g/day) and chronic intake appears to raise blood pressure, plasma triglycerides, and increase the risk of CVD [161–163].

In people with diet-treated diabetes, alcohol consumed with carbohydrate may raise glucose levels, but does not appear to affect glucose or insulin concentrations when consumed alone [78]. However, in people treated with insulin or insulin secretagogues, alcohol increases the risk of hypoglycemia [1, 77]. The risk increases with the quantity of alcohol consumed and may remain elevated the following day [164]. Therefore, in these people, alcohol should be consumed with food [77].

Finally, alcohol is a source of energy and associated with increases in BMI and greater waist : hip ratio [165]. Therefore, recommendations for prevention and management of diabetes are the same as those for the general population: 2–3 units per day in women; 3–4 units per day in men [1, 2]. One alcohol unit is measured as 10 mL or 8 g of pure alcohol. This equals one 25 mL single measure of whisky (ABV 40%), or a third of a pint of beer (ABV 5–6%) or half a standard (175 mL) glass of red wine (ABV 12%). The new UK Department of Health guidelines currently out for consultation recommended only 14 units per week for both men and women [166].

Diet in special circumstances

Diet in pregnancy

Diabetes increases the risk of adverse pregnancy outcomes, and the risk increases with the duration of diabetes (see Chapter 61) [167, 168]. Maintenance of HbA_{1c} level towards the target of 48 mmol/mol (6.5%) is likely to reduce the risk of congenital malformations [168], but may be associated with increased episodes of hypoglycemia [168]. Excess weight gain is associated with poorer glycemic control [77]. Therefore, women with a BMI

of 27 kg/m^2 should be provided with advice and support to attain a healthy weight prior to pregnancy [169]; however, weight reduction should not be attempted during pregnancy [169]. In the UK there are no specific guidelines on weight gain during pregnancy, though NICE emphasizes that energy needs do not change in the first 6 months of pregnancy and increase by a modest degree (approximately 200 kcal/day) in the last 3 months [169]. The Institute of Medicine has more defined guidelines for weight gain over each trimester, which range from 11–20 lbs (5–9 kg) for mothers who are obese at conception to 28–40 lbs (13–18 kg) for underweight mothers [170]. There is little evidence to support particular dietary approaches during pregnancy. However, a low glycemic index diet may modestly improve glycemia [1].

Folic acid requirements increase to 5 mg/day for women with diabetes, as risk of neural tube defects is increased [168]. Folic acid should be taken up to 12 weeks' gestation to prevent neural tube defects. However, in practice, 50% of pregnancies in the UK are unplanned, in which case, folic acid supplementation should be commenced immediately [168].

Diet in children with diabetes

Management of T1DM and T2DM does not differ substantively from adults [77, 171, 172]. Children and their families (or carer) should receive education, which covers insulin therapy and dosage adjustment; blood glucose monitoring; detecting and managing hypoglycemia, hyperglycemia, and ketosis; and the effects of diet, physical activity, and intercurrent illness on blood glucose control [171]. Additionally, age and maturity, emotional well-being and life goals should be considered in an individualized approach. As energy requirements change with age, growth rates have to be monitored and the evaluation of a meal plan should be rechecked at least once a year [171].

As in all healthy children, energy and nutrient intakes should be adequate to ensure optimal growth and development. Good nutrition may also contribute to maintaining normal serum lipid values and meeting blood pressure goals. Meal plans must be individualized to accommodate food preferences and the eating pattern of the family [171, 172].

Exercise and insulin-treated diabetes

Physical activity and exercise have numerous benefits for people with diabetes, including improved glucose control, blood pressure, reduced requirements for medications, and lower CVD risk (see Chapter 26) [1–3]. However, risk of hypoglycemia increases with exercise intensity and duration in insulin-treated diabetes, and careful management of glucose levels is critical [1, 3]. There is not sufficient space to expand on optimal management of different modalities, duration and intensity of exercise here, and referral to a specialist diabetes dietitian is recommended [3]. However, general recommendations for insulin-treated diabetes are to adjust insulin dosing for planned exercise, and provide additional dietary carbohydrate for unplanned exercise [1, 42]. In practice, for the majority of people who engage in moderate physical activity, additional carbohydrate requirements increase only modestly, and an additional 10–15 g per hour should be sufficient to maintain blood glucose levels [42].

For more serious exercisers and athletes, the amount of carbohydrate required will be based on the individual, with sufficient carbohydrate prior to exercise in order to maintain glucose levels during the exercise, and replenishment of glycogen stores in the post-exercise period to enhance performance and prevent hypoglycemia during the next exercise bout, particularly for those who exercise daily [173–175].

Many exercisers, particularly young men engaged in weight training, have specific questions about protein intake. There is little evidence that excessive protein intake increases muscle growth or mass in most casual exercisers; but for weight lifters or endurance athletes, the American College of Sports Medicine recommends 1.4–1.7 g/kg/day [175, 176]. In general, most athletes or weight-training males will meet this protein requirement through diet alone. For individuals who do not consume sufficient protein, protein shakes supplemented with proteins such as whey can be consumed. However, careful monitoring of blood glucose is advised as whey has been shown to lower glucose levels in people without diabetes [177]. Although no studies have been carried out in people with T1DM, whey could theoretically increase the risk of post-exercise hypoglycemia. In practice, most shakes of this type will contain additional carbohydrate which may counteract any glucose-lowering effect.

Key points

- In people with type 1 diabetes exercise improves fitness and strength, reduces cardiovascular risk factors, and improves well-being.
- While regular exercise has not conclusively been found to improve glycemic control in type 1 diabetes, it is associated with decreased long-term morbidity and mortality in this population
- Managing type 1 diabetes in the context of exercise can be complicated by both hypoglycemia and hyperglycemia during and after exercise.
- It is recommended that individuals with type 1 diabetes adjust their insulin dose and carbohydrate consumption prior to, during and/or after exercise to accommodate the type, intensity, and duration of exercise performed.
- Structured, supervised diet and exercise interventions can reduce the risk of developing type 2 diabetes by about 60% in individuals with impaired glucose tolerance.
- Regular exercise improves fitness and strength, reduces cardiovascular risk factors and improves HbA_{1c} and is associated with decreased long-term morbidity and mortality in people with type 2 diabetes.
- In people with type 2 diabetes to maximize the effect of exercise on glucose control combined aerobic and resistance exercises should be undertaken for ≥150 minutes per week.
- While regular exercise has not conclusively been found to prevent gestational diabetes there is emerging evidence that it can improve glycemic control in women with gestational diabetes.

Defining exercise, type of exercise and intensity

Physical activity, exercise, and physical fitness are terms that describe different concepts. However, they are often confused with one another, and the terms are sometimes used interchangeably. Physical activity refers to bodily movements that involve muscle contraction to produce energy expenditures above the basal level, whereas exercise is a form of physical activity, which is planned, structured, and repetitive with the objective of improving or maintaining one's physical fitness [1].

Physical activity is measured in metabolic equivalent (MET) units that estimate the oxygen consumption of an activity. One MET is equivalent to 3.5 mL O_2/kg/min of oxygen consumption in a resting seated adult. Moderate exercise is equivalent to 3–6 METs, which include leisure cycling, swimming, walking, and general house cleaning. Vigorous exercise is activity equivalent to >6 METs such as running, rope jumping, and sit-ups.

Physical fitness refers to the circulatory and respiratory systems' ability to supply oxygen during sustained exercise. The intensity of an exercise is typically measured as percentage of maximal oxygen consumption (VO_{2max}). Moderate activity is when the body utilizes 40–60% of VO_{2max}, whereas high-intensity activity reaches 80–90% VO_{2max}. The volume of exercise is usually measured by the duration of the activity.

Exercise can be categorized into aerobic, anaerobic, and resistance training. There are few data to support that one type of exercise is superior to another in terms of general health benefits [2]. However, an exercise that is enjoyable and suitable to the individual is likely to be performed regularly and maintained for a longer period.

Aerobic exercise engages large muscle groups with repetitive and continuous movements for ≥10 minutes to produce improved oxygen utilization with the aim of enhancing cardiovascular and respiratory fitness. Examples include walking, cycling, and jogging.

Anaerobic exercise comprises short, but high-intensity, bursts of physical activity that rely on rapid release of energy produced via glycolysis, rather than being dependent on oxygen consumption. This exercise builds lean muscles, improves muscle and bone strength, and enhances sports performance.

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

Resistance training enhances muscle strength by working muscles against a resistance load or weight. By altering the combination of weight load and frequency of repetition, this exercise improves muscle endurance and strength as well as increasing the lean muscle mass and metabolic rate.

Aerobic, anaerobic, and resistance training exercises can be used alone or in combination to achieve the desired effect of improving cardiorespiratory fitness, muscle strength and endurance, weight loss and its maintenance. The type, intensity and volume of exercise should be tailored to individual needs to allow maximal adherence and long-term health benefits. Although the benefits greatly outweigh the risks, there are restrictions to exercise for people with certain medical conditions in terms of the type and intensity of physical activity. Gradual increases in exercise intensity and volume are generally advisable, but especially in those who are ordinarily sedentary at the start of an exercise program.

Type 1 diabetes and exercise

Prevention of type 1 diabetes

Most people view type 1 diabetes (T1DM) as affecting young, fit individuals. This together with its autoimmune pathogenesis means that regular exercise is not typically thought to prevent T1DM. Evidence is now emerging that exercise may be one of the modifiable agents that interact with genetic predisposition to determine if and when T1DM develops [3].

Figure 26.1 shows the possible mechanism by which exercise could improve or maintain β-cell mass. Physical exercise induces elevations in circulating levels of growth hormone (GH), IGF-1, glucagon-like peptide 1 (GLP-1), IL-6, and IL-1 receptor agonist (IL-1ra), all of which increase proliferation of β cells [4–8]. By reducing fat and visceral fat mass, exercise reduces pro-inflammatory adipokines, such as leptin and TNF-α, and increases anti-inflammatory adipokines, such as adiponectin, which may help to reduce β-cell death [9]. Exercise may reduce the destructive immune response to the β cell by reducing the Toll-like receptors on monocytes and macrophage immune cells [10]. Finally exercise improves insulin sensitivity which in turn helps to normalize plasma glucose [11] and serum lipids [12], which when chronically elevated cause β-cell death.

In animal models of diabetes, exercise protects the β cell from oxidative stress [13]. In healthy individuals [14], individuals at risk of type 2 diabetes (T2DM) [15] and people with T2DM, regular exercise improves β-cell function [16]. No studies to date have reported on the effect of exercise on β-cell function or incidence of diabetes in people with T1DM. However, the fact that insulin resistance, which is improved by exercise, predicts progression to T1DM [17] and that in a cross-sectional study increased physical activity was associated with better diabetes control, lower insulin needs, and higher C-peptide levels at T1DM onset [18], suggests that more human research is needed in this area.

Treatment of type 1 diabetes

Although the evidence for benefit is not as great as that seen in T2DM, there is sufficient evidence to suggest that exercise should be encouraged in people with T1DM. Figure 26.2 summarizes the benefits that people with T1DM can expect to see with exercise.

Physical fitness, CVD, and mortality

Although there are only a few small studies of fitness in people with T1DM, young adults (17–44 years old) with T1DM are less

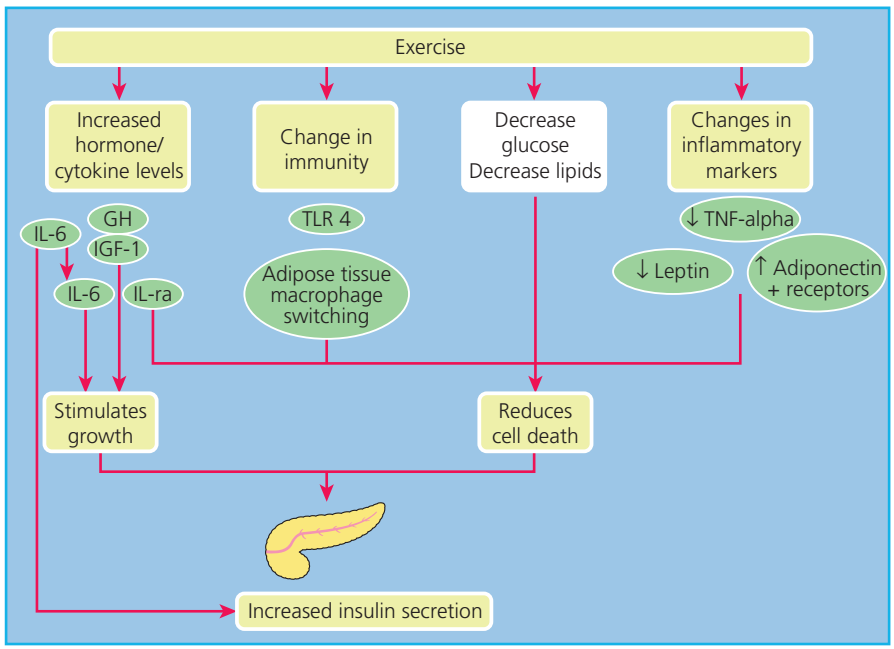

Figure 26.1 Potential mechanisms through which exercise could improve β-cell mass and/or function. Source: Narendran et al. 2015 [3]. Reproduced with kind permission from Springer Science+Business Media.

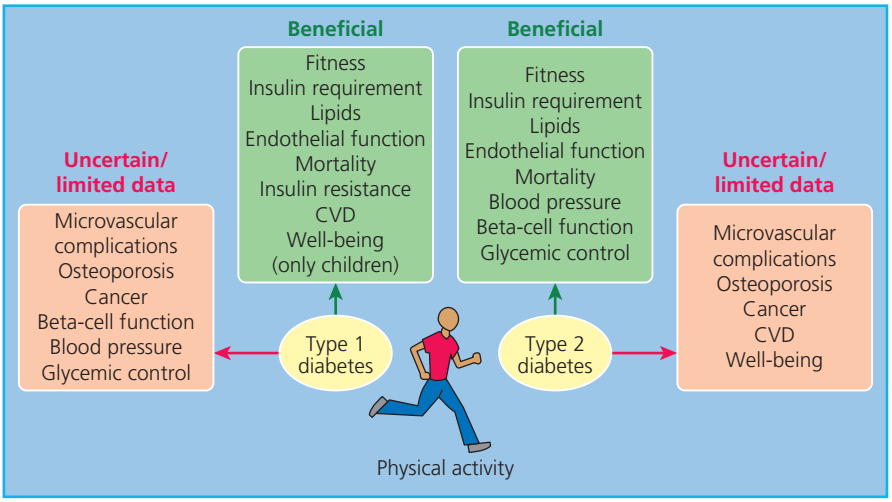

Figure 26.2 Health benefits of physical activity in type 1 and type 2 diabetes. Source: Chimen et al. 2011 [19]. Reproduced with permission from Springer.

fit than matched individuals without diabetes, despite similar levels of physical activity [20–23]. Abnormalities in cardiac muscle and autonomic nerve function [24], as well as an altered cardiac metabolism that favors non-esterified fatty acids (NEFA) over glucose as a fuel source [25], may contribute to this. Supervised physical activity programs do, however, improve fitness in people with T1DM [26–28] with increases in VO_{2max} of up to 27% reported [22, 28–32].

No large RCT or prospective studies have examined whether regular physical activity reduces CVD disease or mortality in T1DM. A large retrospective study, the Pittsburgh IDDM Morbidity and Mortality study, suggests that regular physical activity may be of benefit. This study demonstrated that in men who had had T1DM for 25 years, those who had participated in team sports during high school were three times less likely to report macrovascular disease and had mortality rates three times lower than those who did not [33]. This pattern was not seen in women, but their participation in team sports was lower (24% reported participation vs. 39% in men). The level of physical activity in adulthood (measured using a validated questionnaire) also predicted mortality at 6 years [20]. Sedentary men were three times more likely to die than active men, and a similar (but, again, non-significant) effect was seen in women.

Glycemic control and insulin requirements

The effect of physical activity on glycemic control in people with T1DM is unclear with some studies showing benefit but the majority showing no benefit. Table 26.1 lists the intervention studies where the controls have T1DM and Table 26.2 lists other studies.

The intervention studies have tended to use supervised exercise programs of short duration (1–3 months), have involved small numbers of participants (all but one had fewer than 60), and predominantly involved adolescents or young adults. Three recent meta-analyses of the effect of exercise on HbA_{1c} in T1DM have reported. Kennedy et al. included only studies in which there was a non-intervention group of participants with T1DM [64]. They found no glycemic benefit of exercise in people with T1DM. However, subanalyses suggested that exercise may confer glycemic benefit in the young, and when undertaken for longer periods. They also stated that exercise can be carried out by people with T1DM without significant risk of hypoglycemia. This is important because some studies have reported that hypoglycemia is a barrier to exercise in T1DM [65, 66].

Tonoli et al. [67] used less stringent criteria including trials with no control groups, but excluded some of the studies used in the Kennedy analysis. Exercise overall resulted in a small but statistically significant reduction of 0.3%. When exercise was analyzed by type, aerobic exercise reduced HbA_{1c} by 0.2%, strength training did not lower HbA_{1c}, and combined aerobic exercise and strength training showed a statistically significant reduction in HbA_{1c} of 1.6%.

In the meta-analysis by Yardley et al. [68], studies were only included if they were prospective, randomized and controlled with a non-exercising T1DM control group and the exercise intervention comprised supervised or unsupervised aerobic, resistance or combined physical activity offered at least twice weekly for ≥8 weeks. Only four studies were identified that met their criteria and had HbA_{1c} before and after the intervention. Although there was a 0.8% fall in HbA_{1c} in the exercise group compared to the control group, the authors concluded that there were insufficient well-designed studies to ascertain the true effect of exercise training on HbA_{1c} in T1DM.

Studies in people with T1DM that have examined the effect of exercise on plasma glucose concentrations have also failed to show a consistent benefit on fasting glucose [28, 33, 69, 70]. However, these studies have shown, as seen with healthy individuals [41], that blood glucose decreases (without hypoglycemia) around the time of exercise [37, 71]. The lack of glycemic benefit as assessed by HbA_{1c} may result from rebound hyperglycemia immediately following exercise, and better control of this may show a benefit.

Two main factors may account for the poor effect of exercise on HbA_{1c}. Many individuals with T1DM consume energy when physically active, either as a fuel source or to manage hypoglycemia, and this may counteract any glucose-lowering effect

Table 26.1 Intervention studies evaluating the effect of physical activity on HbA_{1c} in people with type 1 diabetes (T1DM). All studies quoted have included people with T1DM in both the intervention and control groups. The studies are listed in chronological order according to whether or not physical activity improved HbA_{1c}. Source: Chimen et al. 2011 [19]. Reproduced with permission of Springer.

of physical activity [41]. Similarly people with T1DM who exercise regularly reduce their daily insulin dosages by 6–15% [28, 29, 51]. Whilst this may be required to manage hypoglycemia, these reductions may mask improvements in HbA_{1c}.

Vascular risk factors other than glucose

People with T1DM commonly have hypertension and dyslipidemia that are associated with increased risk of vascular disease [70]. Most studies suggest that physical activity in people with T1DM improves lipid profile [22, 26, 28, 29, 31, 44]. These studies were of short duration (generally ≤4 months) and showed similar benefits to those seen in individuals without diabetes. HDL cholesterol increased by 8–30%, while LDL cholesterol and triglycerides decreased by 8–14% and 13–15%, respectively. Exercise also reduces apolipoprotein B, which is pro-atherogenic and is associated with premature mortality in T1DM [71], and increases the anti-atherogenic apolipoprotein A-I [26]. These benefits are independent of changes in glycemic control and weight and most pronounced in those with an adverse lipid profile.

Only four studies have examined the effect of physical activity on blood pressure in T1DM. All four studied young adults and used similar supervised exercise programs. Two showed no benefits in systolic or diastolic blood pressure [29, 31] and two showed a 2–3% reduction in blood pressure [39, 44]. Three studies were small, 26, 14, and 20 participants, respectively [29, 31, 44]. The remaining study was larger and included 196 participants and was one of the studies to show a benefit [39].

People with T1DM have clear evidence of endothelial dysfunction and this is worse if microalbuminuria is present [21]. Regular exercise can reverse endothelial dysfunction [72] and improve vascular function but this improvement is not as great as that seen in individuals without diabetes [29, 73]. Improved vascular function is also seen in vascular beds not supplying exercising muscles suggesting that this is a global rather than local benefit of exercise. Benefits only persist whilst people are exercising regularly and cease soon after regular activity is stopped.

Although less insulin resistant than those with T2DM, people with T1DM are more insulin resistant than matched individuals without diabetes [21, 28]. This insulin resistance can be improved by up to 23% through both resistance and endurance exercises [27–29, 51].

The beneficial effects of physical activity on insulin resistance, as well as on lipid levels and endothelial function, suggest that physical activity should reduce vascular complications in T1DM.

Microvascular complications

Increased physical activity is associated with fewer diabetes-related complications in individuals with T1DM [74]. In the Pittsburgh IDDM Morbidity and Mortality Study [75], in men but not women, activity levels were inversely associated with the risk of nephropathy and neuropathy but not retinopathy. However, a retrospective analysis of baseline physical activity in the Diabetes Control and Complications Trial (DCCT) found the rates of development or progression of diabetic retinopathy, nephropathy, and neuropathy were unaltered by physical activity after a mean follow-up of 6.5 years [76].

Other studies have shown an inverse association between physical activity and the severity of several complications in T1DM [74, 77]. A follow-up study involving 1945 individuals with T1DM reported that those involved in either little leisure time physical activity or low-intensity activity were more likely to have impaired renal function and more proteinuria as well as greater rates of retinopathy and cardiovascular disease when compared to their more frequently and more vigorously active counterparts [74]. Balducci and colleagues randomized 78 people (21 T1DM and 57 T2DM) without signs and symptoms of peripheral diabetic neuropathy to either supervised exercise or a control group [77]. The percentage of people with diabetes who developed motor and sensory neuropathy during the 4 years of the study was significantly higher in the control than the exercise group, 17.0% versus 0.0%, and 29.8% versus 6.4%, respectively. Thus long-term aerobic exercise training seems to prevent the onset of diabetic neuropathy or modify its natural history [77].

More recently, a cross-sectional multi-center study of 18,028 people with T1DM reported [78] that the frequencies of retinopathy and microalbuminuria were lower in active compared with inactive people. However, due to the cross-sectional design no causality can be inferred. It remains unclear whether the presence of comorbidities affected people's ability to exercise or whether being physically active decreased the risk of developing these complications.

Beta-cell function

T1DM is a chronic inflammatory autoimmune disease characterized by destruction of insulin-producing β cells and subsequent insulin deficiency [79]. This loss of β cells is gradual and at the time of diagnosis of T1DM significant β-cell function remains [80]. While it is generally assumed that the remaining β cells are completely destroyed soon after diagnosis, studies now indicate that these cells can persist for many years [81].

The preservation of these remaining β cells has important clinical benefits. A meal-stimulated C-peptide value of >200 pmol/L is associated with improved glucose control for the first 4 years after diagnosis, reduced risk of developing retinopathy and nephropathy, and a >50% reduction in hypoglycemia rates [82]. Thus interventions that have the potential to preserve β-cell function are worth striving for.

In diabetes animal models [13], healthy individuals [14], and people with T2DM physical activity preserves β-cell function [15]. The possible mechanisms by which exercise could preserve β-cell function are shown in Figure 26.1. This benefit of physical activity has not been examined in T1DM although a pilot study is currently underway to examine this [83].

Bone density

People with T1DM have reduced bone mineral density (BMD), osteoporosis and increased risk of fracture [84] but no studies have

examined whether physical activity increases BMD or reduces fracture risk in people with T1DM.

Cancer

Whether people with T1DM are at increased risk of cancer is unknown [85]. Physical activity appears to protect the general population from cancer and improve outcomes in those who do develop cancer (surgical outcome, side effects of chemotherapy, subsequent prevention of recurrence). Again, this has not been examined in T1DM.

Well-being

People with T1DM are 2–3 times more likely to suffer with depression than the general population [86]. In young adults, physical activity is associated with significantly greater satisfaction with life and well-being [58] but these associations were not found in the one study that examined this in children [65].

Exercise and type 2 diabetes

Prevention of type 2 diabetes

Prospective observational studies

The earliest evidence that indicated that exercise might play a role in prevention of diabetes came from large prospective cohort studies. In these studies higher levels of physical activity and/or cardiorespiratory fitness were consistently associated with reduced risk of developing T2DM [87, 88, 90–99]. After adjustment for confounding variables, the most active participants had a 25–60% lower risk of subsequent diabetes compared to those who were most sedentary. This reduction was seen regardless of the presence or absence of additional diabetes risk factors such as hypertension, parental history of diabetes, and obesity. In addition, similar magnitudes of risk reduction were seen with walking compared to more vigorous activity, when total energy expenditures were similar [95].

Non-randomized studies

The first large study to assess the effectiveness of lifestyle modification in preventing and treating diabetes was the Malmö Study [100]. In this non-randomized study, 41 participants with T2DM and 181 with impaired glucose tolerance (IGT) accepted enrolment into a 6–12-month intervention in which they were given advice to reduce energy intake and increase physical activity. The control group comprised 114 healthy individuals and 79 with IGT who declined the intervention.

At 6 years follow-up, 10.6% of those with IGT in the intervention group had progressed to T2DM, compared with 28.6% in the control group, a risk reduction of 63% [16]. Over 12 years, mortality among the controls was 14.0 per 1000 person-years, but only 6.5 per 1000 person-years in the intervention group [101]. Since this seminal study, many randomized controlled trials (RCT) have assessed the effect of lifestyle programs in preventing T2DM.

Randomized studies

A summary of the RCTs that have assessed whether lifestyle can prevent T2DM are shown in Table 26.3. The China Da Qing Diabetes Prevention Study included 577 participants with IGT who were randomized by center into four arms: diet only, exercise only, diet and exercise, or control, and were followed for 6 years [102]. The cumulative incidence of T2DM was 68% in controls, but only 44%, 41%, and 46% in the diet, exercise, and diet and exercise groups, respectively. Even more encouraging is the long-term follow-up which indicates that the benefits from these lifestyle interventions continue for many years after completing "active treatment"; the so-called "legacy effect." After 20 years follow-up, 14 years after leaving the study, those in the interventional groups had 43% lower incidence and spent on average 3.6 fewer years with diabetes compared to the control group [103].

In the Finnish Diabetes Prevention Study 522 people with IGT were randomized to an exercise and diet intervention or control [104]. The intervention was intense and included individualized exercise plans, thrice-weekly supervised facility-based aerobic and resistance exercise, and seven 1-hour meetings with a dietitian focusing on weight reduction, reduced fat intake, and reduced total caloric intake. Participants in the control group had one meeting per year. At 4 years, 22% of the control group and only 10% of the intervention group had developed diabetes, a 58% risk reduction. Again a legacy effect was seen with participants in the intervention arm having a 43% lower risk of developing diabetes 3 years after leaving the study [105].

In the American Diabetes Prevention Program [106], 3234 American men and women with IGT were randomly assigned to placebo, metformin, or a lifestyle-modification program. Again the lifestyle intervention was intense with the participants provided with 16 lessons in the first 24 weeks. These lessons were delivered individually and covered diet, exercise, and behavior modification. A minimum of two supervised exercise sessions per week, and at least monthly contact with the study personnel were maintained thereafter. Cumulative incidences of T2DM were 11.0/100 person-years in the placebo group, 7.8 per 100 person-years in the metformin group, and only 4.8 per 100 person-years in the intensive lifestyle group. The risk of T2DM was 58% lower in the lifestyle group than in the placebo group, and 39% lower than in the metformin group [107].

The Indian Diabetes study randomized 421 men and 110 women with IGT (mean age 45.9 ± 5.7 years, BMI 25.8 ± 3.5 kg/m^2) into four groups [108]. Group 1 was the control, Group 2 was given advice on lifestyle modification (LSM), Group 3 was treated with metformin (MET), and Group 4 was given LSM plus MET. The lifestyle advice was less intense than that given in the American and Finnish prevention studies. Participants in the LSM group were asked to increase their activity to 30 minutes per day; if they were already achieving this they were asked to maintain this activity. Exercise was not supervised.

Table 26.3 Controlled studies that have looked at preventing diabetes. C, control; D, diet; E, exercise; LSM, lifestyle modification; MET, metformin.

Name	Number of participants	Design of study	Study participants	Detail of intervention	Duration	Outcome
Malmö Study [100, 101]	222	Non-RCT	C: 114 healthy and 79 participants with IGT; LSM: 41 participants with T2DM and 181 participants with IGT	Participants were given advice to reduce energy intake and increase physical activity. Intervention lasted for 0.5–1 year.	6 years	Progression to T2DM: 10.6% vs. 28.6% for LSM vs. C group. A 63% risk reduction for the development of T2DM. Over 12 years, mortality was 14 vs. 6.5 per 1000 person-years in the C and LSM groups, respectively.
The China Da Qing Diabetes Prevention Study [102, 103]	577	RCT	Participants with IGT randomized into 4 arms: D, E, D+E, or C	D: received prescribed diet, advice on healthy eating and calorific reduction; E: taught exercise with increased exercise intensity; D+E: include both diet and exercise instructions as the D and E groups. All intervention groups received regular counselling sessions.	6 year, and follow-up at 20 years	Cumulative incidence of T2DM was 44%, 41%, 46%, 68% in D, E, D&E, C groups, respectively. Legacy effect: D, E and D&E groups had 43% lower incidence and spent average 3.6 fewer years with T2DM compared to C group.
Finnish Diabetes Prevention Study [104, 105]	522	RCT	Participants with IGT randomized into 2 arms: LSM and C	LSM; Individualized exercise plans, thrice-weekly supervised facility-based aerobic and resistance exercise, and seven 1-h meetings with a dietitian focusing on weight reduction, reduced fat intake and reduced total caloric intake.	4 years and follow-up at 7 years	Development of DM 10% in LSM compared to 22% in C group. Risk reduction 58%. Legacy effect: 43% lower risk in the interventional arm.
American Diabetes Prevention Program [106, 107]	3234	RCT	Participants with IGT randomized into 3 arms: placebo, MET, or a LSM program	LSM included intense 16 lessons in the first 24 weeks, delivered 1 to 1 and covering diet, exercise and behavior modification. A minimum of two supervised exercise sessions per week, and at least monthly contact with the study personnel were maintained thereafter.	Average 2.8 years	Cumulative incidences of T2DM were 11, 7.8, and 4.8 per 100 person-years in the placebo, metformin, and lifestyle groups, respectively.
Indian Diabetes study randomized [108]	531	RCT	Participants with IGT, randomized into 4 arms: C, LSM, MET, and LSM + MET	LSM: asked to increase or maintain their activity to 30 minutes per day. Non-supervised exercise. Diet modification included reduction in total calories, refined carbohydrates and fats, avoidance of sugar, and inclusion of fiber-rich foods. LSM participants were contacted monthly by telephone and seen 6-monthly during the study.	2.5 years	3-year cumulative incidences of diabetes were 55.0%, 39.3%, 40.5%, and 39.5% in control, LSM, MET, and LSM + MET, respectively. The relative risk reduction was 28.5% with LSM, 26.4% with MET, and 28.2% with LSM + MET as compared with the control group.

Diet modification was advised for each participant and included reduction in total calories, refined carbohydrates and fats, avoidance of sugar, and inclusion of fiber-rich foods. To aid adherence to the LSM, people were contacted monthly by telephone and seen 6 monthly during the study. The median follow-up period was 30 months, and the 3-year cumulative incidences of diabetes were 55.0%, 39.3%, 40.5%, and 39.5% in Groups 1–4, respectively. The relative risk reduction was 28.5% with LSM, 26.4% with MET, and 28.2% with LSM + MET as compared with the control group.

In these prevention studies, weight loss seems to be the main factor in the reduced diabetes incidence. In the US Diabetes Prevention Program, among those in the intervention arm, for every kilogram in weight loss a 16% reduction in diabetes was seen, when adjustment for changes in diet and lifestyle were made [109]. Results from a meta-analysis also suggest that the effectiveness of these lifestyles programs may be greater in more overweight individuals.

Weight loss, however, does not explain all the intervention effects. In the Indian Diabetes Prevention Program a 28.5% reduction in diabetes incidence was achieved without weight loss or reduction in waist circumference [108]. In the exercise intervention arm of the Da Qing IGT and Diabetes Study a 46% reduction in diabetes incidence was achieved without weight loss [102]. These factors suggest that some aspects of diet as well as physical activity, not necessarily related to weight loss, may be involved in mediating the beneficial effect of lifestyle modification in the prevention of T2DM.

Little data exist on the benefits of diet alone or exercise alone interventions for the prevention of diabetes in high-risk populations.

Treatment of type 2 diabetes

There is very clear evidence that exercise alone has profound benefits in people with established T2DM. Figure 26.2 summarizes the benefits that people with T2DM can expect to see with exercise.

