There are several designs of copper-releasing IUDs, and the most common is the Copper T IUD, which releases copper through corrosion over the course of 12 years. The copper particles act to cause a sterile inflammation of the endometrial lining, thus prohibiting contraception. In the many copper-releasing IUDs, the copper wire thickness varies from 0.2 to 0.4 mm with a surface area of exposed copper that varies correspondingly from 200 to 380 mm^2. The corrosion is time dependent and exhibits a linear release pattern, with release directly proportional to the surface area of exposed copper. An exposed area of 375 mm^2 releases 37.5 μg/day of copper and an exposed area of 250 mm^2 releases 25 μg/day (26). Examples of copper-releasing IUDs include the Copper T 380A developed by the Population Council, the polyethylene Nova-T (Cu T Ag 200) developed by Leiras and Outokumpo Oy, Finland, and the polyethylene Multiload developed by Multilan, Switzerland, which is available in several sizes to accommodate different body types (26).

The current version of the Copper T IUD is the ParaGard® T 380A intrauterine copper contraceptive, and has 380 mm^2 of exposed copper wire surface area. It is marketed in the U.S. by Ortho-McNeil Pharmaceutical (27). The IUD is comprised of a polyethylene T, with 176 mg of copper wire on the stem of the device and an additional 66.5 mg of copper wire on the arms. The IUD has a monofilament polyethylene thread attached at the tip of the T to aid in retrieval. In 1994, the FDA approved this device for 10 years of contraceptive use. Its original design was intended for a shorter time frame but recent clinical analysis has shown its contraceptive effect to extend to 10 years. The copper-releasing Copper T 380 Ag IUD manufactured by Leiras is similar to the Copper T 380A, but differs in that the copper wire has a silver core. The silver wire acts to slow the rate of corrosion and fragmentation of the copper. Ortho Pharmaceuticals of Canada markets Gyne T 380 Slimline, a device similar to the original Copper T device. It differs in its structural design; the side arms of the Slimline IUD are designed to fit into the inserter tube more easily for easier administration (19).

There are several marketed IUDs releasing steroid available today. All of the progestin-releasing IUDs produce a local sterile inflammation in the endometrial cavity much like other IUDs. However, the steroid-releasing IUDs do not rely on endometrial inflammation to achieve contraception but instead depend on the effect of the steroid delivered. The only one manufactured in the U.S. is the Progestasert IUD, illustrated in Figure 2 (28). Progestasert releases progesterone and has been marketed in the U.S. since 1976. It was the first contraceptive device to use the natural hormone progesterone, and is currently the only IUD marketed in the U.S. that delivers a steroid (28). The device has solid poly(ethylene vinyl acetate) (EVA) side arms and a hollow core. The microcrystalline progesterone steroid is suspended in the core in medical grade silicone oil along with barium sulfate (for radiopaque properties). The drug reservoir is encased by the EVA (9% w/w vinyl acetate) copolymer membrane. The EVA membrane is 0.25 mm thick and has a surface area of 2 cm^2. Release is governed by diffusion through this rate-limiting membrane. Progestasert is loaded with 38 mg of progesterone and releases at a rate of 65 μg/day over the course of 1 year (28). Release begins at 70 μg/day and decreases over the course of 1 year to 55 μg/day, at which point 60% of the loaded drug has been released (26). The device was originally designed for use as a 1-year contraceptive agent, but testing has shown the same level of efficacy for 18 months. The pregnancy rate at this time is reported as 1.8/100 for parous women and 2.5/100 for nulliparous women (28), whereas the pregnancy rate at 2 years of use is dramatically higher at 7.4/100 (29). Progestasert does not achieve its contraceptive effect by inhibiting ovulation, but instead prevents implantation in the endometrium by suppressing the normal cyclic changes of the endometrium lining as well as thickening cervical mucus (20,29). Progesterone released from the IUD is completely metabolized in the uterine wall and does not reach systemic circulation (29). Ovulation is not inhibited with the Progestasert device. The advantages of Progestasert over other nonsteroidal IUDs is its increased effectiveness, decrease in menstrual blood loss, and decreased dysmenorrhea. Disadvantages include its need to be replaced on a yearly basis, intermenstrual bleeding and spotting, and the possibility of increased ectopic pregnancies (24,29,30).

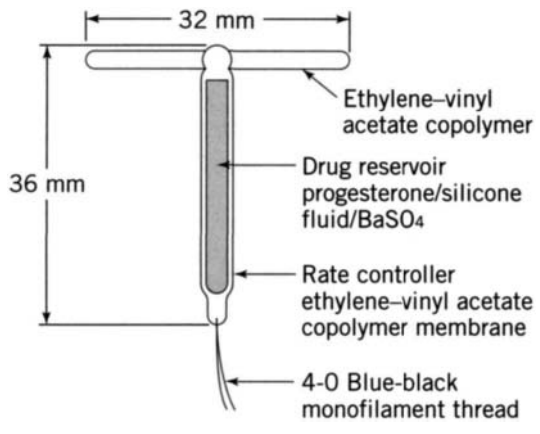

Figure 2. Progestasert IUD. *Source:* ALZA Pharmaceuticals, from Ref. 28.

Other medicated IUDs use the more potent synthetic steroids to achieve contraception. The LNG Nova-T IUD has a polyethylene stem and side arms. The stem is covered by a matrix consisting of Silastic and LNG (2:1 weight ratio) covered with a nonmedicated Silastic membrane. It is designed to release LNG at a rate of 20 μg/day for 5 years. Early designs of this system had a stem outer diameter of 2.5 mm, which consisted of a thinned vertical stem of polyethylene (0.9-mm diameter) encased in the drug-loaded matrix and covered with Silastic tubing (0.41-mm thick) (31). In vivo release rates show an initial release of 24 μg/day, decreasing to 16 μg/day at the end of 2 years. By the end of the fifth year, 60% of the loaded drug is released (26). The synthetic steroid is released into the uterus much like the progesterone released by Progestasert, but avoids complete degradation and is systemically absorbed. The hormone acts to suppress the endometrium as well as inhibit ovulation (26).

Vaginal Contraceptive Film®. The Vaginal Contraceptive Film (VCF®) is a small, thin, semitransparent square composed of 28% nonoxynol 9 in a base of poly(vinyl alcohol) and glycerin. It is a 2-inch by 2-inch square film that is 50 μm thick (32). VCF is the same device as C-Film, marketed in Great Britain since the mid-1970s. VCF contains a total of 70 mg of nonoxynol-9, delivering an average of 56–73 mg of drug (33). Nonoxynol-9 is a nonionic detergent that acts as a spermicide by creating a chemical barrier to spermatozoa in the vagina and disrupting the lipid membrane of the sperm (34). VCF is intended to be placed in the vagina against the cervix and dissolves into a gel upon contact with the vagina, in the time course of 15 minutes to 1 hour. The film and its contents are completely washed away by vaginal and cervical mucus discharge (35). It has a 96% efficacy rate and is an effective spermicide for up to 1 hour, although preliminary studies indicate that a large enough dose to inhibit spermatozoa (0.100 mg/mL) remains in the vagina for up to 4 hours (34). VCF has been available in

the United States since 1986 and is marketed by Apothecus Pharmaceutical Corporation (36).

Precommercial and Preclinical Products. There are many types of contraceptive devices in the design and preclinical stages. Development of new synthetic steroids has led to development of optimal systems, and current regulations require extensive testing of these systems prior to clinical use. This section describes the current formulations still in the research phase.

Vaginal Rings. Development of contraceptive vaginal rings (CVRs) began in the late 1960s and early 1970s. Both the Population Council and the WHO have promoted research of this promising device. Although there are several designs of vaginal rings, the main features are essentially the same. The rings are donut-shaped with an outer diameter of 50–58 mm. They release either a progestin or a combination of progestin and estrogen. The progestin-only rings typically are designed to remain in place for the entire duration of action (normally 3 months), whereas the combined progestin–estrogen delivery system is removed every fourth week to simulate menstrual bleeding. When compared with oral tablets, vaginal rings deliver a lower dosage of hormones to achieve the same contraceptive effect. The rings are simple to self-administer and remove, produce little or no local irritation, provide a near zero-order sustained release of steroid, and the treatment can be ceased at any time to provide a reversible contraceptive effect. The rings are held in place by the vaginal muscles, and it is not necessary to fit the CVR to each user or to position the CVR in a certain place in the vagina. The rings can be removed for 3 hours without decreasing the efficacy of the device (9,37,38).

The mechanism of release is very similar among the many CVR designs. Steroids delivered vaginally are absorbed across the vaginal epithelium directly into the systemic bloodstream without any metabolic alteration in the digestive tract, in specific, within the liver. The release kinetics of the vaginal rings optimize the efficacy of the steroid while minimizing its required loading, aspects that benefit the user by decreasing common side effects of hormone therapy. Vaginal rings are an optimal delivery system for natural progesterone, which is a safe contraceptive for lactating women because it is not harmful to infants but cannot be administered orally because it is metabolized too quickly (39,40). The main disadvantage of the vaginal ring containing progestin only is irregular bleeding; vaginal rings with a combined estrogen and progestin result in better bleeding patterns.

The vaginal rings are made of Silastic and loaded with a steroid. Several different designs releasing both natural progesterone and several varieties of synthetic progestins with or without an estrogen component have been designed (Table 2). The intent of the many designs is to optimize the type of steroid and its daily dosage in a form that minimizes the side effects while still maintaining the contraceptive efficacy of the system. The main mechanism of drug release is diffusion. Diffusion depends on concentration gradients, where one element diffuses from an area of high concentration to an area of low concentration. Silastic is known to be one of the most easily diffused polymers, and lipophilic compounds, such as progesterone, are soluble in and diffuse at a high rate through a solid matrix of Silastic 382 (7,12). There are two types of diffusion controlled polymeric release systems, reservoir and matrix. It is also possible to have a combination of both types in one system, such as in some designs for the vaginal rings.

The best tolerated vaginal rings in clinical studies have an outer diameter of 50–58 mm and a thickness of 7–9.5 mm (41). There are four types of CVR that have been developed to date. The initial design consisted of a homogenous matrix of drug-loaded elastomer. The solid matrix of drug-loaded polymer was not encased within a rate-limiting membrane. Steroid diffused both through the polymer matrix and through pores left by released drug. There was a high burst effect with this design and a rapid decline in release due to depletion of the drug from the outer regions of the matrix, and subsequent testing was abandoned (38,42). Another design is the band design, in which a band of drug-loaded collagen is placed in a groove on the outer surface of a solid ring of polysiloxane (38). The two main types of ring design that have shown reliable and effective release rates over the course of 3 to 6 months are the core and shell designs. In the core design, a 3.5 mm homogenous core of drug-loaded PDMS is covered with a 5 mm layer of nonmedicated polysiloxane (38,42). The shell ring, depicted in Figure 3, is a design in which an inner layer of solid elastomer provides support, the middle layer is a matrix of polymer and drug, and the outer layer is a thin rate-limiting membrane of Silastic (38,40,42,43).

In the core ring, the matrix is in the form of an inner core of polymer loaded with steroid, and the reservoir boundary is an outer layer of pure polymer, generally Silastic. The outermost layer of progesterone in the matrix core diffuses away and leaves pores or channels for the remaining progestin to diffuse out. Because each molecule must still diffuse out of the unloaded outer layer of pure Silastic, the outer membrane maintains constant release rates. It was determined that the core ring device releases drug according to the diffusion model, which can be described by the equation

$$Q = KCDt/h \qquad (2)$$

where Q is the amount of drug released, t is the time, K is the partition coefficient of drug between the polymeric device and surrounding fluid, D is the diffusion coefficient of the drug in the polymer, and h is the thickness of the hydrodynamic diffusion layer (12). After several weeks, the rings deviate from their expected release profile. This is due to a depletion zone that is created as the outermost layer of steroid in the matrix is diffused away, increasing the diffusion distance for the remaining steroid (12). The release of progesterone from core-loaded vaginal rings made of Silastic 382 show an inverse dependence on diffusion distance. This is characteristic of membrane-controlled drug delivery. Release rates can be varied with parameter changes of the inner core to yield high, medium, or low loading depending on the core diameter (12). The natural progesterone is more soluble in Silastic than its synthetic counterpart LNG, and tends to diffuse faster through the membrane than through the inner core, which

Table 2. Designs of Contraceptive Vaginal Rings

Design type	Progestin (or spermicide)	Estrogen	Length of use	Outer layer	Middle layer	Inner layer	Developer/ Manufacturer	Refs.
Homogenous	Progesterone 20 mg/day	None	90 days	PDMS and 22.5% w/w steroid	None	None	WHO/Dow Corning, Population Council	(12,40,42)
Core	LNG 20–25 μg/day	None	90 days	PDMS	None	5 mg LNG and PDMS	WHO	(26,38)
Core	Progesterone 15 mg/day	None	—	PDMS	None	PDMS with 20% w/w progesterone	—	(16,42)

accounts for the decreased release rate over time (42). After insertion, peak plasma levels of LNG from a core CVR design were detected within 1–8 hours, reaching 200% of their constant-release level. Release then becomes fairly constant after the initial burst but decreases by 23% to 26% over the course of 90 days (26). The factors governing release are the dissolution of the drug within the drug-loaded layer, diffusion of the drug through the rate-limiting Silastic membrane, and dissolution of the steroid within the body fluids.

Core ring designs are also being evaluated by Olsson and Odlind for the release of 3-keto desogestrel and ethinylestradiol in clinical trials (44). The core ring for delivery of two steroids is designed a bit differently; the ring is made of two Silastic tubes connected by glass stoppers. The outer diameter of the ring is 6 cm and the cross-sectional diameter is 4.9 mm. This type of CVR was developed by Organon International (Oss, The Netherlands). The rings have a daily release rate of 150 μg 3-keto desogestrel and 15 μg ethinylestradiol. The rings maintain their contraceptive efficacy for three consecutive cycles of 21 days each, with a removal period of 7 days in between cycles. Upon removal, the rings should be rinsed in water and stored in a dry location. Preliminary trials with these two-compartment rings indicate their usefulness as a contraceptive device, but also demonstrate that not all women find the CVR a comfortable means of birth control as there was some discomfort associated with use of the rings as well as some irregular bleeding patterns.

The shell rings are the most successful CVR design (38). The steroid is kept close to the rate-limiting outer Silastic membrane, acting to decrease the diffusion distance from within the matrix to the membrane. The release in these systems is governed by the outer layer of pure polymer, and release is more constant than the core ring design due to the near constant diffusion distance within the drug-loaded matrix. If the outer membrane is doubled in thickness, the release is decreased by one-half, indicating that the outer shell is the rate-limiting membrane (42). The shell CVR device provides a fairly constant diffusion distance due to the narrow inner drug-loaded polymer matrix, which is surrounded by a nonmedicated polymer membrane. The outer membrane is the rate-limiting device, and a thin enclosed ring of drug-loaded polymer provides a near-constant diffusion distance to the outer limiting membrane. These two aspects work together to provide the shell device with fairly constant release kinetics.

The manufacture of the early shell rings was a three-step injection molding process done by hand. With the increase in promising clinical trials, a new technique has emerged that produces uniform shell rings with decreased cost. In the new manufacturing process, a rod of Silastic is coated with a drug-polymer layer. After this first layer has cured, an additional layer of pure polymer is applied. The rod is then cut into sections and formed into a ring with a band of polymer to secure it (42).

Vaginal rings have also been explored for use in delivering spermicides. Vaginal rings of ethylene–vinyl acetate copolymer (EVAc) loaded with 33% of the spermicide nonoxynol-9 and covered with Silastic have been shown to release the agent over 30 days (45). This device can be used intermittently or continuously for a total of 30 days. Additionally, vaginal rings are being investigated as a delivery vehicle for the spermicide RS-37367, tested in macaque monkeys (46). This spermicide is more potent than nonoxynol-9, and has been shown in primates to be effective even when the ring is removed immediately prior to coitus. The RS-37367-containing vaginal rings are 2.3 cm in outer diameter, 1.5 cm in inner diameter, and approximately 0.4 cm in cross section. They are a homogenous matrix of 1.37% w/w drug with Silastic, formed by the injection molding technique described earlier. The devices were tested for up to 8 days in vivo.

There was some initial concern about infection with use of the CVR as it is a foreign device that is removed from and replaced into a body cavity. In 2-year studies, there was no increased incidence of vaginal infection with use of the CVRs, although there was a noted increase in vaginal secretions (38). No cervical changes were noted over this time course either.

The CVR appears to be a very promising delivery vehicle for contraceptive steroids. It is easy to use, requires minimal supervision, maintains constant serum levels of steroid, and there is minimal user requirement (once-a-month insertion). Further testing is needed, however, to optimize drug loading and provide additional safety data.

Implantable Devices. A single implanted rod of nonbiodegradable EVAc similar to Norplant is being developed by Organon to deliver ST-1435, which is 3-keto desogestrel, the main metabolite of desogestrel. The device is called Implanon® (47). One 4-cm rod releases approximately 25 μg/day of steroid for 2 years (3,16,24,48). Due to the potency of the progestin used in this system, less drug than LNG is needed to achieve contraceptive efficacy (minimum serum concentrations of 0.09 mg/dL), and the system has reportedly fewer side effects than systems using LNG (3). Implanon consists of a drug-loaded EVAc matrix core surrounded by a rate-limiting EVAc membrane, with final dimensions of 40 mm in length and 2 mm in diameter. Testing with this contraceptive device has been performed in beagle dogs, and clinical studies have been performed in women. Implanon is manufactured in a coaxial-melt-extrusion process. The steroid is in micronized form, and 68.3 mg of steroid are contained in each rod.

The Nestorone® implant is a single-rod implant, much like the Norplant implants. It is a 4-cm-long device, 2.5 mm in diameter, that contains a core matrix of Nestorone progestin, which is a potent 19-norprogesterone derivative

(ST-1435) that is inactive when delivered orally and Silastic in a 2:1 weight ratio. Much like Norplant and Implanon, Nestorone is a constant, slow release device, and was designed to improve the insertion and removal problems encountered with Norplant (3,4,49,50). Nestorone contains 78 mg of synthetic steroid and is implanted in the ventral aspect of the upper left arm. Nestorone is advantageous because it is a potent steroid that inhibits ovulation but is not effective when delivered via the oral route. Thus, it is safe contraceptive agent for lactating women, as the steroid does not affect breastfeeding infants. The Population Council is developing this device, designed for 2 years of contraceptive efficacy. The device consists of a core of polymer-steroid, covered in a rate-limiting cellulose membrane, then encased within Silastic tubing. The ends of the rod are sealed with Silastic tape. Phase II clinical testing has demonstrated the effective release to be 45–50 μg/day (4).

Another single-rod implant under development is called Uniplant (3,4). This rod contains 38 mg of the progestin nomegestrol acetate, and preliminary clinical trials demonstrate a daily release rate of 75 μg/day. The single capsule is 3.5 cm long and is designed for 1 year of contraceptive efficacy.

Other types of devices still in the clinical development stages are the biodegradable systems. With biodegradable systems, a concern is the amount of time the degraded device remains in the body after release of drug is complete. The longer a device remains in situ after drug delivery, the greater the potential for tissue injury (51). The most common mechanisms of drug delivery through implantable devices is diffusion, biodegradation due to hydrolysis of chemical bonds within the polymer chain or backbone, or a combination of both. The implantable biodegradable systems consist of polyesters, poly(ortho esters) and poly(acyrlic acids). By-products of degradation from these polymers are nontoxic and induce little to no adverse reaction at their location within the body. An additional requirement of biodegradable contraceptive systems is the need to retain structural integrity throughout the length of time of drug delivery in case removal is necessary (3).

Capronor is a system using poly(ϵ-caprolactone) (PCL), which is of the polyester class, and was reported to be clinical testing (9) but no current data could be found regarding present development of this device. The biodegradable polymer is semicrystalline and rigid, and is able to withstand gamma irradiation for sterilization purposes. It is permeable to lipophilic steroids, such as LNG. The contraceptive device consists of a hollow capsule of PCL, which encases about 16 mg of LNG and 61 mg of ethyl oleate as a suspending vehicle. Capronor is 2.4 mm in diameter and 2.5–4 cm in length depending on the amount of drug to be encapsulated (12 or 21.6 mg LNG), with heat-sealed ends (8,26). Release rates of this device are about 45 μg/day, and release is governed by diffusion as the polymer degradation rate is relatively slow (18–24 months) (9). This release is approximately 10 times faster than release of LNG from the Silastic Norplant system (3,8,52). The device is intended to be placed subcutaneously in the ischial area for drug release up to one year (20,53,54). The ester bonds of PCL undergo hydrolytic degradation, which occurs throughout the bulk of the material and is independent of geometry. PCL degrades first to ϵ-hydroxycaproic acid, and then to H_2O and CO_2. The contraceptive is a reservoir-type device in which the drug is encased within a polymer wall. The wall must be thick enough to limit the release of the drug and prevent the smaller drug particles from diffusing out of the device rapidly, leaving the larger particles behind. With a wall of appropriate thickness, the device can approximate zero-order release. Release is modulated with excipients placed in the crystalline steroid region (3,8). The suspending medium for the drug acts to keep the drug in constant contact with the capsule wall, allowing for dissolution of the drug through the wall. The polymer wall degrades slowly via hydrolysis, and there is a long induction period between the time the ester linkages are cleaved and the molecular weight of the material drops off. This allows the polymer wall sufficient time to act as the limiting membrane for diffusion of the drug (53). Studies of the degradation of an implanted device show the half-life for molecular weight to be 10.6 months, as determined by intrinsic viscosity in toluene. The crystallinity over this time frame increased from 46.8 to 60.0%, which is indicative of the structural integrity of the system. Clinical studies of steroid release from Capronor were done on two systems, one comprised of a single 2.5-cm device and the other of a 4.0-cm device. In the trials with the 4.0-cm device, 80% of menstrual cycles showed suppressed ovulation, whereas all cycles with the 2.5-cm device were ovulatory. Thus, the 4.0-cm device is the optimal contraceptive system. It delivers an average of 33 μg/day over the course of one year, with release decreasing with time (3,8). One of the disadvantages of the Capronor system is the possible rupture of the device once it is implanted. Breakage of the PCL membrane would allow the remaining load of steroid to be released as a bolus (55).