Physical fitness, CVD, and mortality

People with T2DM diabetes have a significantly lower VO_{2max} than healthy age, BMI, and activity-matched people without diabetes [110]. Meta-analysis of 9 RCTs ($n = 266$), comparing exercise and control people with T2DM shows that regular exercise, at an intensity of at least 50% of VO_{2Max}, improved overall VO_{2Max} by 11.8% in the exercise group versus a reduction of 1% in the control group. Additionally, higher intensity exercise produces even larger improvements in cardiorespiratory fitness [111].

Observational studies have shown that increased physical activity improves cardiorespiratory fitness and lowers mortality rate in participants without diabetes [112, 113] while prospective studies in people with diabetes report that even walking for 2 hours a week is associated with less cardiovascular mortality; however, the effect is greater with 3–4 hours of walking a week [114]. No RCT has assessed the effect of improved physical fitness on mortality in T2DM.

Glycemic control

Supervised exercise training

Structured exercise training is normally defined as an intervention in which people engage in a planned, individualized, and supervised exercise program. The most recent meta-analysis that examined the effect of structured exercise training on HbA_{1c} in T2DM reported in 2011 [115] (Figure 26.3). This included 23 RCTs with 1533 participants. Studies had to be RCTs of ≥12 weeks' duration and have a control group of people with T2DM. Overall structured exercise reduced HbA_{1c} by 0.7% when compared to control participants. When dividing the studies into exercise type, 18 studies (848 people) demonstrated that structured aerobic exercise training reduced HbA_{1c} by 0.7%, four studies (261 people) showed that structured resistance exercise training reduced HbA_{1c} by 0.6%, and seven studies (404 people) demonstrated that the combined aerobic and resistance exercise reduced HbA_{1c} by 0.5%. This meta-analysis also showed that structured exercise duration of ≥150 minutes per week was associated with greater benefit than structure exercise duration of ≤150 minutes, 0.9% reduction versus 0.4% reduction, respectively.

Using a meta-regression analysis, Umpierre et al. assessed the association between intensity and volume of supervised exercise training (aerobic, resistance or combined) and HbA_{1c} changes in T2DM [138]. Higher baseline HbA_{1c} was associated with greater HbA_{1c} reduction with training. For supervised aerobic training and combined aerobic/resistance training, higher volume of exercise was associated with greater HbA_{1c} reduction. For example, for each set of aerobic exercise added within the exercise week, it produced a 0.4% HbA_{1c} reduction. No exercise variables were found to be possible candidates to explain the effects of supervised resistance training.

A meta-analysis of RCTs that compared supervised resistance exercise with aerobic exercise in people with T2DM sought to clarify whether there was an optimum type of exercise for treating T2DM [139]. The 12 included studies of 626 participants were RCTs of duration of ≥8 weeks that compared supervised resistance exercise with supervised aerobic exercise. Although there was a greater reduction of HbA_{1c} with supervised aerobic exercise compared to supervised resistance exercise, the difference was only 0.2% and not clinically significant.

Two RCTs have compared the three commonly used types of supervised exercise for treating T2DM, namely aerobic, resistance training or a combination [124, 132] (Figure 26.4). In the Diabetes Aerobic and Resistance Exercise (DARE) trial [124], 251 previously sedentary individuals with T2DM were randomized into four arms: aerobic exercise training, resistance exercise training, combined aerobic and resistance exercise training, or a non-exercising control group. Compared to the control groups, HbA_{1c} values decreased significantly in the aerobic group by 0.5% and the resistance group by 0.4%. In the combined exercise group, HbA_{1c} values fell by an additional 0.5% compared with the aerobic group and 0.6% compared with the resistance group.

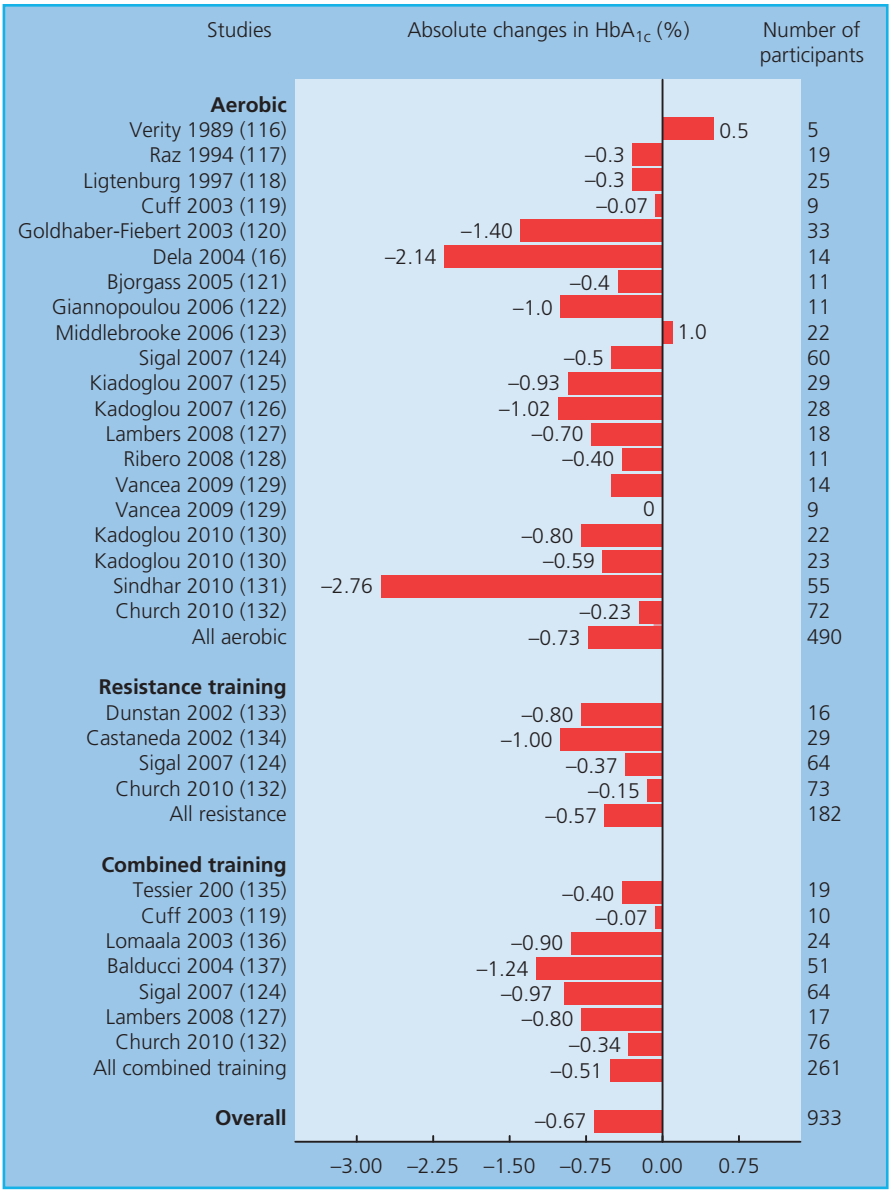

Figure 26.3 Absolute changes in HbA_{1c} of individual studies of structured exercise training versus no intervention. Numbers of participants in each exercise regimen is shown in the far-right column. Source: Adapted from Umpierre et al. 2011 [115].

In people with $HbA_{1c} \leq 7.5\%$, HbA_{1c} only decreased significantly in the combined exercise training group.

Church et al. [132] randomized 262 sedentary people with T2DM to four groups: aerobic exercise training, resistance exercise training, combined aerobic and resistance exercise training, or a non-exercising control group. Compared with the control group, neither the resistance nor aerobic training produced a significant change in HbA_{1c}. For the combination training exercise group, a fall in HbA_{1c} of 0.3% was seen compared to the control group.

High-intensity interval training (HIT) is the newest form of exercise to be tried in the management of T2DM as it takes less time to perform and can produce similar physiological effects to longer duration of standard exercises [140]. Recently a meta-analysis of four small studies which aimed to quantify the effects of HIT on markers of glucose regulation with control conditions or continuous training has reported [141]. Compared with control conditions, in people with T2DM, HIT decreased HbA_{1c} by 0.2%. HIT was not superior to continuous training at lowering HbA_{1c}.

Physical activity advice

Although structured exercise training may be available to a subset of people with T2DM, physical activity advice is more feasible. Physical activity advice is normally defined as formal instructions to exercise regularly with or without an individualized exercise prescription. The most recent meta-analysis that assessed the effect of physical advice on HbA_{1c} in people with T2DM reported in 2011 [115] (Figure 26.5). This included 24 studies with 7025 participants. Overall physical activity advice produced a 0.4% decrease in HbA_{1c} compared to control. When the studies were broken down to those that also gave dietary advice and those

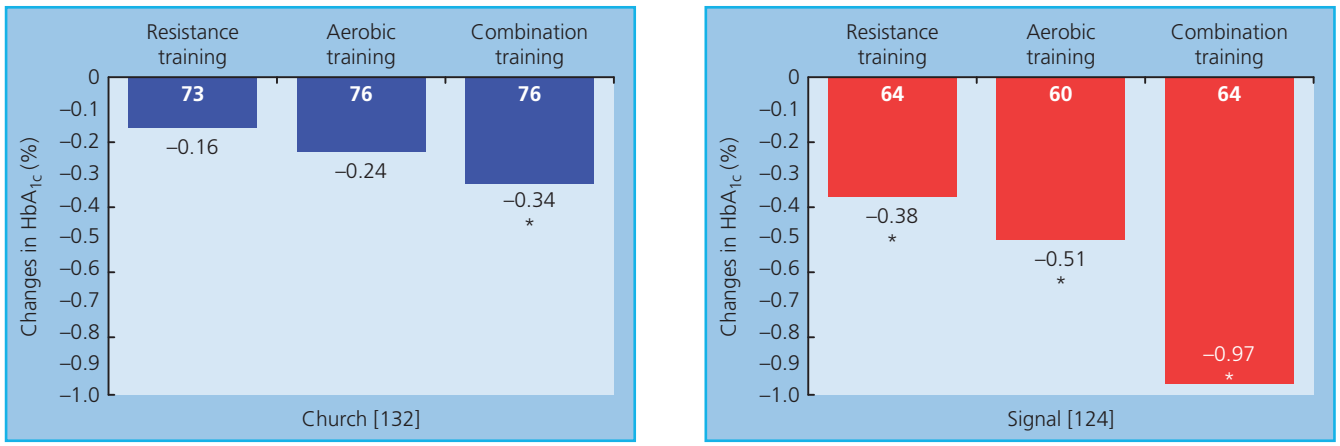

Figure 26.4 Reduction in HbA_{1c} (%) seen with different exercise regimens compared to control group in two studies, Church et al. [132] and Sigal et al. [124]. Numbers of participants in each exercise regimen is shown in the boxes in white. A star denotes significant improvement compared to control group. Source: Adapted from Sigal et al. 2007 [124] and Church et al. 2010 [132].

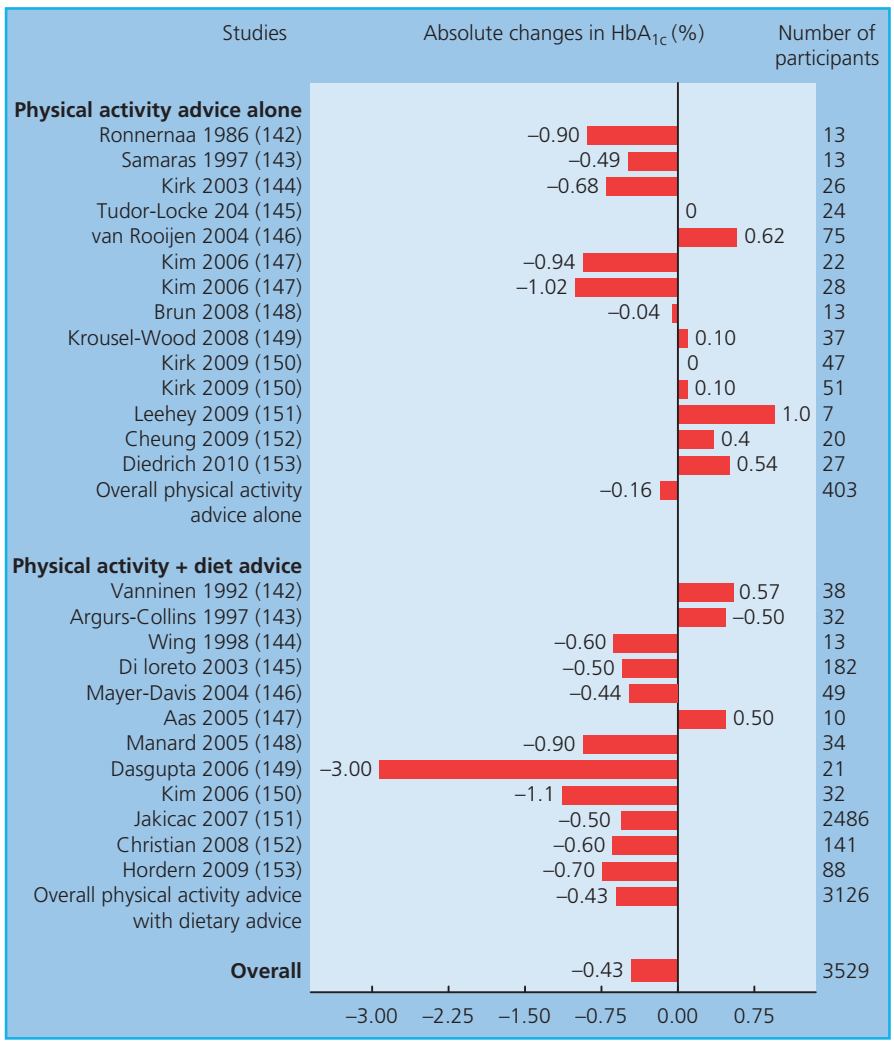

Figure 26.5 Absolute changes in HbA_{1c} of individual studies of physical activity advice versus no intervention. Numbers of participants in each exercise regimen is shown in the far-right column. Source: Adapted from Umpierre et al. 2011 [115].

that did not, some interesting findings were seen. Physical activity advice given with dietary advice (12 studies, 6313 people) was associated with a 0.6% HbA_{1c} reduction as compared with control but physical activity advice alone (14 studies, 712 people) was not associated with HbA_{1c} changes.

Structured exercise training versus physical activity advice

Only one RCT has compared structured exercise training to physical activity advice. In the Italian Diabetes and Exercise Study [166], 606 individuals with T2DM were randomized to a full year of either physical activity advice alone or supervised facility-based combined aerobic and resistance exercise training twice weekly plus physical activity advice. HbA_{1c} fell by 0.1% in the advice group and 0.4% in the supervised exercise group, with this difference being significant. This study suggests that supervised exercise programs are more effective than physical activity advice.

Vascular risk factors other than glucose

In healthy people, aerobic and resistance training lower both systolic (SBP) and diastolic blood pressure (DBP), whereas combined training only lowers DBP [167]. In 2014, Figueira and colleagues conducted a meta-analysis to assess the effect of physical activity advice alone or structured exercise training on blood pressure in T2DM [168]. Thirty RCTs (2217 participants) of structured exercise training and 21 (7323 participants) physical activity advice alone RCTs were identified. Overall structured exercise reduced SBP by 4 mmHg and DBP by 2 mmHg when compared to controls. Greater reductions in blood pressure were seen when exercise duration was ≥150 minutes and when intensity of the exercise was higher. When exercise training was broken down into exercise type, compared to control, aerobic exercise training reduced SDP by 5 mmHg and DBP by 2 mmHg, and resistance exercise training reduced SDP by 4 mmHg and DBP by 3 mmHg. Combined exercise training was not associated with a reduction in blood pressure. Physical activity advice alone produced a 3 mmHg reduction in SBP and a 1 mmHg reduction in DBP.

Several studies have examined the effect of aerobic and combined aerobic and resistance supervised exercise on lipids in T2DM. In a meta-analysis both reduced triglycerides by 0.3 mmol/L but had no effect on HDL cholesterol and LDL cholesterol [169]. Only one study has assessed the effect of resistance training and found no effect on total cholesterol, HDL cholesterol, LDL cholesterol, or triglycerides [124].

People with T2DM have impaired endothelial function [170, 171], which is a powerful and independent predictor of long-term cardiovascular events [172, 173]. Only a few small studies have assessed the effect of exercise on endothelium function in T2DM but a meta-analysis of five studies including 217 participants reported supervised exercise improved endothelium function [173].

Insulin resistance is one of the hallmarks of T2DM and is involved in the pathogenesis of hypertension and CVD. Both aerobic and resistance training improve insulin resistance in T2DM [119]. Although in healthy controls, resistance exercise has a greater effect on insulin sensitivity than aerobic exercise there is insufficient evidence to confirm whether this is the case in T2DM [174].

Microvascular complications

As exercise improves HbA_{1c} and blood pressure, the two key risk factors in the development of diabetic microvascular complications, regular exercise should protect against microvascular complications. Few studies have examined whether this is the case. Impaired exercise capacity is associated with diabetic nephropathy and retinopathy [175]. In retrospective and prospective cohort studies regular physical activity was associated with reduced progression and development of diabetic kidney disease [176, 177]. In the Look AHEAD study people randomized to the intervention arm (diet, exercise, and weight loss) were less likely to develop retinopathy or neuropathy [178]. In contrast in the Japan Diabetes Complications Study in which 2033 participants were randomized to a lifestyle intervention (diet and exercise) or usual care, there was no difference in incident retinopathy or nephropathy between groups at 8 years follow-up [179]. No RCTs have examined the effect of exercise alone on microvascular risk in people with T2DM.

Beta-cell function

In the UK Prospective Diabetes Study, progressive decline of β-cell function was associated with worsening of glycemic control in people with T2DM, irrespective of treatment strategy [180]. Thus maintenance of β-cell function is important if we wish to maintain good control in people with T2DM. Several studies have shown that aerobic exercise of varying intensity improves insulin secretion in T2DM [181–184].

Bone mineral density

People with T2DM are at increased risk of fractures despite normal, or even increased, bone mineral density (BMD) [185]. This increase in fracture risk may be due to altered bone architecture or an increased risk of falling due to neuropathy. No studies have assessed the effect of physical activity on BMD or fracture risk in T2DM.

Cancer

T2DM is associated with an increased risk of developing cancer [186]. In the general population regular physical activity reduces cancer risk and improves outcomes in those who develop it. Again no studies have examined whether this holds true for people with T2DM.

Well-being

People with T2DM have a higher chance of developing depression [187, 188]. They also have a poorer quality of life [189] and a higher prevalence of general anxiety disorder (14%) than the general population [190]. The effects of exercise training on quality of life, symptoms of depression, symptoms of anxiety and emotional well-being in T2DM have been recently reviewed [191]

Table 26.4 Effect of exercise on well-being.

		Number of studies	Length of interventions	Number of participants	Results
Quality of life	Aerobic	Five [127, 194, 196–198]	8, 16, 16 and 52, 12, and 12 weeks	18, 50, 44, 29, 38	Four found no effect [30, 34, 35, 38] and one found effect on physical health and sleep subscales but not on other subscales [33].
	Resistance	Four [164, 201, 204, 205]	16, 16, 12 and 26, and 16 weeks	58, 48, 110, 37	One found no difference [43], one found a significant effect [3], and two found effects on mental component [7] and general health subscale [31] but no effect on other subscales.
	Combined	Ten [127, 135, 161, 193, 195, 197, 199, 203, 205, 207]	24, 52, 16 and 52, 12 and 26, 8, 12, 26, 12, 16, and 16 weeks	84, 606, 64, 109, 36, 77, 43, 28, 38, 29	Six found no effect [34, 36–38, 44, 46]. Three found improvement across all measures of quality of life [32, 42, 47]. The remaining one found improvement in emotional role, mental health, and vitality but not for other subscales [29]
Well-being	Aerobic	Three [192, 202, 206]	6, 8, and 8 weeks	58, 40, 20	Two showed improvement [2, 5] and one no improvement [6]
	Resistance	Two [192, 205]	8, 12, and 26 weeks	20, 110	One showed improvement [7] the other did not [6]
	Combined	One [205]	12 and 26 weeks	109	No effect
Depression	Aerobic	Two [200, 202]	6 and 8 weeks	78, 58	Both showed no effect
	Resistance	One [201]	16 weeks	58	Improved
	Combined	One [193]	8 weeks	36	No effect
Anxiety	Aerobic	One [200]	6 weeks	58	Reduced anxiety
	Resistance	None			
	Combined	None			

(Table 26.4). No form of exercise improved quality of life and emotional well-being while depressive symptoms were only improved by resistance training and anxiety symptoms only improved by aerobic training.

Gestational diabetes and exercise

Prevention of gestational diabetes

Gestational diabetes (GDM) is a condition in which women without a previously diagnosis of diabetes develop glucose intolerance during pregnancy (Chapter 61) [192]. The prevalence of GDM ranges from 1% to 14% depending on the diagnostic criteria used and the population being studied [193]. It is associated with adverse maternal and fetal outcomes; women with GDM have an increased risk of developing GDM in subsequent pregnancies and of developing T2DM. Offspring of mothers with GDM are at high risk of macrosomia [194] and as adults are more likely to become obese [195] and develop T2DM [196]. Preventing GDM is therefore a clinical priority.

A number of prospective studies have shown that low physical activity is associated with the development of GDM. In the largest of these studies (21,765 women) Zhang et al. found that when comparing the highest with the lowest quintiles of vigorous activity there was a relative risk of 0.77 (197). Among women who did not engage in vigorous activities, women who briskly walked ≥30 minutes or climbed ≥15 flights of stairs daily also had lower risk of GDM [197].

A 2012 Cochrane database systematic review including five trials and 1115 pregnant women assessed the effects of physical exercise for preventing glucose intolerance or GDM [198]. GDM incidence did not differ between women receiving additional exercise interventions or routine antenatal care. A more recent Cochrane database systematic review also found no difference in GDM incidence between women receiving routine antenatal care or additional diet and exercise interventions [199]. Both reviews felt that larger better quality studies were needed to confirm or refute these findings. A number of large high-quality studies are underway which will report in the next few years.

Treatment of gestational diabetes

Regular exercise during pregnancy is associated with many benefits, including improved cardiorespiratory fitness, less low back pain, reduced urinary incontinence, reduced depressive symptoms [200], and less weight gain in pregnancy [201]. Although diet and exercise are recommended as the first step in managing GDM, there is debate about whether there is clear evidence

about the effectiveness of exercise. A 2006 Cochrane review concluded that "there is insufficient evidence to recommend, or advise against, diabetic pregnant women to enrol in exercise programs. Further trials, with larger sample size, involving women with gestational diabetes, and possibly type 1 and 2 diabetes, are needed to evaluate this intervention" [202]. A more recent systematic review identified seven studies that had examined the effect of exercise in managing GDM [203]. Five studies found improvements in glycemic control and/or a limitation in insulin use [204–208] but two reported no effect [209, 210].

Exercise advice in type 1 and type 2 diabetes

Exercise guidelines

The American Diabetes Association has published recommendations and guidelines for exercise in individuals with diabetes [211]. These and other guidelines are summarized in Table 26.5.

Where possible advice should be tailored to the individual, taking into account their interests, level of fitness, possible contraindications, and personal goals. There are many examples of people with diabetes competing at the highest level, and so diabetes should not interfere with an individual's sporting goal and treatment should be adjusted according to the demands of the activity. For activities and competitions considered to be high risk for individuals with diabetes (car racing, flying, diving, etc.) individual governing bodies should be consulted regarding restrictions in competition. It is also important to note that insulin is considered a banned substance by the World Anti-Doping Agency, and that elite level athletes with diabetes will be require a Therapeutic Use Exemption (TUE) certificate prior to competition.

Table 26.5 Exercise guidelines for adults and children with type 1 and type 2 diabetes and pregnant women with diabetes. Source: Based on recommendations in [200] and [211].

Categories	Physical activity recommendations
Adults with T1DM and T2DM	At least 150 min/week of moderate-intensity or 75 min/week of vigorous-intensity aerobic physical activity, or equivalent combination of the two. This should be spread over 3 days with no more than 2 consecutive days without exercise. Additionally, muscle-strengthening activities that involve all major muscle groups should be performed on 2 or more days of the week. Reduction in sedentary time is also recommended [1]
Children and adolescents with T1DM and T2DM	At least 60 min of physical activity daily, this should include vigorous-intensity aerobic activity, muscle-strengthening activities and bone-strengthening activities at least 3 days of the week [1]
Pregnant women with DM	At least 30 min or more of moderate exercise daily if there are no medical or obstetric complications [2]

Most guidelines recommend ≥150 minutes of moderate aerobic activity, and/or ≥90 minutes of vigorous aerobic exercise every week, and that this activity be spread over at least three days [211]. A day's activity need not occur in a single session, but may be accumulated in bouts of 10 or more minutes at a time, performed throughout the day. Performing ≥150 minutes of moderate activity is associated with greater benefit, so if a person with diabetes has reached the target of 150 minutes they should be encouraged to do more if possible.

In addition to aerobic exercise, many guidelines also suggest that resistance training should be carried out at least twice per week, as combining aerobic exercise with resistance training has the greatest effect on HbA_{1c}. Ideally at least three sets of resistance exercise should be done at each session as the resistance exercise studies that have used three or more sets have shown the greatest reduction in HbA_{1c} [37, 133, 212]. Weight lifting is safe in people with cardiac disease [213] and is not associated with increased proliferative retinopathy risk [214].

Newer guidelines also recommend that people with diabetes should also try and reduce their sedentary time [211]. This is because higher sedentary time is associated with a poorer metabolic profile in T2DM and reduced sedentary time improves metabolic profile [215].

Minimizing risk of exercise-related adverse events

Assessment

There is often concern about the safety of exercise for people with diabetes, although for most people, the benefits of exercise will outweigh the risks. Prior to starting exercise for the first time or when beginning a program of vigorous physical activity, people with diabetes should be assessed for conditions that might increase the risks associated with certain types of exercise or predispose them to injury. Table 26.6 provides guidance on what pre-exercise assessment should be undertaken.

Specific considerations for people with type 1 diabetes who exercise

In normal healthy individuals changes in insulin and counter-regulatory hormone secretion during exercise are dependent on the type of exercise being performed [216]. These changes facilitate an increase in liver glucose production to match skeletal muscle glucose uptake [156]. A change in the secretion of these hormones is also seen post exercise to facilitate recovery and adaption to exercise. As a result of these changes, blood glucose levels remain relatively stable before, during, and after exercise.

In T1DM, because insulin lies in subcutaneous depots and is not under regulation, insulin levels do not change in a physiological manner during exercise, thus they cannot fall in response to exercise and there may be impaired secretion or action of counter-regulatory hormones. This impairs normal fuel regulation [217].

Table 26.6 Pre-exercise assessment and advice for people with diabetes complications.

Complication	Advice
Cardiovascular disease	Symptoms of cardiovascular disease should be asked about and where there is concern patients should be referred to a cardiologist for further assessment. There is no evidence for screening of asymptomatic individuals. Cardiovascular assessment is recommended for people with autonomic neuropathy.
Peripheral neuropathy	It is vital to ensure that appropriate footwear is worn and feet are examined regularly particularly if peripheral neuropathy is present. Weight-bearing exercise should be avoided in those with active foot disease. Walking does not increase the risk of ulceration in people with peripheral neuropathy There is evidence that exercise delays the progress of neuropathy and so exercise should be encouraged.
Retinopathy	When proliferative or severe non-proliferative retinopathy is present it may be sensible to avoid vigorous activity (both aerobic and resistance) because of the possible increased risk of vitreous hemorrhage or retinal detachment.
Nephropathy	No evidence for restriction of any type of exercise in people with diabetic renal disease. In fact there is evidence that exercise can reduce progression and so exercise should be encouraged.

The inability of the pancreas to modulate insulin and counter-regulatory hormones (in particular glucagon) following exercise can also hamper recovery and adaption to exercise. This increases the risk of hypoglycemia both during and following exercise. Furthermore, hyperglycemia prior to and following some types of exercise can be problematic [218]. Consequently, people with T1DM have three main problems when exercising, which are:

1 problems controlling their blood glucose during and immediately following exercise;

2 unexplained severe hypoglycemia particularly at night;

3 reduced performance through excessive fatigue and reduced muscle strength.

To help overcome these problems people need to understand how different exercises affect glucose, know when it is safe to exercise, and have strategies to manage glucose during and after exercise.

How different exercise effects blood glucose

Both intensity and exercise type will determine what happens to blood glucose concentrations (Figure 26.6). The most rapid drop in blood glucose occurs during aerobic or endurance exercise, when circulating insulin suppresses metabolic fuel production and increases muscle glucose uptake [219]. With intermittent high-intensity exercise, there is a mixture of both aerobic and anaerobic exercise, which is characteristic of team sports and children's play; blood glucose is either stable or falls slowly [220]. High-intensity or anaerobic exercise tends to raise blood glucose, as a result of increased catecholamines that are normally seen with these exercises [221].

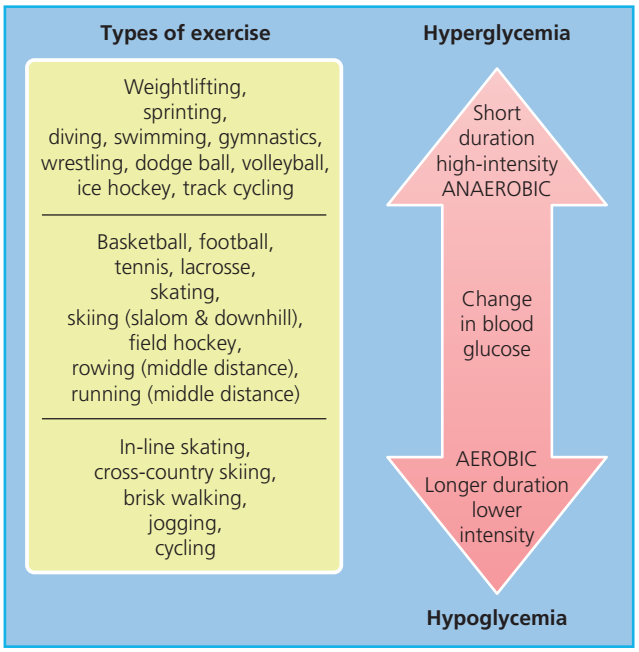

Figure 26.6 Effects of differing sports on blood glucose concentrations.

When it is safe to exercise

Hypoglycemia in the 24 hours preceding exercise blunts the counter-regulatory hormone response to exercise-induced hypoglycemia placing an individual at greater risk of exercise-induced hypoglycemia. This risk is proportional to the severity of the preceding hypoglycemia, with the effect starting at 3.9 mmol/L [222]. There is currently no evidence to guide individuals as to when it is safe to exercise following a hypoglycemic episode. However, we would suggest the following:

- Do not exercise within 24 hours of severe hypoglycemia requiring third-party assistance.
- Do not exercise within 1 hour of self-treated hypoglycemia. If an individual insists on doing so, they should treat the hypoglycemia and wait 45–60 mins once the glucose is stable before commencing activity.
- Take extra precautions when there has been an episode of self-treated hypoglycemia within the previous 24 hours. This would include more frequent glucose testing, exercising with an informed partner, and, if possible, including an anaerobic component to their training because this will tend to raise their blood glucose.

If there is hypoglycemia during exercise, exercise should be discontinued and the hypoglycemia treated. The individual should wait at least 45 mins before recommencing activity (or until blood

Table 26.7 Insulin dose adjustment table for exercise. MHR, maximum heart rate. Borg scale is based on the Borg rating of perceived exertion scale [232].

		Intensity		
	Duration	**Low (<50 MHR % or Borg scale 10)**	**Medium (50–75% MHR or Borg scale 10–15)**	**High (>75% MHR or Borg scale >15)**
% Dose reduction	<30 min	10–20%	20–45%	40–60%
	30–60 min	20–30%	30–55%	50–75%
	>60 min	30–50%	45–70%	100%

glucose is stable). If an episode of severe hypoglycemia occurs during exercise, then the activity should be stopped altogether because of the high risk of further hypoglycemia.

When the blood glucose level is ≥14 mmol/L before exercise, the presence of ketones (capillary or urine) should be assessed [223]. If ketones are present, exercise is contraindicated and supplemental insulin should be considered (1 unit for 2–3 mmol/L glucose reduction). Exercise should only be commenced when ketone-free and blood glucose is ≤14 mmol/L [224]. Where the blood glucose level is ≥14 mmol/L and ketones are not present, advice depends on timing of the last meal (and, therefore, last quick-acting insulin dose). If a meal has been eaten in the last 1–2 hours, commence exercise but monitor blood glucose closely. If the last meal was eaten ≥2 hours ago, then 30% of their usual correction dose should be given.

Strategies to manage glucose during exercise

An initial strategy for managing blood glucose during exercise is to replace the carbohydrate (CHO) that will be used during exercise orally. In its simplest form, this is a fixed CHO replacement regimen. In adults, we initially recommend 15 g of CHO for every 30 min of exercise [225]. Although activities vary widely in terms of fuel requirements, this range represents a safe starting point for most people beginning moderate-intensity exercise. Estimates of CHO requirement based on body mass can be used in preference to fixed dose CHO replacement. Therefore for moderate and intensive activity 0.5 g/kg/h and 1 g/kg/h, respectively may be used [226].

An alternative approach that adjusts for the variable fuel requirements of different exercises is using standardized tables. These have been devised to help athletes of different body

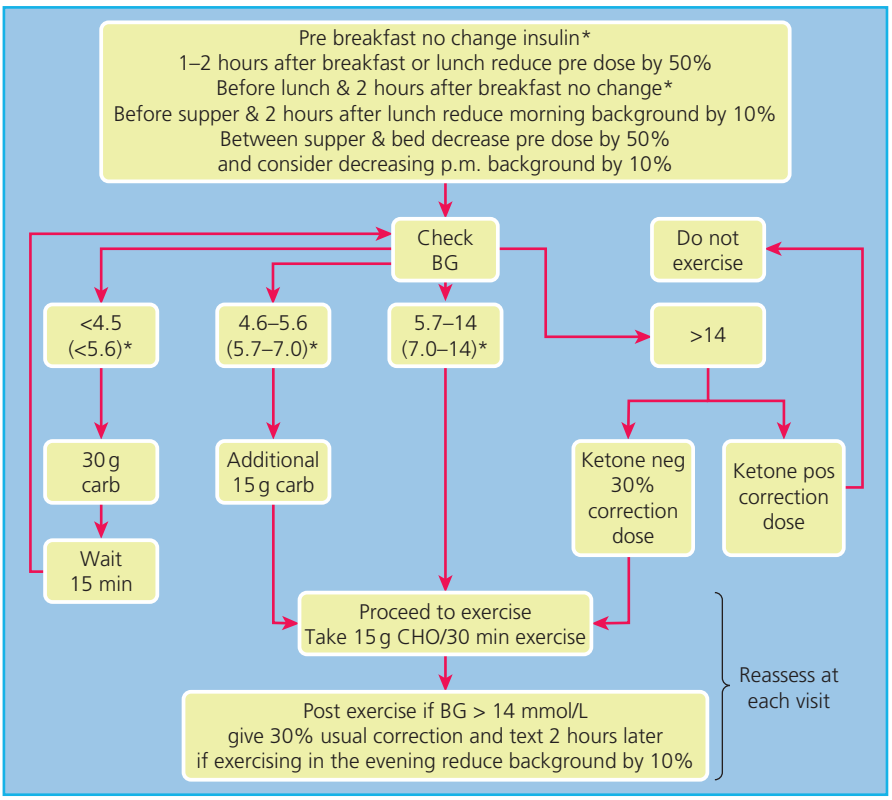

Figure 26.7 Algorithm for people with T1DM suggesting changes to insulin and carbohydrate intake when exercising. Note different blood glucose levels are used in this algorithm if exercising before breakfast or when exercising 2 hours after breakfast and before lunch when no changes in insulin dosages are made, this is denoted by a star. BG, blood glucose.

weight estimate CHO requirements for different exercise intensities [227]. The maximum rate of enteral glucose absorption is 1 g/min. Therefore CHO requirements exceeding 60 g of glucose per hour, would need to comprise a combination of glucose and fructose. In general, once CHO requirements for exercise exceed 60 g/h, we would recommend altering insulin doses.

Several studies have examined insulin dose reductions for exercises of different intensities. This has enabled the development of dose reduction tables (Table 26.7). These tables tend to refer to changes to fast-acting insulin and therefore relate to exercise undertaken within 2 hours of eating (3 hours if on soluble human insulin). To gain the most from these reductions, exercise is best conducted within 30 minutes after eating, and the meal or snack should predominantly contain low glycemic index CHO [228]. Reduction in background insulin can, however, be helpful if people are undertaking prolonged exercise in the morning, or in the afternoon 2 hours after their meal.

Strategies to manage glucose post exercise

Following exercise, carbohydrate is required to replenish muscle and liver glycogen stores. Protein is also needed for post-exercise muscle repair and synthesis. Failure to provide this increases the risk of hypoglycemia in the subsequent hours, and fatigue in subsequent exercise sessions. Initially individuals should be advised to take snacks equivalent to 1 g/kg of carbohydrate and 0.3 g of protein per kg [229]. This snack should be taken with insulin as this increases CHO storage in the exercising muscles and liver [230]. Initially we recommend a third of their normal insulin to CHO ratio.

There is a risk of hypoglycemia several hours after exercise through an increase in insulin sensitivity. If individuals have exercised during the morning or early afternoon, they should monitor their blood glucose and take extra CHO as needed. If exercise has been undertaken in the late afternoon or evening, this may lead to nocturnal hypoglycemia. To prevent this people should reduce their evening background insulin by 10% or take extra carbohydrates before going to bed.

High-intensity aerobic and anaerobic exercise can lead to post-exercise hyperglycemia through increased hepatic glucose output and muscle insulin resistance, brought on by increased production of counter-regulatory hormones [231]. This means that additional insulin may be needed post exercise. Whilst there is currently no evidence to guide an insulin correction dose, we recommend starting with 30% of the usual correction dose for blood glucoses ≥14 mmol/L post exercise. Figure 26.7 shows a simple algorithm that brings together all this advice.

Specific considerations for people with type 2 diabetes

In individuals with T2DM, exercise does not usually cause hypoglycemia and so CHO supplementation is usually unnecessary. If blood glucose declines rapidly during exercise, as may occur in individuals taking oral hypoglycemic agents or insulin, the drug dosage should be reduced or withheld on exercising days.

27 Monitoring Diabetes

Andrew Farmer
Nuffield Department of Primary Care Health Sciences, University of Oxford, Oxford, UK

Key points

- Glycated hemoglobin (HbA_{1c}) levels are now reported using the International Federation of Clinical Chemistry standard expressed as mmol/mol of unglycated hemoglobin. The equivalent of the current HbA_{1c} levels of 6.5% and 7.5% are 48 mmol/mol and 58 mmol/mol.
- For people with type 1 diabetes (T1DM), blood glucose control should be monitored with measurement of HbA_{1c} every 2–6 months depending on the level and stability of blood glucose control and change in therapy.
- People with T1DM should be encouraged to self-monitor blood glucose with capillary blood glucose meters. With treatment regimens intended to produce intensive glycemic control, testing should be frequent (e.g. four or more times a day).
- For people with type 2 diabetes (T2DM), blood glucose control should be monitored using high precision methods for measurement of HbA_{1c} every 3–6 months depending on the level and stability of blood glucose control and change in therapy.
- For people with non-insulin-treated T2DM, self-monitoring of blood glucose is unlikely to be effective for most patients and should therefore not be used routinely and if used, only when training and support is available and a clear purpose for use identified.

Why monitor?

"The overall goal of diabetes management is to achieve as near normal physiological or ideal [glucose] values as possible, without detriment to quality of life and, for glucose control in particular, without causing significant hypoglycemia" [1].

Diabetes is a disorder of glucose homeostasis. It currently affects 415 million people worldwide and is expected to affect 642 million by 2040 [2]. For people without diabetes, glucose levels are maintained in the range of 4–6 mmol/L (80–110 mg/dL). When blood glucose levels increase as a result of glycogen conversion or eating carbohydrate-containing food, insulin is released restoring homeostasis through hepatic conversion of glucose to glycogen, and uptake of glucose into muscle and fat cells. Conversely, if blood glucose levels fall too low as a result of exercise or lack of food, glucagon is released causing hepatic conversion of glycogen to glucose.

The aim of monitoring in diabetes includes:

- allowing people with diabetes to understand the nature of their disorder;
- to determine the optimum times for initiating therapeutic intervention; and
- to guide the day-to-day adjustment of treatment.

Choosing the optimal target for monitoring and assay is important, not only to ensure the best outcomes for an individual, but at a population level, where small differences between the performance of tests, the frequencies with which they are carried out, and their costs may lead to important differences in outcomes and overall costs of care.

The topic of "monitoring in diabetes" could extend across the full range of clinical measurements required for optimal disease management including monitoring of lipids and blood pressure. However, there are specific issues associated with measurement of glycemia in diabetes that require special consideration. People with type 1 diabetes mellitus (T1DM) lack the normal homeostatic mechanism to control levels of blood glucose, while people with T2DM have an impaired or absent response to changing levels of glucose. In addition to insulin, which is the most important of the regulatory mechanisms, corticosteroids, glucagon, growth hormone, thyroxine, and catecholamines are counter-regulatory hormones and lead to increases in blood glucose levels. There is increasing evidence that these hormones are involved in a brain-centered glucoregulatory system [3].

Glycated hemoglobin (HbA_{1c}) and blood glucose are the two most frequently used measures of glycemia in current practice. Glycated hemoglobin provides information about overall control of glucose levels in the previous 6–8 weeks allowing assessment of the need for therapy and therapeutic response with minimal within-person variation in measurement. Blood glucose measurements provide information about the day-to-day level of control,

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

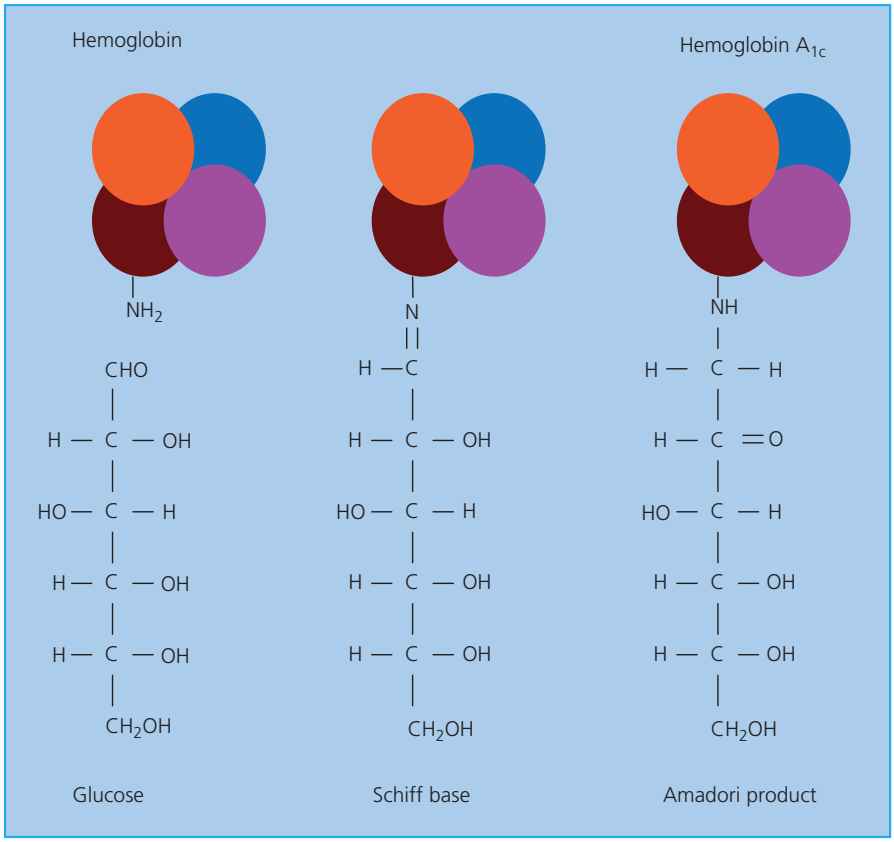

Figure 27.1 The Amadori reaction.

variation in control, and response to therapeutic intervention. This chapter will describe the tests for HbA_{1c} and glucose levels, the characteristics of these tests, the technology used in measuring their levels, and their clinical application in T1DM and T2DM.

Tests and their characteristics

Measurement of glycated hemoglobin

Quality controlled HbA_{1c} measurement has a central role in the management of diabetes, and increasingly a role in diagnosis of T2DM. HbA_{1c} levels are associated with the response to treatment and the risk of developing complications, and therefore provide an evidence-based marker with which to judge the impact of glucose lowering treatment, and prognosis. Its pivotal role derives from its use in reports of the major outcome studies that demonstrated the link between improved glycemic control and important clinical outcomes [4, 5].

Hemoglobin reacts spontaneously with glucose to form glycated compounds (or derivatives) in a non-enzymatic manner. The process occurs slowly, with the extent of glycation determined by the concentration of glucose in blood. Human hemoglobin A undergoes such glycation to form HbA_{1c} from a reaction between the β chain of hemoglobin A0 and glucose (Figure 27.1). Other compounds result from similar reactions on the α and β chains of hemoglobin and these can be measured as the total glycated hemoglobin.

Levels of glycated hemoglobin are measured as the proportion of glycated to total levels of hemoglobin. Formerly expressed as a percentage, the proportion is now increasingly expressed in the units of mmol per mol of unglycated hemoglobin. Work to standardize measurements of glycated hemoglobin to enhance its clinical application has overcome initial problems caused by a range of assays used and lack of agreement over a common reference standard. The publication of DCCT [5] in 1993 led to a number of countries developing national programs to standardize measurement that included external quality assurance schemes ensuring that measurements between laboratories could be compared [6]. As more advanced assays were developed the new reference method based on assaying a specific component of HbA_{1c} (the β-N-terminal hexapeptide) was established.

Despite the increasing standardization of HbA_{1c} measurement, there are over 30 different methods in use for measurement. Manufacturers provide calibration factors for individual machines, and there is a global network of laboratories that maintain and monitor the relationship between the different standards.

The new reference standard for HbA_{1c} agreed by the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) was introduced slowly over a period of time but is now increasingly accepted. It is expressed in the unit of mmol/mol. The new standard continues to be based on a proportion of glycated

Table 27.1 IFCC aligned values for HbA_{1c} and correlation of HbA_{1c} with estimated average glucose.

DCCT aligned HbA_{1c} (%)	IFCC HbA_{1c} (mmol/mol)	Estimated average glucose*	
		mg/dL	mmol/L
4.0	20	68	3.8
5.0	31	97	5.4
6.0	42	126	7.0
7.0	53	154	8.6
8.0	64	183	10.2
9.0	75	212	11.8
10.0	86	240	13.4
11.0	97	269	14.9
12.0	108	298	16.5

The estimated average glucose numbers are based on data from the ADAG trial [8].
The IFCC reference standard can be converted to the former DCCT aligned standard using the formula: IFCC-HbA_{1c} (mmol/mol) = [DCCT-HbA_{1c} (%) − 2.15] × 10.929.

to unglycated hemoglobin, but specifies the proportion of β-N-terminal hexapeptide that has been glycated.

The conversion equation between the IFCC units and DCCT % is:

$$\text{DCCT result (\%)} = (0.0915 \times \text{IFCC result in mmol/mol}) + 2.15$$

Hence the equivalent of the HbA_{1c} levels of 6.5% and 7.5%, commonly used as targets for glycemic control, are 48 mmol/mol and 58 mmol/mol in the new units (Table 27.1).

For both people with diabetes and clinicians, the new standard for reporting HbA_{1c} values has, in addition to clearly separating old and new assay values for HbA_{1c} levels by increasing the order of magnitude in which the measurements are expressed, also reduced potential confusion between reports of blood glucose levels in mmol/L and HbA_{1c} measurements. With the former reference range for HbA_{1c} it was relatively easy to confuse a blood glucose value given in mmol/L with an HbA_{1c} (%) value of a similar order but having different implications for clinical decision-making. By contrast, in countries that still use mg/dL, the potential for confusion is increased and this is one of the reasons why the American Diabetes Association has not adopted the new units. Nevertheless, a considerable education initiative continues to be needed to inform both people with diabetes and clinicians of the change.

In the United States the American Diabetes Association and the American Association for Clinical Chemistry recommend that HbA_{1c} (often referred to as A1C) can be reported with an estimated average glucose (eAG) result (Table 27.1) when a clinician orders the A1C test [7]. The mean plasma glucose numbers are based on data from the ADAG trial [8].

Table 27.2 Conditions that can affect the measurement of glycated hemoglobin.

Iron deficiency anemia
Hemoglobinopathies
Polycythemia
Blood transfusion
Hemolysis (hemolytic anemia)
Uremia caused by renal failure
High levels of vitamin C
HIV infection
Aging
Ethnicity

Analytical techniques and quality assurance for HbA_{1c} measurement

Accurate interpretation of glycated hemoglobin requires a normal lifespan of erythrocytes. The presence of a shortened lifespan, for example with hemolytic disease or blood loss, can lead to underestimates of the true value. By contrast, iron deficiency anemia, which is associated with a longer lifespan, can be associated with an overestimate of the true value. Other conditions, for example hemoglobin variants, uremia, hypertriglyceridemia, and chronic salicylate ingestion, can also lead to inaccurate results (Table 27.2), but specific assays (e.g. high performance liquid chromatography rather than immunochemistry or affinity chromatography methods) can be used in some cases to avoid the problem and obtain an accurate result. Laboratories still differ in whether a result from a heterozygous person with variant hemoglobin is reported as non-comparable to the Diabetes Control and Complications Trial/UK Prospective Diabetes Study (DCCT/UKPDS) standard, or whether it is not reported at all.

HbA_{1c} levels are higher among racial and ethnic minority groups with impaired glucose tolerance after adjustments for a wide range of demographic and risk factors compared to white Europeans [9]. Therefore, using a fixed threshold of 6.5% for the diagnosis of diabetes in different ethnic groups could lead to differences in proportions of people in different ethnic groups being diagnosed with diabetes when compared to use of an oral glucose tolerance test for diagnosis [10]. In addition, HbA_{1c} levels are associated with increasing age in non-diabetic populations, and so the extent to which age-specific diagnostic and treatment thresholds are needed, remains to be determined [11].

Glycated hemoglobin serves as a retrospective indicator of the average glucose concentration over the previous 6–8 weeks. Approximately 50% of the variance in HbA_{1c} is determined by the average blood glucose concentration over the previous month, 25% by the concentration over 30–60 days, and the remaining 25% by the concentration from 60–120 days [12].

Using a laboratory assay with high precision methods to measure glycated hemoglobin levels is recommended to assess the maintenance of glycemic control. Results should now be reported in IFCC units (mmol/mol) alongside the DCCT aligned (%) units. In addition to laboratory-based analyzers, there is now a range of

Table 27.3 Values for diagnosis of diabetes mellitus.

	Glucose concentration (mmol/L)*			
	Plasma		Whole blood	
Time of measurement	Venous	Capillary	Venous	Capillary
Fasting	≥7.0	≥7.0	≥6.1	≥6.1
2 h after a glucose load	≥11.1	≥12.2	≥10.0	≥11.1

*1 mmol/L = 18 mg/dL.

handheld or desk-based analyzers that can be used in an office or bedside setting. The rationale for using these meters is to allow changes in treatment within the consultation, or to allow measurement of HbA_{1c} levels where transport of blood to a laboratory is not possible or laboratory facilities are not available [13].

Measurement of fructosamine

Albumin is the main component of plasma proteins. Albumin contains free amino groups that can react non-enzymatically with glucose to form fructosamine. Measurement of fructosamine reflects glucose levels over the previous 1–3 weeks. Fructosamine measurement is not appropriate for routine use because the assay is markedly affected by excessive turnover or excretion of albumin in, for example, renal disease. In addition, fructosamine assays are not standardized in the same way as HbA_{1c} assays. Fructosamine testing remains useful in a number of circumstances, for example in pregnancy where glucose requirements change rapidly, or in the preconception period where motivation to improve control is high and the changes can be evaluated at shorter intervals. With the lower cost and increased standardization of HbA_{1c}, however, it is possible that more frequent measurements of HbA_{1c} may be an alternative strategy, particularly if evaluating potentially large improvements in the blood glucose over the preceding 4–6 weeks contributing to a clinically important change from a previous HbA_{1c} result [14].

Measurement of blood glucose

Blood glucose (or the level of glucose to which the body's organs are exposed) is expressed as the plasma glucose concentration. Blood samples for analysis of glucose levels need to be taken under controlled conditions. Red blood cells may continue to metabolize glucose after collection, continuing glycolysis, and thus leading to an apparent reduction in reported glucose levels from those at the time of collection. The continuing glycolysis should be avoided by rapid centrifugation, collection onto ice and storage in a refrigerator. If blood is to be transported at room temperature it should be collected into fluoride-containing tubes that inhibit further glucose metabolism. If a patient has an intravenous line *in situ*, blood should be drawn from the arm opposite to the one with the line to prevent contamination of the sample from any infusion.

Blood glucose measurement is a term that is frequently used without precise definition. Measurement of glucose levels is usually carried out either on capillary or venous samples of blood. Most laboratories measure the level of glucose in plasma, which again differs from measurements made on whole blood. Table 27.3 shows the equivalent measurements from the different sites and samples taken.

Blood glucose levels are expressed in SI units (from the French, *Le Système International d'Unités*) as millimoles/liter (mmol/L). The traditional unit for measuring blood glucose is milligrams/decilitre (mg/dL), although use of these units is now largely confined to the USA. To convert mmol/L glucose to mg/dL, multiply by 18 (Table 27.1).

Sampling and preparation of the sample affect measurement. Whole blood glucose is also affected by the concentration of protein (mainly hemoglobin) in the sample. Whole blood concentrations are therefore 12–15% lower than plasma concentrations. Venous blood glucose levels are normally similar to arterial and capillary levels when fasting. The arterial and capillary levels most closely reflect the glucose concentrations at the organ level. After meals, venous blood will have lower glucose concentrations than arterial blood and can be as much as 10% lower.

Analytical techniques and quality assurance for measuring glucose levels

A range of analytical techniques is used for the laboratory measurement of blood glucose concentration. Chemical oxidation or reduction methods have a low cost for reagents and, although less specific, are still valid. Enzymatic analysis of glucose is more specific, although more expensive. The enzymatic reference method for glucose is the hexokinase/G6PDH method. The glucose oxidase methods are comparable, although the presence of reducing substances may cause error. Glucose oxidase methods are frequently used because of their convenience and lower cost. Measurements are accurate and precise with measurement coefficient of variance of around 2%. Electrochemical techniques now predominate [15] and underpin the technology in handheld glucose sensors. Self-measurement of blood glucose is possible using capillary blood glucose meters with test strip systems. Specific issues associated with their use are considered in the next section. Some meters now incorporate the facility to measure blood ketone levels, of particular importance for people with T1DM.

Other meters have the facility to calculate insulin bolus requirements or to download blood glucose results for charting using a computer.

Most of the currently marketed handheld capillary blood glucose meters give results as an equivalent to venous plasma glucose but this is not always the case. The same type of handheld meter may be calibrated to report whole blood glucose in one country and plasma values in another. The calibration of a meter should be checked and the thresholds for action set accordingly.

Measurement of blood glucose in a hospital setting

In a hospital or "site-of-care" setting, capillary blood glucose measurement can be used to replace venepuncture, with greater comfort and more rapidly available results for monitoring patients in an acute situation. Standards have been laid down to ensure that bedside glucose determinations can be made accurately and include the need for well-defined policies which include adequate training, quality control procedures, and regular maintenance of equipment [16]. Some meters used in hospitals support quality assurance procedures by restricting access to trained personnel and transferring the results directly to the electronic patient record.

Blood glucose meters may require entry of a number or insertion of a coding chip to ensure calibration to the batch of testing strips used—although most meters, particularly those now used as handheld devices by people with diabetes, do not now require this extra step.

Self-monitoring of blood glucose

Self-monitoring of blood glucose (SMBG) is now an integral part of self-care for people with T1DM to maintain levels of blood glucose that minimize risks of complications. In addition it is required for people with T2DM using insulin, and for some people with T2DM who have specific indications [7]. Carrying out regular SMBG requires a high level of motivation from a person with diabetes and so its use needs to be carefully discussed and supported [7]. Effective SMBG technique, awareness of how to interpret the results, and a knowledge of action needed on the results obtained are essential for the procedure to be both clinically and cost-effective.

People with diabetes need to be taught how to perform SMBG testing accurately and how to use the data to adjust therapy in relation to food intake and physical activity. Correct technique involves obtaining the blood sample from the side of the finger pulp, wiping and using the second drop of hanging blood, using the meter correctly and disposing of the lancet (Figure 27.2). Alternative sites for sampling include the base of the thumb, forearm, and thigh. Pre-meal readings will be the same between sites, but at times of rapid glucose change (in the postprandial period or during hypoglycemia) forearm and thigh results will be different from the fingertip results, because glucose changes lag behind the fingertip results.

Figure 27.2 Correct technique for self-monitoring of blood glucose improves accuracy of testing.

Measurement issues associated with point of care meters

Although laboratory methods of blood glucose measurement are more accurate than capillary blood glucose meters, their convenience and rapidity of use can, in some circumstances, outweigh their higher coefficient of variance. Therefore, despite a slight reduction in accuracy compared to laboratory testing, and the possibility of user error, they are in wide use. The majority of meters conform to international standards (www.iso.org), with 95% of readings <4 mmol/L (<72 mg/dL) within 0.83 mmol/L (15 mg/dL) of the true result, and within 20% of the true result for higher glucose readings. The newer meters have minimized the possibility of user error by requirement for smaller volumes of blood for measurement and automated calibration methods. Operator error, however, remains a significant source of error, including failure to calibrate meters (most meters do not now require external calibration), poor hand-washing technique and dirty meters [17].

Careful training and consistent technique in making measurements can minimize measurement error. Allowance for the possibility of error in the reading when calculating an insulin dose on the basis of a meter reading should be made. Regular testing should be carried out so that results that do not fit the usual pattern can be identified, with retesting as necessary.

Despite their imprecision, blood glucose meters remain particularly helpful at higher blood glucose values, where, for example, it is of less importance to distinguish a plasma glucose of 11 mmol/L (198 mg/dL) from one of 14 mmol/L (252 mg/dL). In such circumstances, the aim of management is to achieve a substantial reduction in plasma glucose. At lower plasma glucose levels, however, the consequences of an imprecision of 15% are much greater. For many people with well-controlled diabetes aiming to keep

their glucose levels in the range 4–6 mmol/L (72–108 mg/dL), the majority of readings below 4 mmol/L (72 mg/dL) will result from the variance of the measurement rather than reflecting a true "low" value.

Measurement of urinary glucose

Measurement of glucose in urine has limited arguments in favor of its use for routinely monitoring diabetes. It is rapid, inexpensive, non-invasive, and can provide a quantitative result; however, it does not reflect the changing levels of hyperglycemia with any accuracy and so interpretation may be difficult if not impossible. In addition, the renal threshold varies between individuals and varies during pregnancy and with aging. In any case, glucose is not excreted renally at levels where blood glucose is significantly elevated above that which should be targeted to minimize diabetic complications.

Urine fraction should be analyzed immediately, preserved at pH < 5 to inhibit bacterial metabolism or stored at 4 °C. The enzyme used is glucose oxidase/peroxidase, which may lead to false-positive results with hydrogen peroxide and false-negative test results with the presence of ascorbic acid.

Urine testing should no longer be used in most healthcare settings because of the availability of alternative and more accurate tests. For the moment it may have a role in resource-poor settings where identification and treatment of individuals with poorly controlled diabetes is the highest priority.

Monitoring in clinical practice

Effective monitoring of glycemic control requires a partnership between the healthcare professional and the person with diabetes. Optimal regimen and the balance between use of laboratory testing and self-monitoring require consideration of a range of factors extending from, at the one end wholly clinician-directed testing (e.g. during acute illness in a hospital setting) to self-monitoring for a person with diabetes in the community who is otherwise well. The importance of self-management should not be underestimated; attempts by hospital clinicians to take over monitoring of a patient during an admission otherwise unconnected with diabetes can lead to conflict, as can attempts by a clinician in the community to direct testing in someone whom they might only see once or twice a year, where inappropriate testing may have no useful purpose.

Monitoring in type 1 diabetes

People with T1DM should be encouraged to practice SMBG using capillary blood glucose meters. With treatment regimens intended to produce intensive glycemic control, testing should be frequent (e.g. four or more times a day) [18].

People treated with insulin need to measure, interpret and take appropriate action to adjust their insulin dose on a regular basis at home. Detailed records of blood glucose measurements and actions are needed to allow review by both the person with diabetes and their clinician. Blood glucose measurements are particularly helpful in situations where frequent adjustment of therapy is needed. Fasting blood glucose measurements are important in judging the effectiveness of longer-acting insulin therapies. Pre-prandial blood glucose levels are often equated with, but are not equivalent to, fasting blood glucose levels, which require an 8-hour fast. Pre-prandial measurements may be useful for evaluating the impact of a complex insulin schedule, particularly with fast-acting insulin analogs.

When using a typical basal bolus regimen, including three injections of short-acting insulin and one or more injections of long-acting insulin at least four time-points during the day, blood glucose levels need to be monitored, pre-breakfast, pre-lunch, pre-dinner, and before bedtime. Comparison of pre-prandial readings with 1–2 hour postprandial measurements provides a guide to the response to the short-acting insulin. Frequent glucose testing allows identification of periods during the day when plasma glucose levels are higher or lower than ideal and appropriate adjustment of the short-acting or bedtime injections. If the individual has regular routines and varies little in food intake and physical activity from day to day, then monitoring can take place at a frequency of less than four tests a day; for example, a daily fasting blood glucose with four-point sampling on either 1 or 2 days a week, or each day testing at one or more additional time-points to build a picture over the week. Until the dose of long-acting insulin has been established, a series of paired bedtime and fasting readings are needed to allow it to be adjusted to an optimal dose.

Tight control brings with it the risk of hypoglycemia [19]. Additional checks on blood glucose levels should be made in relation to the risk of hypoglycemia, for example, before exercise or driving and in the presence of symptoms that may indicate hypoglycemia. For some people (limited duration of life, inability to make the adjustments required for tight control) intensive control is inappropriate. Accepting less tight control allows the use of less complicated regimens and less frequent monitoring. For individuals using conventional rather than long-acting insulin analogs, and with biphasic regimens more frequent monitoring may be required because of the less stable time course of the long-acting components of the insulin.

For people with T1DM, the overall level of glycemia should be measured with a HbA_{1c} test every 2–6 months [7, 18] depending on the level and stability of blood glucose control and change in therapy. HbA_{1c} measurement should be provided either at site-of-care or carried out by the laboratory before clinical consultation. Glycated hemoglobin measurement for people with T1DM complements blood glucose measurement. The HbA_{1c} measurements provide additional checks on the extent to which glucose results are giving an accurate picture of overall blood glucose control. A record of recent blood glucose measurements indicating good control may need to be re-examined if a HbA_{1c} measurement does not indicate a corresponding level of good control. For example, timing of blood glucose measurements and measurement technique may need reassessing.

Adults with T1DM should be encouraged to achieve and maintain a HbA_{1c} target of 48 mmol/mol (6.5%) or lower to minimize risk of long-term complications, but individualized targets should be agreed based on lifestyle and previous experience of hypoglycemia [18]. Optimal target ranges for blood glucose monitoring for adults are for fasting blood glucose levels, 5–7 mmol/L (90–126 mg/dL), 4–7 mmol/L (72–126 mg/dL) before meals and 5–9 mmol/L (90–162 mg/dL) after meals [18]. Targets for children (aged 0–12 years) are higher because of the high risk of and vulnerability to hypoglycemia. Adolescents and young adults are at particular risk with developmental and psychological issues, but should nevertheless aim for good glycemic control <58 mmol/mol (<7.5%). Optimal target ranges for blood glucose monitoring for children are for fasting blood glucose levels, 4–7 mmol/L (172–126 mg/dL) (or 5–7 mmol/L (90–126 mg/dL), if intending to drive), 4–7 mmol/L (72–126 mg/dL) before meals and 5–9 mmol/L after meals (90–162 mg/dL) [18].

Monitoring diabetes in a hospital setting

Critically ill patients should have blood glucose levels maintained between 7.8 and 10.0 mmol/L (140 and 180 mg/dL) although in those centers with more experience in glucose control, a lower target of 6.1–7.8 mmol/L (110–140 mg/dL) may be aimed for provided that there is no increase in the incidence of severe hypoglycemia (see Chapter 34). For non-critically ill patients the target glucose level should be between 6.0 and 10.0 mmol/L (108 and180 mg/dL), with a level of 4.0–12.0 mmol/L (72–216 mg/dL) being acceptable for medical patients and for awake surgical patients. Concerns about hypoglycemia mean that some institutions have concern about the safety of these goals as initial targets.

Self-management of diabetes in the hospital setting may be appropriate where adult patients are alert, able to self-manage their diabetes at home, and have stable requirements for insulin. This may also provide an opportunity for providing support in learning techniques of insulin adjustment in line with carbohydrate intake.

Monitoring diabetes in a community setting

Glycated hemoglobin and SMBG testing are the two primary techniques for monitoring success in achieving glycemic goals, adjusting therapy and providing information to support lifestyle change. Meters to test HbA_{1c} are now available in a clinic setting. However, there is as yet insufficient evidence for their use in this way unless there are problems in obtaining laboratory measurement [20, 21].

Continuous blood glucose measurement in type 1 diabetes

The need to provide more frequent SMBG measurements to document glucose excursions and guide insulin therapy has led to the development of innovative technologies that can provide up to 300 measurements a day. Detailed data on the magnitude and duration of glucose fluctuations can be used to guide lifestyle and drug therapy in an attempt to produce a near-physiologic control of plasma glucose.