Another type of bioerodible system investigated in the 1980s (no data could be found regarding current studies) is the poly(ortho ester) rod device in which the hydrolysis rates are pH dependent (56–58). The cross-linked poly(ortho ester) matrix is formed at room temperature in a reaction that is nearly instantaneous. The cylindrical devices tested in vitro and in vivo in rabbit models are in the form of molded capsules of 2.4 mm in diameter and 20 mm in length, where the drug is suspended within a polymer matrix. In vitro release rates averaged 20 μg/day, whereas the in vivo release was significantly higher at 33 μg/day. The release of LNG is governed in part by surface erosion of the device, but mainly by solubility of the steroid. The polymer hydrolyzes faster than the drug is solubilized, creating a foamed drug layer around the implant, a layer that also contains relatively insoluble degradation products. The in vitro release appears lower due to the aqueous environment used as the sink, whereas the in vivo release is higher due in part to lipophilic carriers within the body that act to solubilize the drug and the degradation products more quickly. As the osmotic pressure and polymer erosion increase, the matrix is weakened and eventually ruptures, leaving an open cell. The open cells gradually increase the surface area and drug release is accelerated. Slightly acidic salts with low water solubility are incorporated into the matrix to control the swelling. Another way

in which the swelling is controlled is by incorporating an acidic monomer in the polymerization process. The fact that the polymer erodes faster than the drug is solubilized obviates the need for this device; a pellet of solid steroid would achieve similar release. Therefore, the poly(ortho ester) devices are still in the developmental stages.

Rice-sized norethindrone pellets fused with cholesterol are another biodegradable contraceptive system (24,26). The ellipsoidal pellets are composed of 85–90% steroid and 10–15% cholesterol, with each pellet containing about 35 mg of drug. Two to four pellets are implanted subdermally in the upper arm. Release is dependent upon surface area of the pellets, with reported release rates of 110 or 210 μ grams per day, to provide contraceptive efficacy for up to 12 months. Release is dependent solely upon solubility of the steroid in this type of device. It is possible to remove the pellets before they biodegrade, but there is a time limit within which removal can be accomplished. The pellets degrade completely within 24 months. Primary results show the four-pellet system to be most effective, but studies are still underway to determine the number of pellets needed, their size, and the cholesterol–hormone ratio (3).

Hollow fibers made of poly(L-lactic acid) (PLA) have been investigated in rabbits for release of LNG (59). The hollow fibers are manufactured with dry-wet phase inversion spinning technology and form the rate-limiting barrier for a solution of micronized steroid in castor oil. The polymer is extruded through a spinneret into a nonsolvent bath to form a porous membrane. Porosity of the fiber (and thus steroid permeability through the membrane) is greatly affected by the parameters of the solvent-nonsolvent system and process conditions (26). The steroid solution is loaded into the hollow fiber in a series of steps. First, the ends of the hollow fiber are heat sealed with Silastic. The steroid solution is then injected into the fiber through the Silastic end, and finally, the device is heat-sealed at the desired length and the silicone ends are discarded. The PLA hollow fiber is a reservoir device and provides a zero-order release of LNG. Release of steroid is governed by the dimensions of the hollow fiber (length, thickness, porosity, etc.), with the ideal release falling between 0.1 and 10 μg/cm/day for 210 days. PLA provides a useful vehicle for steroid delivery. It is biodegradable but has a low rate of degradation and also has a low permeability for steroids. These factors act to make the hollow fiber device ideal for long-term administration of low doses of steroid and obviate the need for surgical removal. The devices can be administered in a simple injection and have the advantage over other injectable contraceptives in that they can be removed if desired. The dimensions of the device are a maximum length of 3 cm and maximum diameter of 1.5 mm. Experimental data showed release in rabbits at an average of 2 μg/cm/day. The hollow fibers can be sterilized with γ radiation.

PLA has also been investigated for use in a contraceptive delivery device composed of a block copolymer of PLA and PCL. Release from the block copolymer of PCL:PLA is controlled more easily than release from the random copolymer system (55). Ye and Chien (55) describe several devices made from the block copolymer of PCL:PLA. One system is a disc laminate system and the other is a cylinder system for subdermal implantation. Both systems release a combination of LNG and estradiol (E_2). The copolymer in each system is prepared by sequence polymerization in dry toluene at 90°C in the presence of an AL/Zn bimetallic alkoxide catalyst. Release studies of the disc and cylinder systems were conducted in vitro in Valia-Chen permeation cells.

Initially there were two disc systems, one made by solvent casting and another made by compression molding. The solvent cast system exhibited faster release than the compression-molded system due to the channels formed when the solvent evaporated. Additionally, release was also different on each side of the solvent cast film, with release from the side in contact with air slower than release from the side of the film in contact with the casting surface. For these reasons, the solvent cast film system was abandoned. The disc system made by compression molding consisted of combining two matrix systems. The outer matrix system was in contact with the release medium and consisted of the block copolymer loaded with LNG, whereas the inner matrix was loaded with ethinyl estradiol (E_2). The intent of this design was to slow the release of E_2 from the combined system, as E_2 has faster release kinetics than LNG. The investigators found release of LNG from the outer disc to be matrix diffusion controlled, linear with Q vs. $t^{1/2}$. The inner matrix release was found to be quite different, controlled instead by a membrane barrier and linear with Q vs. t. The barrier membrane for release of E_2 from the inner matrix is the outer matrix of block copolymer loaded with LNG. Release from both components of the disc system was found to increase with PCL content of the block copolymer. As the weight fraction of PCL was increased from 0.6 to 0.9, release of LNG increased from 2.7 to 37.5 $\mu g/cm^2/h^{1/2}$ and release of E_2 increased from 9.3 to 32.9 $\mu g/cm^2/h$ per unit thickness of the device. The increase in release with an increasing PCL content is attributed to an overall increase in free volume of the system. Matrix thickness was also investigated for its effect on release, and it was found to affect only release of E_2 from the inner matrix. LNG release was not affected. E_2 release decreased as the outer membrane thickness increased, and the permeation rate was found to be inversely proportional in a linear manner with the outer membrane thickness. An increase in loading of LNG in the outer matrix increased release of LNG but did not affect release of E_2 from the inner matrix (55).

The second type of PCL:PLA block copolymer system investigated by Ye and Chien was a cylinder of the block copolymer. PCL:PLA loaded with both LNG and E_2 was extruded through Teflon tubing (inner diameter 1.6 mm). The device was cut to 0.5 cm in length and coated by dipping into a polymer solution containing 20% LNG (w/w). Various copolymer ratios and drug loadings were evaluated, and all exhibited the typical burst effect with steady release thereafter. A system made with a single coat of LNG-polymer exhibited zero-order release, whereas systems made with additional coats had decreased release rates. LNG release was found to be dependent upon the core loading, the number of external coats, and the loading of each coat, as well as the thickness of the outer coats.

Release of E_2 from the core was dependent upon the core loading and the thickness of the outer coating layers (55).

In both systems described by Ye and Chien, release of LNG and E_2 can be controlled by modulating the parameters of the system, allowing an optimal drug delivery device to be developed for the purpose of contraception. Further research is needed, however, to identify the optimal design and determine in vivo release rates of both LNG and E_2.

Injectable Devices. The advantages of an injectable contraceptive microsphere delivery system are the ease of administration via single injection, biodegradation of the polymer device, low release of steroid with minimal loading, and long duration of release. The disadvantages of any microsphere delivery system are its relative irretrievability after administration (9,60). Microspheres made of poly(DL-lactide-*co*-glycolide) (PLGA) 85:15 exhibit zero-order release over a 3-month period (61–63). The norethindrone–PLGA microspheres are manufactured in a solvent evaporation process. Clinical trials with PLGA spheres loaded with 47% norethindrone (a synthetic progestin) have been conducted in the attempt to optimize the dosage. A release of 100 mg/day appears adequate. The injection is administered with a 21-gauge needle. Serum levels of the progestin are 2 ng/mL, about 15–30 times lower than serum levels for Depo-Provera. The system approximates zero-order, with steadier release of the drug at a concentration low enough to minimize side effects while still maintaining efficacy.

The PLGA-steroid microspheres are a matrix device from which release occurs in two phases. The first phase of release is through diffusion. This occurs for about 2 months, with an initial burst and gradual decline in the amount of drug released. At the end of 2 months, the PLGA spheres begin to degrade, and the drug release gradually increases and peaks as trapped drug particles are made available for diffusion. At the 3-month mark there is very little drug left to maintain adequacy as a contraceptive (26,62).

The principle of norethindrone release from PLGA spheres can also be applied to the release of other steroids, such as norgestimate, another synthetic progestin (64). This system, which was evaluated by Hahn et al. in the 1980s (no current data could be found), has a 20–70 weight % loading, depending on need. These solvent-evaporation particles appear as a "free flowing powder" and encapsulation efficiency is 81.8–91.2%. As the spheres release drug via diffusion, the rate of release can be controlled by geometry as well as crystallinity and molecular weight of the polymer. Generally, a more crystalline polymer releases drug more slowly (due to a decrease in diffusion of the drug through the polymer matrix and increased degradation time of the polymer). A higher molecular weight polymer also tends to decrease the release rate. However, smaller spheres increase the release rate due to the increased surface area available for diffusion of drug. There is also a membrane thickness effect, where higher loading increases the release rate due to smaller effective membrane thickness, reducing the area over which diffusion must take place. In vivo testing on the PLGA–norgestimate microspheres, as well as PLA–steroid microspheres, has been conducted in rats and baboons to determine the optimal loading and dosage necessary for contraceptive efficacy.

PLGA is also the delivery vehicle of choice for administration of natural progesterone in microsphere form. The PLGA-progesterone system was developed by Biotek, Inc., in conjunction with CONRAD. The microspheres released progesterone over a 90-day period in vitro and was further tested in vivo in 77 rabbits. However, the FDA is questioning the use of solvents in the manufacturing process for the PLGA microsphere formulation, and thus testing has been suspended (65).

Sterility is also important in any injectable system. PLGA microspheres can be sterilized via γ irradiation, although this does cause a slight increase in the release rate. Storage is also a major concern for marketability, and the PLGA systems can be stored for up to 12 months in a cool, dry location.

PLGA has also been used as the delivery vehicle for luteinizing hormone-releasing hormone (LH-RH) analog (66,67). The LH-RH analog is a profertility agent when administered in pulsatile manner, but has a contraceptive effect when administered continuously. LH-RH has poor oral bioavailability, so the PLGA system greatly increases its potential as a contraceptive agent. The LH-RH analog is hydrophilic, as opposed to the lipophilic nature of the other steroids commonly used for contraception, and has a rather low diffusivity through PDMS, thus the choice of PLGA as the delivery vehicle (67). Spheres of PLGA and LH-RH analog have shown continuous release for over 40 days in rats. Disks made of the same materials have shown continuous release longer than the microspheres. PLGA was chosen over PLA due to its faster degradation rate of 6 months versus 12 months (66). It is not desired for the spheres to remain in the body much longer than the 3-month release time.

Another contraceptive system, designed by Nuwayser et al., employs PLA to coat steroids (68). The polymer-coated steroid systems are manufactured via air-suspension coating. The thickness of the polymer wall can be adjusted so as to control the diffusion of the drug and hence control the release characteristics of the system. The coated devices are similar to reservoir devices, and release is controlled by geometry, membrane permeability to the drug, and the thermodynamics of the encapsulated steroid. Increasing the thickness of the polymer wall decreases the release rate, and decreasing the capsule size while maintaining the same wall thickness also decreases the release rate. In order to administer these spheres via injection with a 15–22 gauge needle, the particle size must be kept below 500 μm. With the air suspension coating, the wall thickness can easily be controlled as the coating is applied incrementally. The devices under investigation have a high core-to-polymer ratio (on the order of 90:10). Using a high molecular weight PLA also ensures that the drug is released through diffusion before the polymer begins to degrade. The air-suspension-coated devices were tested in rabbits using an intramuscular injection as the route of administration. The release was mainly zero-order with a slight initial burst, and constant release of 2 μg/day/mg spheres continued for over 200 days.

One disadvantage with the PLGA microspheres is their rapid degradation when compared with other polymers, such as PCL. Research has been conducted into developing a zero-order release system that is composed of microspheres made of PLA-PLGA-PCL block copolymers (60,69). The copolymer microspheres are manufactured via solvent evaporation, and zero-order release is obtained with a balance of the ratio of PCL to PLA or PLGA. It was found that microspheres made of 60–65% PCL blocks exhibit zero-order release for approximately 5 months. The release of steroid (LNG) from the PCL blocks is controlled by diffusion because the PCL polymer degrades slowly. Steroid release from the PLA-PLGA block is controlled by erosion due to the faster degradation of these polymers. Thus, the combined system produces a long-acting device in which the release is balanced between the quick zero-order release from PLA-PLGA and the first-order release from PCL, yielding a constant release of drug for an extended length of time.

Another type of injectable contraceptive system uses a natural hydrogel. In vitro work using chitosan as the delivery vehicle began in 1991 (70). Chitosan is a polysaccharide that is hydrophilic, bioabsorbable, and nontoxic. Bioabsorption is due to lysosomal enzymes digesting the partially acetylated chitin derivatives of the chitosan polymer. The chitosan systems investigated are in the form of beads and films. The films are prepared by mixing the steroid and polymer in a solvent and evaporating the solvent, whereas the beads were prepared by a solvent removal technique using compressed air. Chitosan is a good vehicle for release of drugs because it is biocompatible, easy to control, and hydrophilic. The chitosan films showed first-order release due to the large surface area over which swelling occurs rapidly and uniformly. The beads showed zero-order release due to the swelling front, which begins at the outer core and gradually advances to the center of the bead as the pores open up. The drug is released as the matrix swells.

Transdermal Devices. Transdermal delivery is useful when a small amount of drug is needed to accomplish the desired medical purpose. This type of system is beneficial for steroid delivery because the drugs are very potent at low dosages. The main obstacle in steroid delivery is the low permeability of the skin to many compounds. Factors to be considered in transdermal delivery are drug and formulation stability, irritability of the skin, storage properties of the device, and cosmetic appearance (71). Transdermal delivery of steroids is currently being used in estrogen replacement therapy (10,72). In order to use this system for contraceptive purposes, the release rate of drug must be carefully optimized. Transdermal systems are reservoir-type devices that deliver drugs via diffusion. Release is controlled by the membrane through which the drug permeates, the diffusional resistance of the skin, and the thermodynamic activity of the drug (which affects its interaction with the delivery device) (71). Permeation enhancers are often incorporated within the reservoir to alter the drug's thermodynamic activity or the skin permeability.

One type of patch designed for contraceptive use is 4.91 cm^2, made with an impermeable backing of clear polyester film coated with heat-sealable polyethylene, and is being investigated by Friend et al. (72). The reservoir of the device is filled with 6.4 mg of LNG suspended in a hydroxypropyl cellulose and ethyl acetate/ethanol mixture. The membrane of the device is EVAc, adhering to the skin via a silicone-based adhesive. An optimal delivery of 30–35 μg/day of LNG is desired. For the steroid to penetrate the somewhat impermeable barrier of skin, a penetration enhancer must be incorporated into the design of the system. The penetration enhancer that functions most efficiently with a transdermal patch comprised of an EVA membrane is a mixture of ethyl acetate and ethanol. The devices are designed to be worn for 24 hours, and in vivo tests in rabbits indicate that this system may be suitable for contraceptive use in humans. Other transdermal patches are being developed for weekly use, where the user wears three medicated patches over the course of three consecutive weeks and a placebo patch during the fourth week to simulate menstruation through withdrawal bleeding (71).

Experiments delivering a combination of progestin and estrogen transdermally have also been conducted (73). Delivery of LNG and estradiol through a transdermal delivery system with an EVA membrane and ethanol as the permeation enhancer provide promising results. Experiments were performed in vitro on rat and human cadaver skin. It was found that release of steroids was controlled by a variety of factors, namely the composition of the reservoir formulation, the weight fraction of vinyl acetate in the EVA membrane, the membrane thickness, and the loading of steroid. It was also determined that the limiting factor in this system is the polymeric membrane and not the skin.

Intrauterine Devices. Intrauterine devices that release progestins are currently being used in the United States, such as Progestasert. Other IUDs were developed for 3-year use, such as the Intrauterine Progesterone Contraceptive System (IPCS) developed by Alza Corporation. The main difference between the Progestasert and the IPCS is the increased drug loading in the IPCS, which holds 52 mg of progesterone instead of 38 mg. The IPCS is 36 mm long, 32 mm wide, with an 8 mm insertion width. The device is a reservoir-type system, with EVAc encasing a solution of progesterone in silicone oil. The stem holds the drug, while the cross arms are solid copolymer (30). Trials with the IPCS were discontinued due to an increased pregnancy rate at 20–22 months, fully a year before its designed contraceptive efficacy was reached (20). Additionally, there is the Alza UTS system in which drug is released from the side arms as well as from the stem (74).

Another delivery vehicle being investigated is a fibrous system, in which fibers are loaded with steroid and wrapped around IUDs or vaginal rings (75). The fibers can be either biodegradable PLA, PLGA, or PCL, or nonbiodegradable polyethylene and polypropylene. It is possible to have a monolithic device in which the polymer and drug are mixed before spinning the fibers, or a coaxial fiber where the drug is the core of the device and is encased in a polymer sheath. Testing to date has been successful. The fibers are easily manufactured and stored and can be used in a variety of applications.

Another device similar to the IUD is an intracervical device (ICD) that contains a synthetic progesterone (either

LNG or Nestorone) (20,76). It was initially thought that an ICD would be more beneficial than an IUD because placement of the device in the cervix would decrease the basic problems of IUDs associated with intrauterine muscular contractility. The ICD is designed to release 10–25 μg of the progesterone daily over 5 years. The steroid is contained within a Silastic rod affixed to the vertical arm of a frame similar to the Nova-T IUD. In human testing, however, the ICD showed unsatisfactory release of the steroid through the Silastic carrier and an increase in expulsion rate over traditional IUDs.

Hydrogels are being investigated for their role in vaginal spermicide delivery. The spermicide nonoxynol-9 and ethylendiaminetetraacetic acid (EDTA) are loaded into a gel matrix composed of Carbopol 934P (77). Initial testing demonstrated a synergistic effect between EDTA and Carbopol in increasing the potency of nonoxynol-9, thus requiring lower dosage levels. Carbopol 934P is a high molecular weight poly(acrylic acid) polymer produced by B.F. Goodrich (78). It is made by cross-linking acrylic acid with allyl sucrose and polymerizing in benzene. The gel network is highly cross-linked and is typically in the form of a resin. Carbopol has a glass-transition temperature of 105°C when dry, but the glass-transition temperature drops dramatically when water is introduced to the system. Cross-linked networks swell to 1000 times their original volume in pH > 6, and Carbopol 934P is a flexible gel when hydrated. When the polymer is dry, drug is entrapped in the "glassy core." As the water penetrates the external surface of the polymer–drug matrix, the Carbopol polymer forms a gelatinous layer and drug becomes entrapped in the hydrogel domain. Carbopol is unique in that it forms "discrete microgels" of the polymer, and water forms tiny channels between the microgels as the system is hydrated. The water eventually forces the microgels to separate due to osmotic pressure, and the microgel–drug complex is sloughed off. Release of drug continues from within the stable gel layer of the microgel complex. Drug release from Carbopol is affected by the solubility of the drug, the rate of hydration of the polymer network, the degree of cross-linking and swelling of the matrix, as well as ionic interactions between the polymer and the drug. Polymer swelling is affected by the pH of the local environment, which affects drug release as well. Highly soluble drugs typically exhibit Fickian release and the release profile is dependent mainly upon the solubility and diffusion kinetics of the drug. The Carbopol matrix is the limiting membrane in the delivery of poorly soluble drugs, and release is typically near zero-order.

Contraceptive Films. Allendale Labs, Inc., is developing a vaginal contraceptive film much like VCF (marketed by Apothecus Pharmaceutical Corp) (33). The films differ in the composition of the polymeric carrier; VCF contains 70 mg of nonoxynol-9 in a base of poly(vinyl alcohol), whereas the Allendale-N9 film contains 100 or 130 mg nonoxynol-9 in a hydroxypropylmethylcellulose matrix. It is thought that the Allendale-N9 film will be less irritable to the mucosal tissues of the vagina, as well as enhance the stability of the device in warm, humid climates of third world countries. In Phase I clinical trials both Allendale-N9 films inhibited the action of sperm in the vagina, and there were no significant differences detected between VCF and the Allendale-N9 films. Further testing is needed to determine the efficacy of each film.

Another device that is undergoing testing is comprised of EVAc film (40% vinyl acetate by weight) loaded with 65% 2′-carbomethoxyphenyl 4-guanidinobenzoate (MSGB) (79). The EVAc-MSGB film is a nonbiodegradable and nonswellable matrix system that is highly flexible and can be molded into several different forms. MSGB is released from the system through diffusion through interconnecting pores. Its design is for in utero release, as MSGB is a sperm acrosin inhibitor. MSGB is advantageous to hormonal contraceptive systems as it does not interfere with the normal hormonal regulation of the endometrium. It is designed for an application of 1 to 2 years, but no test results on humans have been published.

Male Contraceptives

Very few male contraceptives are available today. However, research is progressing to allow men a wider choice of contraceptive systems. One such system involves delivery of testosterone through an implanted device. In this system, crystalline testosterone is fused into a pellet formation and six 200-mg pellets are implanted in the abdominal wall (80). The pellets are biodegradable and the release of drug suppresses sperm output for about 6 months. The release kinetics have been shown to approach zero-order. Another system that could possibly act as a contraceptive agent in males is the injectable LH-RH-containing PLGA spheres mentioned previously (67). Developments are being made for an injectable system much like Depo-Provera, in which testosterone enanthate would be administered along with DMPA (81). Sundaram et al. report on the use of a synthetic testosterone, 7α-methyl-19-nortestosterone (MENT) for use in subdermal contraceptive implants in men (82). MENT is more potent than testosterone, maintains normal muscle mass, and does not hyperstimulate the prostate because it does not undergo 5α-reduction in the prostate. In conjunction with an LH-RH analogue, this potent steroid could be used in a system designed for 1 year of contraceptive use.

A further development in male contraceptives is the navel administration of testosterone via a transdermal device (83). The device is designed to administer testosterone for one month or longer, and initial testing shows a zero-order release both in vitro and in vivo testing on rhesus monkeys. The system is a disk-shaped bandage-type device that contains microspheres of hormone suspended in liquid and immobilized in a cross-linked polymer. (Further description of the liquid or polymer were not available.) In vitro release rates were 40.25 μg/cm^2/day and in vivo release rates were 27.66 μg/cm^2/day. The decreased in vivo release rate is most likely due to the additional barrier of skin.