There are a number of different systems currently available. All require calibration using capillary blood glucose measurement and utilize a subcutaneously implanted sensor that can remain *in situ* for up to 7 days. This usually transmits data to a wireless monitor. All the continuous glucose monitoring (CGM) systems are intended for intermittent use in order to identify periods of hyperglycemia that can be corrected by changing therapy (e.g. increasing the dose of insulin or changing timing of injections), or detecting periods of biochemical hypoglycemia that may be too brief to cause symptoms but may nevertheless cause some impairment in cognitive function. The devices are not as accurate as a conventional blood glucose meter, and so blood glucose levels should be confirmed before a change in treatment.

Other technologies are now available for interstitial glucose measurement. These include the FreeStyle® Libre device that includes a sensor worn for up to 2 weeks. It is designed for continuous use, does not require calibration, but is scanned, giving readings over the previous 8 hours, using a handheld device that avoids the need for a direct connection between a sensor and the recording device.

Evidence for effectiveness of CGM in selected people with T1DM aged over 25 years using intensive insulin therapy comes from a randomized trial with 322 people with T1DM in which those allocated to the CGM arm experienced a 0.5% (6 mmol/mol) reduction in HbA_{1c} from 7.6 to 7.1% (60 to 54 mmol/mol) compared to conventional therapy [22]. Evidence for HbA_{1c} lowering is less strong in children, teenagers and younger adults, although there may be specific clinical circumstances in which CGM might be helpful. Success correlates with adherence to the ongoing use of the device. Many people with T1DM indicate that CGM is a valued addition to diabetes care with a perceived improvement in HbA_{1c} and reduction in hypoglycemia [23].

CGM systems are now being evaluated as a sensor within a closed-loop system in which insulin delivery through a pump device is regulated by the use of a control algorithm that automatically reduces and increases subcutaneous insulin delivery according to sensor glucose levels. Recent short-term studies in young adults with diabetes in a home setting indicate that glucose control is improved during the day and night with fewer episodes of hypoglycemia [24].

Monitoring in type 2 diabetes

For people with T2DM, the overall level of glycemia should be monitored with a test for the level of HbA_{1c} every 3–6 months depending on the level and stability of blood glucose control and change in therapy [7, 18]. An interval of 3 months between tests is usually recommended following changes in therapy or when levels are unstable, although a test after 2 months may provide some additional information [12, 25]. HbA_{1c} measurements should be provided, usually through a laboratory assay before clinical consultation. There is now an increasing range of point of care devices

available that could be used to provide immediate feedback on glucose levels, although the pragmatic value of these devices in optimizing care in comparison to that based on HbA_{1c} laboratory assay has not yet been evaluated. However, in the absence of timely laboratory measurement of HbA_{1c}, then point of care devices are feasible to use and sufficiently accurate to guide treatment.

Setting HbA_{1c} targets for people with T2DM is important to guide decisions about treatment and to provide feedback to patient and clinician about the effectiveness of treatment. The level at which targets should be set for an individual remains widely debated. Although guidelines provide advice about generally accepted targets, individuals need to be involved in decisions about their own HbA_{1c} target. Once available, the results of tests should be used to encourage people to achieve and maintain their target unless they develop hypoglycemia. In addition to pharmacotherapy, attention to lifestyle should be maintained at all stages of treatment. As levels of HbA_{1c} rise above the selected target, then advice about diet, lifestyle, and adherence to medicines should be further stressed, and increase in treatment considered.

The clinical implications of glycemic variability remain uncertain. Although there are claims that long-term variability in glucose levels are associated with an increased risk of complications, the only evidence available is for an increased risk of hypoglycemia. In addition, there is no evidence that targeting glucose variability leads to improved outcomes.

If HbA_{1c} measurement is unavailable, then a fasting plasma glucose measurement can be used to indicate need for, or response to a treatment that leads to a reduction in fasting hyperglycemia (e.g. metformin or a sulfonylurea). A fasting capillary plasma glucose level of 3.9–7.2 mmol/L is recommended as a target for control.

Glucose monitoring is now infrequently recommended for routine monitoring in non-insulin-treated T2DM where HbA_{1c} testing is available. It continues to have a place where there are concerns about hypoglycemia (e.g. use of sulfonylurea) or HbA_{1c} measurements are not possible or do not provide an accurate measure of glycemia. Although some behavioral feedback on the impact of lifestyle and of drug treatment is available to people with diabetes through SMBG, the additional benefit of doing this routinely alongside standard care has not been demonstrated in rigorous clinical trials and the debate around this issue is discussed in the following section.

Self-monitoring of blood glucose in insulin-treated type 2 diabetes

For people with T2DM who are using insulin, SMBG is needed to adjust insulin dose and check that good control is maintained, although optimal use remains to be established. The recommended schedules for monitoring are derived from trials that have sought to achieve reductions in HbA_{1c} to within recommended levels [26]. The intensity of these schedules has not yet been evaluated in wider populations and those more representative of primary care populations. Fasting blood glucose levels carried out twice a week will allow weekly or 2-weekly titration of long-acting insulin to achieve tight control. Additional 4- or 7-point profiles may be helpful every 3–4 weeks to identify patterns of blood glucose control that require further attention, for example, to address the possibility of hypoglycemia or to identify high levels of postprandial glucose that may require the use of pre-meal short-acting insulin.

Continuous glucose monitoring systems are now being used as a research tool among people with T2DM, but the extent to which the procedure is useful to the person with diabetes or to the clinician remains unclear and its use cannot be recommended in routine clinical practice. Advocates of the procedure suggest that it might be useful as a means of helping people to recognize aspects of their lifestyle that lead to hyperglycemia [27].

Self-monitoring of blood glucose in non-insulin-treated type 2 diabetes

SMBG use for people with T2DM was initially explored to see whether patients might use it to gain a greater understanding of their diabetes and how best to control it, for example by weekly or 2-weekly adjustments of the dose of oral glucose reducing treatment. HbA_{1c} measurement was less widely available when SMBG was first used in this way. Additional proposals for using SMBG in management of T2DM have been put forward based on deductions from physiological observations. For example, blood glucose levels are usually high following meals, and thus contribute to overall blood glucose control. Some studies have therefore been interpreted to suggest that postprandial glucose levels correlate with development of complications better than fasting blood glucose levels (or that glycemic variability may be related to poor outcomes). Attempts to titrate oral hypoglycemic medication by taking account of post-meal measures, however, have not been successful [28].

Where HbA_{1c} measurement is not available, then SMBG may be an option for some people with T2DM. For people with non-insulin-treated T2DM, the within-person coefficient of variation of fasting (pre-breakfast) blood glucose levels is low and measurements vary little from day to day. Measurement of blood glucose levels with a personal meter is therefore a means of assessing day-to-day control and making adjustments to therapy or assessing the impact of lifestyle changes. The frequency of fasting blood glucose measurement for non-insulin-treated T2DM has been suggested from once a week to once a day. The evidence for a particular frequency of testing, however, is lacking, and individual variations (familiarity with ensuring measurement techniques, variation in lifestyle, availability of professional help in supporting patients in interpretation of measurements) will require that a judgment be made on the precise purpose of monitoring. However, using SMBG rather than HbA_{1c} measurement in this way is less preferred by many people with diabetes, and is costly.

Clinical trials over the past 20 years or more among people with T2DM comparing management programs based on the use

of SMBG with management programs not using SMBG suggest that, overall, it has a small and clinically unimportant effect. Systematic reviews report the pooled effect sizes from a wide range of trials in differing settings in support of this conclusion [28]; analyses using patient-level data from the major studies of SMBG also confirm the overall effect is small and do not identify groups who may find SMBG of particular help [30]. An additional concern is that, for some individuals, particularly where regular support and guidance is not available, levels of anxiety can be increased and quality of life reduced [31, 32].

Guidelines for treatment of people with T2DM now draw attention to the lack of evidence for effectiveness and cost-effectiveness of routine use of SMBG [7] and recommend that it should not be routinely used [18]. Where there are concerns that the treatment may lead to hypoglycemia (e.g. use of sulfonylureas) or where HbA_{1c} cannot be used, then SMBG may be helpful, but only where the person with diabetes has been trained in its use, where the purpose is clear, and with regular review for continuing need.

Use of HbA_{1c} in the diagnosis of diabetes

Although current guidance continues to support the diagnosis of diabetes based on at least two laboratory measurements of blood glucose ≥7 mmol/L or random samples of ≥11.1 mmol/L (Table 27.3), there is increasing attention to HbA_{1c} as an alternative approach for diagnosis of T2DM in non-acute settings, for example in screening for diabetes. Improved standardization in the measurement of HbA_{1c} and wider availability of the assay led to a recommendation in 2011 by the World Health Organization that HbA_{1c} could be used instead [33]. HbA_{1c} offers a potentially easier, non-fasting and therefore more acceptable test. Furthermore, there appears to be less intra-individual variation with HbA_{1c} than glucose testing.

Previously, there were concerns that despite the variation in results of oral glucose testing within the same person, the alternative of a single HbA_{1c} test would be unsatisfactory because the threshold for screening (previously identified as 53 mmol/mol [7%]) would have missed a substantial number of people with diabetes. There is also considerable potential for confusion, because current guidance for people with diabetes is to aim, if possible, for HbA_{1c} levels of 48–58 mmol/mol (6.5–7.5%). There has been wide debate about the threshold that should be used, including detailed comparisons of the levels of glycemic control, assessed by different measures that are associated with complications [34]. Some organizations have made specific recommendations for a diagnostic level of 48 mmol/mol (6.5%) [35] (with a requirement for the result of a single abnormal test to be confirmed by a second test), but it is likely that judgments about an appropriate threshold may need to differ between countries. A diagnostic test based solely on using HbA_{1c} will not replace the glucose criteria, as in many parts of the world HbA_{1c} is not available and the need for a glucose-based test in T1DM and in an acute setting, where HbA_{1c} may be falsely negative because of rapidly changing glucose, remains [36, 37].

Gestational diabetes mellitus

Women with diabetes should be advised to test fasting blood glucose levels and blood glucose levels 1 hour after every meal during pregnancy (see Chapter 61). They should be able to adjust their insulin dose to maintain target blood glucose levels. Many oral glucose-lowering medicines are not recommended for use during pregnancy, particularly during the first trimester, and so early training in the use of SMBG and insulin therapy is necessary.

Use of continuous glucose monitoring systems has also been evaluated for pregnant women with insulin-treated diabetes. In a randomized trial those women randomized to continuous glucose monitoring had lower mean HbA_{1c} levels from 32 to 36 weeks' gestation compared with women randomized to standard antenatal care. The authors concluded that continuous glucose monitoring during pregnancy is associated with improved glycemic control in the third trimester, lower birth weight, and reduced risk of macrosomia [38].

Monitoring of diabetes in special situations

Policies and practice for monitoring diabetes, and particularly T2DM may need to change in special situations. HbA_{1c} testing may be unavailable because of difficulties in transport to the laboratory or because laboratory facilities are not available. HbA_{1c} measurement with point of care meters or use of blood glucose testing may be appropriate as an alternative. However, consumables for these meters are expensive. Fasting blood glucose assays are required to assess blood glucose control accurately for people not using insulin.

The costs of SMBG using handheld meters remain high in relative terms, and using it in a resource-poor setting may not be appropriate. Particularly for people with T1DM, there is an urgent need for lower cost test strips, although a requirement for rigorous quality control procedures to maintain accuracy of the assay limits the potential for lower cost equipment.

Urine glucose testing remains an alternative to blood testing or HbA_{1c} measurement for people with diabetes in a country where healthcare resources are limited, or in a healthcare setting where costs of testing equipment are borne directly by the individual with diabetes. There are few data on self-monitoring using urine glucose testing. A meta-analysis from 2005 [33] included two studies that compared SMBG and self-monitoring of urine glucose and reported a non-significant reduction in HbA_{1c} of 2 mmol/mol (0.2%) in favor of SMBG. Although some people do not find the procedure acceptable or helpful [34], a recent study compared SMBG with urine testing and found no added advantage from SMBG, with 80% of participants finding urine testing acceptable and continuing with it [39]. Measurement of urine glucose should therefore not be seen as a substitute for SMBG, but can be used as an alternative where SMBG is not accessible, affordable, or desired. Interpretation of information needs to be focused on the period between last voiding and the production of the current urine specimen. Most people have a renal threshold for glucose of around

8 mmol/L, so information about glucose levels is limited below this threshold. The renal threshold can drop during pregnancy, and so glycosuria is more likely in this situation.

The future of monitoring in diabetes

Current research is focusing on a number of non-invasive methods to enable continuous monitoring. Methods being considered include using infrared, electric currents, and ultrasound. Currently available continuous monitoring systems require calibration, but are then able to record blood glucose levels at 5-minute intervals for up to 72 hours. Efforts are currently being made to improve and further develop integrated systems with glucose meters linked by wireless communication to insulin pumps and with computer algorithms recommending infusion rates. Computerized algorithms for controlling insulin pumps on the basis of blood glucose levels have been developed and have already been evaluated in the setting of intensive care. There is increasing emphasis on integrating novel approaches to monitoring with digital health initiatives. For example, mobile phones have also been linked to blood glucose meters to allow easy review of charted data, real-time feedback of support, and integration of data with medical records [40]. Linkage of monitoring devices, systems for decision support and Internet-linked communication promises better and more efficient use of results, alongside better communication. A series of proof-of-concept studies have indicated the potential for Internet-linked digital devices to improve care, although evidence for implementation at a wider scale, with integration into routine care remains limited [41, 42]. However, despite the increasing availability of technology, optimal strategies for monitoring, and how it can best be used to support behavioral change requires more work [43].

In some clinical areas uptake of telehealth has already been rapid. For example, the period of monitoring required for gestational diabetes is relatively short and many women who are pregnant have access to smartphones. As a result, systems intended to support better monitoring are being developed and evaluated. A recent example has demonstrated that remote monitoring of glycemia by a midwife is acceptable [44], and can lead to more frequent review of insulin treatment than would otherwise be possible with routine hospital visits [45].

Conclusions

Glycemic control should be monitored regularly for all people with diabetes. The optimal method of determining risk of long-term complications is through HbA_{1c} measurement, although if this is not available, then examination of a series of blood glucose measurements, including fasting tests, may provide guidance. Decisions about treatment depend on the clinical setting and the type and stage of the individual's diabetes. People with non-insulin-treated T2DM have little scope for adjusting therapy on the basis of routine SMBG measurements, although some may benefit from exploring the extent of their glycemic variability, monitoring impact of changes in physical activity and diet, self-titration of glucose-lowering medication or checking whether symptoms are related to low blood glucose readings. For adults with T1DM and pregnant women treated with insulin, the evidence for active and regular blood glucose testing (including use of continuous glucose monitoring) to achieve intensive blood glucose control through adjustment of insulin dose in relation to lifestyle is strong. There is also good evidence for the routine use of SMBG for people with insulin-treated T2DM.

28 Drug Therapy: Special Considerations in Diabetes

Bernard M.Y. Cheung[1] and Ronald C.W. Ma[2]

[1] Department of Medicine, The University of Hong Kong, Hong Kong
[2] Department of Medicine & Therapeutics, The Chinese University of Hong Kong, Hong Kong

Key points

- Many drugs interfere with glucose homeostasis or interact with antidiabetes agents and thus can disturb glycemic control in people with diabetes. Specific diabetic complications, such as nephropathy and neuropathy, may require particular drugs to be used with care.
- Hyperglycemia can be caused or worsened by numerous drugs. Those that induce insulin resistance include glucocorticoids, certain oral contraceptives, antipsychotics, HIV protease inhibitors, the fluoroquinolone gatifloxacin, and β-adrenoceptor antagonists. Diabetogenic drugs that damage the β cell include pentamidine and cyclosporine (ciclosporin).
- Sulfonylureas and related agents commonly cause hypoglycemia by interacting with other drugs that block their metabolism in the liver, for example ciprofloxacin inhibits CYP2C9, which degrades glyburide (glibenclamide), or that impair renal function and decrease their elimination (e.g. non-steroidal anti-inflammatory agents).
- Hypoglycemia can be induced by drugs that stimulate insulin secretion (e.g. quinine, especially in children with cerebral malaria) and sulfamethoxazole, which binds to the sulfonylurea receptor. Pentamidine can induce transient hypoglycemia, by causing passive loss of insulin from the β cell, as a prelude to permanent diabetes.
- Hypoglycemia can complicate overdosage with acetaminophen (paracetamol), following hepatic necrosis; or aspirin, which blocks hepatic glucose output and stimulates peripheral glucose uptake. Alcohol inhibits hepatic gluconeogenesis and can provoke, prolong, or exacerbate hypoglycemia.
- Non-selective β-adrenoceptor antagonists inhibit insulin secretion and can impair glucose tolerance. They also decrease certain catecholamine-mediated symptomatic and metabolic responses to hypoglycemia; awareness of hypoglycemia may therefore be reduced, and recovery of normoglycemia delayed. These adverse effects are much less pronounced with cardioselective β_1-adrenoceptor antagonists.
- Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers, relative to other antihypertensive drug classes, are associated with a lower risk of new-onset diabetes and are useful in heart failure and nephropathy.
- Certain drugs require special consideration in people with diabetic complications. Metformin and several sulfonylureas are cleared through the kidney; they are therefore contraindicated in advanced nephropathy and should not be co-administered with nephrotoxic drugs. Vasodilators and ganglion-blocking agents may exacerbate postural hypotension.

Introduction

This chapter discusses the problems posed by drug therapy in the management of people with diabetes. Numerous drugs can affect diabetic control, causing hyperglycemia or hypoglycemia, by interfering with insulin secretion or action or both, or by interacting with antidiabetes agents. Some important examples are illustrated in Figure 28.1. The special considerations that apply when using other drugs in people with diabetes and in the presence of specific diabetic complications are also discussed.

Drugs that raise blood glucose concentrations

Drug-induced diabetes is recognized as a distinct etiologic category, and diabetogenic drugs are discussed in detail in Chapter 19. The main culprits are shown in Table 28.1. Most of these drugs—notably glucocorticoids (a common and important cause of iatrogenic diabetes), contraceptive steroids, and β-adrenoceptor antagonists—act by inhibiting insulin action. By contrast, insulin secretion is inhibited by diazoxide, while pentamidine can cause permanent β-cell damage. More recently, antipsychotic drugs,

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

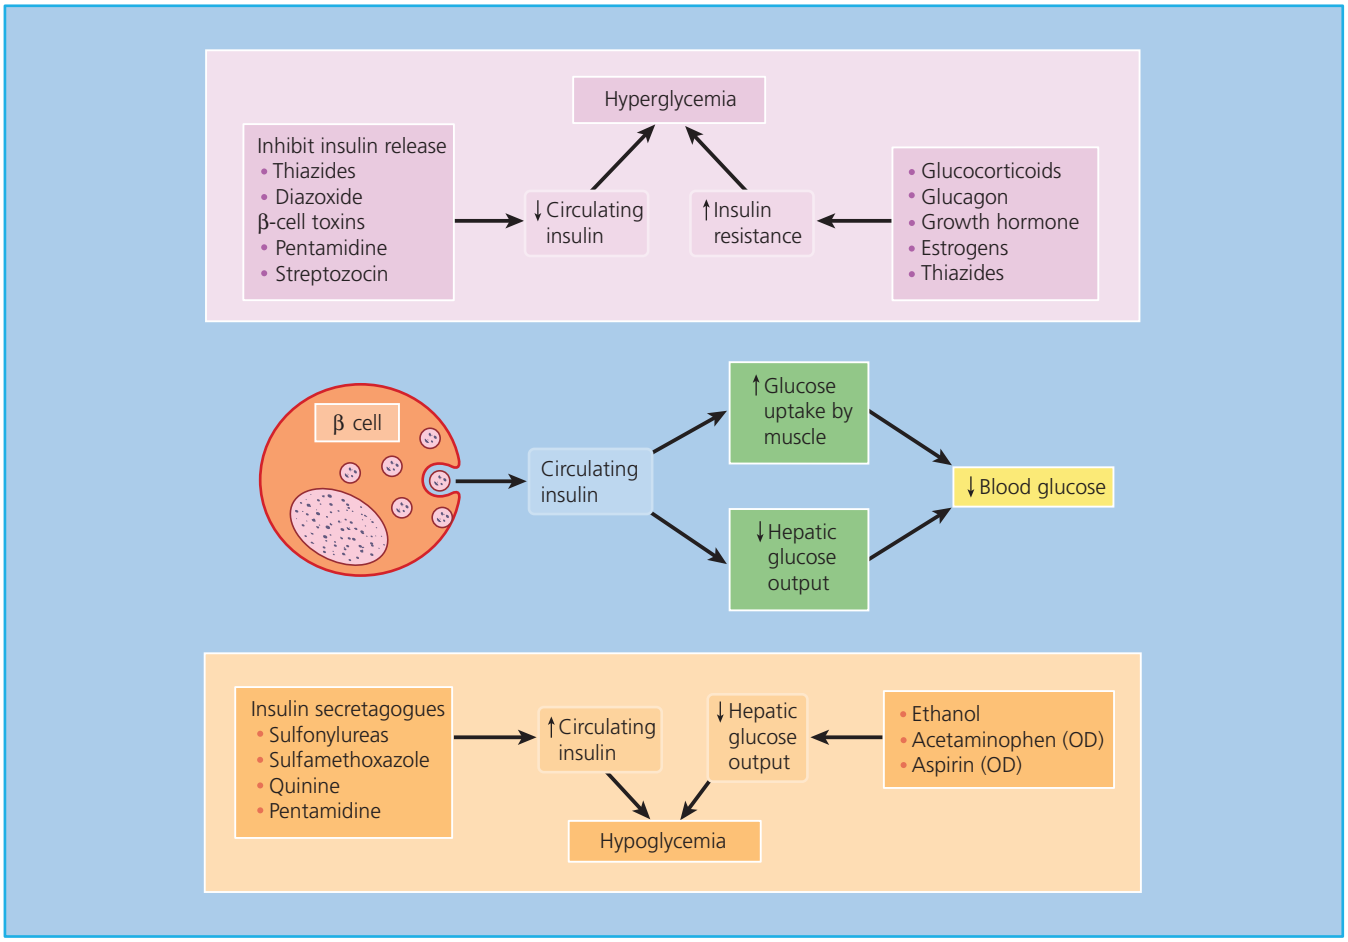

Figure 28.1 General mechanisms of drug-induced hyperglycemia and hypoglycemia. OD, overdose.

HIV protease inhibitors, and the fluoroquinolone antibiotic gatifloxacin have emerged as important causes of hyperglycemia.

Drugs that lower blood glucose concentration

Many drugs can cause hypoglycemia (Table 28.2) [1–11]. These include some that interact with and enhance the action of glucose-lowering drugs. Others act in their own right as insulin secretagogues, or to enhance or mimic the effect of insulin in suppressing glucose production by the liver and stimulating glucose uptake into peripheral tissues. Some drugs (e.g. non-selective β-adrenoceptor antagonists) specifically block the warning symptoms or the neuroendocrine counter-regulatory responses that are normally triggered by hypoglycemia, and so can prolong and intensify hypoglycemic episodes.

Drugs should always be suspected whenever people with previously well-controlled diabetes experience unexplained hypoglycemic episodes, or if dosages of insulin or oral antidiabetes agents decline. As well as prescription drugs, patients should be asked about herbal, traditional, and other alternative medicines. These are now widely used by people with diabetes, up to one-third of participants in one study [12], and some products may contain naturally occurring or synthetic glucose-lowering agents (Table 28.3).

Sulfonylureas

Sulfonylureas are an important and sometimes unrecognized cause of symptomatic hypoglycemia (see Chapter 35). They are also affected by numerous interactions with other drugs (Figure 28.2).

The older long-acting sulfonylureas glibenclamide and chlorpropamide are especially troublesome. In one outpatient survey, 20% of people treated with glibenclamide experienced hypoglycemia in the previous 6 months [13], while other surveys suggested that tolbutamide caused fewer episodes of severe hypoglycemia than either glibenclamide or chlorpropamide [14, 15]. A Swiss study [16] defined the risk of severe hypoglycemia as two episodes per 1000 persons per year in those given glibenclamide, over twice as high as in those taking shorter-acting sulfonylureas such as tolbutamide, gliclazide, or glipizide. The newer sulfonylurea, glimepiride, is said to carry a relatively low risk of

Table 28.1 Drugs that may cause or exacerbate hyperglycemia.

Potentially potent effects	Minor or no effects
Glucocorticoids	Growth hormone (physiologic doses)
	Somatostatin analogs†
	Androgen deprivation therapy for prostate cancer
Oral contraceptives	Oral contraceptives
High-dose estrogen	Progestogen-only pills
	Levonorgestrel in combination pills
Thiazide diuretics (especially high dosages)*	Loop diuretics
Non-selective β-adrenoceptor antagonists	α_1-Adrenoceptor antagonists
β_2-Adrenoceptor agonists	Calcium-channel blockers
Salbutamol	
Ritodrine	
Antipsychotics	Selective serotonin reuptake inhibitors and other antidepressants
HIV protease inhibitors	Lamivudine
Indinavir, nelfinavir, ritonavir and others	
Others	
Pentamidine	Isoniazid
Gatifloxacin	Nicotinic acid
Streptozotocin	
Diazoxide	
Cyclosporine ciclosporin)	
Tacrolimus	
Temsirolimus	
Interferon-α	
L-Asparaginase	

* "High" dosages of thiazides correspond to ≥5 mg/day bendroflumethazide or >25 mg/day hydrocholorothiazide.
† Somatostatin analogs may induce hyperglycemia in type 2 diabetes but not type 1 diabetes.

Table 28.2 Drugs that may cause or exacerbate hypoglycemia.

Anti-diabetes drugs
Insulin
Sulfonylureas
Meglitinides
DPP-4 inhibitors
GLP-1 receptor agonists
SGLT2 inhibitors

Drugs that interact to enhance the actions of sulfonylureas (see also Table 28.4)
Quinolone antibacterials: Levofloxacin, Gatifloxacin [4]
Corticosteroids, including inhaled corticosteroids (when withdrawn may lead to adrenal insufficiency) [5, 6]

Other drugs
Aspirin (in overdosage)
Cibenzoline
Disopyramide
Doxycycline [7, 8]
Etanercept
Ethanol
Hydroxychloroquine
Imatinib
Mefloquine
Non-selective β-adrenoceptor antagonists
Paracetamol (in overdosage) – Acetaminophen
Pentamidine
Quinidine
Quinine
Sulfamethoxazole (in co-trimoxazole)
Valproate (in neonates exposed *in utero*) [9]
Venlafaxine (in overdosage) [10]

hypoglycemia because it binds to a different site on the sulfonylurea receptor from classic sulfonylureas and also has distinct pharmacokinetic properties. Nonetheless, 10–20% of people receiving this drug still experience at least one mild episode each year [17].

Several factors other than the drug itself can increase the risk of hypoglycemia from sulfonylureas, notably increasing age and renal impairment [14, 15, 17–19]. Reduced food intake during intercurrent illness can also contribute [18, 19]. Drug interactions that enhance the action of sulfonylureas are considered below.

Not all those who have sulfonylurea-induced hypoglycemia are people with type 2 diabetes (T2DM); "bystanders" have included toddlers who ate a grandparent's tablet [20], nursing-home residents given the treatment of other patients [21], and people whose prescriptions for other drugs have been misread [22].

Sulfonylurea-induced hypoglycemia can be profound and prolonged, and difficult to manage. People with sulfonylurea-induced hypoglycemia may require admission and treatment with glucose until the effect of the sulfonylurea has worn off. Insulin hypersecretion induced by sulfonylureas can be suppressed effectively with either diazoxide (which opens the β-cell K_{ATP} channel that is closed by sulfonylureas) [23, 24] or by the somatostatin analog octreotide [25].

Other antidiabetes agents

These are described in Chapter 31.

- *Metformin* used alone is not expected to cause hypoglycemia in therapeutic use; but the UK Prospective Diabetes Study (UKPDS) reported instances of unconfirmed hypoglycemia during metformin treatment [26].
- *Thiazolidinedione* (e.g. pioglitazone) potentiates the peripheral actions of insulin. It does not induce hypoglycemia alone, but can enhance hypoglycemia caused by sulfonylureas or insulin when used in combination with them.
- *Meglitinides* (e.g. repaglinide) stimulate insulin release by a mechanism distinct from that of the sulfonylureas and so causes hyperinsulinemic hypoglycemia. A case of factitious hypoglycemia from repaglinide has been reported [27].

- *Acarbose* inhibits intestinal disaccharidase, and so reduces the hydrolysis of sucrose and thus glucose absorption. It does not cause hypoglycemia when used as monotherapy. People treated with acarbose who develop hypoglycemia from other glucose-lowering drugs should be warned that oral glucose, not sucrose, is needed to treat the episode.
- *Incretin mimetics* (e.g. exenatide, liraglutide) are agonists of the glucagon-like peptide-1 (GLP-1) receptor. They enhance the pancreatic insulin response to glucose in the gut. They slow down stomach emptying and stimulate insulin secretion. Unlike insulin, they do not tend to cause hypoglycemia. They promote weight loss and in rodent models and increase pancreatic β-cell mass. The major disadvantages are nausea, the need for subcutaneous injections, and the high cost.
- *DPP-4 inhibitors* increase the circulating levels of incretins by inhibiting dipeptidyl peptidase 4 (DPP-4), the enzyme that breaks down incretins and other peptides. The oral route of administration is an advantage, with low risk of hypoglycemia and no weight gain. Furthermore, their efficacy and overall safety has been demonstrated in several large multi-center randomized clinical trials [28–30].
- *Sodium/glucose cotransporter 2 (SGLT2) inhibitors, or gliflozins,* inhibit glucose reabsorption in the kidney and thereby increase glucose loss in the urine. This reduces blood glucose levels in people with T2DM. The calorific loss also leads to decrease in body weight and blood pressure. There is an increased incidence of urinary tract infection and vulvovaginitis. Hypoglycemia is uncommon, but euglycemic ketoacidosis, although rare, needs to be recognized. This class should be avoided in people with insulin deficiency. Although trials in type 1 diabetes (T1DM) are ongoing, until these are reported, SGLT2 inhibitors should not be used in people with T1DM.

Other drugs

Antimicrobials

- *Quinine and quinine derivatives*. People with falciparum malaria are often extremely ill, and may have hypoglycemia because of the effects of cytokines and malnutrition, both of which diminish hepatic gluconeogenesis. In this context, it is easy to overlook quinine-induced hypoglycemia, which can be profound, especially in children [31, 32]. It is caused by insulin hypersecretion, as quinine has insulin secretagogue activity [33]. Octreotide (a long-acting somatostatin analogue) has been used successfully to inhibit insulin release and raise blood glucose concentrations under these conditions [34]. Quinidine and mefloquine may occasionally cause hypoglycemia, while chloroquine does not [32].
- *Sulfamethoxazole*, which is combined with trimethoprim in co-trimoxazole, has a sulfonylurea-like action and can stimulate insulin secretion; several cases of severe hypoglycemia have been described [35]. This tends to be long-lasting, especially when excessive amounts of glucose solution infused can paradoxically worsen hypoglycemia by further stimulating insulin secretion. Elderly individuals receiving high dosage, and those in renal failure (which causes the drug to accumulate) are at particular risk [36], as are people infected with HIV who receive high doses of co-trimoxazole to treat *Pneumocystis jirovecii* pneumonia (formerly known as *Pneumocystis carinii*) [37].
- *Pentamidine*, a drug used to treat and prevent *P. jirovecii* pneumonia, can also damage pancreatic β cells. This initially leads to the passive leakage of insulin out of secretory vesicles, causing hypoglycemia, but diabetes may develop subsequently [38]. In two series of people with HIV treated with pentamidine, 25% [39] and 14% [40] developed symptomatic hypoglycemia; they invariably developed renal damage from the drug as well. Even inhaled pentamidine can cause hypoglycemia [41].

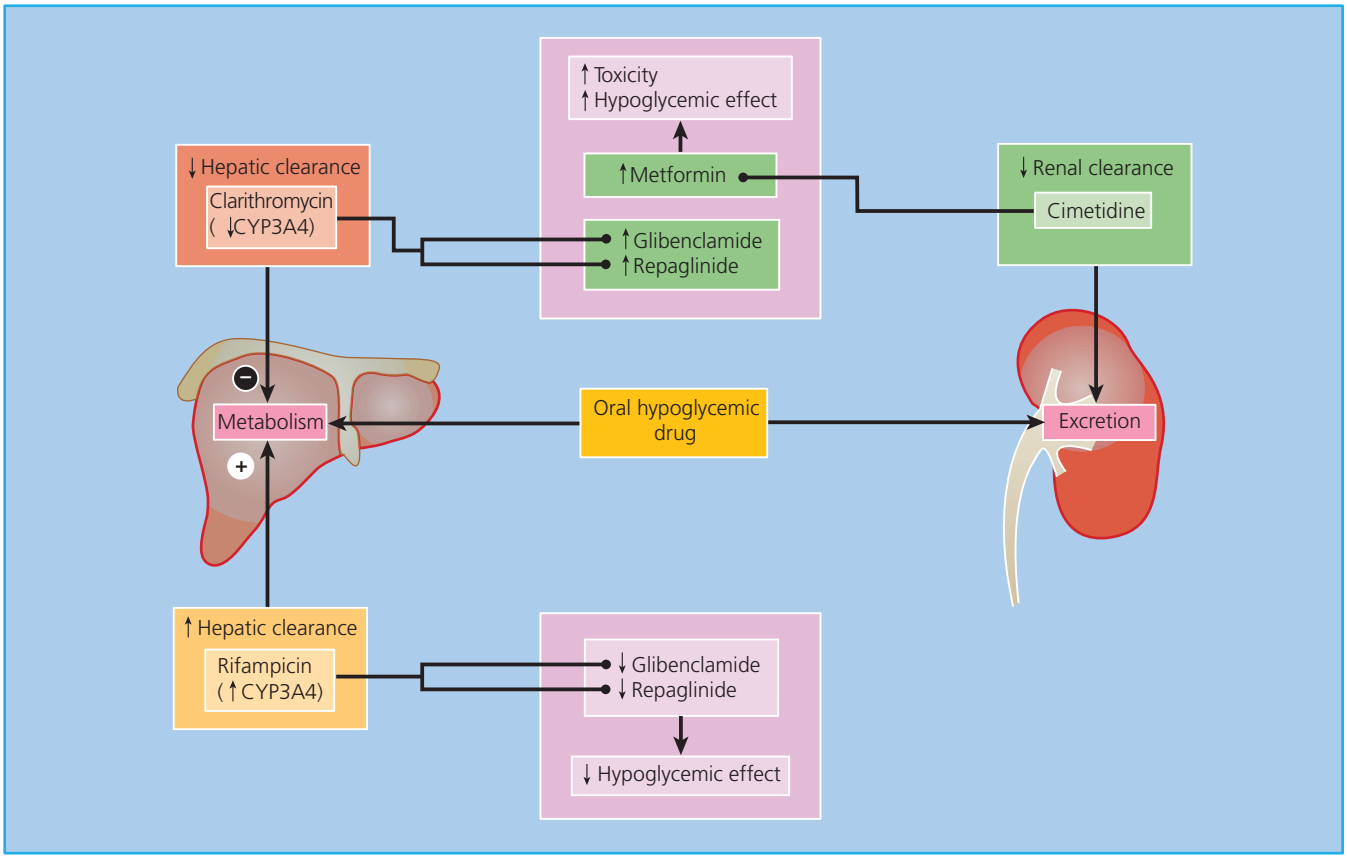

Figure 28.2 Interactions between oral antidiabetes agents and other drugs.

• *Doxycycline* has been suggested to cause hypoglycemia, but the reaction is infrequent and no mechanism has been identified [42].
• *Quinolones*, particularly gatifloxacin, can cause hypoglycemia (and also hyperglycemia). A case–control study defined an adjusted odds ratio for hypoglycemia with gatifloxacin treatment of 4.3 (95% confidence interval [CI]: 2.9–6.3) compared with macrolide treatment [4]. There is also a small increase in risk with levofloxacin.

Miscellaneous drugs

• *Disopyramide* and *cibenzoline* (*cifenline*), class Ia antiarrhythmic agents, can rarely cause symptomatic hypoglycemia; this can occur either with or without hyperinsulinemia [43], suggesting that peripheral effects contribute. In healthy people, disopyramide produces a small but statistically significant fall in fasting glucose concentration [44]. In a Japanese case-control study, cibenzoline treatment was associated with an eightfold increased risk of hypoglycemia; disopyramide did not significantly increase the overall risk, but the confidence intervals were wide [45]. The effect of disopyramide appears to be dose-dependent. In one case, a man developed severe hypoglycemia while taking disopyramide only after starting treatment with clarithromycin, a known inhibitor of hepatic enzymes, for an intercurrent infection [46].
• *Antidepressants*, including monoamine oxidase inhibitors, selective serotonin reuptake inhibitors and nefazodone, have been reported to reduce blood glucose concentrations [47].

Drugs in overdose

• *Acetaminophen* (*paracetamol*), in overdose, can cause hypoglycemia as a complication of acute hepatic necrosis. Overdosage of *aspirin* and other salicylates inhibits hepatic glucose production and also increases peripheral glucose utilization, leading to hypoglycemia, especially in children. Paradoxically, for unknown reasons, hyperglycemia can be encountered in adults.
• *Ethanol* inhibits gluconeogenesis and so it can cause hypoglycemia in children or fasting adults and exacerbate hypoglycemia from another cause even when consumed in relatively modest amounts (see Chapter 58). Results of experimental studies are unclear: modest concentrations of ethanol impaired the growth hormone response to insulin-induced hypoglycemia in volunteers with T1DM, but did not affect glucagon response [48]. The same dose of ethanol impaired the glucagon, but not growth hormone (GH), response to the same degree of hypoglycemia in people with diet-treated T2DM [49]. Rebound hypoglycemia can follow 2–3 hours after drinking alcohol with a glucose load in the form of sweet drinks or foods—so-called "gin-and-tonic hypoglycemia" [50]. Alcohol ingestion also increases the risk of severe

brain damage or death in people who take an intentional overdose of insulin [51].

Non-pharmacopoeial drugs

Some "herbal," "traditional," and "folk" remedies contain compounds with glucose-lowering properties that are generally weak (Table 28.3) [52]. Some preparations, however, have caused severe hypoglycemia and have been found on analysis to contain an undeclared sulfonylurea [53].

Drug interactions that affect blood glucose concentrations

Drug–drug interactions can cause hyperglycemia or hypoglycemia through several mechanisms. Pharmacokinetic interactions can influence the effective concentrations of a glucose-modifying drug; examples are the increased concentrations of disopyramide following co-administration of clarithromycin, as described earlier, and the large number of drugs that increase or decrease circulating concentrations of sulfonylureas (see following section).

Pharmacodynamic interactions occur when the observed action of one drug is modified by the action of another, without a change in the circulating concentration of either. The drugs can act at the same site (e.g. sulfamethoxazole is a ligand at the SUR-1 sulfonylurea receptor) or at different sites. Examples of the latter include β-adrenoceptor antagonists and other drugs that influence the physiologic response to hypoglycemia, and so alter the duration or severity of hypoglycemia from another cause.

Drugs that interact to enhance the actions of insulin secretagogues

Many drugs have pharmacokinetic or pharmacodynamic interactions with sulfonylureas that can cause clinically important disturbances in glycemic control. Some of the more important examples are shown in Table 28.4 and Figure 28.2. The commonest outcome is hypoglycemia, brought about by reduced metabolic or renal clearance. Transient effects from displacement of protein-bound drug may occasionally also be important. Major dangers include the potentiation of the effects of tolbutamide, and possibly of chlorpropamide, glibenclamide, and glipizide, by azapropazone (apazone), chloramphenicol, and fluconazole. Miconazole interacts with glibenclamide and glipizide as well as tolbutamide. All these interactions are caused by the inhibition of sulfonylurea metabolism in the liver. Several oral hypoglycemic agents, including glimepiride, glipizide, glibenclamide, tolbutamide, and nateglinide, are metabolized by CYP2C9. Thus, ciprofloxacin increases the plasma concentrations and therefore enhances the hypoglycemic action of glibenclamide by inhibiting the hepatic CYP2C9 enzyme that metabolizes glibenclamide [54]. Clarithromycin has also been reported to interact with glibenclamide and glipizide, leading to hypoglycemia [55]. A meta-analysis confirms that hypoglycemia is more likely with glibenclamide than other insulin secretagogues (relative risk (RR) 1.52; 95% CI: 1.21–1.92) [55].

Table 28.4 Drugs that interact with sulfonylureas.

Drugs that may enhance the hypoglycemic effect of sulfonylureas
Azapropazone, phenylbutazone
Salicylates
Probenecid
Sulfonamides
Clarithromycin
Nicoumalone
Fluconazole, ketoconazole, miconazole, voriconazole
Fluoxetine
Drugs that may reduce the hypoglycemic effect of sulfonylureas
Rifampicin
Chlorpromazine

By contrast, rifampicin reduces the action of glibenclamide by inducing CYP2C9 and enhancing the hepatic clearance of sulfonylurea. Chlorpromazine also decreases the glucose-lowering effect of sulfonylurea, possibly by inhibiting insulin secretion.

Another important interaction with chlorpropamide (and, to a much lesser extent, with other sulfonylureas) is the cutaneous vasodilatation of the face and occasionally the trunk that is induced by ethanol, the chlorpropamide–alcohol flush (see Chapter 31).

Some individuals may be more susceptible to drug-induced hypoglycemia than others. For example, a Japanese case-control study suggested that people taking levothyroxine and who also had liver disease were at substantially increased risk of mild hypoglycemia, with an odds ratio of 14.7 (range 1.6–137) [56]. Individuals with genetically determined low CYP2C9 activity are at an increased risk of sulfonylurea-associated severe hypoglycemia [57].

Surreptitious ingestion of sulfonylureas such as glibenclamide in alternative medicines can cause hypoglycemia [58].

Interactions with metformin

Metformin is excreted in the kidneys through the organic cation transporter 2 (OCT2). Cimetidine reduces the renal clearance of metformin, and causes it to accumulate (Figure 28.2). Drugs that impair renal function, such as non-steroidal anti-inflammatory agents and aminoglycosides, should be used with care, as they can also raise metformin concentrations, increasing the risk of lactic acidosis. Metformin should be stopped 24 hours before prolonged fasting (e.g. before surgery) and 48 hours before procedures requiring intravenous radiocontrast media. People receiving metformin are advised to avoid alcohol or to drink in moderation as hepatic damage poses a risk of hypoglycemia and lactic acidosis.

Interactions with other antidiabetes agents

- *Rosiglitazone* is metabolized by the hepatic microsomal enzyme CYP2C8, raising the theoretical possibility of interaction with other agents metabolized by this enzyme such as paclitaxel [59].

- *Repaglinide* is metabolized by CYP3A4, which also metabolizes glibenclamide and several other important drugs, and is then excreted in the bile. Clarithromycin, which inhibits CYP3A4, has been reported to increase repaglinide concentration and the risk of hypoglycemia [60]. Rifampicin, which induces the same enzyme, reduces the effective concentrations of repaglinide by 25% in healthy volunteers, and could potentially worsen glycemic control in those with T2DM [60]. Repaglinide is also metabolized by CYP2C8, and so its plasma concentration can be increased by inhibitors of CYP2C8 such as gemfibrozil or clopidogrel. Such an interaction can result in hypoglycemia [60].
- *Glimepiride* is broken down by CYP2C9 and so its metabolism can be inhibited by fluconazole and its hypoglycemic action enhanced [61].
- Among the DPP-4 inhibitors, *sitagliptin* has low potential to interact with CYP3A whilst *vildagliptin* and *linagliptin* are not metabolized by cytochrome P450 (CYP450). *Alogliptin* is metabolized by CYP2D6 to one active metabolite and through acetylation to one inactive metabolite. *Saxagliptin* is metabolized by CYP3A4/5 in liver to an active metabolite and therefore a dose reduction is recommended to avoid hypoglycemia when co-administered with strong CYP3A4 inhibitors such as ketoconazole and clarithromycin, whilst glycemic control may deteriorate if CYP3A4 inducers such as carbamazepine, rifampicin, and phenytoin are prescribed [62].
- The new class of agents, SGLT2 inhibitors, are also in general less affected by drug–drug interactions. Both *dapagliflozin* and *canagliflozin* are metabolized through glucuronidation by uridine diphosphate-glucuronosyltransferase (UGT) 1A9. Since potent inhibitors of UGT1A9 are rare, clinically relevant interactions are infrequently reported [63]. Clinical studies so far have also noted absence of any relevant drug–drug interactions with *empagliflozin* [64].

Hazards of general drugs when used in people with diabetes

The presence of diabetes can influence the choice of agent for treating several important conditions. Drugs to treat cardiovascular diseases, hypertension, angina, arrhythmias, and heart failure, and hyperlipidemia are of particular importance, because these conditions are common in people with diabetes.

Drugs with cardiovascular actions

Antihypertensive agents

Calcium-channel blockers

In vitro and *in vivo* studies have suggested that calcium-channel blockers may impair glucose metabolism, possibly because of impaired insulin secretion. Very few cases of clinically significant hyperglycemia, however, have been reported, and most of these were associated with excessive dosages of the drugs. When used appropriately, calcium-channel blockers are as safe in people with and without diabetes (see Chapter 42). In people of Asian or African origin, calcium-channel blockers are relatively more efficacious in lowering blood pressure. This is especially relevant in populations that have a high incidence of stroke.

Angiotensin-converting enzyme inhibitors

ACE inhibitors are now widely used to treat hypertension and heart failure in both people with and without diabetes. The evidence of benefit of ACE inhibition after myocardial infarction, in systolic ventricular dysfunction and chronic heart failure is strong [65–67]. Similarly, ACE inhibitors reduce proteinuria and the endpoint of doubling of serum creatinine, or the need for dialysis or transplantation [68]. This protective effect on the kidney is encouraging their use in normotensive people with early nephropathy (see Chapter 39). By contrast, the use of ACE inhibitors in people with coronary heart disease without systolic ventricular dysfunction remains controversial. Two large randomized controlled trials showed reductions in cardiovascular events [69, 70], but this was not confirmed in a third trial [71].

ACE inhibitors do not cause hyperglycemia, and neither do they adversely affect lipid metabolism [72, 73]. Indeed, there is some evidence from the HOPE study that ACE inhibitors may reduce the likelihood of new-onset diabetes [74]. The DREAM study, which specifically addressed this issue, did not confirm this. In comparison with diuretics and beta-blockers, the effect is striking. ACE inhibitors can improve insulin sensitivity and lower blood glucose concentrations, occasionally causing severe hypoglycemia [75, 76]. Case-control studies in the Netherlands and Scotland have demonstrated a threefold increase in the risk of severe hypoglycemia (requiring hospital admission) in people with diabetes taking ACE inhibitors [77, 78].

In people with or without diabetes, ACE inhibitors are contraindicated if the renal arteries are stenosed because of the high risk of renal impairment, which is usually reversible but sometimes permanent. There may be significant renal artery stenosis in up to 20% of individuals with both hypertension and T2DM [79].

Angiotensin receptor blockers

Like ACE inhibitors, ARBs are also indicated for hypertension, heart failure, post-myocardial infarction, and diabetic nephropathy [80]. One study showed a marked reduction in stroke and mortality in people with diabetes on an ARB-based regimen [81]. There is also evidence from meta-analysis that ARBs reduce the risk of new-onset diabetes [82]. There are no trials demonstrating that ARBs are superior to ACE inhibitors in terms of outcome. On the other hand, ARBs do not cause the characteristic dry cough associated with ACE inhibitors. Combining an ACE inhibitor and an ARB has no demonstrable value in coronary heart disease or diabetic nephropathy, other than reducing urinary albumin excretion further [83, 84]. Furthermore, it may be associated with significant hyperkalemia.

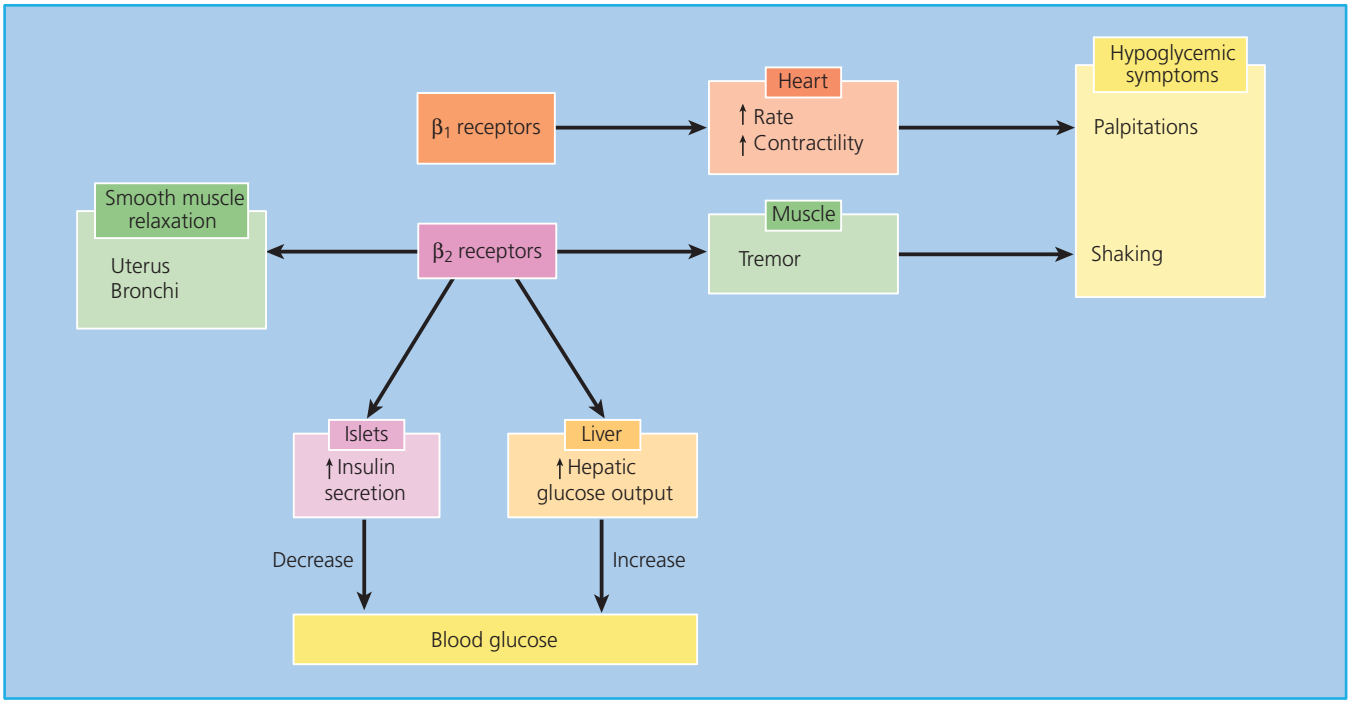

Figure 28.3 Effects mediated by β-adrenoceptors.

β-*Adrenoceptor antagonists*

These are useful in the treatment of hypertension, angina, arrhythmias, and heart failure. They are effective cardioprotective agents that reduce mortality following myocardial infarction in people with and without diabetes [85, 86]. β-Adrenoceptor antagonists are indicated in those with chronic heart failure as they improve left ventricular function and reduce mortality [87]. The β-adrenoceptor antagonists should be started in stable patients, at a very low dose and escalated gradually.

β-Adrenoceptor antagonists can interfere with several aspects of glucose homeostasis (Figure 28.3). In the islets, insulin secretion is enhanced by β_2-adrenoceptor stimulation, while the β_2-adrenoceptor-mediated response to hypoglycemia in the liver promotes hepatic glycogenolysis and increases hepatic glucose output, a crucial part of the counter-regulatory response that restores blood glucose to normal.

Long-term treatment with β-adrenoceptor antagonists, especially in combination with high-dose thiazide diuretics, has been shown to be diabetogenic. This is discussed further in Chapter 19. β-Adrenoceptor antagonists were used in combination with thiazide diuretics in most of the early large clinical trials of hypertension treatment. In clinical trials testing a β-adrenoceptor antagonist on its own, its effect on stroke was less favorable than comparative drugs. This led to its relegation to fourth-line treatment in the fourth British Hypertension Society guidelines [88]. In people with diabetes, their effect on insulin resistance may make them a less suitable choice than an ACE inhibitor or ARB. People with diabetes require good blood pressure control to reduce macrovascular complications, so multiple drugs might be needed to achieve this. In such instances, a beta-blocker could be added. People with diabetes frequently have ischemic heart disease, which is another indication for β-adrenoceptor antagonists.

β-Adrenoceptor stimulation is responsible for major hypoglycemic symptoms: the pounding heart and palpitation are secondary to β_1-adrenoceptor-mediated increases in heart rate and contractility, while tremor and sweating are both β_2-mediated (sweating also has a cholinergic component) (Figure 28.3). Non-selective β-adrenoceptor antagonists that antagonize both β_1- and β_2-receptors can reduce the awareness of hypoglycemia and also delay recovery from hypoglycemia.

Cardioselective β_1-adrenoceptor antagonists are less likely to interfere with awareness of or recovery from hypoglycemia, and so are preferable in those treated with insulin or sulfonylureas. Even low doses of cardioselective β_1-adrenoceptor antagonists can modify some of the symptoms and signs of hypoglycemia (e.g. tachycardia), while other symptoms that are robust indicators of hypoglycemia (e.g. sweating) are unchanged or even more pronounced in the presence of β_1-blockade [89, 90]. Overall, cardioselective β-adrenoceptor antagonists rarely impair recognition of hypoglycemia. The incidence of hypoglycemia is not increased during treatment with β_1-selective adrenoceptor antagonists, even in those prone to the condition [91, 92]. By contrast, the non-selective drugs can impair recovery from hypoglycemia [89, 93, 94].

Concerns about the adverse metabolic effects of β_1-selective adrenoceptor antagonists have probably been exaggerated and the

potential benefits of their cardioprotective effects underplayed [85]. Moreover, studies in heart failure have now provided extensive data showing that low-dose β-adrenoceptor antagonists are safe in the elderly [95].

α_1-*Adrenoceptor antagonists*

α_1-Adrenoceptor antagonists are effective hypotensive agents. They are generally thought to have beneficial metabolic effects, including improved insulin sensitivity, with falls in blood insulin, glucose and lipid concentrations [96–98], although one report [99] has suggested that the use of doxazosin may worsen glycemic control in people with diabetes. Despite their potential advantages, these drugs are not currently in extensive use, perhaps because of the side effect of postural hypotension. In the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), the α-blocker arm of the study was prematurely terminated because of an increased incidence of congestive heart failure compared to the diuretic arm [100]. This probably reflects the benefit of diuretics in treating the symptoms of heart failure rather than worsening of heart failure by α-adrenoceptor antagonists.

Thiazides

It has become unfashionable to use thiazide diuretics in people with diabetes, even though they are generally well tolerated, inexpensive, and at least as effective as newer agents in preventing stroke and myocardial infarction. The concerns are the reversible impairment of glucose tolerance that can occur with thiazides, unfavorable changes in serum lipid profile and the worry that they may cause erectile dysfunction [101–118]. Many of these concerns stem from old trials in which high doses of thiazide diuretics (e.g. 5 mg bendroflumethiazide) were used.

The diabetogenic potential of the thiazides is discussed in detail in Chapter 19. The consensus is that low dosages (e.g. 2.5 mg bendroflumethiazide), which are just as effective as higher dosages in lowering blood pressure, cause little if any deterioration in glycemic control [119]. The effects on lipids of low dosages are minor, and outweighed by the benefits of blood pressure reduction [116, 117, 120]. Finally, one large study (Treatment of Mild Hypertension Study) found no excess of erectile dysfunction attributable to thiazide treatment among middle-aged hypertensive men, who had a high prevalence incidence of this complaint [118]. Overall, the thiazides have a useful place in the treatment of hypertension in people with diabetes [121].

Loop diuretics

Loop diuretics, such as furosemide (frusemide), ethacrynic acid, and bumetanide, seem to have less impact on glucose homeostasis than thiazide diuretics, although several reports suggest that they can cause hyperglycemia [122, 123]. Recent *in vitro* studies have shown that furosemide inhibits enzymes in the glycolytic pathway [124], leading to poor glucose utilization and hyperglycemia. In practice, however, few problems are encountered in using loop diuretics in people with diabetes; it has been argued that any insulin resistance and hyperglycemia are not actually drug-induced, but instead are the consequence of the conditions that require potent diuretic therapy.

Antihyperlipidemic agents

The relationship between diabetes mellitus and dyslipidemia is discussed in detail in Chapter 43. Hypertriglyceridemia is often ameliorated by the effective treatment of hyperglycemia; conversely, some evidence indicates that lowering lipids (including free fatty acid concentrations) can improve blood glucose control. In practice, drugs are often prescribed independently for diet-resistant hyperglycemia and hyperlipidemia and so interactions between agents used to treat the conditions are potentially important.

Statins

People with diabetes have elevated cardiovascular risk. Statins (hydroxymethyl-glutaryl coenzyme A inhibitors) are therefore usually indicated, even before there is overt cardiovascular disease. Meta-analysis has shown that people with diabetes benefit from statin therapy [125], but has also revealed a small increase in the risk of developing diabetes in people without diabetes, particularly when high-dose statins are used [126]. Overall, the cardiovascular protection outweighs the slight increase in the risk of developing diabetes.

Fibrates

People with diabetes tend to have a dyslipidemic lipid profile characterized by raised triglycerides and low HDL cholesterol. Studies of fibrates showed some benefit in cardiovascular event prevention [127], but fibrates do not lower LDL cholesterol as effectively as statins and the combined use of a fibrate and a statin increases the risk of myositis. The Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) study tested if fenofibrate was beneficial in people with diabetes [128]. Although fenofibrate was safe, even when used in combination with a statin, it did not significantly reduce the risk of the primary outcome of coronary events. It appeared to reduce non-fatal myocardial infarctions and revascularizations [128]. In the Action to Control Cardiovascular Risk in Diabetes (ACCORD) Lipid Trial, adding fenofibrate to simvastatin did not reduce the rate of major cardiovascular events compared with simvastatin alone [129]. These two important trials suggest that a fibrate should not be routinely added to a statin in those with diabetes. Myalgia and more serious muscle damage (with rhabdomyolysis and myoglobinuria) are rare but well-established complications of both statins and fibrates and the risks are increased by co-administration, albeit the risk is lower for combination of fenofibrate with statins. There is emerging evidence that fibrates may slow the progression of diabetic maculopathy and so they may still have a role in people with diabetes.

Nicotinic acid and its derivatives

Nicotinic acid (niacin) has been used for treating low HDL-C, which is commonly found in those with diabetes. It causes

Table 28.5 Drugs requiring caution in specific diabetic complications.

Complication and drug	Problem	Action to be taken
Nephropathy		
Sulfonylureas	Accumulate in renal failure; increased risk of hypoglycemia and toxicity	Use insulin or a sulfonylurea not cleared through the kidneys (e.g. gliquidone, gliclazide)
Metformin	Accumulates in renal failure; increased risk of lactic acidosis	Avoid if eGFR <30 mL/min/1.73 m^2
DPP-4 inhibitors	Accumulate in renal failure	Reduced dose needed for sitagliptin, vildagliptin, saxagliptin, and alogliptin. No dose adjustment required in renal impairment for linagliptin.
SGLT2 inhibitors	Reduced efficacy in renal impairment	Avoid if eGFR <60 mL/min/1.73 m^2
ACE inhibitors or ARBs	Initial rise in plasma creatinine; risk of hyperkalemia	Use with caution and appropriate monitoring of renal function
NSAIDs or COX-2 inhibitors	Further compromise renal function	Avoid if possible
Radiocontrast media	Reduce renal function	Adequate hydration before procedure
Oral sodium phosphate solution for bowel cleansing	Acute renal failure	Close monitoring of fluid status and renal function or use alternative bowel preparation such as polyethylene glycol (PEG)
Cardiovascular disease		
β-Adrenoceptor antagonists	Accentuate hypoglycemia May cause modest VLDL elevation	Consider alternative antihypertensive Antianginal or antiarrhythmic drugs (e.g. ACE inhibitors, calcium-channel blockers)
Thiazide diuretics (high dose)	Worsen glycemic control in type 2 diabetes Exacerbate hyperlipidemia	Reduce dose, or use loop diuretic or alternative antihypertensive drugs
Retinopathy		
Mydriatics (eyedrops or systemic atropinic drugs)	In those with rubeosis or previous eye surgery, glaucoma may be precipitated	Seek ophthalmologic advice before dilating pupils
Anticoagulants	May predispose to vitreous hemorrhage in patients with proliferative changes	Avoid if possible
Abciximab	May predispose to vitreous hemorrhage in patients with proliferative changes	Avoid if possible
Somatropin	Can worsen proliferative retinopathy	Avoid
Autonomic neuropathy		
Phosphodiesterase inhibitors (e.g. sildenafil)	Aggravates postural hypotension	Avoid, especially in the elderly and those taking nitrates
Ganglion-blocking agents and vasodilators	Aggravate postural hypotension	Use with caution
Erectile dysfunction		
Ganglion-blocking agents β-Adrenergic blockers Clonidine α-Methyldopa	Aggravate erectile failure	Use alternative antihypertensive drugs (e.g. ACE inhibitor, calcium-channel blocker or α-adrenergic blocker)

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; COX, cyclo-oxygenase; NSAID, non-steroidal anti-inflammatory drug; VLDL, very-low-density lipoprotein.

flushing, which can be ameliorated to some extent by using a slow-release formulation or an inhibitor of prostaglandin D2, laropiprant. It can also cause hyperglycemia [130]. Niacin is no longer recommended for dyslipidemia because its efficacy in reducing vascular events could not be demonstrated in two large randomized controlled trials, the Heart Protection Study 2–Treatment of HDL to Reduce the Incidence of Vascular Events (HPS2-THRIVE) [131] and the Atherothrombosis Intervention in Metabolic Syndrome with Low HDL/High Triglycerides: Impact on Global Health Outcomes (AIM-HIGH) [132].

Anion-exchange resins

Anion-exchange resins such as cholestyramine could theoretically reduce the absorption of antidiabetes drugs from the gut, although clinically significant interference has not been reported.

Other drugs

The UK Summaries of Product Characteristics of many products contain contraindications to using the product in people with diabetes or diabetic complications. Some of the less obvious examples are oxymetazoline hydrochloride nasal spray and verruca gels

containing salicylic acid [133]. In addition, there is a wide range of warnings that medicines should be used with caution in diabetes; for example, oral rehydration solutions and ribavirin [133]. Oral sodium phosphate bowel preparation is also best avoided in those with diabetes, with use of alternatives such as polyethylene glycol (PEG) being preferred [134].

Special precautions in diabetic complications

Some drugs are relatively or absolutely contraindicated in the presence of certain diabetic complications. These include oral contraceptives or hormone replacement therapies in women with diabetes and severe vascular disease, the antiplatelet agents abciximab and cilostazol, growth hormone in people with proliferative retinopathy, and propranolol by injection in those prone to hypoglycemia [133]. Important examples are shown in Table 28.5.

Given the increasing proportion of people with diabetes and chronic kidney disease (CKD), particular attention should be paid to the adjustment of medications in CKD. Metformin is contra-indicated for those with eGFR <30 mL/min/1.73 m^2. The DPP-4 inhibitors in general need dose reduction in the setting of CKD, except for linagliptin. For the SGLT2 inhibitors, efficacy is reduced in the setting of CKD, and this class of agents are in general not recommended for people with eGFR <60 mL/min/1.73 m^2.

There has been controversy about the risks of inducing vitreous hemorrhage with thrombolytic treatment (e.g. streptokinase) for myocardial infarction in those with proliferative retinopathy. Current advice is to give thrombolytic drugs according to the usual indications, as the likely benefits far outweigh the potential threat to vision.

Drug interference with monitoring of diabetic control

Urine testing for glucose is no longer recommended for screening or monitoring of diabetes but is subject to interference by several drugs [135], including ascorbic acid, which can give false-negative urine glucose readings with glucose oxidase strips (see Chapter 27) [136], and by the SGLT2 inhibitors, which lower blood glucose by inducing glycosuria.

Blood glucose measurements, using dry-reagent glucose oxidase test strips, can potentially be affected by drugs such as aspirin if present in very high concentrations [137]. Readings can also be misleading if fingers are contaminated with alcohol from swabs (which inactivates glucose oxidase) or with glucose (e.g. from sugary drinks) [138]. The complex sugar icodextrin, used as a peritoneal dialysate, can give spuriously high glucose concentrations; this can mask underlying hypoglycemia [139]. Paracetamol has been reported to interfere with continuous glucose monitoring sensing and results in falsely elevated readings [140].

Conclusions

Rational prescribing is a difficult task that demands the integration of data about the drugs being used, the patient, and the conditions that affect the patient. There are three major areas of difficulty when prescribing for people with diabetes. First, a large number of drugs affect glucose tolerance. They include important agents, such as oral corticosteroids, which can be life-saving but confound attempts to achieve euglycemia. Second, people with diabetes are now commonly asked to take several medicines to control glycemia, and to treat the complications of diabetes. The number of potential interactions between pairs of drugs increases rapidly with the number of different drugs prescribed. As the number of prescribed medicines increases from 5 to 10, the number of possible pair-wise interactions increases from 10 to 45 (and the number of three-way interactions from 10 to 120). Third, those with diabetes are at high risk of other disorders that require the prescribing of other medicines. For example, treatment after myocardial infarction, five times more likely in the presence of diabetes, would commonly involve one or more antiplatelet agents, a statin, an ACE inhibitor, and a β-adrenoceptor antagonist.