Cylindrical capsules of PLGA have also been investigated for their use in delivering buserelin acetate (84). Buserelin is a gonadotropin-releasing hormone (GnRH) agonist (D-Ser(Bu^t)^6-GnRH-(1-9)nonapeptide-ethylamide). GnRH, previously known as LH-RH, is one of the hypothalamic peptides and promotes pituitary secretion of follicle stimulating hormone (FSH) and luteinizing hormone (LH).

FSH induces spermatogenesis and LH causes the testicular Leydig cells to produce testosterone. A GnRH agonist will inhibit FSH and LH secretion from the pituitary, thus decreasing testosterone secretion and suppressing spermatogenesis. The PLGA capsules are 10 mm in length and contain 3.3 mg of buserelin acetate. The devices can be sterilized by γ-irradiation and are intended to be implanted subcutaneously in the abdominal wall lateral to the rectus abdominis muscle. Preliminary testing of the device as a contraceptive has been inconclusive as the delivery of GnRH agonists must be carefully combined with the administration of androgens so as to inhibit only spermatogenesis and avoid adversely affecting other androgen-supported functions in the body.

ABORTIFACIENTS

In the past, prostaglandin analogs have commonly been used as abortion-inducing agents. However, there are many side effects of prostaglandin use, especially to the gastrointestinal tract; vomiting and diarrhea are very common. To avoid the side effects, 24-hour delivery systems for the prostaglandin were developed. One such device is a polyethylene-oxide based hydrogel strip into which 3 mg of drug have been loaded (85). The strip measures 1.3 $\times$ 10 $\times$ 30 mm, and releases an average of 53% of the drug over 24 hours. The hydrogel is cross-linked with aliphatic difunctional isocyanate and an aliphatic triol. It swells to three times its dry volume and releases the drug through diffusion at zero-order. It has been demonstrated to be 85% effective, yet some of the side effects still persist. Another abortifacient device is a reservoir-type system (86). The device consists of three layers, a drug-loaded membrane surrounded by an outer rate-controlling membrane on one side and a drug-impermeable membrane on the other. The system is mounted on a holder and delivers from 50 to 100 μg/hour depending on loading. The device is 1.5 cm in diameter and 3.7 cm in length.

SUMMARY

There are many types of contraceptive agents both in use and being developed today. This article was limited to discussing the contraceptive devices involving controlled release and does not touch upon systems involving vaccines or pure polymer systems without drug release (such as a plug of silicon placed in the vas deferens for male contraception). There is quite a variety of controlled release systems, and as research progresses more and more of these systems will become available to the general public. Additionally, advances in the types of synthetic steroids used in contraceptive devices act to minimize the numerous side effects of current systems and will greatly improve the efficacy and acceptability of future devices.

INTRODUCTION

Controlled-release pharmaceutical dosage forms may offer one or more advantages over conventional (immediate release) dosage forms of the same drug, including a reduced dosing frequency, a decreased incidence and/or intensity of adverse effects, a greater selectivity of pharmacologic activity, and a reduction in drug plasma fluctuation resulting in a more constant or prolonged therapeutic effect. In some cases, controlled-release products may be therapeutically advantageous primarily for certain subpopulations of patients. For example, a controlled-release drug product may allow a child to attend school without drug administration during the school day. In other instances, controlled-release products may have no significant advantages or may actually be less effective or more hazardous than conventional dosage forms of the same drug. Therefore, not all drugs are good candidates for formulation as controlled-release drug products (1). For example, some drugs are more effective if fluctuation in plasma concentrations occur. For such drugs, tolerance to drug effect may develop with the constant levels seen with controlled-release drug products. Ordinarily, oral controlled-release dosage forms result in a longer recommended dosing interval for the controlled-release dosage form, usually twice as long, compared with the dosing interval for the immediate release dosage form. Also, a controlled-release drug product may be warranted if significant clinical advantages for the controlled-release dosage form can be demonstrated, for example, decreased side effects resulting from a lower peak plasma concentration with the controlled-release dosage form relative to the immediate-release dosage form.

TYPES OF CONTROLLED-RELEASE PRODUCTS

The most common type of controlled-release products are oral dosage forms. These products normally provide for a 12- or 24-h dosing interval. Dosing intervals for oral controlled-release products beyond once-a-day dosing are limited by physiologic characteristics of the human gastrointestinal tract. Gastrointestinal transit time, which normally averages 24 h but can vary from a few hours to several days, prevents oral controlled-release products with a dosing interval beyond 24 h. Other types of controlled-release products include transdermal patches that are applied to the skin for periods of 1 day to perhaps 1 week. In addition, controlled-release implants are dosage forms that are implanted below the skin surface and have been developed for continuous therapy for as long as 5 years.

DEFINITIONS

Before beginning a discussion of the regulatory requirements of controlled-release products, it is useful to understand several commonly used definitions for these types of products:

Controlled-release dosage forms. A class of pharmaceuticals or other biologically active products from which a drug is released from the delivery system in a planned, predictable, and slower-than-normal manner (2).

Modified-release dosage form. This refers, in general, to a dosage form for which the drug-release characteristics of time course and/or location are chosen to accomplish

INTRODUCTION

Controlled-release pharmaceutical dosage forms may offer one or more advantages over conventional (immediate release) dosage forms of the same drug, including a reduced dosing frequency, a decreased incidence and/or intensity of adverse effects, a greater selectivity of pharmacologic activity, and a reduction in drug plasma fluctuation resulting in a more constant or prolonged therapeutic effect. In some cases, controlled-release products may be therapeutically advantageous primarily for certain subpopulations of patients. For example, a controlled-release drug product may allow a child to attend school without drug administration during the school day. In other instances, controlled-release products may have no significant advantages or may actually be less effective or more hazardous than conventional dosage forms of the same drug. Therefore, not all drugs are good candidates for formulation as controlled-release drug products (1). For example, some drugs are more effective if fluctuation in plasma concentrations occur. For such drugs, tolerance to drug effect may develop with the constant levels seen with controlled-release drug products. Ordinarily, oral controlled-release dosage forms result in a longer recommended dosing interval for the controlled-release dosage form, usually twice as long, compared with the dosing interval for the immediate release dosage form. Also, a controlled-release drug product may be warranted if significant clinical advantages for the controlled-release dosage form can be demonstrated, for example, decreased side effects resulting from a lower peak plasma concentration with the controlled-release dosage form relative to the immediate-release dosage form.

TYPES OF CONTROLLED-RELEASE PRODUCTS

The most common type of controlled-release products are oral dosage forms. These products normally provide for a 12- or 24-h dosing interval. Dosing intervals for oral controlled-release products beyond once-a-day dosing are limited by physiologic characteristics of the human gastrointestinal tract. Gastrointestinal transit time, which normally averages 24 h but can vary from a few hours to several days, prevents oral controlled-release products with a dosing interval beyond 24 h. Other types of controlled-release products include transdermal patches that are applied to the skin for periods of 1 day to perhaps 1 week. In addition, controlled-release implants are dosage forms that are implanted below the skin surface and have been developed for continuous therapy for as long as 5 years.

DEFINITIONS

Before beginning a discussion of the regulatory requirements of controlled-release products, it is useful to understand several commonly used definitions for these types of products:

Controlled-release dosage forms. A class of pharmaceuticals or other biologically active products from which a drug is released from the delivery system in a planned, predictable, and slower-than-normal manner (2).

Modified-release dosage form. This refers, in general, to a dosage form for which the drug-release characteristics of time course and/or location are chosen to accomplish

therapeutic or convenience objectives not offered by conventional dosage forms (2).

Extended-release dosage form. This is a specific type of modified-release dosage form that allows at least a two-fold reduction in dosage frequency as compared to that drug presented as an immediate- (conventional-) release dosage form (2).

Delayed-release dosage form. This is a specific type of modified-release dosage form that releases a drug at a time other than promptly after administration. An example is enteric-coated tablets (2).

The requirements discussed in this article cover all types of controlled-release dosage forms. The primary focus will be on oral controlled-release drug products, which are most common. Requirements for other types of controlled-release drug products, such as transdermal patches or implants, are similar to those described in this article.

LAWS, REGULATIONS AND GUIDANCES FOR CONTROLLED-RELEASE PRODUCTS

Need for Clinical Studies

Premarketing evaluation of a controlled-release product should include consideration of the possible development of tolerance to the drug, the occurrence of sensitivity reactions or local tissue damage due to dosage-form-dependent persistence or localization of the drug, the clinical implications of dose dumping or of an unexpected decrease in bioavailability by physiological or physicochemical mechanisms, and a quantitative alteration in the metabolic fate of the drug related to nonlinear or site-specific disposition.

Specific claims for all therapeutic advantages of a controlled-release product over the conventional dosage forms should be based on adequate clinical studies, the results of which should be available to health professionals upon request. Where no therapeutic advantage is claimed, the need for clinical studies may be lessened.

An important consideration for the development of controlled-release products as original new drugs is the quantity of evidence needed in particular circumstances to establish substantial proof of effectiveness. The usual practice for all new molecular entities is to accept as proof two or more clinical studies that conclusively define the safety and efficacy of the drug. Within the U.S. Food and Drug Administration (FDA) Modernization Act of 1998 are described situations in which alternative approaches regarding the quantity of evidence to support effectiveness may be possible (3). These include (*1*) situations in which effectiveness of a new use may be extrapolated entirely from existing efficacy studies; (*2*) situations in which a single adequate and well-controlled study of a specific new use can be supported by information from other related adequate and well-controlled studies, such as studies in other phases of a disease; in closely related diseases; or other conditions of use (different dose, duration of use, regimen), of different dosage forms, or of different endpoints; and (*3*) situations in which a single multicenter study, without supporting information from other adequate and well-controlled studies, may provide evidence that a use is effective. In each of these situations, it is assumed that any studies relied on to support effectiveness meet the requirements for adequate and well-controlled studies in 21 CFR 314.126 (4). It should also be appreciated that reliance on a single study of a given use, whether alone or with substantiation from related trial data, leaves little room for study imperfections or contradictory (nonsupportive) information. In all cases, it is presumed that the single study has been appropriately designed; that the possibility of bias due to baseline imbalance, unblinding, post hoc changes in analysis, or other factors is judged to be minimal; and that the results reflect a clear prior hypothesis documented in the protocol. Moreover, a single favorable study among several similar attempts that failed to support a finding of effectiveness would not constitute persuasive support for a product use unless there were a strong argument for discounting the outcomes in the studies that failed to show effectiveness (e.g., if the study was obviously inadequately powered or there was a lack of assay sensitivity as demonstrated in a three-arm study by failure of the study to show efficacy of a known active agent).

Whether to rely on a single study to support an effectiveness determination is not often an issue in contemporary drug development. In most drug development situations, the need to find an appropriate dose, to study patients of greater and lesser complexity or severity of disease, to compare the drug with other therapy, to study an adequate number of patients for safety purposes, and to otherwise know what needs to be known about a drug before it is marketed will result in more than one adequate and well-controlled study upon which to base an effectiveness determination.

In certain cases, effectiveness of a new controlled-release drug product may be demonstrated without additional adequate and well-controlled clinical efficacy trials. Ordinarily, this will be because other types of data provide a way to apply the known effectiveness to a new population or a different dose, regimen, or dosage form. Controlled-release dosage forms may be approved on the basis of pharmacokinetic data linking the new dosage form to a previously studied immediate-release dosage form. Because the pharmacokinetic patterns of modified- and immediate-release dosage forms are not identical, it is generally important to have some understanding of the relationship of blood concentration to response, including an understanding of the time course of that relationship, to extrapolate the immediate-release data to the modified-release dosage form (3).

Bioavailability Study Requirements for Controlled Release Products

The bioavailability requirements for controlled-release products are covered in the U.S. Code of Federal Regulations under 21 CFR 320.25(f) (5). The aims of these requirements are to determine that the following conditions are met:

- The drug product meets the controlled-release claims made for it.
- The bioavailability profile established for the drug product rules out the occurrence of clinically significant dose dumping. This is usually achieved by the conduct of a food effect study whereby the drug is administered with and without a high-fat breakfast.
- The drug product's steady-state performance is equivalent to a currently marketed noncontrolled- or controlled-release drug product that contains the same active drug ingredient or therapeutic moiety and that is subject to an approved full new drug application.
- The drug product's formulation provides consistent pharmacokinetic performance between individual dosage units.

The reference material for such a bioavailability study shall be chosen to permit an appropriate scientific evaluation of the controlled-release claims made for the drug product. The reference material is normally one of the following:

- A solution or suspension of the active drug ingredient or therapeutic moiety
- A currently marketed immediate-release drug product containing the same active drug ingredient or therapeutic moiety and administered according to the dosage recommendations in the labeling of immediate-release drug product
- A currently marketed controlled-release drug product subject to an approved full new drug application containing the same active drug ingredient or therapeutic moiety and administered according to the dosage recommendations in the labeling proposed for the controlled-release drug product

Guidelines for the evaluation of controlled-release pharmaceutical dosage forms provide assistance to those designing, conducting, and evaluating studies. However, a drug may possess inherent properties that require considerations specific to that drug and its dosage form that may override the generalities of these guidelines. Guidances related to the evaluation of controlled-release drug products as well as many other types of guidances are available on the Internet at the Center for Drug Evaluation and Research Web site (*http://www.fda.gov/cder/*).

Controlled-Release New Drug Applications

As mentioned earlier, a fundamental question in evaluating a controlled-release product is whether formal clinical studies of the dosage form's safety and efficacy are needed or whether only a pharmacokinetic evaluation will provide adequate evidence for approval. A rational answer to this question must be based on evaluation of the pharmacokinetic properties and plasma concentration/effect relationship of the drug. Where there is a well-defined predictive relationship between the plasma concentrations of the drug and the clinical response (regarding both safety and efficacy), it may be possible to rely on plasma concentration data alone as a basis for the approval of the controlled-release product. In the following situations, it is expected that clinical data be submitted for the approval of the controlled-release New Drug Application (NDA):

- When the controlled-release product involves a drug that is an unapproved new molecular entity, because there is no approved reference product to which a bioequivalence claim could be made
- When the rate of input has an effect on the drug's efficacy and toxicity profile
- When a claim of therapeutic advantage is intended for the controlled-release product
- When there are safety concerns with regards to irreversible toxicity
- Where there are uncertainties concerning the relationship between plasma concentration and therapeutic and adverse effects or in the absence of a well-defined relationship between plasma concentrations and either therapeutic or adverse clinical response
- Where there is evidence of functional (i.e., pharmacodynamic) tolerance
- Where peak-to-trough differences of the immediate-release form are very large

In all of these instances except for the first, a 505(b)(2) NDA could be submitted for approval to the FDA. The regulations for such application are covered under 21 CFR 314.54. These regulations state that any person seeking approval of a drug product that represents a modification of a listed drug, for example, a new indication or a new dosage form, and for which investigations other than bioavailability or bioequivalence studies are essential to the approval of the changes may submit a 505(b)(2) application. However, such an application may not be submitted under this section of the regulations for a drug product whose only difference from the reference-listed drug is that the extent of absorption or rate of absorption is less than that of the reference-listed drug or if the rate of absorption is unintentionally less than that of the reference-listed drug (6).

INFORMATION TO CHARACTERIZE THE DRUG ENTITY

Physicochemical Characterization

Although the required physicochemical information to characterize the drug entity in a controlled-release dosage form should generally be no different from that for the drug entity in an immediate-release dosage form, additional physicochemical information related to solubility, dissolution, stability, and other release-controlling variables of the drug under conditions that may mimic the extremes of the physiologic environment experienced by the dosage form is necessary (7).

Pharmacokinetic Characterization

Absorption. It is necessary to characterize the relative bioavailability and the fractional absorption profile versus

time for the drug entity in the controlled-dosage form to evaluate the input profile of the controlled-release dosage form. This can be achieved by using deconvolution techniques that allow one to determine the fraction of drug absorbed versus time. Two commonly used techniques are the Wagner–Nelson method, which is used for drugs exhibiting one-compartment pharmacokinetics, and the Loo–Riegelman method, for drugs with two-compartment pharmacokinetic characteristics. The fractional absorption input profile can serve to assess the drug-release claims for that formulation. Further drug-release-rate and release-rate constants can be determined from the fractional absorption data. Moreover, this information, together with the disposition characteristics for the drug entity, can be used to characterize and predict changes in the bioavailability of the drug entity when input is modified for the controlled-release dosage forms. For example, the drug may exhibit saturable first-pass hepatic metabolism, which could result in decreased systemic availability when the input rate is decreased.

Although it may not be a regulatory requirement in designing a controlled-release dosage form, it may be useful to determine the absorption characteristics of the drug entity in various segments of the gastrointestinal tract (particularly the colon for dosage forms that may release drug in the color) (8).

Disposition. The information required to characterize the disposition processes for the drug entity in a controlled-release dosage form should include those generally determined for the drug entity in an immediate-release dosage form. This may include the following:

- Disposition parameters—clearance, volume of distribution, half-life, mean residence time, or model dependent or noncompartmental parameters
- Linearity or characterization of nonlinearity over the dose and/or concentration range that could possibly be encountered
- Accumulation of drug in the blood following multiple doses
- Ratio of parent drug to metabolites if different from immediate-release products

The following information is usually not included in a controlled-release NDA but is known from the development of the molecular entity as an immediate-release formulation:

- Metabolic profile and excretory organ dependence with special attention to active metabolites and active enantiomers of racemic mixtures
- Enterohepatic circulation
- Protein-binding parameters and dialyzeability
- Effect of age, gender, race, and relevant disease states on drug disposition from the controlled-release drug product.
- Plasma/blood ratio

In addition, in cases where the drug can be given in the morning or at bed time or where there is evidence that the clinical response varies significantly as a function of the time of the day, it is recommended that circadian variability in the drug's disposition parameters and pharmacodynamics be characterized to determine whether changes in the rate of drug input with time have an impact on safety and efficacy.

INFORMATION TO CHARACTERIZE THE DOSAGE FORM

Physicochemical Characterization

Similar characterization of the physicochemical properties of the dosage form should be undertaken as for the drug entity. Dissolution profiles from pH 1 to pH 7.4 should be obtained, with particular attention to the effect of the formulation changes on dissolution characteristics. A determination of whether the release of the drug from the formulation is dependent on the dissolution conditions such as pH, rotation speed, and type of apparatus and medium. Characterization of formulations that are highly insoluble in purely aqueous systems may require the addition of small amounts of surfactant to mimic in vivo conditions, where bile salts act as surfactants, more closely.

Bioavailability/Bioequivalence Studies

The type of bioavailability studies that need to be carried out depends upon how much is known about the drug, its clinical pharmacokinetics and biopharmaceutics, and whether bioequivalence studies are intended to be the sole basis for product approval. Several dosage strengths of the controlled-release dosage form should normally be developed to allow flexibility for clinicians to titrate the patient over the recommended therapeutic dose range of the marketed immediate-release dosage form. Scoring of the tablet is sometimes possible in the case where it does not affect the controlled-release mechanism of the formulation.

Each strength of the controlled-release product should be included in a single-dose crossover that involves a reference treatment that can consist of an approved formulation whether immediate or controlled-release, a solution or a suspension. In certain cases for substitution claims, the bioequivalence of the different strengths should be assessed. Also, a multiple-dose, steady-state study using the highest dose of the controlled-release dosage form versus a reference product is required for NDA approval (9,10). Comparison of such parameters such as AUC, C_{max}, T_{max}, and fluctuation index as well as C_{min} at steady state should be made between the controlled-release product and the reference product. If the drug exhibits nonlinear characteristics in its absorption or disposition, then a steady-state study would also be required for the lowest and highest strength.

In the case of a controlled-release dosage form, where the dosage strengths differ from each other only in the amount of identical beaded material contained, a single-dose and a multiple-dose steady-state study at the highest dosage strength will be sufficient for NDA/Abbreviated New Drug Application (ANDA) approval as long as supported by dissolution data. The types of studies needed can be categorized in the following sections.

Case I: Controlled-Release Oral Dosage Form of a Marketed Immediate-Release Drug for which Clinical Studies Have Been Conducted. The following studies would be needed for most controlled-release dosage forms. If approval is to be sought without clinical trials, it is recommended that there be preconsultation with the regulatory authorities to ensure that an adequate database exists for such approval.

Single-Dose Crossover Study. A single-dose crossover study would include the following treatments: the controlled-release dosage form administered under fasting conditions, an immediate-release dosage form administered under fasting conditions, and the controlled-release dosage form administered immediately after completion of a high-fat meal typically consisting of the following: two eggs fried in butter, two strips of bacon, two slices of toast with butter, 4 oz of hash brown potatoes, and 8 oz of whole milk (11). Alternatively, other meals with 1,000-calorie content, with 50% of the calories derived from fat, could be used. The dosage form should be administered immediately following the completion of the breakfast or meal. Absence of food effect will be concluded when the 90% confidence interval for the ratio of means (population geometric means based on log transformed data) of fed and fasted treatments fall within 80–125% for AUC and 70–143% for C_{max} (11). If there are no significant differences seen in the rate (C_{max}) or extent of bioavailability of the controlled-release product in this food effect study, then no further food effect studies are necessary. If significant differences in bioavailability are found, it would be useful to define the cause of the food effect on the controlled-release dosage form as well as the effect of time between meal and drug administration on the food–drug effect.

The purposes of this study are to assess bioavailability, rule out dose dumping, determine whether there is any need for labeling specifications regarding special conditions for administration with respect to meals, and provide information concerning the pattern of absorption of the controlled-release dosage form (12). The drug input function should be defined for controlled-release dosage forms by an appropriate method, for example, the Wagner–Nelson, Loo–Riegelman, or other deconvolution methods. This will aid in assessing the release-rate characteristics of the controlled-release product as well as in the development of an appropriate in vitro dissolution test. For dosage forms that exhibit high intrasubject variability, replicate design studies, in which subjects receive each treatment twice, are suggested.

An illustration of the importance of the study of the effect of food on the bioavailability of a drug from a controlled-release formulation is the case of nisoldipine (13). Nisoldipine is formulated as a once-a-day controlled-release formulation of a dihydropyridine calcium channel blocker that is approved in the United States for the treatment of hypertension.