Rational prescribers will consider, in consultation with the person with diabetes, therapeutic purpose, and the potential benefit and the possible harm of any additional treatment to the individual prior to prescribing. They will also review long-standing prescriptions from time to time to revisit previous decisions in the light of changes in the patient, the reason for prescribing, and the pharmacopoeia.

6 Treatment of Diabetes

29 Insulin and Insulin Treatment

Stephen Gough[1] and Parth Narendran[2]

[1] Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford and Churchill Hospital, Oxford, UK
[2] Institute of Biomedical Research, The Medical School, University of Birmingham, and The Queen Elizabeth Hospital, Birmingham, UK

Key points

- Insulin is a potent anabolic hormone essential for life. Insulin has a circulating concentration of 15–20 mU/L in the fasting state, and 60–80 mU/L postprandially.
- Early insulins were extracted from the pancreases of pigs and cows but good glycemic control was difficult to achieve due to impurities in the preparation. The newer and purer animal insulins are better tolerated and can potentially achieve a level of glycemic control similar to synthetic human insulins. Significant hypoglycemia rates between the human and animal insulins appear to be similar.
- The challenge of insulin replacement therapy is to reproduce a normal physiological insulin profile without incurring significant hypoglycemia. A range of insulin preparations with differing durations of actions are available to achieve this: rapid-acting insulin analogs (about 3 hours), soluble insulin (about 6–8 h), neutral protamine Hagedorn (NPH) insulin (12–18 h), Lente insulins (about 12–24 h), long-acting insulin analogs (about 24 h), and ultra-long-acting insulin analogs (about 40 h).
- Current recommendations for the injection of insulin are to use the abdomen, upper buttocks, upper back of the arms and upper thighs, and to rotate injection sites to avoid lipohypertrophy. The needle should be injected at right angle to the skin and left there for 10 sec before removing the needle. Injection needle lengths should be as short as possible to minimize trauma and to avoid intramuscular delivery. For those using insulin pens, 4 mm needles are available. Syringe needles remain at 8 mm. Alternative routes of insulin delivery such as continuous subcutaneous insulin infusion can also be highly effective.
- Multiple dose insulin therapy is an appropriate initial approach to reproducing the physiological insulin profile in people with absolute insulin deficiency such as those with type 1 diabetes. This consists of a long-acting insulin preparation administered once or twice a day to meet the basal insulin requirement, with the injection of a short-acting insulin preparation with each meal.
- A number of different insulin injection regimens are available for people with type 2 diabetes who may already be treated with non-insulin-based therapies. These include a once daily injection of a long-acting insulin, a once daily injection of a long-acting insulin with an injection of a short-acting insulin with the main meal, twice a day injections of insulin mixtures, and multiple dose injections. In addition insulin can be administered with other injectables such as GLP-1 receptor agonists.

Life (and death) before insulin

Insulin is a potent anabolic hormone, and its absence induces a profound catabolic state that affects fat, carbohydrate, and protein stores. Absolute insulin deficiency, such as that characterized by type 1 diabetes (T1DM), will result in death if left untreated (Figure 29.1). What the study of people with diabetes in the pre-insulin era taught us is the surprisingly long period that can be survived without insulin. Leonard Thompson was the first person to have effective insulin treatment. He was 12 years old when he was diagnosed with diabetes in 1919 and had survived over 2 years when at 11 am on January 22, 1922 he received his first injection of insulin. That said it was a miserable existence without insulin. Other than the weight loss, the constant tiredness, thirst, urination, and frequent infections, there was the certain knowledge that a death sentence had been passed, and that death would be an agonizing and slow process. The most effective therapy available at that time appeared to be severe nutritional restriction, perhaps most popularly expounded by Frederick Allen from the Rockefeller Institute in New York [1]. This, however, was a difficult regimen that did not appear to prolong life expectancy significantly, and when death came it was not clear whether it was the result of diabetes or starvation.

The discovery of insulin

Though there had been previous attempts at identifying a pancreatic agent that could control blood glucose, most notably by the Romanian physiologist Nicolas Paulescu, the story of insulin may be considered to start in autumn of 1920 when Frederick

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

Figure 29.1 A boy with diabetes before and after insulin therapy.

Grant Banting who, while preparing a lecture on carbohydrate metabolism, considered a way to isolate the internal secretion of the pancreas. By the summer of the following year he had arranged with John Macleod, Professor of Physiology at the University of Toronto, for facilities and the support of a science student Charles Best to start experimentation (Figure 29.2). They showed that tying off the pancreatic ducts induced atrophy of the exocrine glands of the pancreas thus allowing the "internal" secretions to be isolated. They tested the effect of this internal secretion on blood sugar by injecting it into dogs rendered diabetic through pancreatectomy. With the help of a biochemist, James Collip, they were able to purify this abstract sufficiently for the early experiments on patients. For this work, Banting and Macleod shared the Nobel Prize in Medicine in 1923.

This discovery was by no means a straightforward process, and according to one particularly harsh commentator "the production of insulin … originated in wrongly conceived, wrongly conducted and wrongly interpreted series of experiments …" [2]. The discovery of insulin nevertheless was a defining moment in the history of diabetes and the molecule has gone on to be well studied, with work on it contributing to three further Nobel prizes: Frederick Sanger in 1958 for determining its primary amino acid sequence, Dorothy Hodgkin in 1964 for X-crystallographic studies, and Rosalyn Yalow et al. in 1977 for contributing to the development of the radioimmunoassays.

The first insulins

Commercially available insulin was initially extracted from porcine and bovine pancreases. The tissue would undergo acid-ethanol treatment to solubilize insulin, which would then be salted out with sodium chloride, precipitated, and crystallized [3]. This procedure resulted in insulin with a purity of 80–90%, the contaminants largely being pancreatic polypeptides and glucagon. Though this insulin was effective, it was often complicated by immune-mediated side effects, in particular lipoatrophy and antibody-mediated insulin resistance [4], both factors which can profoundly influence the kinetics of insulin action. These impurities also contributed to an allergic reaction that sometimes resulted in swelling and pain at the site of injection.

Animal insulin continues to be porcine and bovine derived. The amino acid structure of beef insulin differs from that of human by three amino acids (position 30 of the B chain, and 8 and 10 of the A chain) and that of pork from human by just one amino acid (position 30 of the B chain) [5, 6]. These differences

Figure 29.2 Charles Best and Frederick Banting on the roof of the medical building at the University of Toronto, summer 1921.

aside, it was the purity of the insulin preparation that appeared to influence its immunogenicity. Additional purification steps in the 1970s resulted in an insulin, called mono-component or single-component insulin, with fewer side effects and which was better tolerated (Table 29.1). The incidence of lipoatrophy and allergy decreased as these purer insulins became more widely available. It was a logical step, therefore, to move on to treatment with human insulin in an effort to reduce immune-mediated complications and improve glucose control further.

Human insulin has been obtained using three techniques. The earliest attempts were to isolate and purify it directly from human cadaveric pancreases. However, the supply of human tissue was never sufficient to enable this technique to provide sufficient quantities. The technique of "semi-synthesis" chemically converts porcine insulin to the human sequence through substituting the one amino acid difference in the primary sequence. It was not until 1980 with the introduction of recombinant DNA technology that human insulin therapy became widely available. The technique involves the insertion of the human DNA sequence into a host cell, usually baker's yeast or the bacteria *Escherichia coli*, allowing it to

Table 29.1 Insulin therapy milestones.

1922	Isolation of insulin and treatment of the first patient (January 22nd)

2013	Ultra-long-acting insulin analogs
2015	Biosimilar insulins

synthesize the insulin molecule [7]. The protein would then be purified usually via chromatography columns to achieve a 99.5–99.9% insulin purity. The quality of the human insulin preparation achieved with this technique, as indeed with the purified pork insulin, has virtually eliminated problems associated with immune-mediated side effects.

Counter to expectations, rigorous and well-designed studies comparing purified animal insulin with recombinant human insulin have yet to demonstrate a significant benefit in glycemic control. A meta-analysis of 45 randomized controlled trials involving a total of 2156 participants comparing animal and human insulin failed to show a significant difference between these two therapies [8]. Most (36 of the 45) of these studies used highly purified porcine insulin.

The move from animal to human insulin was associated in some patients with higher incidences of severe hypoglycemia, largely due to changes in hypoglycemia warnings [9, 10], but systematic reviews have failed to substantiate this finding [8, 11].

There has been a large-scale uptake of recombinant human insulin such that less than 7% of global insulin sales are now animal insulin. The phasing out of animal insulins by the leading insulin manufactures has certainly contributed to this. Several companies, however, continue to provide this alternate source, and both beef- and pork-derived insulin remain available in many countries.

Modifying the duration of action of insulin without altering its molecular structure

The biological action of soluble insulin lasts about 5–6 hours. The early preparations were often associated with pain and swelling at the site of injection, and the needles and syringes were not optimized for painless injection. Attempts were, therefore, made in the 1920s and 1930s to provide the daily insulin requirement in just one injection. To this end, modifying agents such as lecithin, oil, and cholesterol [12] were used. However, their duration of

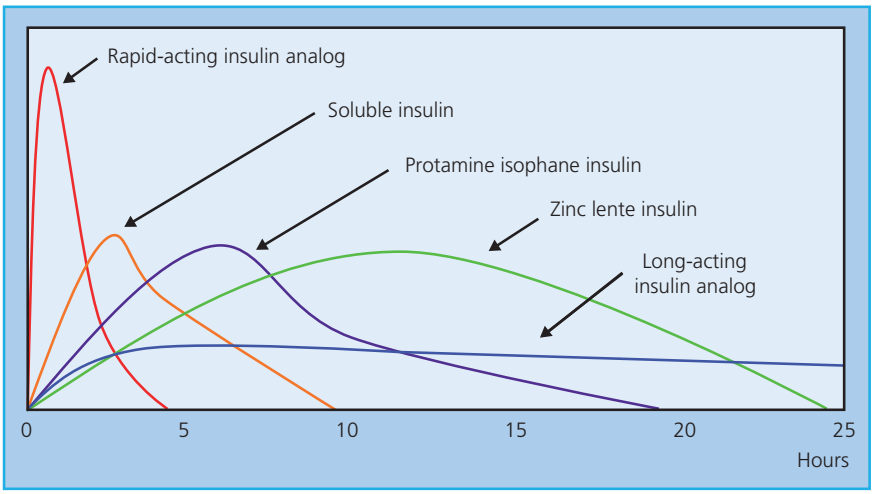

Figure 29.3 Time action profiles of the different insulin formulations.

action varied significantly from injection to injection which limited their clinical utility.

In 1936 a method for incorporating insulin into a poorly soluble complex, thus slowing its absorption, was reported [13]. This technique involved the addition of a highly basic protein, protamine, derived from the sperm of salmon or trout. The complex was further stabilized by the addition of a small amount of zinc such that it lasted about 24 hours. This insulin was called protamine-zinc insulin. It was difficult to make consistent batches and absorption again tended to be erratic. In 1946 the technique was further refined such that protamine and zinc were added in stoichiometric proportions (so that there was no free protamine or zinc), which resulted in a preparation that was absorbed at a more consistent rate and lasted between 12–24 hours. This insulin was called Isophane or neutral protamine Hagedorn (NPH), and became clinically available in 1940. In 1951 a development which prolonged the action of insulin without the need for protamine was reported. This required that zinc be added in excess and in acetate buffer resulting in crystals of relatively insoluble zinc-insulin complexes, called the Lente insulins [14]. The size of the crystals could be adjusted by changing the pH such that larger crystals, which were more slowly absorbed (Ultralente), and smaller crystals (called Semilente), could be produced. A preparation containing a 70 : 30 ratio of the Ultralente and Semilente insulins, called Lente insulin, was the most popular form of the zinc insulins and was used widely in clinical practice.

Modifying the duration of insulin action through altering its molecular structure

Insulin circulates as single molecules in the blood at concentrations of about 10^{-9} mol/L. At higher concentrations such as in commercial preparations, insulin molecules tend to associate non-covalently into dimers, tetramers, and hexamers [15]. The presence of zinc further stabilizes the hexamer association. Following injection, fluid is drawn into the injected insulin depot through osmosis. This leads to dilution of the insulin and dissociation of the insulin molecules; a spontaneous but gradual process that must occur before insulin crosses the capillary walls as monomers into the blood circulation [16, 17]. People with diabetes are, therefore, advised to inject their soluble insulin 15–20 minutes before a meal so that circulating insulin levels are optimal at the time their meal is being absorbed (Figure 29.3). A significant proportion of people with diabetes find it hard to follow this advice because of the planning required. Even when they do, the calculated doses may be inaccurate, particularly if the preparation and presentation of the meal is not under the individual's control.

The association between insulin molecules can be reduced by specific changes to insulin's amino-acid sequence [18], many of these centering on the B28-29 amino acids. These changes result in faster absorption of insulin into the blood stream, and allow it to be injected closer to the mealtime, and often just before starting to eat. To date, three such rapid-acting analogs have become available. Insulin lispro (Humalog®, Lilly) differs from human insulin in that amino acid proline at position B28 is replaced by lysine, and the lysine in position B29 is replaced by proline. Insulin aspart (NovoRapid®, Novo Nordisk) again has a substitution at B28, where proline is replaced with an aspartic acid. Insulin glulisine (Apidra®, Sanofi-Aventis) differs from human insulin in that amino acid lysine in position B29 is replaced by glutamic acid, and asparagine at position B3 is replaced by lysine. These analogs act more quickly (within 10–20 min) and have a shorter duration of action (3–5 h) than soluble insulin [19] (30–60 min, and 6–8 h, respectively) (Figure 29.3). A number of studies have now demonstrated the safety of rapid-acting analogs in both T1DM and T2DM, as part of a "basal bolus" insulin injection regimen combined with intermediate-acting insulins, and in continuous subcutaneous insulin infusion (CSII) [20]. The time action profile of rapid-acting analogs is well suited to mimicking the requirement at mealtimes and, therefore, they probably control postprandial hyperglycemia more effectively than soluble insulin. As a result, individuals can achieve better glycemic control with fewer episodes of hypoglycemia with rapid-acting analogs than with

soluble insulin. The benefits of rapid-acting analogs over soluble insulin appear to be clearer in studies involving people with T1DM than T2DM, and using CSII than for multiple dose injections [19].

Though delayed action insulin such as insulin Lente and Isophane (NPH insulin) can cover the 12–24-hour period, they do not display this extended duration of action in all people with diabetes. Furthermore, absorption from subcutaneous tissue can vary significantly [21]. Therefore, attempts at stringent glucose control can be associated with an increased risk of hypoglycemia. As for rapid-acting analogs, modification of the insulin molecule primary amino acid sequence can also result in a longer and more reproducible duration of action. Again there are currently three such insulin analogs. Glargine (Lantus®, Sanofi) achieves a prolonged insulin action through amino acid substitutions that make the insulin molecule less soluble. Glargine insulin forms microcrystals following subcutaneous injection that dissolve slowly over an 18–26-hour period [22]. In non-inferiority studies, insulin glargine achieves similar glycemic control to isophane insulin, and appears to do so with less hypoglycemia [23]. Insulin detemir (Levemir®, Novo Nordisk) has a fatty acid side-chain addition to the insulin molecule that promotes binding to circulating albumin, which then slowly dissociates giving it a duration of action just a little short of glargine insulin. Detemir is as efficient as isophane insulin at improving glycemic control, but appears to do so with less hypoglycemia and weight gain [24]. The most recent addition to the long-acting insulin analogs has been insulin degludec (Tresiba®, Novo Nordisk). Degludec also has a fatty acid side-chain but structured in such a way as to encourage it to form long multihexamer chains following subcutaneous injection. This chain disassembles very slowly and gives degludec a very long duration of action (half-life exceeding 25 h) such that it has been termed an ultra-long-acting insulin analog [25]. This long duration of action allows a very flat insulin profile, and a more reproducible duration of action that is not significantly affected by variations in the time of day-to-day administration. Non-inferiority studies have shown that insulin degludec is able to achieve similar levels of glycemic control to insulin glargine, but with less overall and nocturnal hypoglycemia [26].

Comparative studies of the long-acting analog insulins, have been designed to demonstrate equivalence rather than superiority in terms of glycemic control [27]. They do, however, demonstrate that the same level of glycemic control can be achieved with less hypoglycemia, and possibly with less weight gain. These benefits come at a cost. NPH insulin in the UK costs about £8, compared to £30 for the long-, and ultra-long-acting insulin analogs.

Biosimilar insulins

Biosimilar insulins have recently entered clinical practice and a mention of them is pertinent in this edition of this textbook [6]. Several patent protections for many analog insulin preparations have expired, and the pharmaceutical industry has explored these opportunities to develop "copy cat" insulins to compete with original formulations. Because insulins are currently produced biologically (i.e. through expression in living cells), they are more correctly termed "biological" or "biosimilar" drugs than "generic" drugs. Biosimilars (such as peptide hormones and monoclonal antibodies) are already in clinical practice and are required to undergo a more rigorous testing than standard generic drugs. This testing includes a direct comparison of the biological activity, pharmacology, clinical safety, and efficacy of the biosimilar with the reference insulin. Whilst the development of biosimilars will be more expensive than development of a generic drug, it will not be as expensive as developing the original insulin, and any cost savings will likely be magnified through long-term prescription. Therefore, these insulins will likely be cheaper, thus expanding market competition and increasing availability for people with diabetes. Currently only one biosimilar insulin (based on insulin glargine) has been approved (September, 2014) [28].

Different insulin concentrations

Injecting large volumes of insulin, as is required in those who are insulin-resistant, slows absorption kinetics and reduces the effectiveness of the insulin. Furthermore, it can be more painful. Splitting the dose across different injection sites can reduce the volume. However, in some people, the use of more concentrated insulin is more appropriate. Insulin preparations are currently standardized to 100 U, that is, 100 units of biological activity per mL of insulin. U200, U300, and U500 formulations are available (or becoming available) for clinical use and have been demonstrated to be clinically effective [29–31]. Their exact place in management still needs to be evaluated as they are currently generally reserved for those with very high insulin requirements, but may also benefit those on lower doses.

Reproducing physiological insulin delivery—the size of the problem

In health, the background insulin secretion is low and stable between meals, with significant prandial surges (Figure 29.4) [32]. What is important to appreciate is that in health, pancreatic-derived insulin acts directly on the liver via the portal circulation. In the fasting state, this insulin is at concentrations of 15–20 mU/L, and is sufficient to suppress hepatic glucose production. Fifty to eighty percent of the insulin is metabolized by the liver [33] such that much lower and tightly regulated insulin levels enter the systemic circulation. Peripheral tissues such as muscle also take up glucose but this is at higher insulin concentrations (60–80 mU/L) and tends to occur predominantly postprandially.

The administration of insulin by subcutaneous injection delivers it to the systemic circulation, with relatively lower levels reaching the liver. Therefore, glucose uptake by muscle and adipose tissue is preferential to liver. The lower exposure of the liver to insulin

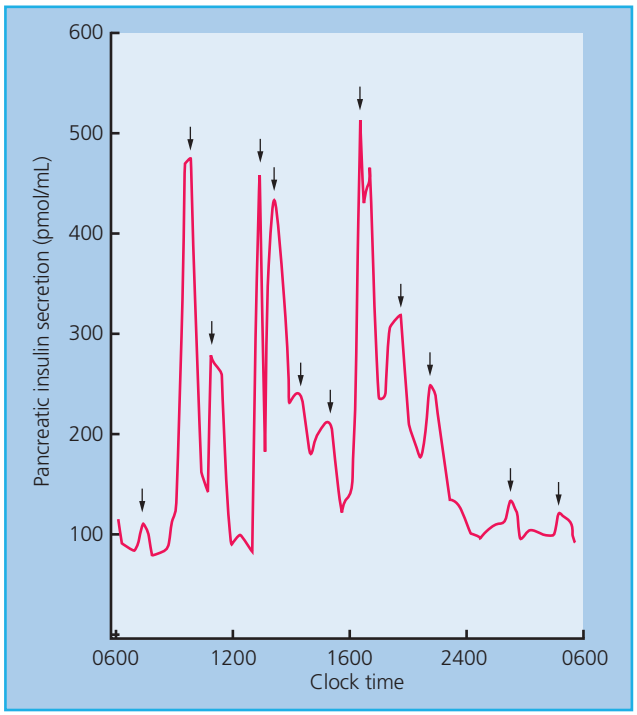

Figure 29.4 Pancreatic insulin secretion in a healthy non-obese individual. Meals were consumed at 0900, 1300, and 1800. Statistically significant pulses of secretion are shown by the arrows. Source: Polansky KS, et al. 1988 [32]. Reproduced with permission from the American Society for Clinical Investigation

also results in greater hepatic glucose production, making the control of blood glucose even more challenging.

The challenge of insulin replacement therapy is to reproduce the physiological insulin profile even though it is being delivered at an "unphysiological" site, and without incurring hypoglycemia. One approach to targeting insulin action to the liver is through the development of hepatoselective insulin [34], including the technique of making the insulin molecule larger through PEGylation to favor it leaving the circulation at the hepatic sinusoids.

Oral, inhaled, intraperitoneal and intramuscular routes of insulin administration

The early experiments of Frederick Banting quickly revealed that the oral route of insulin administration was not an effective means of insulin delivery, as the insulin molecule was functionally degraded by gut peptides. Subcutaneous injection of insulin has become the most popular route of insulin delivery because of its relatively reproducible kinetics of absorption, and the ease with which it can be administered, but it is worth visiting some of the other routes.

Intramuscular injection is more painful, and absorption more rapid, than subcutaneous injection and is, therefore, not recommended for any of the insulin formulations [35]. However, this route can be useful, for example, in the emergency situation when intravenous access is difficult. Inadvertent intramuscular administration should be considered in the slim individual with diabetes who complains of pain on insulin injection, and who may experience erratic glucose control and hypoglycemia. The correct choice of insulin needles can help address this problem (see later).

The delivery of insulin directly into the peritoneal space, for example, with implantable pumps or directly via a port [36] mimics physiological insulin secretion in that insulin bypasses the systemic circulation and directly enters the portal circulation. The theoretical advantages of portal delivery include rapid insulin absorption, near physiological carbohydrate and lipid metabolism, and avoiding peripheral hyperinsulinemia [37]. Clinically, the advantages of intraperitoneal insulin delivery have been explored in a number of clinical trials (reviewed in [38]). Whilst large randomized controlled trials are awaited, current studies suggest some evidence for improvement in HbA_{1c} and improved quality of life in selected people with T1DM [39].

The oral administration of insulin is another route through which this drug can enter the portal circulation, thus avoiding high levels of peripheral insulin. Clinical trials of oral insulin preparations are currently ongoing. These insulins avoid degradation in the gut either through encapsulation, or through modification of the insulin molecule to engender resistance to degradation [40–42]. Concerns about accuracy of insulin dosing, and the anabolic effect of insulin on lower gut tumors will need to be addressed as these insulins come to the market.

Administration of insulin via the respiratory mucosal surface avoids degradation by gut peptides and can be an effective route for insulin delivery, particularly for those who are needle phobic [43]. Inhaled insulin was made available in the UK (Exubera, Pfizer) in 2006, but was withdrawn within a year due to poor uptake by patients and healthcare professionals. A newer device that is smaller, and with a potentially more effective insulin was approved in the USA for marketing in 2015 (Afrezza®, Mannkind-Sanofi) for use as a meal-time rapid-acting insulin. With both formulations, there is a reduction in lung function that reverses when the therapy is stopped, and there is the potential risk of lung cancer in heavy smokers. Afrezza is also not recommended in people who are current smokers, because safety and efficacy has not been demonstrated in this population. It is also contraindicated in people with reactive airway diseases such as asthma or chronic obstructive pulmonary disease. Whilst trials of newer inhaled insulins are awaited, systematic reviews of previous formulations suggest it is as clinically effective, but not as cost-effective as short-acting injectable insulin, in unselected people with diabetes [44].

Technique for subcutaneous injection of insulin

Subcutaneous insulin administration is the most popular route of insulin therapy. The recommended sites for injection are the abdomen centered around the umbilicus, back of the upper arms below the deltoid region, upper lateral thighs, and upper buttocks. The area should be clean and free from signs of infection

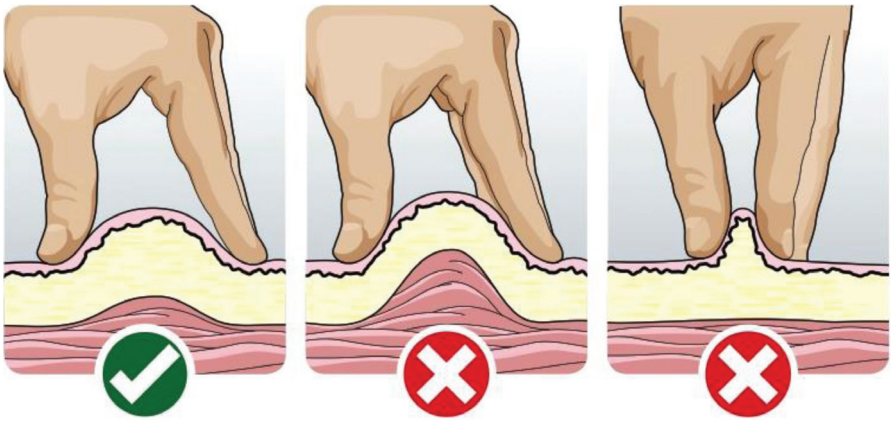

Figure 29.5 The recommended technique for lifting skin folds for the subcutaneous injection of insulin. Source: The Forum for Injection Technique Guidelines 2011. Reproduced with kind permission of BD Medical Diabetes Care.

or lipohypertrophy (see "Complications of subcutaneous insulin therapy" later).

Insulin can be directly dialed up on a pen device, or drawn up using a disposable syringe. If the insulin preparation is cloudy (e.g. pre-mixed insulin), it should be gently rolled and inverted 10 times. This will allow the insulin crystals to disperse and for the mixture to turn to a milky-white suspension. If using a pen device for insulin delivery, the device should be properly primed and a drop of insulin should be visible at the tip of the needle. Similarly, if an insulin syringe is being used, the barrel should be tapped and any air excluded by squeezing the plunger. These maneuvers ensure that air is not contributing to the volume of insulin that has been dialed/drawn, and that an accurate dose of insulin is delivered.

The needle should enter the skin at right angles to the surface in a smooth process, the plunger squeezed gradually and completely, and left there for 10 seconds to allow the insulin to enter the tissue. The needle should then be removed and discarded appropriately. Pen needles and disposable syringes should be replaced at each injection. Rubbing of the skin following injection is discouraged because this increases the rate of insulin absorption, and may increase the risk of hypoglycemia.

Syringe needle lengths are currently restricted to 8 mm. Pen needles come in a variety of lengths from 4, 5, 6, and 8 mm. There is no clinical reason for needles longer than 8 mm. Longer needles increase the risk of injecting directly into muscle, with the associated rapid absorption and risk of hypoglycemia. Currently 4 mm needles are recommended for many adults and most children and these can be often used without the need for lifted skin folds. Injecting into lifted skin folds is appropriate in children, slim adults, and when there is a risk of injecting into muscle. The correct technique for lifting skin folds needs to be taught; it should not lift up underlying muscle, nor be so tight as to cause blanching of the skin (Figure 29.5). The use of lifted skin folds is recommended for all people who use 8 mm needles. Injecting through clothing is to be discouraged because as needle lengths get shorter, there is a risk of intradermal injection.

Studies of absorption of subcutaneously administered insulin have used a variety of techniques including measuring the rate of loss of I^{125} labelled insulin from the site of injection using a gamma counter [45]. They show that the rate can vary significantly between individuals, but also from one injection to another within the same individual [21]. Absorption rates in obese individuals are slower than in people without obesity, and there does not appear to be any clear differences in the rate of absorption between the different injection sites. In lean individuals, the absorption of analog insulins (both rapid- and long-acting analogs) does not appear to vary by injection site [46, 47]. However, in these individuals, absorption of human insulin from the abdomen appears to be faster than the arm or leg [48], and the upper abdomen faster than the lower abdomen [49]. This difference can be utilized to good effect, for example, injecting isophane NPH insulin into the thigh or buttock ensures a slower absorption, and soluble mealtime insulin in the abdomen, a more rapid absorption.

Repeated injection of insulin at the same site results in local hypertrophy of adipose tissue, resulting in slower and more erratic insulin absorption. Patients should always be advised to rotate their insulin injection sites to avoid this complication, and should be shown an easy to follow rotation scheme (Figure 29.6). Other local factors such as edema or local inflammation can influence rates of absorption. Exercise results in greater blood flow to the skin and can result in faster uptake of insulin, particularly when injected into an area close to the muscle groups being exercised. Individuals who are planning to run, for example, should be advised that injection into the leg may be less favorable than injecting into the arm or abdomen [50]. Similarly temperature influences cutaneous blood flow and can influence insulin absorption [51]. Hot climates or sitting in the sauna may result in a rapid surge in insulin levels whereas the converse, travelling to cooler climates can result in a slower uptake. There are also reports that hypoglycemia and smoking can reduce the rate of insulin absorption [52, 53].

Standard insulin preparations have a shelf life of 4–6 weeks when stored at under 25 °C. Storage for longer periods will require that they be kept in a fridge (4 °C), which then allows them to be stored until their expiry date. Exposure of insulin to high temperatures or to microwaves can render them inactive.

Complications of subcutaneous insulin therapy

The major and most feared complication of insulin injections, for most people, is hypoglycemia. The causes, avoidance, consequences and management of hypoglycemia are discussed in Chapter 35. The fear of hypoglycemia may be a major barrier to insulin initiation.

Insulin not only restores fat and muscle mass in newly or suboptimally treated insulin-requiring patients but can lead to excessive weight gain [54]. This remains a major concern for many people, particularly for the already overweight individual with T2DM who can no longer be controlled on oral antidiabetes agents. Weight gain can be reduced by concomitant advice from the dietician, and an insulin regimen tailored to the requirement of the individual, which wherever possible provides most insulin when needed, that is, at meal times. Over-aggressive insulin titration regimens leading to low blood glucose and stimulation in appetite can lead to excessive weight gain. Some people, particularly but not exclusively young females, can pose a management challenge when they reduce their insulin dose to suboptimal levels to manipulate body weight (See Chapter 57).

Immune responses to the older animal insulins have been well reported but such responses to current human and analog insulins are less common [55]. Allergies may rarely develop in response to the insulin molecule (this may become a more common issue with the introduction of biosimilar insulins where folding may differ) or to components of the insulin preparation (such as the protamine or metacresol). Most commonly, allergic reactions manifest as local acute urticarial reactions. These are best managed with intradermal skin testing of 1 : 20 dilutions of different insulin preparations, and then switching to that which is best tolerated [56]. Antihistamines may be of benefit in such patients as too may be the use of high-dose steroids in exceptional circumstances. More rarely, widespread systemic reactions develop as a reaction to the insulin and patients may benefit from referral to clinical immunology services.

Lipoatrophy in which subcutaneous tissue at the site of injection disappears or atrophies is also an allergic response seen predominantly with the older animal insulins. It is rarely seen today. In contrast, lipohypertrophy is not uncommon, and is not an allergic response at all but develops because of an increase in adipose tissue as a trophic response to insulin. It is most commonly seen in those with a poor injection technique and usually in people who do not rotate their insulin injection sites. The patient usually finds the appearance unsightly and further injections into sites of hypertrophy can lead to poor and delayed insulin absorption with consequent effects on blood glucose levels [57]. Lipohypertrophy generally resolves within 2 months if injecting into that area is avoided. Occasionally mild ulceration, pitting and, more commonly, bruising can occur at injection sites. Rotating injection to another site, and selecting a shorter needle may be indicated.

Insulin regimens

As insulin preparations have evolved from the early animal insulins to both human and analog insulins we have also seen the development of more versatile and indeed flexible treatment regimens that enable the doctor and nurse to provide the person with diabetes requiring insulin with a bespoke treatment that fits in better with their individual needs and lifestyle.

In people without diabetes it is well known that the β cells of the pancreas have the ability to produce insulin both between meals and at meal times to maintain blood glucose values within a narrow physiological range. In people with T1DM, who are no longer producing endogenous insulin, the administration of exogenous insulin is required to try, as far as is possible, to mimic physiological insulin release using a combination of both fast- or rapid-acting insulin to deal with the glucose challenge presented at meal times and more longer acting or basal insulin to provide a background control of glucose between meals. In people with T2DM, the principle is the same although as the β cells may still be producing some insulin the addition of exogenous insulin to existing oral antidiabetes agents can also be used to try and achieve control of blood glucose levels.

We will discuss how each of the individual insulins mentioned earlier can be used either alone although more often in combination in conjunction with lifestyle and diet and other treatments to control blood glucose.