During the course of development, a food effect study was conducted that revealed that a high-fat breakfast had a profound effect on the bioavailability of nisoldipine from this formulation. As can be seen from Figure 1, food increased the peak plasma concentration (C_{max}) from 2.75 to 7.5 ng/mL, an increase of 2.75-fold, while the area under

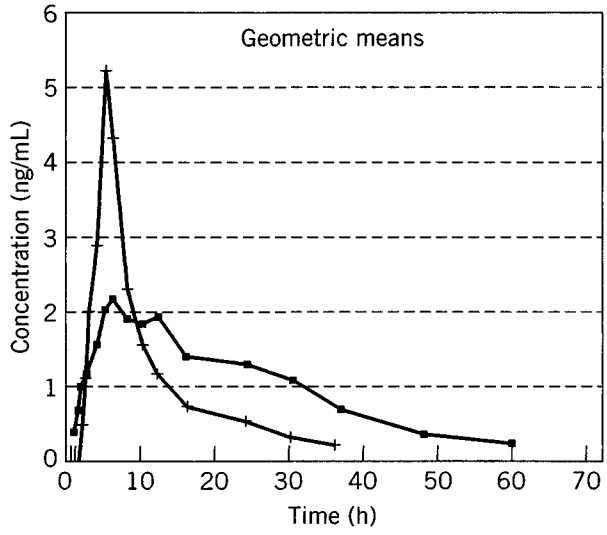

Figure 1. Nisoldipine plasma concentration time profile with and without the administration of a high-fat breakfast.

the curve (AUC) decreased from 70.4 to 53 ng × h/mL. These results raised a question related to the safety and efficacy of this controlled-release formulation when taken with food.

However, an E_{max} pharmacokinetic pharmacodynamic (PK/PD) model established the relationship between nisoldipine plasma concentrations and the reduction in blood pressure. This model was constructed using data from a study in which 23 patients with essential hypertension were given, on an escalating basis, 30, 60, 90, and 120 mg of nisoldipine as could be tolerated by the patients. The EC_{50} was estimated to be 3.54 ng/mL, and the E_{max}, expressed as the maximum drop in diastolic pressure, was 23.9 mm of Hg (14). The PK/PD model enabled the assessment of the clinical impact of the rapid increase in the rate of bioavailability of nisoldipine from this controlled-release formulation when taken with food. Because the relationship between dose and blood pressure lowering was log linear (the dose of drug would have to be increased greatly to observe an effect on the blood pressure) and the maximal drop in diastolic blood pressure would not be expected to pose any harmful hemodynamic effect to the patient and, with some additional experience in the fed state available from the clinical trials, the effect of food on the bioavailability of nisoldipine was not deemed to pose any safety concerns to the patients. However, in the labeling of this drug, it was recommended that Sular® be administered on an empty stomach for optimal efficacy (15).

Multiple-Dose, Steady-State Studies. When data exist for the immediate-release product establishing linear pharmacokinetics, a steady-state study with the controlled-release product at one dose level (at the high end of the dosage range) using an immediate-release formulation as a control should be conducted. At least three consecutive trough concentrations (C_{min}) taken at the same time of the day should be taken to ascertain that the subjects are at steady state. Concentrations over at least one dosage interval of the controlled-release product should be mea-

sured in each leg of the crossover study. In cases where the controlled-release dosage interval is not 24 h, it may be preferable to measure concentrations over an entire day in each leg for purposes of assessing diurnal variation.

Where it exists, consideration must be given to the "therapeutic window." of the drug. The occupancy time, which is defined as the percentage of time over a dosage interval where the concentration lies within the therapeutic window, should be determined.

Appropriate concentration measurements should include unchanged drug and major active metabolites. For racemic drugs, consideration should be given to specific measurement of the active enantiomers. However, approval of the controlled-release product is based on the results of the clinical trials. The pharmacokinetic data is used to establish the pharmacokinetic and bioavailability characteristics of the controlled-release formulation.

If the controlled-release product is aimed at a specific subpopulation, for example, children, it should be tested in that subpopulation. A controlled-release dosage form does not necessarily have to be administered at the same total daily dose as for the immediate-release reference. For example, if first-pass metabolism was greater for the controlled-release dosage form, the total daily dose may be more than the total daily dose of the immediate release product. Also, transdermal patches may contain a reservoir of drug that will not be absorbed during the time of use of the patch. The goal of differences in treatment dosage is to achieve equal exposure.

Steady-state studies in selected patient population groups and/or drug interaction studies may also be necessary, depending upon the therapeutic use of the drug and the type of individuals for which the controlled-release product will be recommended. In such studies, it may be advisable to carry out more than one interval measurement per patient to assess variability with both the controlled-release and the immediate-release dosage forms.

Example of an NDA with Clinical Data. This NDA for a once-a-day diltiazem formulation is a typical example of an NDA application with clinical data. The clinical data consisted of two clinical trials. The first study was a multicenter placebo-controlled randomized-dose-ranging study in which 198 patients participated. This clinical trial combined a dose-escalation arm with 180 to 540 mg doses and a fixed-dose parallel arm involving doses of 90 to 360 mg. In the fixed-dose arm, those patients randomized to 90 or 180 mg remained on these doses throughout the study. Those randomized to 360 mg received 180 mg for the first 2 weeks before receiving the 360-mg dose. The second clinical study was also a randomized double-placebo-controlled-dose escalation study, with doses from 120 to 540 mg in 56 patients with mild to moderate hypertension.

Figure 2 shows the changes in blood pressure among the different doses compared with the placebo (16). The biopharmaceutics and clinical pharmacology portion of the NDA consisted of six studies, including (17)

- A single-dose relative bioavailability study comparing the controlled-release product to an approved immediate-release diltiazem

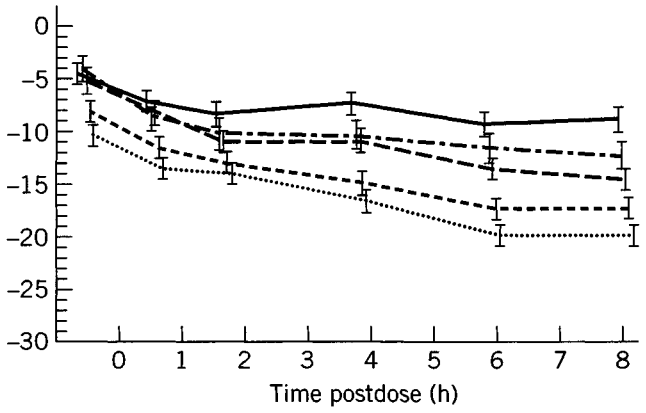

Figure 2. Change in supine diastolic blood pressure from baseline predose levels (mm Hg) compared with placebo across all dose levels.

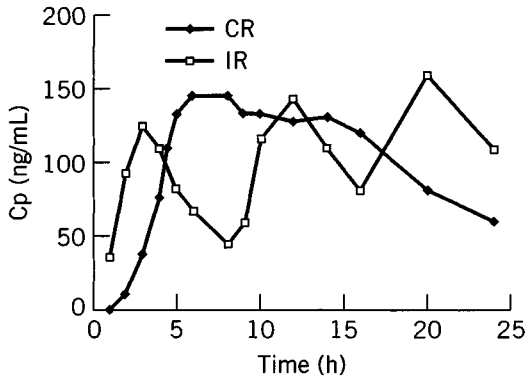

Figure 3. Comparative single-dose plasma concentration time profile of diltiazem from a once-a-day controlled-release (CR) formulation and three doses of the immediate-release (IR) formulation.

- A multiple-dose relative bioavailability study comparing the controlled-release product to an approved immediate-release diltiazem
- A food effect study

Figure 3 shows the comparative plasma concentration time profile for this controlled release formulation relative to the approved immediate release formulation. These three studies, along with the clinical data, fulfilled the regulatory requirements for this NDA.

It is to be noted that the trough level at the end of the dosing interval for the controlled-release product was lower than that of the immediate release formulation as can be seen in Figure 4. However, because the efficacy of the controlled-release product was established in the two clinical trials, the lower trough levels were of no clinical concern.

The sponsor also conducted the following:

- A dose proportionality study, because diltiazem is known to undergo saturable first-pass metabolism, and thus the degree of nonlinearity in pharmacokinetics needed to be characterized for the controlled-release product.

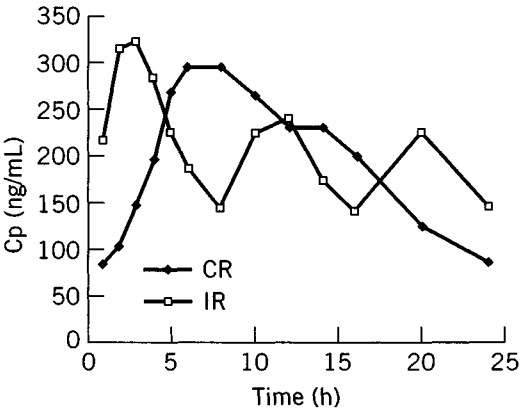

Figure 4. Comparative steady-state plasma concentration time profile of diltiazem from a once-a-day controlled-release formulation and three doses of the immediate-release formulation given during a 24-h dosing interval.

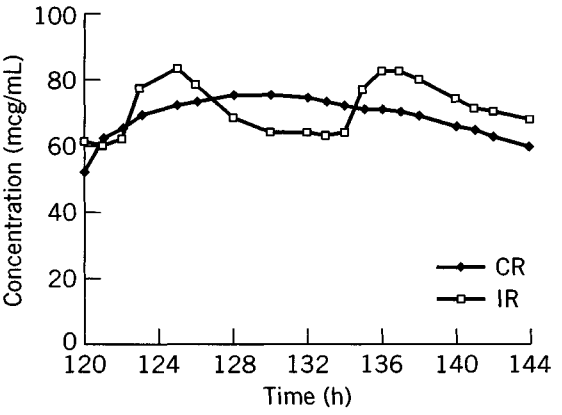

Figure 5. Example of a controlled-release product with steady-state C_{min} values at the end of the dosing interval lower than those for the corresponding immediate-release product.

- A bioequivalence study comparing this once-a-day product with the two other once-a-day diltiazem products that are already approved for marketing. This study was undertaken for marketing purposes by the sponsor of the NDA and was not required from the regulatory point of view.
- An in vivo/in vitro correlation study that would enable the sponsor to obtain in vivo bioavailability waivers and possibly wider dissolution specifications. Such a study is highly desirable in an NDA but is not a requirement.

Case II: Controlled-Release NDA with No Clinical Studies or PK/PD Information. It may be possible to obtain approval of an NDA for a controlled-release drug product based on bioequivalence data alone. In this situation, there is an absolute need to establish bioequivalence conclusively. To allow marketing of a controlled-release drug product in the absence of clinical data or PK/PD information for the controlled-release product requires that all parameters related to bioequivalence be shown to meet the equivalence criteria under steady-state conditions. These parameters include C_{max}, AUC, and C_{min} (absolute lowest concentration over an interval).

Similar C_{max} comparisons for the test and reference products relate to establishing comparable safety and efficacy. Safety relates to the fact that the controlled-release product should not have C_{max} or C_{min} values significantly higher than the immediate-release product, whereas efficacy could relate to the controlled-release product not having a C_{max} or C_{min} significantly lower than the immediate-release product. AUC could relate to both safety and efficacy, and the controlled- and immediate-release products should show comparable AUCs during a dosing interval at steady state. In addition, C_{min} values should be comparable related to efficacy at the end of the dosing interval for the controlled-release product. Lower C_{min} values for the controlled-release product would raise issues in this regard, and this is illustrated in Figure 5. The lower values of C_{min} for this controlled-release product, which was the subject of an NDA that contained no clinical data, caused concerns regarding its approvability. To allow the marketing of this controlled-release product without prior testing in patients to establish efficacy was considered to be unacceptable.

Case III: Oral Controlled-Release Dosage Form of a Marketed Immediate-Release Drug for Which Extensive Pharmacodynamic/Pharmacokinetic Data Exist. The same bioavailability/bioequivalence requirements as discussed in Case I apply to the controlled-release dosage form of a marketed immediate-release drug for which extensive PK/PD data exist. In certain cases the PK/PD information can serve in lieu of clinical trials to establish the safety and efficacy profile of the controlled-release drug product.

Case IV: Nonoral Controlled-Release Dosage Form of a Marketed Immediate-Release Drug for Which Extensive Pharmacodynamic/Pharmacokinetic Data Exist. The bioavailability studies described earlier (except for the food effect study) would be appropriate for the evaluation of a controlled-release formulation designed for nonoral route of administration. If an altered biotransformation pattern of active metabolites is observed, the need for clinical data becomes more apparent. One or more clinical efficacy studies would be required. In addition to bioavailability studies, special studies should be concerned with specific risk factors, for example, irritation and/or sensitization at the site of application or injection.

Case V: Generic Equivalent of an Approved Controlled-Release Product. The Drug Price Competition and Patent Term Restoration Act amendments of 1984 to the Food, Drug and Cosmetic Act of 1938 gave the FDA statutory authority to accept and approve for marketing ANDAs for generic substitutes of pioneer products, including those approved after 1962. To gain approval according to the law, ANDAs for a generic controlled-release drug product must, among other things, be both pharmaceutically equivalent

and bioequivalent to the innovator controlled-release product, which is termed the *reference-listed drug product* as identified in FDA's *Approved Drug Products with Therapeutic Equivalence Ratings* (the "Orange Book").

Pharmaceutical Equivalence. As defined in the Orange Book, to be pharmaceutically equivalent, the generic and pioneer formulations must (*1*) contain the same active ingredient, (*2*) contain the same strength of the active ingredient in the same dosage form, (*3*) be intended for the same route of administration, and (*4*) be labeled for the same conditions of use. The FDA does not require that the generic and reference-listed controlled-release products contain the same excipients or that the mechanism by which the release of the active drug substance from the formulation be the same (18). For substitution purposes, the two products have to be pharmaceutical equivalents.

Bioequivalence Requirements. The same bioequivalence requirements apply to the establishment of the equivalence of the formulation used in efficacy trials if it is different from the formulation intended for marketing and generic controlled-release product approval. For development of a generic equivalent of an approved controlled-release product, the new generic formulation must be comparable with respect to rate and extent of bioavailability (usually using AUC, C_{max}, C_{min}, and the degree of fluctuation as criteria) in a crossover steady-state study compared to the reference controlled-release product.

In 1993, the Division of Bioequivalence of the Office of Generic Drugs issued a Guidance entitled "Oral Extended (Controlled) Release Dosage Form In Vivo Bioequivalence and In Vitro Dissolution Testing," which outlines the required studies for the approval of a controlled-release product (19). The following is a summary of the required studies as outlined in the 1993 guidance.

Single-Dose Fasting Two-Way Crossover Bioequivalence Study. The objective of this study is to compare the rate (as measured by C_{max}) and extent of absorption (as measured by AUC) of a generic formulation with that of a reference-listed formulation when administered in equal labeled doses. The FDA-designated reference product is identified by the symbol + in the Orange Book.

Design. The study design is a single-dose, two-treatment, two-period, two-sequence crossover with an adequate washout period between the two phases of the study. An equal number of subjects should be randomly assigned to the two possible dosing sequences. An institutional review board should approve the proposed protocol for the study prior to its initiation.

Selection of Subjects. The applicant should enroll a number of subjects sufficient to ensure adequate statistical results. It is recommended that a minimum of 24 subjects be used in this study. More subjects may be required for a drug that exhibits high intrasubject variability in metrics of rate and extent of absorption. Subjects should be healthy volunteers, 18 to 50 years of age, and within 10% of ideal body weight for height and build. Written, informed consent must be obtained from all subjects before their acceptance into the study.

Procedure. Following an overnight fast of at least 10 hours, subjects should be administered a single dose of the test or reference product with 240 mL water. They should continue fasting for 4 h after administration of the test or reference treatment.

Blood Sampling. In addition to the predose (0 h) sample, venous blood samples should be collected postdose so that there are at least four sampling time points on the ascending part and six or more on the descending part of the concentration-time curve. The biological matrix (plasma, serum, or whole blood) should be immediately frozen after collection and, as appropriate, centrifugation and kept frozen until assayed.

Analysis of Blood Samples. The active moieties should be assayed using a suitable analytical method validated with regard to specificity, accuracy, precision (both within and between days), limit of quantitation, linearity, and recovery. Stability of the samples under frozen conditions, at room temperature, and during freeze–thaw cycles, if appropriate, should be determined. If the analytical method is a chromatographic method, chromatograms of unknown samples, including all associated standard curve and quality control chromatograms, should be submitted for one-fifth of subjects, chosen at random (20).

Pharmacokinetic Analysis of Data. Calculation of area under the plasma concentration-time curve to the last quantifiable concentration (AUC 0—t) and to infinity. Calculation of C_{max} and T_{max} should be performed according to standard techniques.

Statistical Analysis of Pharmacokinetic Data. The log-transformed AUC and C_{max} data should be analyzed statistically using analysis of variance. These two parameters for the test product should be shown to be within 80–125% of the reference product using the 90% confidence interval (21–23).

Clinical Report and Adverse Reactions. Subject medical histories, physical examination reports, and all incidents of adverse reactions to the study formulations should be reported.

Multiple-Dose, Steady-State, Two-Way Crossover Bioequivalence Study. The objective of this study is to document that the steady-state rate and extent of absorption of the test controlled-release product is equivalent to the rate and extent of absorption of the reference-listed drug containing the same amount of the active ingredient in the same dosage form.

Design. The study design is a multiple-dose, two-treatment, two-period, two-sequence crossover with adequate washout period between the two phases of the study. An equal number of subjects should be randomly assigned to the two possible dosing sequences. Before initiation of the multiple-dose steady-state study, an institutional review board should approve the study protocol. Moreover, the steady-state study should be done after the completion of the single-dose study.

Selection of Subjects. Same as for the single-dose study.

Procedures. Controlled-release products that are administered once a day should be dosed following an overnight fast of at least 10 h; subjects should continue fasting for 4 h postdose. For controlled-release products that are dosed every 12 h, the morning dose should be given following an overnight fast of about 10 h, and subjects should continue fasting for 4 h postdose; the evening dose should be administered after a fast of at least 2 h, and subjects

should continue fasting for 2 h postdose. Each dose should be administered with 240 mL water.

Blood Sampling. At least three trough concentrations (C_0) on three consecutive days should be determined to ascertain that the subjects are at steady state prior to measurement of rate and extent of absorption after a single-dose administration in a dosing interval at steady state. For controlled-release drug products administered more often than every 24 h, assessment of trough levels just prior to two consecutive doses is not recommended because a difference in the consecutive trough values may occur due to circadian rhythm irrespective of whether or not steady state has been attained. Adequate blood samples should be collected at appropriate times during a dosing interval at steady state to permit estimation of the total area under the concentration-time curve, peak concentration (C_{max}), the absolute lowest plasma concentration (C_{min}), and time to peak concentration (T_{max}).

Pharmacokinetic Data. The following pharmacokinetic data are to be reported for the evaluation of bioequivalence of the generic controlled-release product to the reference-listed product:

- Individual and mean blood drug concentration levels.
- Individual and mean trough levels (C_0) as well as the lowest plasma concentration (C_{min}).
- Individual and mean peak level (C_{max}).
- Calculation of individual and mean steady-state AUC.
- Individual and mean percent fluctuation; fluctuation for the test product should be evaluated for comparability with that for the reference product.
- Individual and mean time to peak concentration (T_{max})

Statistical Analysis of Pharmacokinetic Data. Same as for the single-dose study.

Clinical Report and Adverse Reactions. Same as for the single-dose study.

For controlled-release capsule formulation marketed in multiple strengths, a single-dose bioequivalence study under fasting conditions is required only for the highest strength, provided that the compositions of the lower strengths are proportional to that of the highest strength and that all strengths contain identical beads or pellets. Single-dose bioequivalence studies may be waived for the lower strengths on the basis of acceptable dissolution profiles. Multiple-dose steady-state and single-dose food/fasting studies are to be conducted on the highest strength of the capsule formulation. For controlled-release products that are not beaded and are not compositionally proportional, the single-dose bioequivalence study is required for each strength, and the multiple-dose bioequivalence study is required only to the highest strength. This requirement can also be waived in the presence of an in vivo/in vitro correlation whose predictability has been established. For this waiver to be granted the following conditions have to be met:

- The lower strengths must be compositionally proportional or qualitatively the same
- The lower strengths must have the same release mechanism
- The lower strengths must have similar in vitro dissolution profiles
- The lower strengths must be manufactured using the same type of equipment and the same process, and at the same site as other strengths that have bioavailability data

In addition one of the following situations should exist:

- Bioequivalence has been established for all strengths of the reference-listed product.
- Dose proportionality has been established for the reference-listed product, and all reference product strengths are compositionally proportional or qualitatively the same; they must have the same release mechanism, and the in vitro dissolution profiles for all strengths must be similar.
- Bioequivalence has been established between the generic product and the reference-listed product at the highest and lowest strengths; for the reference-listed product, all strengths are compositionally proportional or qualitatively the same and have the same release mechanism, and the in vitro dissolution profiles are similar.

The criterion for granting such waivers is that the difference in predicted means of C_{max} and AUC is no more than 10% based on dissolution profiles of the highest-strength and the lower-strength product.

Single-Dose, Food/Fasting Study. The objective of this study is to document that the rate and extent of absorption of the generic controlled-release product is equivalent to the rate and extent of absorption of the reference-listed drug when both products are administered immediately after a high-fat meal and to assess the effect of a high-fat meal on the bioavailability of the generic controlled-release product.

Statistical Analysis. Absence of food effect will be concluded when the 90% confidence interval for the ratio of means (population geometric means based on log-transformed data) of fed and fasted treatments fall within 80–125% for AUC and 70–143% for C_{max}.

Case VI: Controlled Release Dosage Form as a New Molecular Entity. Independent of whether a controlled-release dosage form is evaluated by clinical studies, this dosage form should be characterized as described previously; that is, per dose proportionality, food effects, absorption characteristics (rate, pattern, and extent), and fluctuation. Moreover, the additional requirements for an immediate-release new molecular entity will also be applicable to controlled-release applications.

Retention of Samples. The clinical laboratory conducting any in vivo study should retain an appropriately identified reserve sample of the test and reference products for a period of 5 years. Each reserve sample should consist of at least 200 dosage units. For more information on retention

of bioequivalence samples, please refer to 21 CFR 320.63.V (24).

Dissolution Testing for Controlled-Release Drug Products

In vitro dissolution testing is important for (*1*) providing process control and quality assurance, (*2*) determining stable release characteristics of the product over time, and (*3*) facilitating certain regulatory determinations (e.g., absence of effect of minor formulation changes or of change in manufacturing site on performance). In certain cases, especially for oral controlled-release formulations, the dissolution test, related to an in vivo/in vitro correlation (IVIVC), can serve not only as a quality control for the manufacturing process but also as an indicator of how the formulation will perform in vivo. A main objective of developing and evaluating an IVIVC is to establish the dissolution test as a surrogate for human bioequivalence studies.