Basal only regimen

In excess of 50% of people with T2DM will require insulin injections at some point in their life [58]. Often as T2DM progresses

the transition from oral antidiabetes agents to insulin injections can be a time of great stress and anxiety to many people for a number of related reasons [59]. Whilst healthcare professionals employ a whole variety of skills and techniques to minimize what people see as a life-changing event, we remain very aware of the many anxieties insulin injections can induce. These may include a sense of personal failure in not being able to control blood glucose levels with lifestyle, diet, and oral therapy; a feeling that the diabetes is now much more serious than it was as it now requires injections rather than tablets; apprehensions, fears and, very occasionally, real phobias over the need to self-inject a treatment [59]; worries of hypoglycemia leading to coma and death; concerns over weight gain; and also the fact that the use of insulin may severely affect an individual's occupation and certain lifestyle activities.

One way in which insulin injections can be introduced to people who are no longer able to manage their blood glucose with diet, lifestyle, and oral therapy alone is to start with only one injection a day. This is usually added on to existing oral therapies rather than as a replacement therapy. An increasing number of studies have now been published demonstrating that a once a day basal insulin can be used as an add-on therapy to metformin, a sulfonylurea, thiazolidinedione, pioglitazone and as an add-on to these agents when used as a dual or triple oral therapy [60]. National and international guidelines in the UK, Europe, and the USA also recommend the use of a basal insulin with oral therapy as a way of initiating insulin in people with T2DM [61–63]. Some of the newer incretin-based therapies including the DPP-4 inhibitors and the GLP-1 receptor agonists have also recently gained licenses for use with insulin therapy in people with T2DM. The concomitant use of insulin and a sodium glucose co-transporter 2 (SGLT-2) inhibitor, where indicated, is also supported by recent clinical trials.

The initiation of insulin therapy, whether in the hospital, or now more commonly in the community should only take place within a structured programme employing active insulin dose titration. The program should include appropriate education, ongoing telephone/text/email support, the use of self-monitoring to help with dose titration to an agreed target, an understanding of diet, avoidance and management of hypoglycemia, and support from appropriately trained and experienced healthcare professionals.

A number of guidelines continue to recommend initiation with a human NPH insulin taken once or twice a day according to need [61]. However, many healthcare professionals are opting for long-acting insulin analogs particularly in people who require assistance with injections from a carer or healthcare professional and where the use of an analog would reduce the number of injections from twice to once a day. Long-acting analog insulins may also be preferred in people whose lifestyle is restricted by recurrent, symptomatic hypoglycemia, those who would otherwise need twice daily insulin injections in combination with oral therapy, and those who have difficulties with the device required for injection of NPH insulin [60]. Similarly indications for switching from NPH insulin to a long-acting basal analog include failure to reach agreed HbA_{1c} target because of hypoglycemia regardless of HbA_{1c}.

Once started on a basal insulin it is important to adjust insulin doses appropriately to achieve an agreed target. A number of algorithms have been developed to assist with this with almost all based upon the fasting blood glucose measured in the community and usually by the person with diabetes themselves [60, 64, 65]. Whilst self-monitored readings are important in the dose titration process, the ultimate measure that determines the success or otherwise of the basal insulin is the HbA_{1c} value. If this is proving difficult to control with satisfactory fasting plasma glucose values the next step including a prandial fast or rapid-acting insulin component may be required.

Combinations of prandial and basal insulins

In people with T2DM a rising HbA_{1c} in the face of normal or near normal fasting glucose values suggests significant postprandial glucose excursions and the need for a meal-time insulin. This can be achieved in different ways including the addition of a prandial insulin with the main meal followed as needed with the addition of a prandial insulin before every subsequent meal [60]. Alternatively patients can be switched from a basal insulin to a premixed insulin which traditionally has been given twice at the time of breakfast and the evening meal but which increasingly is also being given initially once a day with the main meal and increased up to three times a day [63, 66].

Clearly for people with T1DM a basal insulin alone is inadequate and either a complete basal bolus regimen is required with prandial insulin before each meal alongside a basal insulin or alternatively a twice or thrice daily insulin premix can be used.

Basal plus

The addition of a fast-acting human insulin or rapid-acting analog insulin prior to the main meal of the day can be a useful next step in intensification after starting a basal insulin in people with T2DM [63, 67]. Increasingly healthcare professionals are using rapid-acting insulin analogs over fast-acting human insulins, for convenience, as they can be given immediately before, during, and even immediately after a meal [68, 69]. The dietary intake of the individual will determine which their main meal of the day is and, therefore, with which meal the single injection of fast-/rapid-acting insulin will be given. Once again it is important to titrate the prandial insulin to a glucose target. The ideal time to test the impact of the prandial insulin, and certainly a rapid-acting insulin analog, is 90 minutes to 2 hours after the meal. As with basal insulin adjustment it is advisable not to make too frequent a change in insulin dose and ideally no less than inside 3 days or twice a week. The person with diabetes may vary the amount of insulin administered based upon the size of the meal, although as the insulin is given with the main meal of the day, the dose is usually fairly stable from one day to another. As glycemic control becomes more difficult to achieve a second prandial insulin injection may be necessary taken before the second main meal of the

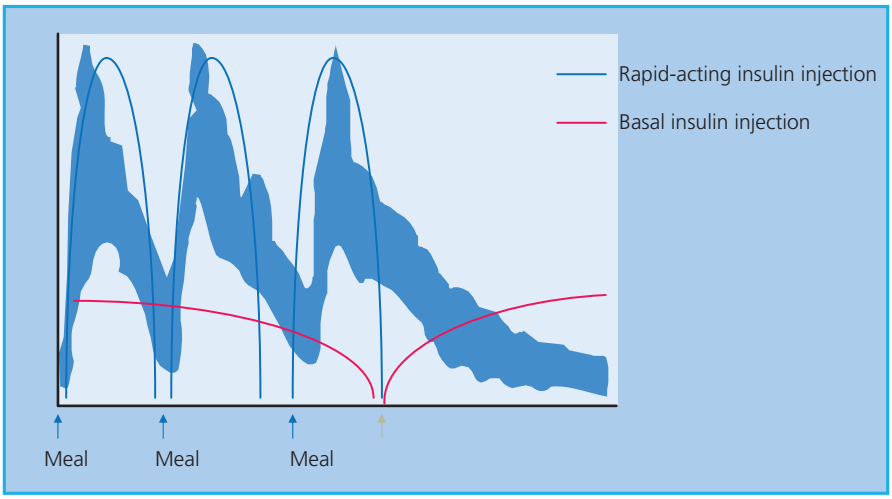

Figure 29.7 Schematic representation of the attempt to mimic physiologic insulin release following three main meals using a basal bolus regimen.

day using a similar dose titration procedure to that for the single prandial injection [67].

Basal bolus

The use of the basal bolus regimen in people with T1 and T2DM attempts to mimic as closely as possible the normal physiological secretion of insulin by providing a background 24-hour coverage of insulin along with a bolus injection at each meal time (Figure 29.7). In most people with diabetes, with the development of long-acting analog insulins, the basal injection is administered once a day. However, based on the results of pre-meal self-monitored blood glucose values some people may require two basal injections approximately 12 hours apart to achieve satisfactory before meal glucose values without hypoglycemia. Traditionally with animal and then human insulins, basal injections are given in the evening, often before bed. However, this is less important with the basal analog insulins and indeed many people benefit from having their once a day basal injection at the same time each morning. As discussed earlier, it is important that insulin doses are adequately titrated to achieve target glucose and HbA_{1c} values, and for the basal bolus regimen the dose of the basal insulin is determined by measurement of fasting (pre-meal) glucose values and the most appropriate fast human or rapid-acting analog insulin dose is best determined by 2-hour postprandial glucose values.

Insulin mixtures

Whilst a few people with diabetes still self mix either animal or human fast-acting and long-acting insulins prior to injection, most people using insulin mixes inject premixed insulin preparations. In recent years we have seen a whole spectrum of insulin premix insulins ranging from a 10 : 90 to 50 : 50 short-/long-acting insulin ratios. In reality many of these premixes were not required and consequently through lack of use the range of premixes has contracted down to 25 : 75, 30 : 70, and 50 : 50 mixes of short- and long-acting, respectively. Most people with diabetes use premixed insulin twice a day before breakfast and the evening meal.

In people with T2DM insulin initiation may start with a once a day premix insulin with the main meal increasing up to two injections a day when needed based on self-monitored blood glucose values and the HbA_{1c} [63, 67]. Some people with T1DM but more frequently people with T2DM move to three injections a day by also administering an injection before lunch. For those escalating to three injections a day, the 50 : 50 mixture providing more rapid-acting insulin at meal times may be more appropriate than the more commonly used 25 : 75 or 30 : 70 mixture usually given twice a day.

Selecting the most appropriate insulin regimen

Most people who have had either T1DM or T2DM try a number of treatment regimens throughout their lives. There are many factors that influence the decision to opt for a specific regimen and ultimately the most important is individual choice rather than evidence from clinical trials.

Type 1 diabetes

All people with T1DM, unless they have been fortunate to become insulin-independent following a pancreas or islet cell transplant, will require exogenous insulin to provide 24-hour background and meal-time coverage. For many this is provided by the basal bolus regimen. The advantage of such an approach is that it is generally better at providing a more physiological insulin replacement with a greater degree of 24-hour flexibility than less frequent premix insulin. Whilst it has the disadvantage of involving more daily insulin injections and requiring many more frequent home blood glucose monitoring which is not popular with some people with T1DM, particularly young and teenage children, it does provide a much greater degree of flexibility throughout the day. Importantly, for example, it allows the individual to vary the meal time dose at up to three different time points during the day to accommodate different daily activities and meal sizes. For some, this "freedom"

is less important and the administration of only two injections a day sways them towards an insulin premix.

Type 2 diabetes

Whilst in some people with T2DM insulin requirements are similar to those with T1DM, for many insulin initiation and intensification is a more gradual process. Views differ on the insulin of choice for initiation, particularly as an add-on to oral hypoglycemic therapy. Prior to the introduction of the long-acting basal analogs many people with T2DM requiring insulin were started on a twice a day premix insulin often as an add-on to metformin. If they were also on a sulfonylurea this was usually stopped. Supported by clinical trials, which demonstrated lower rates of hypoglycemia with long-acting basal analogs as an add-on to existing oral therapy compared to NPH insulin, once a day long-acting basal insulins are now recommended in T2DM treatment guidelines and have found significant popularity, particularly in the community as a means of introducing the person with T2DM to insulin [60, 64]. Anecdotally, however, whilst this is a popular way of starting insulin, many healthcare professionals struggle to achieve satisfactory glycemic targets with this regimen and many people with T2DM will require a second insulin injection with a meal time component within 6–12 months. Trials comparing twice daily premixed insulins compared to a long-acting basal analog when added to metformin in insulin-naïve individuals appear to show a benefit in favor of twice daily premixed insulin with respect to the numbers achieving target HbA_{1c} values [70, 71]. The relative merits of basal only, prandial only, and premix insulin [72] have been evaluated [73]. Clearly there are advantages and disadvantages associated with each approach. A pragmatic response is to consider the person sat in clinic in front of you and consider their lifestyle, social circumstances, and comorbidities and, taking into account what their insulin needs are likely to be in the longer term, make a clinical judgment. If it seems likely that if started on a basal insulin they are likely to remain on this as a single injection or as part of a basal bolus regimen in the future, the basal insulin may be the best option. However, if it seems likely that the individual will be switched to a premixed insulin if a long-acting bolus does not achieve target, then initiating with a premixed insulin would seem sensible. Starting the premixed insulin as a once a day injection increasing to two and sometimes three injections is also an option with some clinical evidence to support it.

Starting insulin for the first time

In the past insulin initiation, particularly for people with T1DM, was conducted either as an inpatient or as a day case in a hospital diabetes center. As confidence grew with the development of purer animal insulins and most recently with human and analog insulins and also with the introduction of disposable syringes, pen injectors and needles, more insulin starts are performed as an outpatient. Lately, with an increased emphasis on community-based diabetes care, insulin initiation, particularly in people with T2DM, is taking place in health centers and GP surgeries [74]. Whilst older algorithms for helping to decide when and where insulin should be initiated have been published, national and local guidelines now seem more appropriate as varying levels of expertise, infrastructure, and service delivery are present.

Wherever insulin is initiated it is vital that for it to be successful a good insulin initiation programme must be in place, with a qualified and competent diabetes nurse specialist. A number of programs are available most with appropriate training courses for healthcare professionals. Insulin initiation involves much more than teaching a patient how to use a needle and syringe and the process of starting and successfully stabilizing them on insulin will require a number of structured contacts with the nurse and also a 24-hour emergency contact number for any urgent problems that may arise (Table 29.2).

Table 29.2 Out-patient/community pathway for people starting insulin for the first time.

Session 1

- The need for insulin has already been discussed with the person with diabetes by a doctor or diabetes nurse specialist and the person with diabetes has been seen by dietician
- A regimen will have been agreed upon and the first prescription has been obtained by the person with diabetes
- A review of "what is diabetes" including what insulin does and the need for insulin injections usually takes place
- Nurse demonstrates the basics and use of insulin injection device and the person with diabetes gives first injection
- Further discussions including:
  - **i** sites for injection/site rotation
  - **ii** timing of injections
  - **iii** where and how to obtain equipment (insulin, pens, needles, self-monitoring equipment, sharps disposal equipment)
  - **iv** recognition and management of hypoglycaemia and hyperglycaemia
  - **v** self-blood glucose monitoring
  - **vi** driving and legal issues surrounding insulin 24-hour contact details provided

Session 2 (around 2 weeks after insulin initiation)

- Prior to session 2 the person with diabetes and nurse will usually have had telephone contact over insulin injections and blood glucose readings
- Review of information provided in session 1
- Review of insulin injection technique

Session 3 (around 4 weeks after insulin initiation)

- Review of session 1 and 2
- Further information provided about:
  - **i** insulin on holiday and when travelling
  - **ii** insulin injections when travelling through time zones (e.g. transatlantic travel)
  - **iii** insulin management during periods of acute sickness
  - **iv** foot care, other diabetes related complications and in women of child-bearing potential – pregnancy

Session 4 (around 10 weeks after insulin initiation)

- Review of previous sessions
- Assessment of glycemic control and need for further doctor/nurse follow-up
- Book follow-up clinic/surgery appointment

For those presenting acutely ill with nausea and vomiting with or without ketosis, admission to hospital for insulin initiation and, where needed, intravenous fluids, is a necessity.

Use of animal, human, and analog insulins

The evolution from animal to human and then analog insulins has been discussed at the start of this chapter. We have subsequently outlined above some of the advice included in national guidelines regarding the use of human and analog insulin. In clinical practice all three types of insulin are in regular use. At the present time, people on animal insulin wishing to stay on animal insulin should, wherever possible, be allowed to do so. There are also advantages associated with the use of the analog insulins although generally they are more expensive to prescribe than human insulin and concerns have been raised over cost–benefits when prescribed routinely. Whilst some of the individual benefits appear small, collectively these benefits are likely to have an impact on many people with diabetes [68]. Whilst those responsible for healthcare budgets seek persuasive clinical trial data it is most unlikely that we will ever see direct head to head studies that provide incontrovertible data one way or another. Ultimately, it will come down to clinical judgment and a decision involving the person with diabetes.

Assessments of glycemic control

Whilst national and international guidelines have made recommendations on glycemic targets based predominantly on the HbA_{1c} [61–63], self-monitoring of blood glucose not only helps people with diabetes achieve HbA_{1c} targets by adjustment of insulin doses but also helps them better understand their own diabetes and blood glucose levels (See Chapter 27). The timing of glucose tests and their role in determining the most appropriate insulin dose in discussed earlier under insulin regimens. Generally speaking people with diabetes should be advised to test at different times on different days including pre-meal and 2 hours postprandial testing to obtain 24-hour glucose profiles over a number of days rather than performing a large number of tests every day. To achieve strict glycemic control, as seen in the T1DM [54], pre-meal blood glucose readings should fall between 4 and 7 mmol/L and post-meal levels from 4–10 mmol/L with a value >7 mmol/L before bed. Whilst individual specialists often follow their own dose adjustment algorithms, in general terms, a change in dose of 2 units or 10% of a dose (whichever is the greater), is a sensible adjustment for most people taking insulin.

Similar targets may be sought for people with T2DM although recent trials based on achieving very tight HbA_{1c} values, with some aiming for <6%, serve to highlight the dangers of hypoglycemia [75]. The frequency of blood glucose testing is extremely variable with patients being recommended to test anything from seven times a day down to four or five tests a week. The most important aspect of regular self-monitoring by people on insulin, is that the test result should be used as part of a management plan to help decide prospectively on insulin dose. There are, however, other points that should be considered when advising on when to self-test, including times of intercurrent illness to adjust insulin dose, symptoms and treatment of hypoglycemia, and foreign travel. Whilst more frequent testing generally provides more information, it is also important to remember not to recommend unnecessary testing as pricking the finger is painful and for most people with diabetes is worse than injecting insulin.

Declaration of interest

At time of writing, Dr Stephen Gough was employed at the University of Oxford but has since taken a position as Senior Principal Clinical Scientist with Novo Nordisk in Copenhagen.

30 New Technologies for Glucose Monitoring and Insulin Administration

David L. Horwitz[1] and David C. Klonoff[2]

[1] College of Medicine, University of Illinois (Retired); Former Chief Medical Officer, Johnson & Johnson Diabetes Institute, Wayne, PA, USA

[2] Diabetes Research Institute, Mills-Peninsula Health Services, San Mateo, CA, USA

Key points

- Self-monitoring of blood glucose is evolving to meet new accuracy standards, and data processing tools are enabling individuals and physicians to use the data better.
- Real time continuous glucose monitoring has led to improved glucose control when used regularly.
- Continuous subcutaneous insulin infusion with an insulin pump can lead to improved glycemic control in selected individuals.
- Considerable progress has been made in developing closed-loop systems, using a stepwise approach to incremental feedback control.
- Insulin pens and inhaled insulin are providing alternative means of insulin administration, and may have some clinical benefits.

Introduction

A primary goal of insulin therapy in diabetes has been to optimize glycemic control by reproducing the physiological insulin release that is seen in response to glucose and other stimuli when the pancreatic islets are functioning normally. Recent developments in glucose measurement, insulin delivery, algorithms that relate these two processes, and data management software to demonstrate glycemic patterns have shown the potential to improve the lives of people with diabetes. This chapter reviews the current status of these developments, and their use in the management of insulin-treated diabetes.

Episodic blood glucose monitoring

Self-monitoring of blood glucose (SMBG) has been considered an essential component in the treatment of type 1 diabetes mellitus (T1DM) since the Diabetes Control and Complications Trial [1]. SMBG is also indicated for persons with type 2 diabetes mellitus (T2DM) on insulin therapy and may, when prescribed as part of a broader educational context, be helpful for other people with T2DM when used to guide treatment decisions or self-management [2, 3]. The accuracy of SMBG technology has come into question, however [4]. Because of concerns over the accuracy of monitoring systems, the ISO standard for such systems was changed in 2013 [5]. The previous standard from 2003 required 95% of values to be within 20% of a reference standard (or, for glucose values less than 100 mg/dL [5.6 mmol/L], within 20 mg/dL [1.1 mmol/L] of a reference value). The newer standard requires that 95% of values be within 15% of a reference value (within 15 mg/dL [0.8 mmol/L] for values less than 100 mg/dL). A draft guidance from the United States Food and Drug Administration (FDA) in 2014 proposed the stricter requirement that 95% of all values within the claimed measuring range of the system be within 15% of the reference value and that 99% of all values be within 20% of the reference [6]. The FDA recognizes that not all systems may be able to meet this requirement, particularly at lower glucose ranges, and the proposed standard states that, in this case, the manufacturer may need to raise the proposed lower end of the measuring range. The expectation is that the device will be accurate in the 50–400 mg/dL range [7]. This standard has not yet been implemented.

SMBG data may be used in various ways. With multiple daily insulin (MDI) therapy, individual values are used to determine the next dose of insulin and to teach people the effects of specific foods, exercise, and other activities on blood glucose levels. For people on all types of therapy, SMBG data may be used by the physician to make treatment decisions based on the overall pattern of results. Because of the large volume of data that may be generated, and the often haphazard record-keeping by individuals, recognizing glycemic patterns may be difficult. For this reason, there has been a movement to incorporate new

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

technology to simplify this task and make it more accurate. Such developments have come from manufacturers of blood glucose monitoring systems, from suppliers of mobile phones and other telemedicine systems, and from various start-up companies. Many of these were summarized in a recent review [8]. Mobile applications (apps) for downloading SMBG data are available from many sources on both iOS and Android platforms, but many have not had definitive studies to demonstrate their safety or their impact on overall glycemic control. In the Mobile Diabetes Intervention Study, a mobile diabetes software application was used to enter glucose data, carbohydrate intake, and medication and other information. Participants received automated real-time educational, behavioral, and motivational messaging specific to the entered data. A web portal augmented this with a secure messaging service and other information, including a personal health record. In one group, providers had access to a decision support system based on analyzed patient data linked to standards of care and evidence-based guidelines, and in another group providers had access only to unanalyzed data. After 12 months, participants receiving usual care had a decline in HbA_{1c} averaging 0.7%, whereas those in the group using mobile technology without decision support had a decline of 1.2% and those with decision support a decline of 1.9% [9]. Telemedicine diabetes support systems have also been shown to improve quality of life [10] and patient and physician satisfaction [11].

Systems have also been designed to produce graphical results of glucose patterns and have been shown to improve glycemic control. The graphical output can be either on the meter itself [12] or using software that downloads SMBG data from the meter [13]. Figure 30.1 represents an example of download software that

Patterns

! Low Pattern: Overall, 6 glucose readings were below target (13.6%).

! Low Pattern: Overnight, 2 glucose readings were below target (25.0%). Low Pattern: After Lunch, 2 glucose readings were below target (25.0%).

! Low Pattern: 4 glucose readings tagged After Meal were below target (19.0%).

Additional patterns have been detected and may be viewed by selecting different reports to view

Comparative Statistics

	Current Date Range	Previous Date Range	
	1/2/2015 - 1/15/2015	12/19/2014 - 1/1/2015	Change Δ
Blood Glucose (SMBG)

Lowest / Highest Readings	49 mg/dL	369 mg/dL			

Glucose by Time of Day

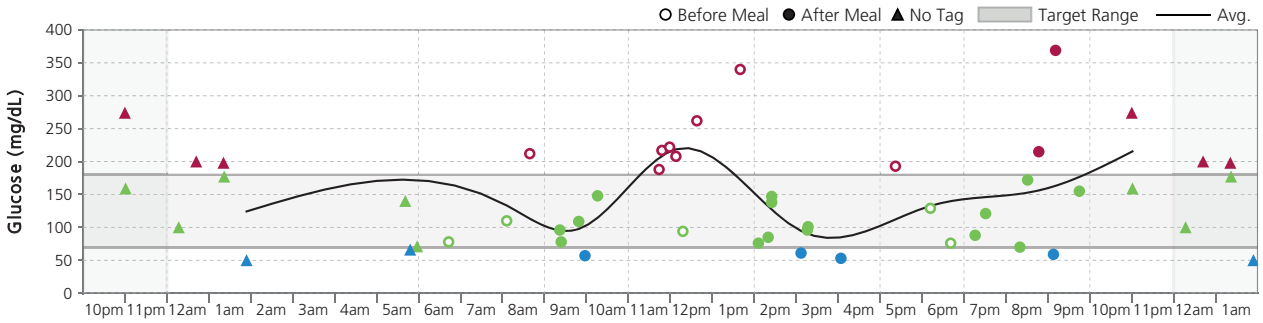

Figure 30.1 Meter downloads provide a rapid means of identifying patterns of glycemic control, such as the overnight and postprandial hypoglycemia seen in this individual. Source: Screen shot from Lifescan, Inc. Reproduced with permission.

Sensor Transmitter Receiver

Figure 30.2 Three components of a continuous glucose monitoring (CGM) device: sensor/probe, transmitter, and receiver. Source: Dexcom, Inc. Reproduced with permission.

can help identify patterns, such as episodes of hypoglycemia, that would be more difficult to detect or take longer to detect by simply reviewing a handwritten logbook.

A new approach to episodic glucose monitoring was recently announced by Abbott Diabetes Care [14]. Given the name FreeStyle Libre Flash® glucose monitoring, the system involves a sensor that is worn on the arm for up to 14 days without any need for calibration by the individual, according to Abbott, and is scanned by a reader to obtain a glucose reading. The device provides a subcutaneous fluid glucose value, unlike meter and strip methods that measure capillary blood glucose. At the time of release it was available in Europe but not the United States. Although similar in concept to continuous monitors, it is labeled only for episodic glucose monitoring and it does not indicate glucose trends.

Real-time continuous glucose monitoring

A number of real-time continuous glucose monitoring (RT-CGM) devices are currently available, including the Medtronic Guardian® REAL-time CGM System and the Dexcom G4 Platinum. The components of a typical CGM system are shown in Figure 30.2, and consist of a subcutaneous sensor that contains the glucose detection chemistry, a receiver that analyzes and displays results, and a transmitter that sends data from the sensor to the receiver. These devices have a transcutaneous glucose oxidase-based electrochemical sensor that measures glucose every 1 min, smooths the data, and displays the glucose concentration in the interstitial fluid every 5 min. Data can be downloaded into a graphical display, as shown in Figure 30.3. There can be a lag between the time a blood glucose level rises or falls and the time when the new concentration is recognized on the CGM. The lag is composed of three components: a physiological lag affected by blood flow to the skin, a sensor reaction time lag for data acquisition, and a sensor processing lag time for signal processing and data smoothing. The total lag can be as short as 5 min or as long as 15 min if the glucose levels are changing rapidly. Because of accuracy limitations [15, 16], the current generation of CGM devices do not have regulatory approval for use as stand-alone devices, and users are required to perform adjunctive capillary blood glucose measurements; however, this limitation is compensated by the additional detailed information provided by the CGM about glucose patterns, the rate and direction of change in the glucose level, and adjustable alarms that are triggered by both hyper- and hypoglycemia (Figure 30.4) [17].

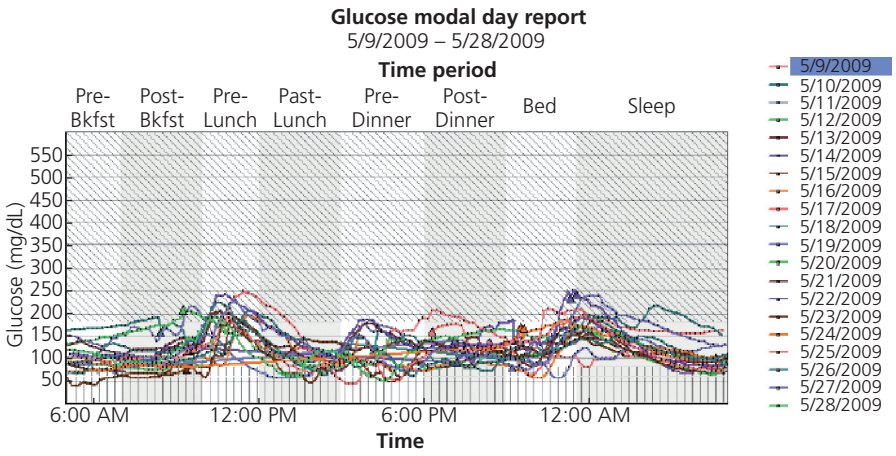

Figure 30.3 Modal day report from an individual who eats breakfast at 9:00 a.m. and supper at 10:00 p.m. daily. It indicates a rapid spike in glucose levels post-meal that had not been detected with intermittent fingerstick blood glucose monitoring. Treatment recommendations focused on changing to more slowly absorbed lower glycemic index carbohydrates (e.g. oatmeal) and/or injection of bolus insulin earlier before the meal.

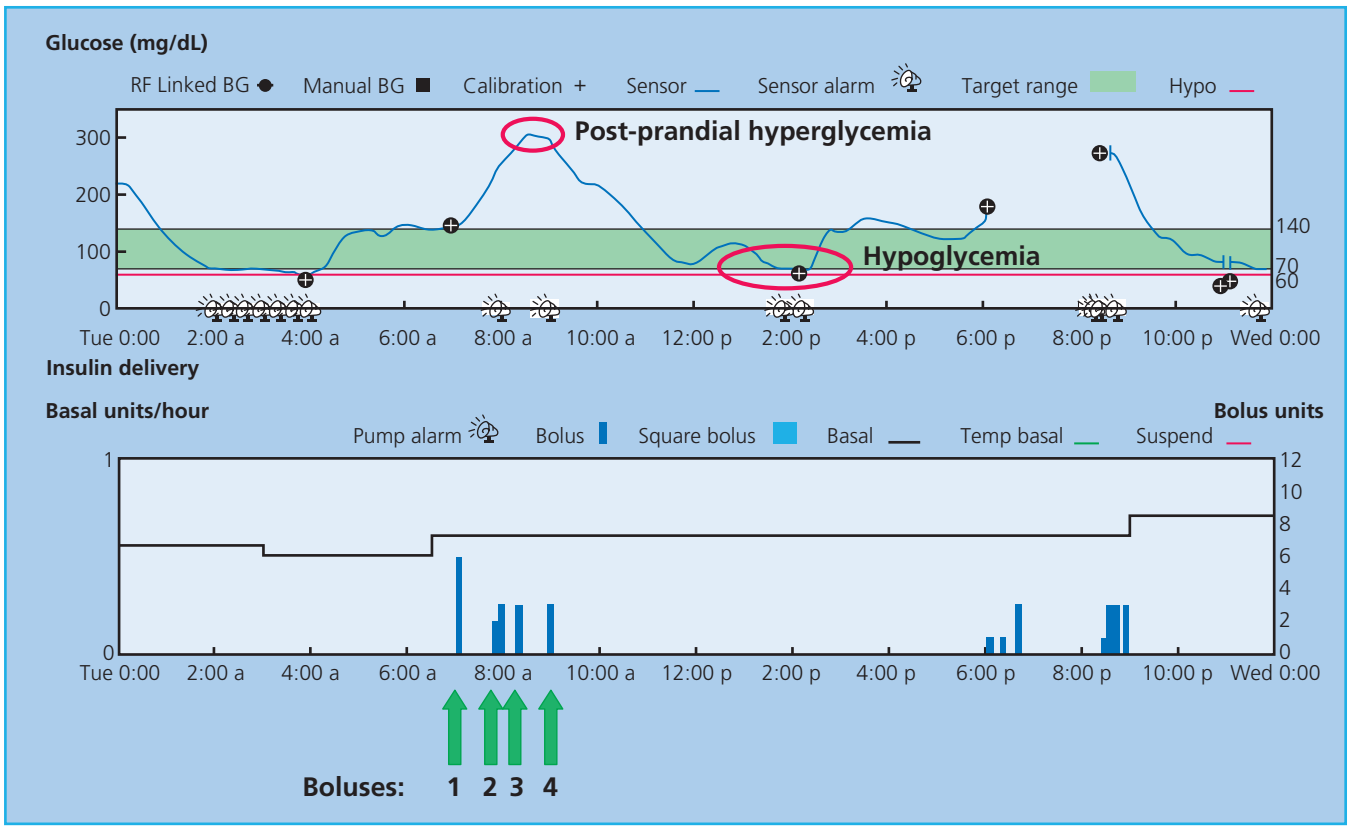

Figure 30.4 Device download: the top panel shows continuous glucose tracing and the bottom panel insulin delivery (each blue bar represents an insulin bolus with units of insulin shown on the vertical axis on the right). Following breakfast, the glucose level increased to 300 mg/dL (16.7 mmol/L), prompting the individual to take multiple boluses with resultant hypoglycemia. The display shows the times when the device produced an alarm to indicate hypo- or hyperglycemia. RF, radio frequency.

Clinical efficacy of RT-CGM

Many randomized controlled trials have been performed to evaluate the clinical benefits of CGM. The initial reported studies, the durations of which were only a few days, showed that the use of RT-CGM leads to a reduction in both hyper- and hypoglycemic excursions with more time in the target glucose range [18, 19]. The GuardControl trial using the Medtronic Guardian was the first longer duration study of RT-CGM. This study enrolled 156 adults and children with T1DM using both pumps and MDI therapy [20]. At 3-month follow-up, the group randomized to RT-CGM use showed a 1.0 ± 1.1% (11 ± 12 mmol/mol) reduction in HbA_{1c} (down from 9.5 ± 1.1% [80 ± 12 mmol/mol] at baseline) compared with a 0.4 ± 1.0% (5 ± 11 mmol/mol) reduction in the control group ($p = 0.003$). In addition, at 3 months, 50% of participants in the CGM group had HbA_{1c} reductions of ≥1% compared with 15% of those in the control group, and 26% in the CGM group had HbA_{1c} reductions of ≥2% compared with 4% in the control arm. Reported results from this industry-supported study did not include any specific information on the treatment protocols used in the trial or data on the effect of CGM on hypoglycemia.