An IVIVC describes a meaningful relationship between in vitro dissolution and expected in vivo bioavailability results. The availability of an IVIVC provides for excellent control of product quality, particularly for marketed batches of a drug product, that will not be tested in humans. The concept of IVIVC, particularly for oral controlled-release drug products, has been studied considerably over the years. Several workshops and publications have provided useful information regarding IVIVCs.

The *Report of the Workshop on CR Dosage Forms: Issues and Controversies* (1987) indicated that the state of science and technology at that time did not permit consistently meaningful IVIVC for oral controlled-release dosage forms and encouraged IVIVC as a future objective. Dissolution testing was considered useful only for process control, stability, minor formulation changes, and manufacturing site changes (7).

A U.S. Pharmacopeial Convention (USP) Pharmacopeial Forum stimuli article in 1988 established the classification of IVIVC into levels A, B, and C. In addition, USP Chapter 1088 describes techniques appropriate for level A, B, and C correlations and methods for establishing dissolution specifications (25).

A level A correlation is usually estimated by a two-stage procedure: deconvolution followed by comparison of the fraction of drug absorbed with the fraction of drug dissolved. A correlation of this type (shown in Figure 6) is generally linear and represents a point-to-point relationship between in vitro dissolution and the in vivo input rate (e.g., the in vivo dissolution of the drug from the dosage form). In a linear correlation, the in vitro dissolution and in vivo input curves may be directly superimposable or may be made to be superimposable by the use of a scaling factor. Nonlinear correlations, although uncommon, may also be appropriate (26).

A level B correlation uses the principles of statistical moment analysis. The mean in vitro dissolution time is compared either to the mean residence time or to the mean in vivo dissolution time. A level B correlation does not uniquely reflect the actual in vivo plasma level curve because a number of different in vivo curves will produce similar mean residence time values. An example of such a correlation is shown in Figure 7.

A level C correlation establishes a single-point relationship between a dissolution and a pharmacokinetic parameter. A level C correlation does not reflect the complete shape of the plasma concentration-time curve, which is important to the definition of the performance of oral controlled-release products. A multiple level C correlation relates one or several pharmacokinetic parameters of interest to the amount of drug dissolved at several time points of the dissolution profile. This is illustrated in Figure 8, where the relationship between the maximum plasma concentrations and percent dissolved at several time points is given (27).

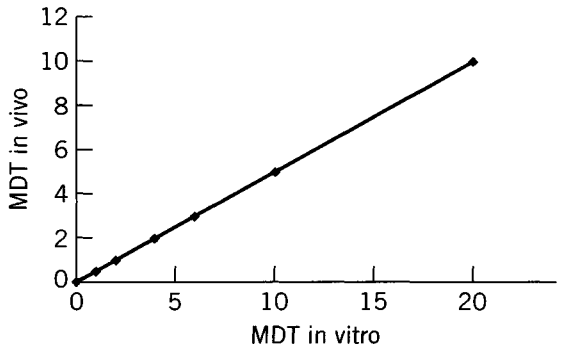

Figure 7. Level B correlation.

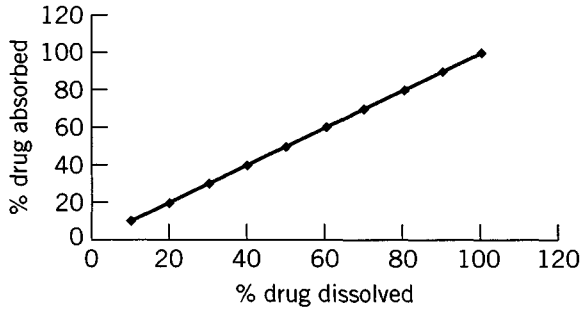

Figure 6. Level A correlation.

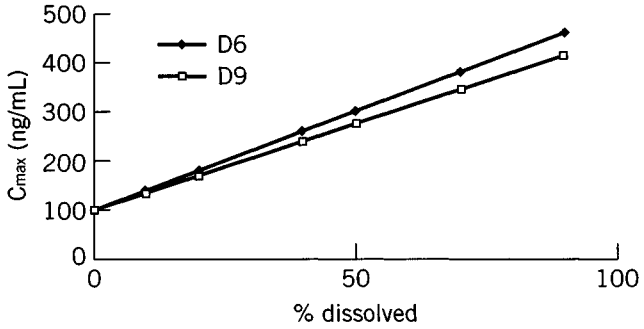

Figure 8. Multiple level C correlation.

The report entitled *In Vitro / In Vivo Testing and Correlation for Oral Controlled / Modified Release Dosage Forms* (8) concludes that although science and technology may not always permit meaningful IVIVC, the development of an IVIVC is an important objective on a product-by-product basis. Procedures for development, evaluation, and application of an IVIVC are described. Validation of dissolution specifications by a bioequivalence study involving two batches of product with dissolution profiles at the upper and lower dissolution specifications is suggested.

Further information related to IVIVCs was developed in a USP/American Association of Pharmaceutical Scientists/FDA-sponsored workshop that resulted in a report entitled *Workshop II Report: Scale-up of Oral Extended Release Dosage Forms* (20). This report identified the objectives of an IVIVC to be the use of dissolution as a surrogate for bioequivalence testing as well as an aid in setting dissolution specifications. The report concluded that dissolution may be used as a sensitive, reliable, and reproducible surrogate for bioequivalence testing. The report gave support to the concepts of USP Chapter 1088 and further found that an IVIVC may be useful for changes other than minor changes in formulation, equipment, process, manufacturing site, and batch size (28,29).

An FDA Guidance for Industry, "Extended Release Solid Oral Dosage Forms: Development, Evaluation and Application of In Vitro/In Vivo Correlations," provides recommendations for establishing useful IVIVCs (30). Human data should be utilized for regulatory consideration of an IVIVC. Bioavailability studies for IVIVC development should be performed with enough subjects to adequately characterize the performance of the drug product under study. Although crossover studies are preferred, parallel studies or cross-study analyses may be acceptable. The reference product in developing an IVIVC may be an intravenous solution, an aqueous oral solution, or an immediate-release product. IVIVCs are usually developed in the fasted state. When a drug is not tolerated in the fasted state, studies may be conducted in the fed state. Any in vitro dissolution method may be used to obtain the dissolution characteristics of the oral controlled-release dosage form, but the same system should be used for all formulations tested. The most commonly used dissolution apparatus is USP apparatus (basket) or II (paddle), used at compendially recognized rotation speeds (e.g., 100 rpm for the basket and 50–75 rpm for the paddle). In other cases, the dissolution properties of some oral controlled-release formulations may be determined with USP apparatus III (reciprocating cylinder) or IV (flow through cell). An aqueous medium, preferably not exceeding pH 6.8, is recommended as the initial medium for development of an IVIVC. For poorly soluble drugs, addition of surfactant may be appropriate. In general, nonaqueous and hydroalcoholic systems are discouraged unless all attempts with aqueous media are unsuccessful. The dissolution profiles of at least 12 individual dosage units from each lot should be determined. A suitable distribution of sampling points should be selected to define the profiles adequately (31–33).

IVIVCs are established in two stages. First, the relationship between dissolution characteristics and bioavailability characteristics needs to be determined. Second, the reliability of this relationship must be tested. The first stage may be thought of as developing an IVIVC, whereas the second stage may involve evaluation of predictability. The most commonly seen process for developing a level A IVIVC is to (*1*) develop formulations with different release rates, such as slow, medium, fast, or a single-release rate if dissolution is condition independent; (*2*) obtain in vitro dissolution profiles and in vivo plasma concentration profiles for these formulations; and (*3*) estimate the in vivo absorption or dissolution time course using an appropriate deconvolution technique for each formulation and subject [e.g., Wagner–Nelson, numerical deconvolution (34)]. These three steps establish the IVIVC model. Alternative approaches to developing level A IVIVCs are possible. The IVIVC relationship should be demonstrated consistently with two or more formulations with different release rates to result in corresponding differences in absorption profiles. Exceptions to this approach (i.e., use of only one formulation) may be considered for formulations for which in vitro dissolution is independent of the dissolution test conditions (e.g., medium, agitation, pH).

The in vitro dissolution methodology should adequately discriminate among formulations. Dissolution testing can be carried out during the formulation screening stage using several methods. Once a discriminating system is developed, dissolution conditions should be the same for all formulations tested in the bioavailability study for development of the correlation and should be fixed before further steps toward correlation evaluation are undertaken. During the early stages of correlation development, dissolution conditions may be altered to attempt to develop a one-to-one correlation between the in vitro dissolution profile and the in vivo dissolution profile.

Time scaling may be used as long as the time-scaling factor is the same for all formulations (35). An IVIVC that has been developed should be evaluated to demonstrate that predictability of in vivo performance of a drug product from its in vitro dissolution characteristics is maintained over a range of in vitro dissolution release rates and manufacturing changes. Because the objective of developing an IVIVC is to establish a predictive mathematical model describing the relationship between an in vitro property and a relevant in vivo response, a logical evaluation approach focuses on the estimation of predictive performance or, conversely, prediction error. Depending on the intended application of an IVIVC and the therapeutic index of the drug, evaluation of prediction error internally and/or externally may be appropriate. Evaluation of internal predictability is based on the initial data used to develop the IVIVC model. Evaluation of external predictability is based on additional test data sets that may reduce the number of bioequivalence studies performed during the initial approval process as well as with certain scale-up and postapproval changes. However, for the applications outlined in the following sections, the adequacy of the in vitro dissolution method to act as a surrogate for in vivo testing should be shown through an IVIVC for which predictability has been established (36). The criterion for granting in vivo bioavailability/bioequivalence waivers with an IVIVC is that the predicted C_{max} and AUC from

the in vitro dissolution data for the test and reference formulation should not differ by more than 20%. This is illustrated in Figure 9.

Waivers of bioequivalency studies are possible without an IVIVC for small changes in oral controlled-release drug products. For formulations consisting of beads in capsules, with the only difference between strengths being the number of beads, approval of lower strengths without an IVIVC is possible, provided bioavailability data are available for the highest strength and the dissolution profiles in several media are the same across strengths. Where the FDA Guidance for Industry Scale Up and Post-Approval Changes for Modified Release oral dosage forms (SUPAC-MR) *Modified Release Solid Oral Dosage Forms; Scale-Up and Postapproval Changes: Chemistry, Manufacturing, and Controls, In Vitro Dissolution Testing, and In Vivo Bioequivalence Documentation* (37) recommends a biostudy, biowaivers for the same changes made on lower strengths are possible without an IVIVC if (*1*) all strengths are compositionally proportional or qualitatively the same, (*2*) in vitro dissolution profiles of all strengths are similar, (*3*) all strengths have the same release mechanism, (*4*) bioequivalence has been demonstrated at the highest strength (comparing changed and unchanged drug product), and (*5*) dose proportionality has been demonstrated for this oral controlled-release drug product. In the last circumstance, documentation of dose proportionality may not be necessary if bioequivalence has been demonstrated on the highest and lowest strengths of the drug product, comparing changed and unchanged drug product for both strengths as recommended in SUPAC-MR.

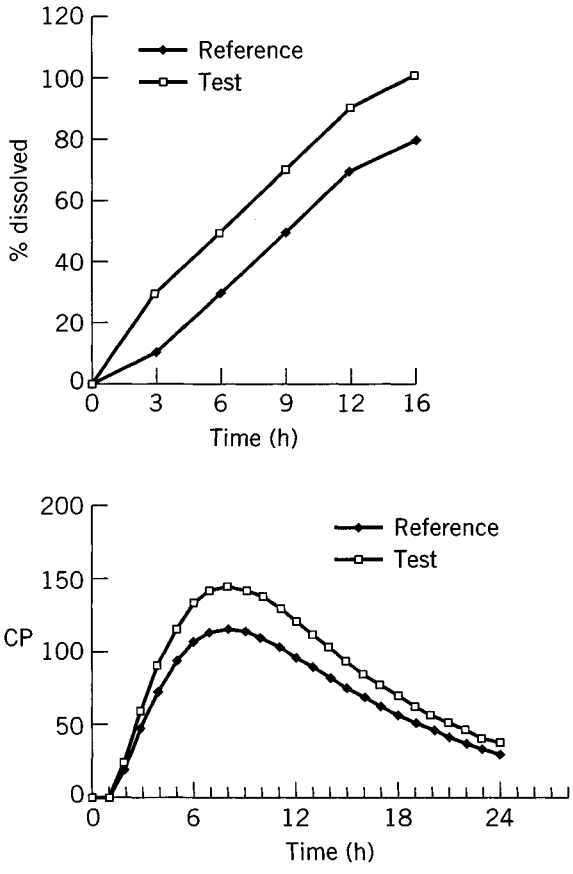

Figure 9. Criterion for granting an in vivo bioavailability waiver based on predicted C_{max} and AUC from in vitro dissolution data using IVIVC.

If an IVIVC has been established, waivers for more significant changes are possible. A biowaiver will likely be granted for an oral controlled-release drug product using an IVIVC for (*1*) level 3 process changes as defined in SUPAC-MR, (*2*) complete removal of or replacement of nonrelease-controlling excipients as defined in SUPAC-MR, and (*3*) level 3 changes in the release-controlling excipients as defined in SUPAC-MR.

If an IVIVC is developed with the highest strength, waivers for changes made on the highest strength and any lower strengths may be granted if these strengths are compositionally proportional or qualitatively the same, the in vitro dissolution profiles of all the strengths are similar, and all strengths have the same release mechanism.

This biowaiver is applicable to strengths lower than the highest strength, within the dosing range that has been established to be safe and effective, provided that the new strengths are compositionally proportional or qualitatively the same, have the same release mechanism, have similar in vitro dissolution profiles, and are manufactured using the same type of equipment and the same process at the same site as other strengths that have bioavailability data available.

Certain changes almost always necessitate in vivo bioavailability testing and in some cases might necessitate clinical trials, even in the presence of an IVIVC. These include the approval of a new formulation of an approved oral controlled-release drug product when the new formulation has a different release mechanism, approval of a dosage strength higher or lower than the doses that have been shown to be safe and effective in clinical trials, approval of another sponsor's oral controlled-release product even with the same release-controlling mechanism, and approval of a formulation change involving a non-release-controlling excipient in the drug product that may significantly affect drug absorption (38).

Setting Dissolution Specifications

In vitro dissolution specifications should generally be based on the performance of the clinical/bioavailability lots. These specifications may sometimes be widened within the range allowed in the guidance so that scale-up lots, as well as stability lots, meet the specifications associated with the clinical/bioavailability lots. This approach is based on the use of the in vitro dissolution test as a quality control test without any in vivo significance, even though in certain cases (e.g., oral controlled-release formulations), the rate-limiting step in the absorption of the drug is the dissolution of the drug from the formulation. An IVIVC adds in vivo relevance to in vitro dissolution specifications, beyond batch-to-batch quality control. In this approach, the in vitro dissolution test becomes a meaningful predictor of in vivo performance of the formulation, and dissolution specifications may be used to minimize the possibility of releasing lots that would exhibit different in vivo performance.

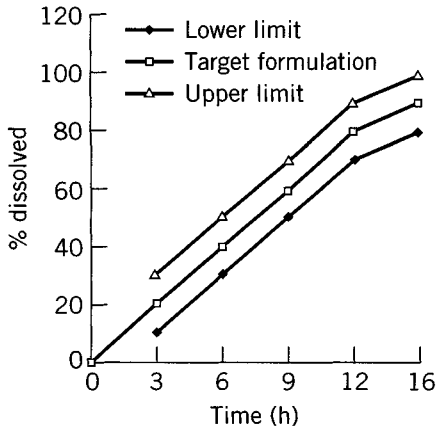

Figure 10. Upper and lower dissolution specifications in a case where no IVIVC exists.

A minimum of three time points is recommended to set the specifications. These time points should cover the early, middle, and late stages of the dissolution profile. The last time point should be the time point where at least 80% of drug has dissolved. If the maximum amount dissolved is less than 80%, the last time point should be the time when the plateau of the dissolution profile has been reached.

Specifications should be established based on average dissolution data for each lot under study, equivalent to USP stage 2 testing. Specifications that allow lots to pass at stage 1 of testing may result in lots with less than optimal in vivo performance passing these specifications at USP stage 2 or stage 3.

Setting Dissolution Specifications without an IVIVC. The recommended range at any dissolution time point specification is ± 10% deviation of the labeled claim from the mean dissolution profile obtained from the clinical/bioavailability lots as shown in Figure 10. In certain cases, reasonable deviations from the ± 10% range can be accepted provided that the range at any time point does not exceed 25%. Specifications greater than 25% may be acceptable based on evidence that lots (side batches) with mean dissolution profiles that are allowed by the upper and lower limit of the specifications are bioequivalent.

Setting Dissolution Specifications Where an IVIVC Has Been Established. Optimally, specifications should be established such that all lots that have dissolution profiles within the upper and lower limits of the specifications are bioequivalent. Less optimally but still possible, lots exhibiting dissolution profiles at the upper and lower dissolution limits should be bioequivalent to the clinical/bioavailability lots or to an appropriate reference standard. In the case where an IVIVC whose predictability has been established, dissolution specifications should be set in such a way that the average predicted C_{max} and AUC that correspond to the lower and upper limit of the dissolution specifications should differ by no more than 20% from each other.

Importance of Proper Dissolution Conditions. Dissolution testing of controlled-release products is a very important test that can show a relationship to the expected bioavailability for the lots of controlled-release product being tested. However, the dissolution conditions during the test are very important and if not properly chosen can give results that are not predictive of the actual in bioavailability.

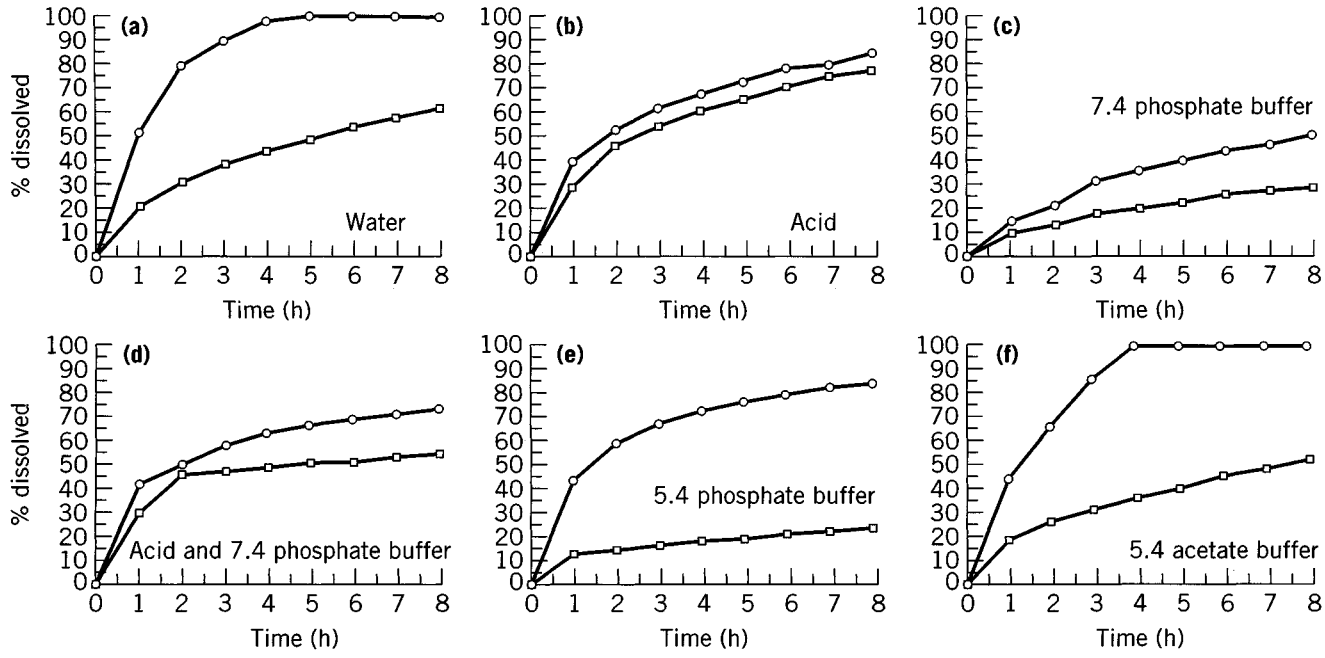

Figure 11. Quinidine gluconate dissolution profiles in several different media.

In Figure 11, dissolution profiles for two products tested under varying dissolution conditions are shown. Condition (b), which is dissolution testing in acid, shows similar dissolution profiles for the two products. If these two products were comparable in bioavailability, these conditions might be appropriate for testing these products; however, looking at other dissolution conditions, for example, in water, as can be seen in Figure 11(a) the data show significant differences in the dissolution profiles for these two products. If the products have different bioavailability characteristics, testing in, for example, water, might be more appropriate. For these two products it was established that the unapproved product had only approximately 40% of bioavailability of the reference product. Therefore, dissolution conditions shown in Figures 11(c)–(f) that distinguish between these two products—that is, conditions that show differing dissolution profiles—would be appropriate, whereas dissolution conditions that do not distinguish these two products would be inappropriate. In this particular example, the product with poor bioavailability was marketed without FDA approval. It is possible that only dissolution testing in acid was utilized by the manufacturer to show comparability between the two products. As it turns out, this was a very risky choice. The unapproved product, which was marketed, had very poor bioavailability that could not be determined by dissolution testing in acid. Only by conducting the bioequivalence study prior to marketing, establishing bioequivalence, then determining appropriate dissolution conditions, can bioequivalence between two controlled-release products be ensured (39).

Bibliography

Hydrogels are three-dimensional, water-swollen structures composed of mainly hydrophilic homopolymers or copolymers (1). They are rendered insoluble due to the presence of chemical or physical cross-links. The physical cross-links can be entanglements, crystallites, or weak associations such as van der Waals forces or hydrogen bonds. The cross-links provide the network structure and physical integrity.

Hydrogels are classified in a number of ways (1,2). They can be neutral or ionic based on the nature of the side groups. They can also be classified based on the network morphology as amorphous, semicrystalline, hydrogen-bonded structures, supermolecular structures, and hydrocolloidal aggregates. Additionally, in terms of their network structures, hydrogels can be classified as macroporous, microporous, or nonporous (1–3).