The results of two large-scale multicenter randomized controlled trials of 6 months' duration have been published: the industry-supported STAR-1 trial and the Juvenile Diabetes Research Foundation (JDRF)-sponsored CGM trial. The STAR-1 trial enrolled 146 participants aged 12–72 years with T1DM treated with CSII pumps [21] who were randomized to pump therapy with RT-CGM using the Medtronic 722 pump system or pump therapy with fingerstick self-monitoring of blood glucose. The primary endpoint was not achieved; there was a similar reduction in HbA_{1c} (0.71 ± 0.71% in the sensor group vs. 0.56 ± 0.072% in the control group; p = non-significant) over the 6-month trial. Importantly, in those using RT-CGM, the improvement in glycemic control was accomplished without any change in biochemical hypoglycemia ($p < 0.0002$), whereas in the control group who were using fingerstick glucose monitoring there was an increase in biochemical hypoglycemia (documented with blinded CGM devices). More severe hypoglycemic events occurred in the group using RT-CGM than in the control group (11 vs. 4; $p = 0.04$). During six of the 11 severe events in the RT-CGM group, the individuals were not using a sensor. The Data Safety Monitoring Board determined that in the remaining five severe hypoglycemic events there was evidence of the following:

1 failure of the individuals to respond to alarm warnings of hypoglycemia;

2 multiple insulin boluses without use of the pump bolus calculator, resulting in dose stacking; or

3 "blind boluses" (i.e. treatment decision based on sensor readings showing hyperglycemia without confirmatory fingerstick capillary blood glucose measurements).

This clinical experience from the Star 1 trial was incorporated into the treatment protocols and patient education materials used in the JDRF CGM trial.

The JDRF CGM trial enrolled 451 people with T1DM aged 8–74 years and HbA_{1c} <10% (86 mmol/mol) to an RT-CGM group or a group that continued with capillary blood glucose monitoring [22, 23]. This study involved people using both insulin pumps and injection therapy and used three different CGM devices (Abbott Navigator®, Dexcom Seven®, and Medtronic Guardian/722®), with assignment based on patient preference with investigator guidance. By design, the cohorts with HbA_{1c} at randomization of <7.0% (<53 mmol/mol; $n = 129$) and 7–10% (53–80 mmol/mol; $n = 322$) were analyzed separately.

For individuals with T1DM who have already managed to achieve HbA_{1c} levels in the optimal target range with intermittent capillary blood glucose monitoring, the main therapeutic challenge is minimizing the risk for hypoglycemia that accompanies intensive glucose control. Accordingly, for the cohort enrolled in this trial with baseline HbA_{1c} <7.0% (<53 mmol/mol), the prespecified primary endpoints were focused on changes in hypoglycemia rather than HbA_{1c} per se. At 26 weeks, biochemical hypoglycemia ≤3.9 mmol/L (70 mg/dL) was less frequent in the CGM group than in the control group using intermittent fingerstick monitoring (median 54 vs. 91 min/day), but this was not statistically significant. The median time spent with glucose level ≤3.3 mmol/L (60 mg/dL) was 18 vs. 15 min/day, respectively ($p = 0.05$). There were similar numbers of severe hypoglycemic events in the two groups; however, the trial was not adequately powered to detect a treatment group difference. More people in the CGM group than the control group had a decrease in HbA_{1c} of ≥0.3% without having a severe hypoglycemic event (28% vs. 5%; $p < 0.01$) [24].

For the cohort with baseline HbA_{1c} 7–10% (53–86 mmol/mol), the prespecified primary endpoint was HbA_{1c} reduction. A significant between-group difference in change in HbA_{1c} from baseline to 26 weeks was seen in those aged ≥25 years old, favoring the continuous monitoring group (mean difference in change –0.53%; $p < 0.001$), but not in the younger participants. Biochemical hypoglycemia evaluated by CGM was similar in the two treatment groups and there were no significant differences in the incidence of severe hypoglycemic events between the study groups. In the adult cohort, the frequency of the combined outcome of 26-week HbA_{1c} <7.0% (<53 mmol/mol) and no severe hypoglycemic events was 30% in the CGM group and 7% in the control group ($p = 0.0006$). A follow-up 6-month extension to this study in 83 adults showed, after 12 months, a reduction of HbA_{1c} of –0.4%. The incidence of severe hypoglycemia, in events per 100 person-years, dropped from 21.8 to 7.1 [25]. The finding that RT-CGM leads to an improvement in glycemic control without an associated worsening in hypoglycemic events is in direct contrast to other intervention studies such as the DCCT, in which intermittent capillary glucose monitoring had been used to guide intensification of metabolic control, and points to the promise hat this technology offers for people with T1DM.

The American Diabetes Association, in its clinical guidelines, concluded that CGM in conjunction with intensive insulin therapy is a useful tool to lower HbA_{1c} in selected adults aged ≥25 years with T1DM (level of evidence A: clear evidence from randomized clinical trials), that it may be helpful in younger adults, teenagers, and children, depending on adherence with the device (level of evidence C: supportive evidence from poorly controlled or uncontrolled trials), and that it may be a supplemental tool to SMBG in those with hypoglycemia unawareness and/or frequent episodes of hypoglycemia (level of evidence E: expert opinion or clinical consensus) [26].

Practical issues with the use of RT-CGM

The randomized controlled trials that have demonstrated the benefits of RT-CGM have involved individuals with a high level of engagement in their diabetes self-care (the mean number of daily capillary blood glucose measurements performed by people enrolling in the JDRF trial was six). Furthermore, to use this technology successfully, individuals need to have advanced diabetes self-management. In the following sections, we discuss several key issues that need to be addressed in the training of people starting on CGM.

Physiological lag between blood and interstitial glucose

The lag in the equilibration of glucose levels between the capillary blood (measured using a home blood glucose monitoring device) and the interstitial fluid in the subcutaneous tissue (measured by the CGM device) [27, 28] has important practical implications. In general, increases or decreases in the glucose concentration will first be apparent in the blood followed by the interstitial fluid. Currently available CGM devices are calibrated using fingerstick capillary blood glucose measurements, and to optimize sensor accuracy it is important that the device be calibrated only when the glucose level is relatively stable, and there is steady-state equilibration between glucose concentrations in the blood and interstitial fluid. In practice, calibrations should be performed preprandially or at least 3 h after a bolus (Box 30.1). Each manufacturer's instructions should be consulted to determine the timing and frequency of calibration for a specific CGM device.

The physiological lag has implications with regard to the detection and treatment of hypoglycemia. Because of the lag of interstitial glucose behind blood glucose, when the glucose level is declining the interstitial (sensor) glucose can be in the normal range even though the actual blood glucose is low [29]. Users should be instructed to perform a fingerstick blood glucose measurement before driving if the sensor glucose reading is normal and the trend graph or rate-of-change arrows on the sensor display indicate that the glucose level is declining (Box 30.2). As shown in

Box 30.1 Patient teaching points: calibration dos and don'ts.

- *Do* follow the manufacturer's instructions regarding the time and frequency of calibration to achieve the greatest possible accuracy.
- *Do* use only very recent blood glucose measurements for calibration.
- *Do not* calibrate when the blood glucose is changing at a significant rate, as indicated by trend arrows on the display. Some times when rapid blood glucose change may occur include:
  - within 3–4 h of a meal or an insulin bolus
  - during exercise
  - after recovering from hypoglycemia.

Box 30.2 Patient teaching points: circumstances where fingerstick capillary glucose must be checked.

- If the sensor indicates that the glucose is elevated, the reading must first be confirmed with a fingerstick capillary blood glucose measurement before the person takes a corrective bolus.
- When subjective symptoms are not in keeping with the sensor reading, such as a low CGM reading in the absence of hypoglycemic symptoms, a fingerstick reading should be taken to confirm the glucose level.
- Before or during driving, if the sensor reading is normal and the continuous glucose monitoring rate of change indicator or tracing indicates that the glucose level is falling, the person must measure fingerstick blood glucose.
- Following treatment of a low glucose level, if the sensor still shows a low reading, the person should check fingerstick blood glucose and use this measurement to decide whether to take in more carbohydrate. Reliance on the sensor reading to assess response can lead to overtreatment.

the study by Wilson et al. [30], when the glucose is falling rapidly, the physiological lag can also lead to underestimation of the true rate of fall of the blood glucose by the rate-of-change indicator of the CGM device. The practical implication is that if the person feels hypoglycemic or has reason to suspect that the glucose is declining, but this is not corroborated by the sensor, they should disregard the sensor data and carry out a fingerstick glucose measurement.

This lag phenomena also has practical implications for the treatment of hypoglycemia. During the recovery from hypoglycemia, the increase in the interstitial glucose will often lag behind the blood glucose [31], and when blood glucose has already normalized the sensor/interstitial glucose may still be in the low range. Individuals should be informed of the need to perform fingerstick glucose measurements to assess the response to treatment of hypoglycemia accurately. Those who rely on the RT-CGM to judge whether the glucose level is improving following ingestion of carbohydrates may mistakenly assume that they need to consume more glucose than necessary.

Setting glucose alarms

The alarms for hypoglycemia and hyperglycemia are an important feature of RT-CGM devices. There are trade-offs in the adjustment of alarm thresholds, and settings need to be individualized based on specific clinical considerations [32]. If the alarm thresholds are set at target or ideal glucose levels (e.g. low = 5 mmol/L [90 mg/dL]; high = 10 mmol/L [180 mg/dL]), there will be increased sensitivity for the detection of high and low glucose; however, the frequent false alarms can be a source of irritation and disrupt sleep, leading to "alarm fatigue" in some individuals, with a related tendency to ignore the alarms. There is also a risk of people sleeping through alarms. Buckingham et al. [33] found that people who were videotaped while sleeping awoke to only 29% of individual alarms and 66% of repeated alarms.

The adjustment of alarm thresholds is a stepwise process:

1 deciding on initial thresholds when initiating use of the sensor;
2 optimizing alarm thresholds over time based on retrospective review of continuous glucose tracings.

For persons with hypoglycemia unawareness or a history of severe hypoglycemic reactions, where the overriding imperative is on reducing hypoglycemia, the low glucose alarm threshold should be set at 4.5 mmol/L (80 mg/dL) or higher. Because of the physiological lag between blood and interstitial glucose, when the sensor alarm is triggered the blood glucose level will often be lower than the sensor measurement.

For individuals without a history of problematic hypoglycemia, it is a common practice to set the initial glucose thresholds at 3–3.5 mmol/L (55–60 mg/dL) and ≥14 mmol/L (250 mg/dL). This ensures that during the initial period after starting the use of CGM, while the individual is mastering the use of the technology, there will be fewer intrusive and irritating alarms, and less risk for alarm burnout. Over time, as the patient uses the information from the sensor to reduce glucose excursions, the alarm settings can be brought closer to target glucose levels, and this can assist with further tightening of glycemic control. A snooze alarm prevents the CGM from sounding continuously for a prolonged episode. Typically, this alarm will be set for 15–30 min for hypoglycemic events and for 2–3 h for hyperglycemic events (which take longer to resolve than hypoglycemic events). In some CGMs, a predictive alarm can be set to sound when the glucose level is predicted to reach a preset threshold. During follow-up visits, the clinician should enquire whether the sensor alarm alerted the individual to low or markedly elevated glucose levels, and whether they were troubled by frequent false alarms. If there are frequent high glucose levels (especially during the overnight period) and the person is not being appropriately alerted by the sensor to take

corrective action, the high alarm threshold should be reduced. Conversely, if the individual has experienced hypoglycemic reactions without being alerted by the CGM alarm, the low alarm threshold will need to be set at a higher level.

Risk for hypoglycemia from excessive postprandial bolusing

Although the glucose alarms and trend indicators on CGM devices can be helpful in minimizing hypoglycemia, some individuals will overreact to the postprandial glucose spikes revealed by the continuous sensor by taking excessive doses of insulin [34], leading to an increased risk for hypoglycemia. Minimizing this tendency for postprandial overbolusing (known as stacking—not considering remaining insulin from prior injections) should be a major focus in the training of the individual using CGM. People need to factor in the amount of residual insulin on board from the previous bolus before taking additional insulin to treat postprandial hyperglycemia. "Insulin-on-board" (IOB) calculators to help in this determination are available on insulin pumps (discussed later in this chapter) and for non-pump users bolus calculators that include an IOB estimation are being developed both as a feature of a glucose monitor or as a mobile app. In 2014, the Roche ACCU-CHEK® Aviva Expert system became the first and only freestanding blood glucose meter system with a built-in insulin bolus calculator to be approved by the FDA.

Continuous subcutaneous insulin infusion pumps

Continuous subcutaneous insulin infusion (CSII) pumps were first introduced almost 40 years ago [35, 36]. They consist of an insulin reservoir and a delivery catheter that infuses insulin continuously into the subcutaneous tissue. In recent years, there has been growing adoption of this technology in diabetes care. Several factors have contributed to this increased use, including the focus on intensive therapy triggered by the Diabetes Control and Complications Trial (DCCT), improvements in the reliability and usability of pumps, patient preferences, and also the growing recognition by clinicians that CSII delivery is associated with reduced risk for hypoglycemia. Recent literature has pointed out the potential advantages of pumps as a tool for insulin administration and newer developments in pump technology such as bolus calculator software and square-wave delivery have made these devices easier to use.

Glycemic control with insulin pumps compared with multiple daily insulin injections

Several published meta-analyses have examined the role of CSII pumps as a tool for intensifying glycemic control [37–39]. These meta-analyses of the randomized controlled trials in the published literature indicate that CSII use in people with T1DM is associated with 0.4–0.5% (5–6 mmol/mol) lower HbA_{1c} than for multiple daily injection (MDI) therapy. The improvements in HbA_{1c} with the change to pump therapy appear to be greater in individuals who have poorer glycemic control [40, 41]. Most of the studies examined in these meta-analyses involved MDI regimens using neutral protamine Hagedorn (NPH) or ultralente insulins; however, more recent randomized controlled trials suggest that CSII is also superior to MDI regimens using the newer long-acting insulin analogs insulin glargine and insulin aspart [42, 43].

Although CSII has been studied primarily in T1DM, a recent study in individuals with T2DM who did not achieve adequate glycemic control on MDI compared participants randomized to either MDI using analog insulin or MDI, and found that mean HbA_{1c} declined by 1.1% in the CSII group and by 0.4% in the MDI group ($p < 0.0001$). The mean total insulin dose was 97 units on CSII and 122 units on MDI, with no significant difference in weight change in the two groups [44]. Two adverse events requiring hospitalization occurred in the CSII group: hyperglycemia and ketosis without acidosis. One episode of severe hypoglycemia occurred in the MDI group and none in the CSII group. Device malfunction and problems with either the infusion set or the infusion site may occur with modern pump technology, which points to the importance of providing education on proper catheter site care and ketoacidosis prevention to all individuals using pumps. In addition, a small-scale crossover study in obese individuals with T2DM and insulin resistance also demonstrated a significant reduction in HbA_{1c} and postprandial glucose excursion with the use of pump therapy [45]. On the other hand, the studies by Raskin et al. [46] and Herman et al. [47] showed similar HbA_{1c} changes with both modes of insulin delivery.

Because of the more controlled delivery of insulin, CSII can be an effective tool for reducing glycemic variability, and this can be of benefit for reducing the risk for hypoglycemia brought about by insulin replacement therapy [48]. Clinical guidelines from several national and international organizations recommend consideration of pump therapy for individuals with T1DM with suboptimal glycemic control and problematic hypoglycemia, as summarized in Box 30.3 [25, 49, 50]. Although earlier studies gave conflicting results, the meta-analysis of randomized controlled trials by Pickup and Sutton [51], which was restricted to studies published since 1995 (i.e. since the introduction of more reliable pump technology) with a baseline (pretrial) rate of severe hypoglycemia of >10 episodes per 100 patient-years and ≥6 months of CSII use, showed that there was a 2.9-fold (95% confidence interval [CI] 1.45–5.76) reduction in severe hypoglycemia during CSII compared with MDI. The analysis also indicated that the benefit from pump therapy was greater in individuals with higher rates of severe hypoglycemia ($p < 0.001$) and those with longer duration of diabetes ($p = 0.025$). A meta-analysis commissioned by the Endocrine Society reached different findings, and concluded that in comparison with MDI, CSII was not associated with a significant reduction in severe or nocturnal hypoglycemia [52]. The validity of these conclusions is limited by the inclusion of studies of relatively short duration with low incidence rates of severe hypoglycemia that would be underpowered to detect any significant decrease in the incidence

of hypoglycemia and would therefore bias against recognition of benefit from insulin pump therapy. In addition, the rates of minor and nocturnal hypoglycemia were determined using intermittent fingerstick glucose monitoring, which can be unreliable in detecting nocturnal hypoglycemic events [53] and would therefore be relatively insensitive to detecting treatment-related differences. Furthermore, it should also be noted that the studies examined in the Endocrine Society analysis were performed using almost entirely older pump types that did not incorporate the bolus calculator software now available in updated pumps, which can help to limit hypoglycemia related to doses stacking up from repeated boluses. These factors limit the generalizability of the conclusions from this analysis to clinical practice. The weight of evidence from published studies suggests that clinicians caring for motivated individuals with T1DM with recurrent hypoglycemia and especially a history of severe hypoglycemic reactions should recommend a trial of insulin pump therapy. The STAR 3 study in children and adolescents demonstrated that sensor-augmented pump therapy improved HbA_{1c} and glucose area under the curve with no increased risk of hypoglycemia compared with MDI therapy [54]. An interesting ancillary finding in the STAR 3 study was that improving overnight and post-breakfast glucose levels had the greatest effect on lowering HbA_{1c} levels [55].

Box 30.3 Pump therapy: indications and considerations.

- Severe hypoglycemia and hypoglycemia unawareness.
- HbA_{1c} above goal.
  Caution: Intentional insulin omission (to facilitate weight loss) is a not uncommon cause of poorly controlled diabetes, especially in young women [56]. Before initiating pump therapy, it is important to rule out this problem. Because these individuals habitually underdose insulin and are frequently hyperglycemic, they do not routinely troubleshoot for insulin non-delivery by the pump and can therefore be at increased risk for developing ketoacidosis.
- Diurnal variations in basal insulin requirements caused by the dawn phenomenon [57] and steroid therapy [58] have been reported to be more readily managed using the multiple basal rates provided by the pump than by long-acting injected insulins. However, Bouchonville et al. reported that people who programmed their pump to counteract the dawn phenomenon did not reduce the dawn phenomenon and also had more frequent hypoglycemia [59]. A potential reason for the failure to improve therapy with programming, the authors proposed, was the unpredictable occurrence of the dawn phenomenon. Continuous subcutaneous insulin infusion can be of special benefit for the person with diabetes post-renal transplant on steroid therapy who is striving for intensive glycemic control.
- Preconception and pregnancy.

Box 30.3 (*Continued*)

- Practical advantages of pumps for bolus insulin delivery include:
  - *Dosing precision:* The extra precision of insulin dosing with pumps can be an important advantage for young children (especially infants and neonates) [60] and adults who are on very low insulin doses. In addition, accurate dosing of insulin boluses in fractions of a unit allows the patient to correct hyperglycemia more precisely without overshooting and causing hypoglycemia. For those patients in whom fear of hypoglycemia is an impediment to tight glycemic control, this added assurance can be critical in overcoming reluctance to intensification. In practice, it can be helpful to reduce missed food boluses, facilitate interprandial "correction" bolusing, and help simplify eating at restaurants and social occasions (with the use of extended/square-wave boluses and multiple bolusing).
  - *Optimizing postprandial insulin coverage:* Facilitates dosing for higher fat, complex carbohydrate, and/or larger meals. Dietary fat delays gastric emptying [61] and induces postprandial insulin resistance [62], so high-fat meals cannot usually be adequately covered using a single injection of rapid-acting insulin [63]. Use of the extended/dual bolus [64] and increased temporary basal can help optimize postprandial glycemic control following these meals [65].
  - *Gastroparesis:* Use of the extended/dual-wave bolus can allow for better matching of carbohydrate absorption and insulin action.

When people are unable to achieve adequate glycemic control, several practical issues should be considered (Box 30.4). A number of publications, oriented to both people with diabetes and health-care providers, can provide detailed strategies [66, 67].

Box 30.4 Practical issues to consider in people on pump therapy with erratic glucose control.

- *Infusion site issues including scarring, hyperpigmentation, lipohypertrophy, and lipoatrophy:* Infusion sites should be routinely examined in pump users with unexplained glucose fluctuations.
- *Infusion catheter kinking or dislodgement:* Plastic catheters may kink or become dislodged, especially with activity or perspiration. Solutions include changing to sets with a shorter cannula, or other types of plastic infusion sets that are less prone to kinking, and sets that insert obliquely.
- *Failure to change the pump reservoir and infusion system on a regular basis:* This may manifest in a tendency for

Box 30.4 (*Continued*)

elevated and erratic glucose in the period preceding infusion set changes.

- *Review of pump downloads can be helpful:*
  - Check priming history to assess how frequently the infusion system is being changed.
  - Check bolus history to detect possible missed meal boluses.
  - Check percentage of basal to bolus insulin. A high percentage of basal insulin in the person with frequent hyperglycemia may indicate that bolus doses are frequently being missed. A high percentage of basal insulin in the person with frequent hypoglycemia may indicate that high basal rates are contributing to hypoglycemia, and would point to a need to re-evaluate basal rate settings. A low percentage of basal insulin can result in high preprandial glucose levels followed by large correction doses at mealtime followed by occasional resultant postprandial hypoglycemia.
  - Check for a history of pump suspension or basal rate reduction. Even temporary removal of the pump to bathe can lead to elevations in the glucose levels; people need to be reminded to bolus to replace the missed basal when reconnecting the pump. Some individuals using the pump will get into the practice of reducing the basal rate or suspending the pump when they are hypoglycemic; the end result will often be exaggerated rebound hyperglycemia
- *Insulin instability in the pump infusion system:* This can manifest as increases in the glucose levels in the period preceding infusion set changes or even precipitation in the infusion system [68].
- *Pump malfunction.*
- *Air bubbles in the infusion system* resulting from poor filling technique.
- Temperature of pump and insulin exceeds the storage range recommended by the manufacturer of each short-acting insulin, which is no lower than 36 °F and no higher than 75–86 °F, depending on the product.

Quality of life benefits and patient expectations

Many people describe improvements in quality of life when they change to pump therapy [69]; however, there have been few carefully designed studies that have examined patient perspectives of pump therapy and differences in psychosocial functioning with CSII compared with MDI. People will vary in their perceptions about the potential quality of life benefits (including increased lifestyle flexibility, dietary freedom, and reduced fear for hypoglycemia) relative to some of the potential drawbacks of CSII (including body image concerns and the need for frequent blood glucose monitoring) [70]. Wolpert and co-workers conducted a focus group investigation of 30 people followed at the Joslin Diabetes Center to examine how psychosocial factors impacted the use of the pump [71]. Those with better glycemic control viewed the pump as a tool for diabetes self-management rather than as a panacea. In contrast, individuals on pump therapy with poorer HbA_{1c} had more unrealistic expectations, including the perception that the use of technology was a substitute for attentiveness to self-care and that pump therapy allowed them to do whatever they wanted, particularly with regard to eating. Before initiating pump therapy, healthcare professionals need to assess patients' expectations of the pump, dispel unrealistic notions (often promoted by marketing materials) and ensure that they recognize that although the pump allows life with diabetes to be more flexible and convenient, it is not a vehicle for total freedom from diabetes.

Bolus calculators and insulin-on-board

Software programs that assist people with bolus calculations have been incorporated into insulin pumps. The insulin : carbohydrate ratio (the number of grams of carbohydrate covered by 1 unit of insulin) and correction/sensitivity factor (a measure of the glucose-lowering effect of 1 unit of insulin) is programmed into the pump software. Based on planned carbohydrate intake of the pump user and the blood glucose level, the bolus calculator will recommend a bolus dose. Although this dose calculation software can simplify the daily self-care routines of the pump users, patients should receive appropriate education to ensure that they can manually calculate bolus doses in the event that they need to discontinue pump therapy. In addition, it is important that the programming of the bolus calculator software is adjusted to individual needs and not left automatically at the manufacturer's default settings. These bolus calculators have an important role in minimizing the risk for hypoglycemia from multiple boluses that result in cumulative dose stacking, which are a common practical problem for some pump users. When calculating an insulin dose, the pump software will consider the amount of active insulin-on-board resulting from earlier boluses (commonly referred to as IOB) and subtract this IOB from the recommended dose. This IOB calculation is based on insulin action plots that predict the amount of insulin remaining as a function of time; the assumed insulin duration of action used by the software in this calculation is individually programmed by the person with diabetes or healthcare professional, and can be varied depending on the pump type [72]. In practice, the major consideration in setting the insulin duration of action in the bolus calculator software is usually a best guess based on a clinical assessment of the hypoglycemia risk of the individual and the imperative for achieving tight glycemic control (in particular, preconception and pregnancy) [73]. For those with frequent hypoglycemia, hypoglycemia unawareness, or a history of severe hypoglycemic reactions, the duration of action may be set longer, whereas for the woman who is pregnant or trying to conceive, a shorter duration of action is often set. The glucose records of the individual can be assessed to determine if the duration of action settings are appropriate. If the duration of action time programmed into the software is less than the true duration of action,

the pump will indicate that there is less IOB than is actually the case, and the pump user will mistakenly take more insulin than required; the glucose records will show evidence of hypoglycemia from "stacking" of doses. Conversely, if the setting programmed into the pump is longer than the true duration of insulin action, this can lead to underdosing of insulin and hinder attempts to optimize glycemic control.

Patch pumps

Although insulin pumps have become significantly smaller since they were first introduced, they are still relatively bulky and, owing to their electronic sophistication, relatively expensive. Several companies are now working on various types of "patch pumps," devices that have a low, flat profile that fit snugly against the body. They generally do not have the ability to deliver multiple basal rates or preprogrammed boluses. Primarily intended for use in T2DM, various configurations of patch pumps may deliver only basal insulin at a prefixed rate, insulin boluses in fixed increments when manually activated by the user, or both basal and bolus insulin. Their simpler structure allows for a less expensive device. Clinical studies are ongoing to determine the clinical benefits of such systems.

Closed-loop insulin delivery: the artificial pancreas

Insulin pump therapy as it is currently used is considered to be an "open-loop system," in which the person with diabetes must make decisions about when to check the glucose level and what to do with the information. Clearly, there is inherent human error in this system and overdosing or underdosing of insulin based on a small miscalculation could result in subsequent hypoglycemic or hyperglycemic episodes, respectively. In a "closed-loop system" that integrates a continuous glucose monitor and insulin pump, together with an automated algorithm to control insulin delivery, the person with diabetes would be removed from the decision loop, and the system would essentially function as an artificial pancreas.

At present, one of the major challenges for the fully automated closed-loop system may be in the development of a fail-safe algorithm that is capable of "interpreting" a person's metabolic state based on data obtained from the continuous glucose monitor and then relaying this information to the pump for automatic insulin delivery of the appropriate dose of insulin. Several algorithms, including model predictive control and proportional integral derivative control, are already being evaluated in both *in vivo* and *in silico* settings [74]. There are also several technical obstacles to developing a closed-loop system, including having glucose sensors that are both accurate and reliable (e.g. minimal calibration drift, limited potential mechanisms for sensor failure), and also physiological lag, which can be particularly problematic during times of rapid rates of change in blood glucose levels (e.g. during meals or exercise) [75]. Hence the development of a sensor with a short lag time would also be important.

Because of the amount of research that must be done to establish the effectiveness, and especially the safety, of a fully closed-loop system, intermediate steps have been suggested [76]. An initial approach is a system that will automatically discontinue insulin administration if the glucose sensor detects a level below a preset value, or if the glucose trend predicts that a low glucose is likely. Such a type of sensor-augmented pump therapy with low glucose threshold suspend has been shown to lead to a 38% reduction in nocturnal hypoglycemic events without increasing glycated hemoglobin values [77]. The first closed-loop product with any automatic control of insulin is the Medtronic (Northridge, CA, USA) low glucose suspend sensor augmented pump, known as 530G with Enlite in the United States and Veo in Europe. Predictive algorithms have also been shown to reduce the incidence of hypoglycemia during exercise in preliminary studies [78]

A second step in the development of an artificial pancreas is the control to range (CTR) approach. A CTR system reduces the likelihood of a hypoglycemic event or a hyperglycemic event (when blood glucose is dangerously high) by adjusting insulin dosing only if a person's glucose level approaches the low or high glucose thresholds. People using this system will still need to check blood glucose levels and give themselves insulin to maintain control of glucose levels. The final stage would be a control to target (CTT) system. A CTT system sets target glucose levels and tries to achieve these levels at all times. This system is fully automated and requires no interaction from the user except for calibration of the continuous glucose monitoring system [76]. A CTT system could be based on an insulin-only approach, a bihormonal approach (using one hormone to lower glucose and another to raise it), or a hybrid approach that allows the individual to supplement insulin automatically before a meal [76].

A small study of a CTR system using a fully automated closed-loop single-hormone system demonstrated that during the study period, which included unannounced meals and exercise, 80% of values could be maintained between 70 and 180 mg/dL and there were no values below 60 mg/dL [79]. Weinzimer et al. compared a fully closed-loop (FCL) insulin-only system with a hybrid closed-loop (HCL) system in which the individual could manually give a premeal priming bolus. Mean glucose levels were 135 ± 45 mg/dL in the HCL group versus 141 ± 55 mg/dL in the FCL group ($p = 0.09$), and daytime glucose levels averaged 149 ± 47 mg/dL in the HCL group versus 159 ± 59 mg/dL in the FCL group ($p = 0.03$). Peak postprandial glucose levels averaged 194 ± 47 mg/dL in the HCL group versus 226 ± 51 mg/dL in the FCL group ($p = 0.04$). Nighttime control was similar in both groups (111 ± 27 vs. 112 ± 28 mg/dL) [80]. A multicenter study using a CTR algorithm demonstrated that the mean percentage of values in the 71–180 mg/dL range was 66%. The system fared better overnight than during the day and had difficulty preventing postprandial excursions above the target range. Performance was variable between participants even after individualization [81].

Haidar et al. studied a bihormonal artificial pancreas, using insulin and glucagon, and compared it with an insulin-only artificial pancreas and with conventional insulin pump therapy (CSII) in a randomized crossover study [82]. They found that both single and dual hormonal therapy provided better glycemic control than conventional CSII. The mean proportional time in the glucose target range was 62% with single hormonal therapy, 63% with dual hormone therapy, and 51% for CSII. Both closed-loop systems were statistically improved over CSII. There were 52 hypoglycemic events with conventional insulin pump therapy (12 of which were symptomatic), 13 with the single-hormone artificial pancreas (five of which were symptomatic), and nine with the dual-hormone artificial pancreas (none of which were symptomatic); the number of nocturnal hypoglycemic events was 13 (0 symptomatic), 0, and 0, respectively. A bihormonal fully automatic closed-loop system was also studied by Russell et al. [83]. Their "bionic" pancreas consisted of a glucose sensor and two infusion pumps, with an algorithm on a mobile phone wirelessly controlling the pumps. Over a 5-day unrestricted outpatient period, the "bionic" pancreas improved mean glucose levels, with less frequent hypoglycemic episodes, compared with conventional insulin pump therapy.

Insulin pens

The insulin pump frees people with diabetes from the need to draw up insulin accurately from an insulin vial prior to each injection. This eliminates a potential source of patient error in insulin therapy, but adds a new level of complexity in filling and priming the pump. For those who do not require the flexibility of basal-bolus therapy that a pump offers, the insulin pen offers a way to inject insulin conveniently and accurately without the need to carry an insulin vial and individually draw up each dose. A pen may be a prefilled disposable device or may use a replaceable insulin cartridge, and includes a mechanism for delivering a specified number of units. Compared with a syringe and insulin vial, pens have been shown to be more accurate, particularly at doses less than 5 units [84], and to lead to increased patient satisfaction [85]. Studies in hospitalized patients have also shown that nurses felt that pens were easier to use and led to increased dosing confidence [86] and greater patient and provider satisfaction, improved safety, and reduced costs. [87] Newer pens, such as the NovoPen Echo®, HumaPen®, LUXURA® HD, and JuniorSTAR® can deliver in half-unit increments. Some pens also have a memory to review dosing.

Inhaled insulin

Survey studies have indicated that fear of needles and discomfort and inconvenience from injecting insulin are barriers to the use of insulin by many. The lung is an attractive mode for administration of a systemic drug because of its large available area for drug absorption and accessibility. A number of approaches to inhaled insulin have been tried. In January 2006, the FDA approved the use of Exubera® (Pfizer), the first inhalable insulin, but this was later withdrawn from the market for commercial reasons.

Afrezza® (insulin human) Inhalation Powder, developed by MannKind Corporation, was approved by the FDA in 2014. It is based on Technosphere® technology in which insulin particles are optimized for inhalation (2.5 μm in diameter) and dissolve rapidly after inhalation (pH-sensitive carrier particles). Pharmacokinetic studies have demonstrated that this formulation has very rapid systemic insulin uptake (insulin T_{max} ≈12–14 min), a fast onset of action (maximum activity ~20–30 min), and a short duration of action (~2–3 h) [88], which could potentially provide better postprandial control than subcutaneously injected insulin [89].