Since the development of poly(2-hydroxethyl methacrylate) gels in the early 1960s, hydrogels have been considered for use in a wide range of biomedical and pharmaceutical applications, mainly due to their high water content and rubbery nature. Because of these properties, hydrogel materials resemble natural living tissue more than any other class of synthetic biomaterials (1,4). Furthermore, the high water content allows these materials to exhibit excellent biocompatibility. Some applications of hydrogels include contact lenses, biosensors, sutures, dental materials, and controlled drug delivery (1,4–8). Park and Park (9) present a very useful commentary in relation to the biocompatibility of implantable hydrogel-based delivery systems.

The use of hydrogel-based controlled release systems that can swell in the presence of a biological fluid has been studied for over 30 years. A goal of many researchers is to develop hydrogel devices to provide time-independent, sustained release of bioactive agents (8). Researchers have attempted to achieve these goals by manipulation of the polymer composition and the device geometry. Hydrogel devices have been proposed for delivery by almost all of the conventional routes.

Two of the most important characteristics in evaluating the ability of a polymeric gel to function in a particular controlled release application are the network permeability and the swelling behavior. The permeability and swelling behavior of hydrogels are strongly dependent on the chemical nature of the polymer(s) composing the gel as well as the structure and morphology of the network. As a result, there are different mechanisms that control the release of drugs from hydrogel-based delivery devices. Such systems are classified by their drug release mechanism as diffusional-controlled release systems, swelling-controlled release systems, chemically controlled release systems, and environmentally responsive systems (2).

Hydrogels may exhibit swelling behavior dependent on the external environment. Thus, in the last 30 years there has been a major interest in the development and analysis of environmentally or physiologically responsive hydrogels (10). These hydrogels show drastic changes in their swell-

ing ratio due to changes in their external pH, temperature, ionic strength, nature of the swelling agent, and electromagnetic radiation. Some advantages to environmentally or physiologically responsive hydrogels are relevant in drug delivery applications. In an exceptional new review in the field, am Ende and Mikos (11) offer a thorough physicochemical and mathematical interpretation of the conditions of diffusional release of various bioactive agents in hydrogels and other polymeric carriers, with emphasis on the conditions of stability of peptides and proteins during delivery.

An additional advantage of hydrogels, which has received considerable attention recently, is that they may provide desirable protection of drugs, peptides, and especially proteins from the potentially harsh environment in the vicinity of the release site (12). In particular, such carriers may be able to function as carriers for the oral delivery of sensitive proteins or peptides (13). Finally, hydrogels may be excellent candidates as biorecognizable biomaterials (14). As such, they can be used as targetable carriers of bioactive agents, as bioadhesive systems or as conjugates with desirable biological properties.

In this article, we present an overview of the structure and properties of hydrogels, the diffusional behavior of hydrogels, and the mechanisms for release from polymeric controlled release systems. Additionally, we review important contributions in this area with specific emphasis on new synthetic methods that promise to provide imaginative solutions of drug delivery problems.

STRUCTURE AND PROPERTIES OF HYDROGELS

In order to evaluate the feasibility of using a particular hydrogel as a drug delivery device, it is important to know the structure and properties of the polymer network. The structure of an idealized hydrogel is shown in Figure 1. The most important parameters that define the structure and properties of swollen hydrogels are the polymer volume fraction in the swollen state, $\upsilon_{2,s}$, effective molecular weight of the polymer chain between cross-linking points, $\overline{M}_c$, and network mesh or pore size, ξ (15).

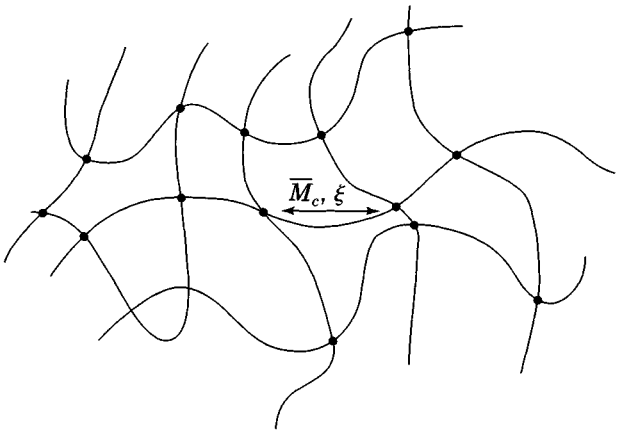

Figure 1. Schematic representation of the cross-linked structure of a hydrogel. $\overline{M}_c$ is the molecular weight of the polymer chains between cross-links (●) and ξ is the network mesh size.

The polymer fraction of the polymer in the swollen gel is a measure of the amount of fluid that a hydrogel can incorporate into its structure.

$$\upsilon_{2,s} = \frac{\text{volume of polymer}}{\text{volume of swollen gel}} = \frac{V_p}{V_{\text{gel}}} = 1/Q \qquad (1)$$

This parameter can be determined using equilibrium swelling experiments (16). The molecular weight between cross-links is the average molecular weight of the polymer chains between junction points, both chemical and physical. This parameter provides a measure of the degree of cross-linking in the gel. This value is related to the degree of cross-linking in the gel (X) as:

$$X = \frac{M_o}{2M_c} \qquad (2)$$

Here, M_o is the molecular weight of the repeating units making up the polymer chains.

The network mesh size represents the distance between consecutive cross-linking points and provides a measure of the porosity of the network. These parameters, which are not independent, can be determined theoretically or through a variety of experimental techniques.

Equilibrium Swelling Theories

Neutral Hydrogels. Flory and Rehner (17) developed the initial depiction of the swelling of cross-linked polymer gels using a Gaussian distribution of the polymer chains. They developed a model to describe the equilibrium degree of cross-linked polymers that postulated that the degree to which a polymer network swelled was governed by the elastic retractive forces of the polymer chains and the thermodynamic compatibility of the polymer and the solvent molecules. In terms of the free energy of the system, the total free energy change upon swelling is written as:

$$\Delta G = \Delta G_{\text{elastic}} + \Delta G_{\text{mix}} \qquad (3)$$

Here, $\Delta G_{\text{elastic}}$ is the contribution due to the elastic retractive forces and $\Delta G_{\text{elastic}}$ represents the thermodynamic compatibility of the polymer and the swelling agent.

Upon differentiation of equation 3 with respect to the number of solvent molecules in the system (at constant T and P), an expression can be derived for the chemical potential change ($\Delta\mu$) in the solvent in terms of the contributions due to swelling.

$$\mu_1 - \mu_{1,0} = (\Delta\mu)_{\text{elastic}} + (\Delta\mu)_{\text{mix}} \qquad (4)$$

Here, μ_1 is the chemical potential of the swelling agent within the gel and $\mu_{1,0}$ is the chemical potential of the pure fluid. At equilibrium, the chemical potential of the swelling agent inside and outside of the gel must be equal, therefore the elastic and mixing contributions to the chemical potential balance one another at equilibrium.

The chemical potential change upon mixing can be determined from the heat of mixing and the entropy of mixing. Using appropriate thermodynamic relationships, the chemical potential of mixing can be expressed as:

$$(\Delta\mu)_{\text{mix}} = RT(ln(1 - v_{2,s}) + \chi_1 v_{2,s}^2) \quad (5)$$

where χ_1 is the polymer solvent interaction parameter defined by Flory (17,18).

The elastic contribution to the chemical potential is determined from the statistical theory of rubber elasticity (18). The elastic free-energy is dependent on the number of polymer chains in the network, v_e, and the linear expansion factor, α. For gels that were crosslinked in the absence of a solvent, the elastic contribution to the chemical potential is written as:

$$(\Delta\mu)_{\text{elastic}} = RT\left(\frac{V_1}{v\bar{M}_c}\right)\left(1 - \frac{2\bar{M}_c}{\bar{M}_n}\right)\left(v_{2,s}^{1/3} - \frac{v_{2,s}}{2}\right) \quad (6)$$

where v is the specific volume of the polymer, V_1 is the molar volume of the swelling agent, and $\bar{M}_n$ is the molecular weight of linear polymer chains prepared using the same conditions in the absence of a cross-linking agent. By combining equations 5 and 6, the swelling behavior of neutral hydrogels cross-linked in the absence of a solvent can be described by the following equation.

$$\frac{1}{\bar{M}_c} = \frac{2}{\bar{M}_n} - \frac{(v/V_1)[ln(1 - v_{2,s}) + v_{2,s} + \chi_1 v_{2,s}^2]}{\left(v_{2,s}^{1/3} - \frac{v_{2,s}}{2}\right)} \quad (7)$$

In many cases, it is desirable to prepare hydrogels in the presence of a solvent. If the polymers were cross-linked in the presence of a solvent, the elastic contributions must account for the volume fraction density of the chains during cross-linking. Peppas and Merrill (19) modified the original Flory-Rehner to account for the changes in the elastic contributions to swelling. For polymer gels cross-linked in the presence of a solvent, the elastic contribution to the chemical potential is:

$$(\Delta\mu)_{\text{elastic}} = RT\left(\frac{V_1}{v\bar{M}_c}\right)\left(1 - \frac{2\bar{M}_c}{\bar{M}_n}\right)v_{2,r}\left(\left(\frac{v_{2,s}}{v_{2,r}}\right)^{1/3} - \frac{v_{2,s}}{2v_{2,r}}\right) \quad (8)$$

Here, $v_{2,r}$ is the volume fraction of the polymer in the relaxed state. The relaxed state of the polymer is defined as the state of the polymer immediately after cross-linking of the polymer but prior to swelling or deswelling. For the case of gels prepared by cross-linking in the presence of a solvent, the equation for the swelling of the polymer gel can be obtained by combining equations 5 and 8 as the mixing contributions for both cases are the same. The swelling of hydrogels cross-linked in the presence of a solvent can then be written as:

$$\frac{1}{\bar{M}_c} = \frac{2}{\bar{M}_n} - \frac{(v/V_1)[ln(1 - v_{2,s}) + v_{2,s} + \chi_1 v_{2,s}^2]}{v_{2,r}((v_{2,s}/v_{2,r})^{1/3} - (v_{2,s}/2v_{2,r}))} \quad (9)$$

By performing swelling experiments to determine $v_{2,r}$, the molecular weight between cross-links can be calculated for a particular gel using this equation (16).

Ionic Hydrogels. Ionic hydrogels contain pendent groups that are either cationic or anionic in nature. For anionic gels, the side groups of the gel are unionized below the pK_a and the swelling of the gel is governed by thermodynamic compatibility of the polymer and the swelling agent. However, above the pK_a of the network, the pendent groups are ionized and the gels swell to a large degree due to the development of a large osmotic swelling force due to the presence of the ions. In cationic gels, the pendent groups are unionized above the pK_b of the network. When the gel is placed in fluid of pH less than this value, the basic groups are ionized and the gels swell to a large degree (Figure 2). The pH-dependent swelling behavior of ionic gels, which is completely reversible in nature, is depicted in Figure 3.

The theoretical description of the swelling of ionic hydrogels is much more complex than that of neutral hydrogels. Aside from the elastic and mixing contributions to swelling, the swelling of an ionic hydrogel is affected by the degree of ionization in the gel, ionization equilibrium between the gel and the swelling agent, and the nature of the counterions in the fluid. As the ionic content of a hydrogel is increased, in response to an environmental stimulus, increased repulsive forces develop and the network becomes more hydrophilic. The result is a more highly swollen network. Because of Donnan equilibrium, the

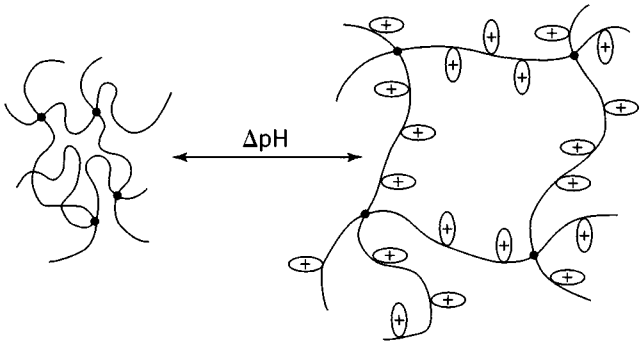

Figure 2. Expansion (swelling) of a cationic hydrogel due to ionization of pendent groups, at specific pH values.

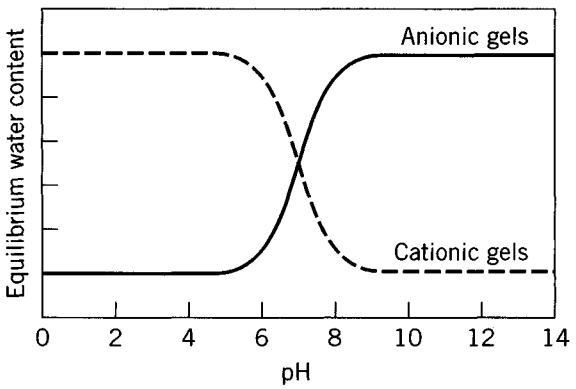

Figure 3. Equilibrium degree of swelling of anionic and cationic hydrogels as a function of the swelling solution pH.

chemical potential of the ions inside the gel must be equal to the chemical potential of the ions in the solvent outside of the gel (20). An ionization equilibrium is established in the form of a double layer of fixed charges on the pendent groups and counterions in the gel. Finally, the nature of counterions in the solvent affects the swelling of the gel. As the valence of the counterions increase, they are more strongly attracted to the gel and reduce the concentration of ions needed in the gel to satisfy Donnan equilibrium conditions.

The swelling behavior of polyelectrolyte gels was initially described as being a result of a balance between the elastic energy of the network and the osmotic pressure developed as a result of the ions (20–27). In electrolytic solutions, the osmotic pressure is associated with the development of a Donnan equilibrium. This pressure term is also affected by the fixed charges developed on the pendant chains. The elastic term is described by the Flory expression derived from assumptions of Gaussian chain distributions.

Models for the swelling of ionic hydrogels were developed by equating the three major contributions to the swelling of the networks. These contributions are due to mixing of the polymer and solvent, network elasticity, and ionic contributions. The general equation is given as

$$\Delta G = \Delta G_{\text{mix}} + \Delta G_{\text{el}} + \Delta G_{\text{ion}} \tag{10}$$

In terms of the chemical potential, the difference between the chemical potential of the swelling agent in the gel and outside of the gel is:

$$\mu_1 - \mu_{1,0} = (\Delta\mu)_{\text{elastic}} + (\Delta\mu)_{\text{mix}} + (\Delta\mu)_{\text{ion}} \tag{11}$$

For weakly charged polyelectrolytes, the elastic contribution and mixing contributions do not differ from the case of nonionic gels. However, for highly ionizable materials there are significant ionization effects and $\Delta\mu_{ion}$ is important. At equilibrium, the elastic, mixing, and ionic contributions must sum to 0.

The ionic contribution to the chemical potential is strongly dependent on the ionic strength and the nature of the ions. Brannon-Peppas and Peppas (26,27) and Ricka and Tanaka (20) both developed expressions to describe the ionic contributions to the swelling of polyelectrolytes. Assuming that the polymer networks under conditions of swelling behave similarly to dilute polymer solutions, the activity coefficients can be approximated as 1 and activities can be replaced with concentrations. Under these conditions, the ionic contribution to the chemical potential is described by the following:

$$(\Delta\mu)_{\text{ion}} = RTV_1\Delta c_{\text{tot}} \tag{12}$$

Here, Δc_{tot} is the difference in the total concentration of mobile ions within the gel. The difference in the concentration of mobile ions is due to the fact that the charged polymer requires the same number of counterions to remain in the gel to achieve electroneutrality. The difference in the total ion concentration could then be calculated from the equilibrium condition for the salt.

Brannon-Peppas and Peppas (26,27) developed expressions for the ionic contributions to the swelling of polyelectrolytes for anionic and cationic materials. The ionic contribution for anionic network is:

$$(\Delta\mu)_{\text{ion}} = \frac{RTV_1}{4I}\left(\frac{v_{2,s}^2}{v}\right)\left(\frac{K_a}{10^{-pH} + K_a}\right)^2 \tag{13}$$

For the cationic network, the ionic contribution is:

$$(\Delta\mu)_{\text{ion}} = \frac{RTV_1}{4I}\left(\frac{v_{2,s}^2}{v}\right)\left(\frac{K_b}{10^{pH-14} + K_a}\right)^2 \tag{14}$$

In these expressions, I is the ionic strength, K_a and K_b are the dissociation constants for the acid and base, respectively. It is significant to note that this expression has related the ionic contribution to the chemical potential to characteristics about the polymer/swelling agent that can readily determinable (e.g., pH, K_a, and K_b).

For the case of anionic polymer gels that were cross-linked in the presence of a solvent, the equilibrium swelling can be described by:

$$\frac{V_1}{4I}\left(\frac{v_{2,s}^2}{v}\right)\left(\frac{K_a}{10^{-pH} + K_a}\right)^2 = (ln(1 - v_{2,s}) + v_{2,s} + \chi_1 v_{2,s}^2) + \left(\frac{V_1}{v\overline{M}_c}\right)\left(1 - \frac{2\overline{M}_c}{\overline{M}_n}\right)v_{2,r} \cdot \left(\left(\frac{v_{2,s}}{v_{2,r}}\right)^{1/3} - \frac{v_{2,s}}{2v_{2,r}}\right) \tag{15}$$

For the cationic hydrogels prepared in the presence of a solvent, the equilibrium swelling is described by the following expression:

$$\frac{V_1}{4I}\left(\frac{v_{2,s}^2}{v}\right)\left(\frac{K_b}{10^{pH-14} + K_a}\right)^2 = (ln(1 - v_{2,s}) + v_{2,s} + \chi_1 v_{2,s}^2) + \left(\frac{V_1}{v\overline{M}_c}\right)\left(1 - \frac{2\overline{M}_c}{\overline{M}_n}\right)v_{2,r} \left(\left(\frac{v_{2,s}}{v_{2,r}}\right)^{1/3} - \frac{v_{2,s}}{2v_{2,r}}\right) \tag{16}$$

For the case of ionic hydrogels, the molecular weight between cross-links can be calculated by performing swelling experiments and applying equations 15 (anionic gels) or 16 (cationic gels).

Rubber Elasticity Theory

Hydrogels are similar to natural rubbers in that they have the ability to respond to applied stresses in a nearly instantaneously and almost irreversible manner (18,28). These polymer networks have the ability to deform readily under low stresses. Also, following small deformations (less than 20%) most gels can fully recover from the deformation in a rapid fashion. Under these conditions, the behavior of the gels can be approximated to be elastic. This property can be exploited to calculate the cross-linking density or molecular weight between cross-links for a particular gel.

The elastic behavior of cross-linked polymers has been analyzed using classical thermodynamics, statistical thermodynamics, and phenomenological models. Based on classical thermodynamics, the equation of state for rubbers can be expressed as (18,28):

$$f = \left(\frac{\partial U}{\partial L}\right)_{T,V} + T\left(\frac{\partial f}{\partial T}\right)_{L,V} \tag{17}$$

where f is the retractive force of the elastic polymer in response to an applied load, U is the internal energy and L is the length of the sample. For an ideal elastomer, $(\partial U/\partial L)_{T,V}$ is zero as deformation of the sample does not result in changes in the internal energy as the bonds are not stretched.

The connection between the classical and statistical thermodynamics can be made after applying the following Maxwell equation:

$$\left(\frac{\partial S}{\partial L}\right)_{T,V} = -\left(\frac{\partial f}{\partial T}\right)_{L,V} \tag{18}$$

By combining equations 17 and 18, the retractive force of an ideal elastomer can be written as:

$$f = -T\left(\frac{\partial S}{\partial L}\right)_{T,V} = -kT\left(\frac{\partial\, ln\Omega(r,\, T)}{\partial r}\right)_{T,V} \tag{19}$$

Here, r is the end-to-end distance of the polymer chain and Ω is the probability that a polymer chain of length r will have a specific conformation at a given temperature (T).

Upon evaluation of this equation for a system of n chains, the change in the Helmholtz free energy upon elastic deformation can be written as:

$$(\Delta A)_{elastic} = \frac{3nKT}{\bar{r}_f^2}\int_{\bar{r}_f}^{\bar{r}} r dr \tag{20}$$

Assuming that elastic deformation is not accompanied by a volume change, integration yields the classical equation for rubber elasticity.

$$\frac{f}{a} = \tau = \frac{\rho RT}{\overline{M}_c}\frac{\bar{r}_o^2}{\bar{r}_f^2}\left(\alpha - \frac{1}{\alpha^2}\right) \tag{21}$$

Here, a is the cross-sectional area, τ is the stress, ρ is the density of the polymer, α is the elongation ratio and $\bar{r}_o^2/\bar{r}_f^2$ is the front factor. The front factor is the ratio of the end-to-end distance of polymer chains in a real network and dilute chains in solution. Typically, this factor can be assumed less than or equal to one.

The previous expression was derived assuming an ideal network without any defects. In the ideal networks, all of the chains would participate equally to the elastic stress. However, in real networks, defects exist such as entanglements or dangling chain ends. After correcting for the case of real networks and assuming a front factor of one, the equation of state for rubber elasticity becomes:

$$\tau = \frac{\rho RT}{\overline{M}_c}\left(1 - \frac{2\overline{M}_c}{\overline{M}_n}\right)\left(\alpha - \frac{1}{\alpha^2}\right) \tag{22}$$

A similar analysis can be applied to swollen hydrogels where the polymer volume fraction in the network is less than unity. For the case of swollen gels, the number of cross-links per unit volume is different than for the case of unswollen polymer networks. The equation of state for real, swollen polymer gels can be expressed as:

$$\tau = \frac{\rho RT}{\overline{M}_c}\left(1 - \frac{2\overline{M}_c}{\overline{M}_n}\right)\left(\alpha - \frac{1}{\alpha^2}\right)\upsilon_{2,s}^{1/3} \tag{23}$$

This equation holds for networks cross-linked in the absence of any diluents. For the case of a swollen network cross-linked in the presence of a solvent, the equation of state can be written as (29):

$$\tau = \frac{\rho RT}{\overline{M}_c}\left(1 - \frac{2\overline{M}_c}{\overline{M}_n}\right)\left(\alpha - \frac{1}{\alpha^2}\right)\left(\frac{\upsilon_{2,s}}{\upsilon_{2,r}}\right)^{1/3} \tag{24}$$

For elongation of a polymer network along a single axis, the stress is inversely proportional to the molecular weight between cross-links in the polymer network. From mechanical analysis under short deformations, important structural information about the polymer networks can be obtained (30–32).

Network Pore Size Calculation

One of the most important parameters in controlling the rate release of a drug from a hydrogel is the network pore size, ξ. The pore size can be determined theoretically or using a number of experimental techniques. A direct technique for measuring this parameter is quasielastic laser-light scattering (33) or electron microscopy. Some indirect experimental techniques for determination of the hydrogel pore size include mercury porosimetry (34,35), rubber elasticity measurements (30), or equilibrium swelling experiments (16,36). However, the indirect experiments allow for calculation of the porous volume (mercury porosimetry) or the molecular weight between cross-links (rubber elasticity analysis or swelling experiments).

Based on values for the cross-linking density or molecular weight between cross-links, the network pore size can be determined by calculating end-to-end distance of the swollen polymer chains between cross-linking points (16,18,36).

$$\xi = \alpha(\bar{r}_o^2)^{1/2} \tag{25}$$

In this expression, α is the elongation of the polymer chains in any direction and $(\bar{r}_o^2)^{1/2}$ is the unperturbed end-to-end distance of the polymer chains between cross-linking points. Assuming isotropic swelling of the gels, the elongation is related to the swollen polymer volume fraction.

$$\alpha = \upsilon_{2,s}^{-1/3} \tag{26}$$

The unperturbed chain distance is calculated through the Flory characteristic ratio, C_n.

$$(\bar{r}_o^2)^{1/2} = l(C_n N)^{1/2} \tag{27}$$

Here, l is the length of the bond along the backbone chain (1.54 Å for vinyl polymers). The number of links per chain, N, is related to the cross-link density as:

$$N = \frac{2\overline{M}_c}{M_o} \tag{28}$$

Here, M_o is the molecular weight of the monomeric repeating units. Upon combination of these equations, the pore size of a swollen polymeric network can be calculated using the following equation:

$$\xi = \left(\frac{2C_n\overline{M}_c}{M_o}\right)^{1/2} l v_{2,s}^{-1/3} \tag{29}$$

DIFFUSION IN HYDROGELS

The release of drugs and other solutes from hydrogels results from combination of classical diffusion in the polymer network and mass transfer limitations (2). To optimize a hydrogel system for a particular application, the fundamental mechanism of solute transport in the membranes must be understood completely. In this section, we focus on the mechanism of drug diffusion in hydrogels as well as the importance of network morphology in controlling the transport of drugs in hydrogels.

Macroscopic Analysis

The transport or release of a drug through a polymeric controlled release device can be described by classical Fickian diffusion theory (2,37). This theory assumes that the governing factor for drug transport in the gels is ordinary diffusion. Drug delivery devices can be designed so that other mechanisms control the release rate such as gel swelling or polymer erosion.

For the case of one-dimensional transport, Fick's law can be expressed as (38):

$$J_i = -D_{ip}\frac{dC_i}{dX} \tag{30}$$

Here, J_i is the molar flux of the drug (mol/cm^2 s), C_i is the concentration of drug and D_{ip} is the diffusion coefficient of the drug in the polymer. For the case of a steady-state diffusion process, i.e., constant molar flux, and constant diffusion coefficient, equation 30 can be integrated to give the following expression:

$$J_i = K\frac{D_{ip}\Delta C_i}{\delta} \tag{31}$$

Here, δ is the thickness of the hydrogel and K is the partition coefficient, defined as

$$K = \frac{\text{drug concentration in gel}}{\text{drug concentration in solution}} \tag{32}$$

For many drug delivery devices, the release rate will be time dependent. For non–steady-state diffusion problems, Fick's second law is used to analyze the release behavior. Fick's second law is written as:

$$\frac{\partial C_i}{\partial t} = \frac{\partial}{\partial X}\left(D_{ip}\frac{\partial C_i}{\partial X}\right) \tag{33}$$

This form of the equation is for one-dimensional transport with nonmoving boundaries. Equation 33 can be evaluated for the case of constant diffusion coefficients and concentration-dependent diffusion coefficients.

Constant Diffusion Coefficients. Equation 33 can be solved by application of the appropriate boundary conditions. Most commonly, perfect-sink conditions are assumed. Under these conditions, the following boundary and initial conditions are applicable (Fig. 4):

$$t = 0, \quad X < \pm\frac{\delta}{2}, \quad C_i = C_o \tag{34a}$$

$$t > 0, \quad X = 0, \quad \frac{\partial C_i}{\partial X} = 0 \tag{34b}$$

$$t > 0, \quad X = \pm\frac{\delta}{2}, \quad C_i = C_s \tag{34c}$$

Here, C_o is the initial drug concentration inside the gel and C_s is the equilibrium bulk concentration. Upon application of the boundary conditions, Fick's second law for planar geometries can be integrated and the solution can be written in terms of the amount of drug released at a given time, M_t, normalized to the amount released at infinite times, M_∞ (38).

$$\frac{M_t}{M_\infty} = 1 - \sum_{n=0}^{\infty}\frac{8}{(2n+1)^2\pi^2}\,exp\left[\frac{-D_{ip}(2n+1)^2\pi^2 t}{\delta^2}\right] \tag{35}$$

Alternatively, the solution to equation 33 can be written in terms of the integrated complimentary error function, *ierfcx* (39).

$$\frac{M_t}{M_\infty} = 4\left(\frac{D_{ip}t}{\delta}\right)^{1/2}\left[\frac{1}{\pi^{1/2}} + 2\sum_{n=0}^{\infty}(-1)^n ierfc\,\frac{n\delta}{2(D_{ip}t)^{1/2}}\right] \tag{36}$$

At short times, equation 36 can be approximated as:

$$\frac{M_t}{M_\infty} = 4\left(\frac{D_{ip}t}{\pi\delta}\right)^{1/2} \tag{37}$$

Concentration-Dependent Diffusion Coefficients. In most systems, the drug diffusion coefficient is dependent on the

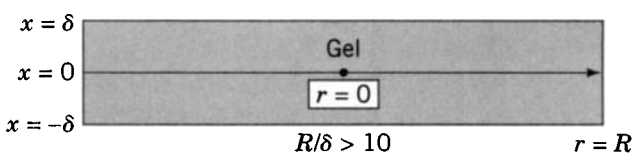

Figure 4. Depiction of the slab geometry used for one-dimensional analysis of Fick's second law.

drug concentration as well as the concentration of the swelling agent. In order to analyze the diffusive behavior of drug delivery systems when this is the case, one must choose an appropriate relationship between the diffusion coefficient and the drug concentration. Based on free-volume theory, Fujita (40) proposed the following relationship between the diffusion coefficient and the drug concentration in the gel.

$$D_{ip} = D_{iw}\, exp[-\beta(C_i - C_o)] \tag{38}$$

Here, D_{iw} is the diffusion coefficient in the pure solution, β is a constant dependent on the system, and C_o is the concentration of drug in solution. Additionally, a similar equation was written to relate the diffusion coefficient to the concentration of the swelling agent and the drug in the gel.

$$D_{ip} = D_{iw}\, exp[-\beta(C_s - C_i)] \tag{39}$$

Here, C_s is the swelling agent concentration.

Effects of Network Morphology

The structure and morphology of a polymer network significantly affects the ability of a drug to diffuse through a hydrogel. For all types of release systems, the diffusion coefficient (or effective diffusion coefficient) of solutes in the polymer is dependent on a number of factors such as the structure and pore size of the network, the polymer composition, the water content, and the nature and size of the solute. Perhaps the most important parameter in evaluating a particular device for a specific application is the ratio of the hydrodynamic radius of the drug, d_h, to the network pore size, ξ (Figure 5). Accordingly, hydrogels for controlled release applications are classified according to their pore size (3). The transport properties of drugs in each type of gel vary according to the structure and morphology of the network.

Macroporous Hydrogels. Macroporous hydrogels have large pores, usually between 0.1 and 1 μm. Typically, the pores of these gels are much larger than the diffusing species. In the case of these membranes, the pores are sufficiently large so that the solute diffusion coefficient can be described as the diffusion coefficient of the drug in the water-filled pores. The process of solute transport is hindered by the presence of the macromolecular mesh. The solute diffusion coefficient can be characterized in terms of the diffusion coefficient of the solute in the pure solvent (D_{iw}) as well as the network porosity (ϵ) and tortuosity (τ). Additionally, the manner in which the solute partitions itself within the pore structure of the network affects the diffusion of the drug. This phenomenon is described in terms of the partition coefficient, K_p. These parameters can be incorporated to describe the transport of the drug in the membranes in terms of an effective diffusion coefficient (D_{eff}).

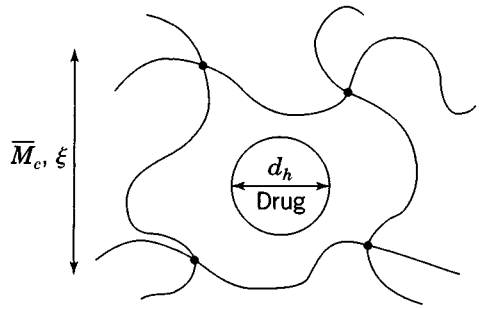

Figure 5. The effects of molecular size (r_s) on the diffusion of a solute in a network of pore size ξ.

$$D_{eff} = D_{iw}\frac{K_p\epsilon}{\tau} \tag{40}$$

Microporous Hydrogels. These membranes have pore sizes between 100 and 1000 Å. In these gels, the pores are water filled and drug transport occurs due to a combination of molecular diffusion and convection in the water-filled pores. In these gels, significant partitioning of the solute within the pore walls may occur for systems in which the drug and polymer are thermodynamically compatible. The effective diffusion coefficient can be expressed in a form similar to that for macroporous membranes.

Transport in microporous membranes is different from macroporous membranes because the pore size begins to approach the size of the diffusing solutes. Numerous researchers have attempted to describe transport for the case of the solute pore size being approximately equal to the network pore size. The rate of the diffusion coefficient in the membrane and pure solvent can be related to the ratio of the solute and pore radius.

$$\frac{D_{ip}}{D_{iw}} = (1 - \lambda^2)(1 - 2.104\lambda + 2.09\lambda^3 - 0.95\lambda^5) \tag{41}$$

In this expression, the diffusion coefficient in the membrane, D_{ip}, is related to λ, the ratio of the solute radius (r_s) to the pore radius (r_p).

$$\lambda = \frac{r_s}{r_p} \tag{42}$$

This theory was initially proposed by H. Faxen in 1923; however, other researchers have provided more recent corrections to this theory (41–43). An excellent review of all of these diffusional theories has been provided by Deen (44).

Nonporous Hydrogels. Nonporous gels have molecular sized pores equal to the macromolecular correlation length, ξ (between 10 and 100 Å). Gels of this type are typically formed by the chemical or physical cross-linking of the polymer chains. In these gels, the polymer chains are densely packed and serve to severely limit solute transport. Additionally, the cross-links serve as barriers to diffusion. This distance between the physical obstructions is known as the mesh size. Transport of solutes in these membranes occurs only by diffusion.

The macromolecular mesh of nonporous membranes is not comparable to the pore structure microporous gels.

Therefore, the theories developed for the microporous membranes are nonapplicable to nonporous gels. The diffusional theories developed for nonporous membranes are based on the concept of free-volume. The free-volume is the area within the gel not occupied by the polymer chains (45). Diffusion of solutes in nonporous membranes will occur within this free volume.

The first theory describing transport in nonporous gels was presented by Yasuda et al. (46). This theory relates the normalized diffusion coefficient, the ratio of the diffusion coefficient of the solute in the membrane ($D_{2,13}$) to the diffusion coefficient of the solute in the pure solvent ($D_{2,1}$), to degree of hydration of the membrane, H (g water/g swollen gel). The subscripts 1, 2, and 3 represent the solvent or water, solute, and the polymer. The normalized diffusion coefficient can be written as

$$\frac{D_{2,13}}{D_{2,1}} = \varphi(q_s)exp\left[-B\left(\frac{q_s}{V_{f,1}}\right)\left(\frac{1}{H} - 1\right)\right] \quad (43)$$

where $V_{f,1}$ is the free-volume occupied by the water, φ is a sieving factor which provides a limiting mesh size below which solutes of cross-sectional area q_s cannot pass, and B is a parameter characteristic of the polymer. Based on this theory, a permeability coefficient for the drug in the swollen membrane, $P_{2,13}$ is given by

$$P_{2,13} = \frac{D_{2,13}K}{\delta} \quad (44)$$

Yasuda and Lamaze (47) confirmed this theory experimentally using urea, creatinin and secobarbital.

Peppas and Reinhart (48) also developed a theoretical model to describe solute transport in highly swollen, nonporous hydrogels. In this description, the diffusional jump lengths of the solute were assumed the same in the gel and the pure solvent. Additionally, the free-volume of the hydrogel was taken to be the same as the free-volume of the pure solvent. Using this approach, the normalized diffusion coefficient can be described in terms of the degree of swelling and the molecular weight of the polymer chains as

$$\frac{D_{2,13}}{D_{2,1}} = k_1\left(\frac{\overline{M}_c - \overline{M}_c^*}{\overline{M}_n - \overline{M}_c^*}\right)exp\left(-\frac{k_2 r_s^2}{Q - 1}\right) \quad (45)$$

where k_1 and k_2 are parameters based on the polymer structure, Q is the degree of swelling (g swollen polymer/g dry polymer), r_s is the solute radius, $\overline{M}_c$ is the molecular weight of the polymer chains between cross-links, $\overline{M}_n$ is the molecular weight of linear polymer chains prepared using the same conditions in the absence of a crosslinking agent and $\overline{M}_c^*$ is the critical molecular weight between cross-links below which a solute of size r_s could not diffuse. In this depiction, the term $(\overline{M}_c - \overline{M}_c^*/\overline{M}_n - \overline{M}_c^*)$ is comparable to the sieving factor (φ) presented by Yasuda. These researchers experimentally verified the dependence of the diffusion coefficient on the solute size and cross-linking density (49). Recently, the group of Prausnitz has studied the size exclusion effects in highly swollen networks (50).

Peppas and Moynihan (51) developed a theory for the case of moderately or poorly swollen, nonporous networks. In this case, the diffusional jump length of the solute in the membrane ($\lambda_{2,13}$) does not equal the diffusional jump length of the solute in the pure solvent ($\lambda_{2,13}$) and the free-volume of the gel does not equal the free-volume of the pure solvent. In this model, the normalized diffusion coefficient is written as

$$\frac{D_{2,13}}{D_{2,1}} = f(v_{2,s}^{-3/4})exp[k_3(\overline{M}_c - \overline{M}_n) - \pi r_s^2 l_s \Phi(V)] \quad (46)$$

where $f(v_{2,s}^{-3/4})$ is a parameter representing the characteristic size of the diffusional area, k_3 is a structural parameter and l_s is the length of the solute. The free-volume contributions, $\Phi(V)$, are expressed as

$$\Phi(V) = \frac{V_1 - V_3}{(Q - 1)V_1^2 + V_1 V_3} \quad (47)$$

where V_1 and V_3 are the free-volumes of the polymer and the pure solvent.

Harland and Peppas (52) developed a theory for diffusion in a semicrystalline polymer. In this type of gel, the diffusion occurs only in the pores between the impermeable crystalline regions. The diffusion coefficient of the solute in the crystalline phase (D_c) can be expressed in terms of the diffusion coefficient in the amorphous phase (D_a) as

$$D_c = \frac{D_a(1 - v_c)}{\tau} \quad (48)$$

where τ is the tortuosity and v_c is the volume fraction of the crystalline region.

For the case of semicrystalline hydrogels, the crystallites present the greatest obstacle to diffusion. Therefore, the diffusion coefficient for the gel in the swollen membrane is assumed to be equal to the diffusion coefficient of the solute in the crystalline regions. For the case of moderately or poorly swollen networks, the normalized diffusion coefficient can be written as

$$\frac{D_{2,13}}{D_{2,1}} = \frac{(1 - v_c)}{\tau} f(v_{2,s}^{-3/4})exp[k_3(\overline{M}_c - \overline{M}_n) - \pi r_s^2 l_s \Phi(V)] \quad (49)$$

For highly swollen networks, the normalized diffusion coefficient can be expressed as

$$\frac{D_{2,13}}{D_{2,1}} = \frac{(1 - v_c)}{\tau}\left(\frac{\overline{M}_c - \overline{M}_c^*}{\overline{M}_n - \overline{M}_c^*}\right)exp\left(-\frac{\pi r_s^2 l v_a}{V_w v_s}\right) \quad (50)$$

where v_a is the volume fraction of the amorphous region, v_s is the volume fraction of the solvent and V_w is the volume fraction of the water.

Experimental Determination of Diffusion Coefficients

Membrane Permeability Experiments. The membrane permeation method is used to study the diffusion coeffi-

cients of solutes through thin membranes. The drug permeates through an equilibrium-swollen membrane from a reservoir containing a high concentration of drug (donor cell) to a reservoir containing a lower concentration (receptor).

In these experiments, the drug concentration should be monitored over time in the receptor cell. The solute permeability, P, can be determined from the following expression.

$$ln\left(\frac{2C_o}{C_t} - 1\right) = \frac{2A}{Vl} Pt \tag{51}$$

In this expression, C_o is the donor cell concentration (initially), C_t is the time-dependent receptor cell concentration, A is the cross-sectional area of the membrane, V is the volume of the cells and l is the membrane thickness. A plot of $(Vl/A)ln(2C_o/C_t - 1)$ versus time yields a straight line of slope P if the gel remains at equilibrium.

The diffusion coefficient is related to the partition coefficient by equation 44. The partition coefficient can be determined experimentally through equilibrium partitioning studies. In this type of experiment, hydrogels are swollen to equilibrium in drug solutions of concentration C_o. Once equilibrium has been reached, the partition coefficient is calculated as

$$K = -\frac{C_{m,eq}}{C_{s,eq}} \tag{52}$$

where $C_{m,eq}$ is the equilibrium concentration of drug in the membrane and $C_{s,eq}$ is the equilibrium concentration of the drug in the solution.

Controlled Release Experiments. Another relatively easy technique for determination of diffusion coefficients is to measure the release of drug release from thin hydrogels (aspect ratio >10). In release experiments, the membranes containing the dispersed drug are placed in drug-free solutions and the concentration of the drug in the solutions is monitored over time. It is recommended that nearly perfect sink conditions be maintained throughout the experiment.

The diffusion coefficient can be found by fitting the release data to equation 37. This equation is valid for the initial 60% of the total amount released. This technique is most accurate for systems in which diffusion is the dominant mechanism for drug release. In order to determine whether a particular device is diffusion controlled, the early time release data can be fit to the following empirical relationship proposed by Ritger and Peppas (39).

$$\frac{M_t}{M_\infty} = kt^n \tag{53}$$

The constants, k and n, are characteristics of the drug–polymer system. The diffusional exponent, n, is dependent on the geometry of the device as well as the physical mechanism for release. For classical Fickian diffusion, Ritger and Peppas (39) determined that value for the diffusional exponent was 0.5 for slab geometries, 0.45 for cylindrical devices, and 0.43 for spherical devices.

By determining the diffusional exponent, n, one can gain information about the physical mechanism controlling drug release from a particular device. Based on the diffusional exponent (53), the drug transport in a slab geometry is classified as Fickian diffusion ($n = 0.5$), Case II transport ($n = 1$), non-Fickian or anomalous transport ($0.5 < n < 1$) and Super Case II transport (Table 1). Representative release curves for each case are shown in Figure 6. For systems exhibiting Case II transport, the dominant mechanism for drug transport is due to polymer relaxation as the gels swells. These types of devices, known as swelling-controlled release systems, are described in more detail later. Anomalous transport occurs due to a coupling of Fickian diffusion and polymer relaxation.

Berens and Hofenberg (54) proposed the following model to describe the release behavior of dynamically swelling hydrogels.

$$\frac{M_t}{M_\infty} = k_1 t + k_2 t^{1/2} \tag{54}$$

This expression describes the release rates in terms of relaxation-controlled transport process, $k_1 t$, and the diffusion-controlled process, $k_2 t^{1/2}$.

Other Techniques. There are several other methods for experimental determination of diffusion coefficients in polymeric systems. These techniques involve more complex instrumentation techniques that cannot be described in depth in this work. These techniques include NMR spec-

CLASSIFICATIONS

Because of their nature, hydrogels can be used in many different types of controlled release systems. These systems are classified according to the mechanism controlling the release of the drug from the device. Hydrogel-based drug delivery systems are classified as diffusion-controlled systems, swelling-controlled systems, chemically controlled systems, and environmentally responsive systems (2). In this section, the mechanism of drug release in each type of system is described.

Diffusion-Controlled Release Systems

Diffusion is the most common mechanism controlling release in hydrogel-based drug delivery system. There are two major types of diffusion-controlled systems; reservoir devices and membrane devices. Drug release from each type of system occurs by diffusion through the macromolecular mesh or through the water-filled pores.

Reservoir Systems. Reservoir systems consist of a polymeric membrane surrounding a core containing the drug (Fig. 7). Typically, reservoir devices are capsules, cylinders, slabs, or spheres. The rate-limiting step for drug release is diffusion through the outer membrane of the device. For a device with a membrane thickness of δ, the molar flux of drug leaving the device is described by equation 31.

To maintain a constant release rate or flux of drug from the reservoir, the concentration difference must remain constant. This can be achieved by designing a device with excess solid drug in the core. Under these conditions, the internal solution in the core remains saturated. This type of device is an extremely useful device as it allows for time-independent or zero-order release.

The major drawback of this type of drug delivery system is the potential for catastrophic failure of the device. In the event that the outer membrane ruptures, the entire content of the device are delivered nearly instantaneously. When preparing these devices, care must be taken to ensure that the device does not contain pinholes or other defects that may lead to rupture.

Matrix Systems. In matrix devices, the drug is dispersed throughout the three-dimensional structure of the hydrogel (Fig. 8). Release occurs due to diffusion of the drug throughout the macromolecular mesh or water-filled pores. The fractional release from a one-dimensional device can be modeled using equation 33. In these systems, the release rate is proportional to time to the one-half power. This is significant in that it is impossible to obtain time independent or zero-order release in this type of system with simple geometries.

Drug can be incorporated into the gels by equilibrium partitioning, where the gel is swollen to equilibrium in concentrated drug solution, or during the polymerization reaction. Equilibrium partitioning is the favorable loading method for drug–polymer systems with large partition coefficients or for sensitive macromolecular drugs such as peptides or proteins that could be degraded during the polymerization.

Swelling-Controlled Release Systems

In swelling-controlled release systems, the drug is dispersed within a glassy polymer. Upon contact with biological fluid, the polymer begins to swell. No drug diffusion occurs through the polymer phase. As the penetrant enters the glassy polymer, the glass transition temperature of the polymer is lowered allowing for relaxations of the macromolecular chains. The drug is able to diffuse out of the swollen, rubbery area of the polymers. This type of system is characterized by two moving fronts: the front separating the swollen (rubbery) portion and the glassy regions which moves with velocity, v, and the polymer–fluid interface (Fig. 9). The rate of drug release is controlled by the velocity and position of the front dividing the glassy and rubbery portions of the polymer.

For true swelling-controlled release systems, the diffusional exponent, n, is 1. This type of transport is known as Case II transport and results in zero-order release kinetics. However, in some cases, drug release occurs due to a combination of macromolecular relaxations and Fickian diffusion. In this case, the diffusional exponent is between 0.5 and 1. This type of transport is known as anomalous or non-Fickian transport. A complete mathematical treatment of this type of release behavior has been provided in two excellent reviews (37,53).

Chemically Controlled Release Systems

There are two major types of chemically controlled release systems: erodible drug delivery systems and pendent chain systems (58,59). In erodible systems, drug release occurs due to degradation or dissolution of the hydrogel. In pendent chain systems, the drug is affixed to the polymer back-

troscopy (55), scanning electron microscopy (56), Fourier transform infrared spectroscopy (57), and quasielastic laser-light scattering (33).

CLASSIFICATIONS

Because of their nature, hydrogels can be used in many different types of controlled release systems. These systems are classified according to the mechanism controlling the release of the drug from the device. Hydrogel-based drug delivery systems are classified as diffusion-controlled systems, swelling-controlled systems, chemically controlled systems, and environmentally responsive systems (2). In this section, the mechanism of drug release in each type of system is described.

Diffusion-Controlled Release Systems

Diffusion is the most common mechanism controlling release in hydrogel-based drug delivery system. There are two major types of diffusion-controlled systems; reservoir devices and membrane devices. Drug release from each type of system occurs by diffusion through the macromolecular mesh or through the water-filled pores.

Reservoir Systems. Reservoir systems consist of a polymeric membrane surrounding a core containing the drug (Fig. 7). Typically, reservoir devices are capsules, cylinders, slabs, or spheres. The rate-limiting step for drug release is diffusion through the outer membrane of the device. For a device with a membrane thickness of δ, the molar flux of drug leaving the device is described by equation 31.

To maintain a constant release rate or flux of drug from the reservoir, the concentration difference must remain constant. This can be achieved by designing a device with excess solid drug in the core. Under these conditions, the internal solution in the core remains saturated. This type of device is an extremely useful device as it allows for time-independent or zero-order release.

The major drawback of this type of drug delivery system is the potential for catastrophic failure of the device. In the event that the outer membrane ruptures, the entire content of the device are delivered nearly instantaneously. When preparing these devices, care must be taken to ensure that the device does not contain pinholes or other defects that may lead to rupture.

Matrix Systems. In matrix devices, the drug is dispersed throughout the three-dimensional structure of the hydrogel (Fig. 8). Release occurs due to diffusion of the drug throughout the macromolecular mesh or water-filled pores. The fractional release from a one-dimensional device can be modeled using equation 33. In these systems, the release rate is proportional to time to the one-half power. This is significant in that it is impossible to obtain time independent or zero-order release in this type of system with simple geometries.

Drug can be incorporated into the gels by equilibrium partitioning, where the gel is swollen to equilibrium in concentrated drug solution, or during the polymerization reaction. Equilibrium partitioning is the favorable loading method for drug–polymer systems with large partition coefficients or for sensitive macromolecular drugs such as peptides or proteins that could be degraded during the polymerization.

Swelling-Controlled Release Systems

In swelling-controlled release systems, the drug is dispersed within a glassy polymer. Upon contact with biological fluid, the polymer begins to swell. No drug diffusion occurs through the polymer phase. As the penetrant enters the glassy polymer, the glass transition temperature of the polymer is lowered allowing for relaxations of the macromolecular chains. The drug is able to diffuse out of the swollen, rubbery area of the polymers. This type of system is characterized by two moving fronts: the front separating the swollen (rubbery) portion and the glassy regions which moves with velocity, v, and the polymer–fluid interface (Fig. 9). The rate of drug release is controlled by the velocity and position of the front dividing the glassy and rubbery portions of the polymer.

For true swelling-controlled release systems, the diffusional exponent, n, is 1. This type of transport is known as Case II transport and results in zero-order release kinetics. However, in some cases, drug release occurs due to a combination of macromolecular relaxations and Fickian diffusion. In this case, the diffusional exponent is between 0.5 and 1. This type of transport is known as anomalous or non-Fickian transport. A complete mathematical treatment of this type of release behavior has been provided in two excellent reviews (37,53).

Chemically Controlled Release Systems

There are two major types of chemically controlled release systems: erodible drug delivery systems and pendent chain systems (58,59). In erodible systems, drug release occurs due to degradation or dissolution of the hydrogel. In pendent chain systems, the drug is affixed to the polymer back-

bone through degradable linkages. As these linkages degrade, the drug is released.

Erodible Drug Delivery Systems. Erodible drug delivery systems, also known as degradable or absorbable release systems, can be either matrix or reservoir delivery systems. In reservoir devices, an erodible membrane surrounds the drug core. If the membrane erodes significantly after the drug release is complete, the dominant mechanism for release would be diffusion. Predictable, zero-order release could be obtained with these systems. In some cases, the erosion of the membrane occurs simultaneously with drug release. As the membrane thickness decreased due to erosion, the drug delivery rate would also change. Finally, in some erodible reservoir devices, the drug diffusion in the outer membrane does not occur. Under these conditions, drug release does not occur until the outer membrane erodes completely. In this type of device, the entire contents are released in a single, rapid burst. These types of systems have been investigated for use as enteric coatings.

For erodible matrix devices, the drug is dispersed within the three-dimensional structure of the hydrogel. Drug release is controlled by drug diffusion through the gel or erosion of the polymer. In true erosion-controlled devices, the rate of drug diffusion is significantly slower than the rate of polymer erosion, and the drug is released as the polymer erodes (Fig. 10).

In erodible system, there are three major mechanisms for erosion of the polymer. The first mechanism for erosion is the degradation of the cross-links. This degradation can occur by hydrolysis of water-labile linkages, enzymatic degradation of the junctions, or dissolution of physical cross-links such as entanglements or crystallites in semicrystalline polymers. The second mechanism for erosion is solubilization of insoluble or hydrophobic polymers. This could occur as a result of hydrolysis, ionization, or protonation of pendent groups along the polymer chains. The final mechanism of erosion is the degradation of backbone bonds to produce small molecular weight molecules. Typically, the degradation products are water soluble. This type of erosion can occur by hydrolysis of water-labile backbone linkages or by enzymatic degradation of backbone linkages. The most commonly studied erodible polymer systems are poly(lactic acid) (PLA), poly(glycolic acid) (PGA), and copolymers of PLA and PGA.

Pendent Chain Systems. Pendent chain systems consist of linear homo- or copolymers with the drug attached to the backbone chains. The drug is released from the polymer by hydrolysis or enzymatic degradation of the linkages (Fig. 11). Zero-order release can be obtained with these systems, provided that the cleavage of the drug is the rate-controlling mechanism.

Environmentally Responsive Systems

Hydrogels may exhibit swelling behavior dependent on the external environment. Over the last 30 years there has been a significant interest in the development and analysis of environmentally or physiologically responsive hydrogels (10). Environmentally responsive materials show drastic changes in their swelling ratio due to changes in their external pH, temperature, ionic strength, nature and composition of the swelling agent, enzymatic or chemical reaction, and electrical or magnetic stimulus (60). In most responsive networks, a critical point exists at which this transition occurs.

Responsive hydrogels are unique in that there are many different mechanisms for drug release and many different

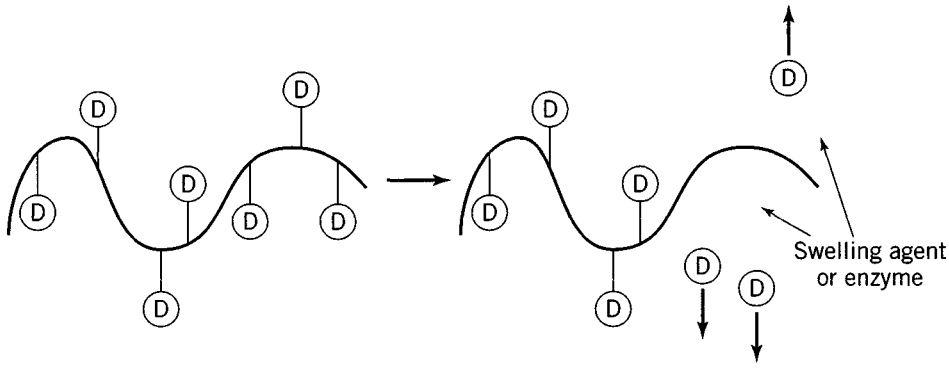

Figure 11. Schematic diagram of the release of drug from a pendent chain system due to scission of the bonds connecting the drug to the polymer backbone.

types of release systems based on these materials. For instance, in most cases drug release occurs when the gel is highly swollen or swelling and is typically controlled by gel swelling, drug diffusion, or a coupling of swelling and diffusion. However, in a few instances, drug release occurs during gel syneresis by a squeezing mechanism. Also, drug release can occur due to erosion of the polymer caused by environmentally responsive swelling.

Another interesting characteristic about many responsive gels is that the mechanism causing the network structural changes can be entirely reversible in nature. This behavior is depicted in Figure 12 for a pH- or temperature-responsive gel. The ability of these materials to exhibit rapid changes in their swelling behavior and pore structure in response to changes in environmental conditions lends these materials favorable characteristics as carriers for bioactive agents, including peptides and proteins. This type of behavior may allow these materials to serve as self-regulated, pulsatile drug delivery systems. This type of behavior is shown in Figure 13 for pH- or temperature-responsive gels. Initially, the gel is in an environment in which no swelling occurs. As a result, very little drug release occurs. However, when the environment changes and the gel swells, rapid drug release occurs (either by Fickian diffusion, anomalous transport, or Case II transport). When the gel collapses as the environment changes, the release can be turned off again. This can be repeated over numerous cycles. Such systems could be of extreme importance in the treatment of chronic diseases such as diabetes. Peppas (60) and Siegel (61) have presented detailed analyses of this type of behavior.

pH-Sensitive Hydrogels. One of the most widely studied types of physiologically responsive hydrogels is pH-responsive hydrogels. These hydrogels are swollen from ionic networks. These ionic networks contain either acidic or basic pendent groups. In aqueous media of appropriate pH and ionic strength, the pendant groups can ionize developing fixed charges on the gel as shown in Figure 2 for an ionic gel. The swelling behavior of these materials has been analyzed in a previous section.

There are many advantages to using ionic materials over neutral networks. All ionic materials exhibit a pH and ionic strength sensitivity. The swelling forces developed in these systems are increased over the nonionic materials. This increase in swelling force is due to the localization of fixed charges on the pendent groups. As a result, the mesh size of the polymeric networks can change significantly with small pH changes. In these materials, the drug diffusion coefficients and release rates vary greatly with environmental pH.

Temperature-Sensitive Hydrogels. Another class of environmentally sensitive materials that are being targeted for use in drug delivery applications is thermally sensitive polymers. This type of hydrogel exhibits temperature-sensitive swelling behavior due to a change in the polymer–swelling agent compatibility over the temperature range of interest. Temperature-sensitive polymers typically exhibit a lower critical solution temperature (LCST), below which the polymer is soluble. Above this temperature, the polymers are typically hydrophobic and do not swell significantly in water (62). However, below the LCST, the cross-linked gel swell to significantly higher degrees because of the increased compatibility with water. For polymers that exhibit this sort of swelling behavior, the rate of drug release would be dependent on the temperature. The highest release rates would occur when the temperature of the environment is below the LCST of the gel.

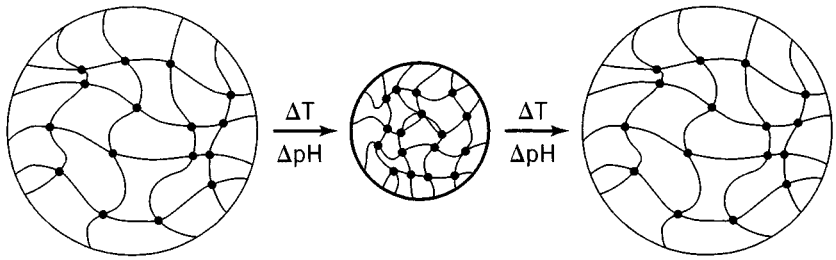

Figure 12. Swollen temperature- and pH-sensitive hydrogels may exhibit an abrupt change from the expanded (left) to the collapsed (syneresed) state (center) and then back to the expanded state (right) as temperature and pH change.

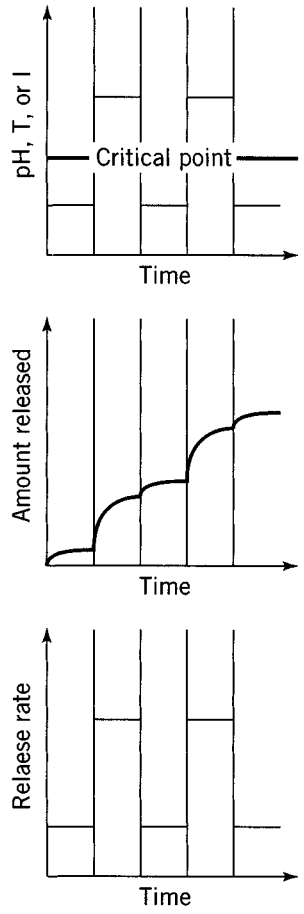

Figure 13. Cyclic change of pH, T, or ionic strength (I) leads to abrupt changes in the drug release rates at certain time intervals in some environmentally responsive polymers.

Complexing Hydrogels. Some hydrogels may exhibit environmental sensitivity due to the formation of polymer complexes. Polymer complexes are insoluble, macromolecular structures formed by the noncovalent association of polymers with the affinity for one another. The complexes form due to association of repeating units on different chains (interpolymer complexes) or on separate regions of the same chain (intrapolymer complexes). Polymer complexes are classified by the nature of the association as stereocomplexes, polyelectrolyte complexes, and hydrogen-bonded complexes (63). The stability of the associations is dependent on such factors as the nature of the swelling agent, temperature, type of dissolution medium, pH and ionic strength, network composition and structure, and length of the interacting polymer chains.

In this type of gel, complex formation results in the formation of physical cross-links in the gel. As the degree of effective cross-linking is increased, the network mesh size and degree of swelling is significantly reduced. As a result, the rate of drug release in these gels decreases dramatically upon the formation of interpolymer complexes.

Materials Sensitive to Chemical or Enzymatic Reaction. More recently, researchers have proposed controlled release devices that can respond to specific chemicals or enzymes in the body (64,65). Under normal conditions, the structure of the hydrogel would be sufficient to prevent drug release from occurring. However, in the presence of specific substances, chemical or enzymatic reactions could occur that may hydrolyze specific groups of the polymer chain resulting in an increased pore structure and rate of drug release from the gel. If degradation of the gel occurs, the systems cannot be fully reversible.

In some instances, enzymes can be incorporated into the structure of the hydrogel. In the presence of specific chemicals, the enzyme could trigger a reaction which would change the microenvironment of the hydrogel. Changes in the local microenvironment (such as pH or temperature) could lead to gel swelling or collapse. In these situations, the release rates would be altered significantly. This type of system could be completely reversible in nature.

Magnetically Responsive Systems. Magnetically responsive systems consist of polymers or copolymers containing magnetic microbeads (66). These systems can be prepared from most polymers; however, the most commonly used copolymer for these systems is the hydrophobic polymer, poly(ethylene-*co*-vinyl acetate) (PEVAc). Such systems are not typically classified as hydrogels because they do not swell to any appreciable degree. The drug release mechanism from a typical magnetic system is shown in Figure 14. The three-dimensional structure of these systems is such that no drug release can occur when no magnetic field is applied. However, when a magnetic field is applied, the microbeads pulsate allowing for the formation of micropores. Additionally, the pulsation of the beads "squeezes" the drug out of the gel through these pores. When the field is removed, drug release is halted rapidly. Such systems have been targeted for use as pulsatile drug delivery vehicles and have shown to exhibit extremely reproducible behavior.

APPLICATIONS

Neutral Hydrogels

A major goal in drug delivery is to develop systems that deliver drugs at a constant rate over an extended period. This can be achieved by using release systems in which gel swelling is the controlling mechanism for drug release. Researchers have also attempted to develop constant-release systems by alteration of device geometry and polymer composition. One of the first researchers to use hydrogels for swelling-controlled release was Good (67). In this work, glassy poly(2-hydroxyethyl methacrylate) (PHEMA) containing tripelennamine hydrochloride was swollen in water. The release rate of the solute was non-Fickian, but zero-order release was not obtained. The first such system in which zero-order release was observed was developed by Hopfenberg and Hsu (68). In these systems, cross-linked polystyrene was used to release red dyes into hexane. Other polymers that have been used extensively in controlled release systems include poly(vinyl alcohol) (PVA), poly(*N*-vinyl-2-pyrollidone) (PNVP), poly(ethylene glycol) (PEG), poly(ethylene oxide) (PEO), and PEVAc or

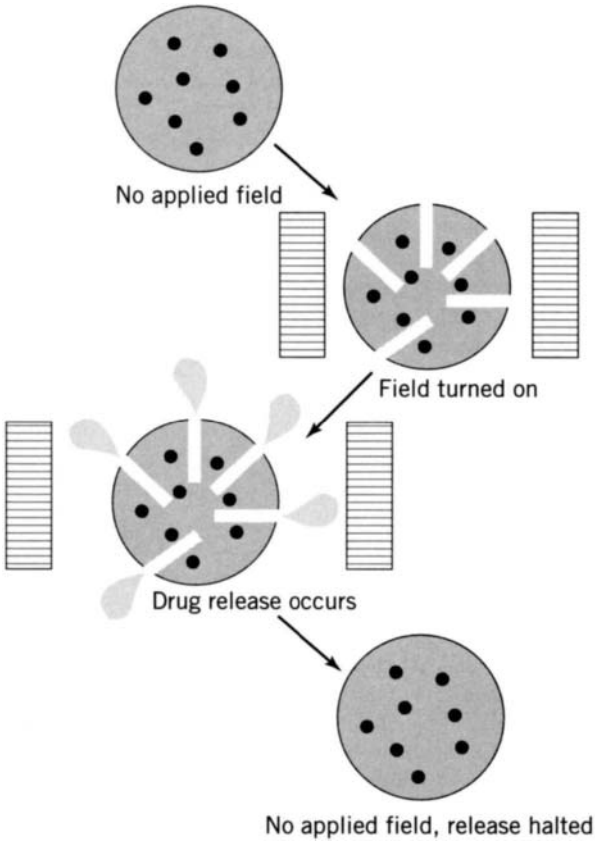

Figure 14. Schematic representation of drug release from a magnetically controlled system. Initially, when the field is off, no drug release occurs. When the field is turned on, the oscillations of the beads creates macropores (●) through which drug release occurs. Drug release is halted when the field is switched off.

copolymers thereof. In this section, we discuss applications of some of these materials.

Poly(2-hydroxyethyl methacrylate). PHEMA has been the most widely used polymer in drug delivery applications. It is an extremely hydrophilic polymer and is highly stable. The permeability of these membranes is easily controlled based on the degree of cross-linking used. Researchers have studied the swelling behavior, morphology, and diffusional behavior of PHEMA gels and copolymers thereof. The release of a wide range of drugs from these gels has also been studied. For example, Anderson et al. (69) studied the release behavior of hydrocortisone from PHEMA gels. The release behavior was non-Fickian, but true zero-order release was not achieved with these gels. Another significant study was performed by Sefton and Nishimura (70). They investigated the diffusional behavior of insulin in PHEMA-based hydrogels. Song et al. (71) developed one of the first pharmaceutically relevant zero-order release systems. They used a reservoir device consisting of a cross-linked PHEMA cylinder encapsulating a solution of silicon oil and progesterone. Zero-order release was obtained with these devices for up to 10 days. Lee (72,73) was able to use PHEMA to achieve zero-order release for short periods of time. In his work, oxprenolol was released from highly cross-linked PHEMA gels at constant rates for up to 3 hours.

The group of Peppas contributed greatly to the understanding of the underlying phenomena of macromolecular relaxations in swelling-controlled release systems. In particular, they studied hydrogels prepared from PHEMA and hydrophobic poly(methyl methacrylate) (PMMA). Franson and Peppas (74) prepared cross-linked copolymer gels of PHEMA-*co*-MAA of varying compositions. Theophylline release was studied and it was found that near zero-order release could be achieved using copolymers containing 90% PHEMA. Further studies by Davidson and Peppas (75) studied the effects of hydrophobicity and cross-link density on the release kinetics and diffusional properties of PHEMA-*co*-MMA membranes. Additionally, Korsmeyer and Peppas (76) examined the behavior of copolymer gels consisting of PHEMA and hydrophilic PNVP (PHEMA-*co*-NVP). In this work, zero-order release of theophylline was observed for up to 5 hours.

Poly(vinyl alcohol). Another hydrophilic polymer that has received attention is PVA. This material holds tremendous promise as a biological drug delivery device because it is nontoxic, hydrophilic, and exhibits good mucoadhesive properties (77). In one of the first applications of this material, Langer and Folkman (78) investigated the use of copolymers of PHEMA (Hydron®) and PVA as delivery vehicles for polypeptide drugs.

Two methods exist for the preparation of PVA gels. In the first method, linear PVA chains are cross-linked using glyoxal, gluteraldehyde, or borate. In the second method, pioneered by Peppas (79), semicrystalline gels were prepared by exposing aqueous solutions of PVA to repeated freezing and thawing. The freezing and thawing induced crystal formation in the materials and allowed for the formation of a network structure crosslinked with the quasipermanent crystallites. The latter method is the preferred method for preparation as it allows for the formation of an "ultrapure" network without the use of toxic cross-linking agents.

Korsmeyer and Peppas (80) prepared PVA gels by cross-linking with borate. They studied the swelling behavior and mechanical properties of these gels. In this work, the release rate of theophylline was dependent on the degree of cross-linking. Future studies by Moriomoto et al. (81) examined the release behavior of a wide range of drugs. In this work, they were able to release indomethacin, glucose, insulin, heparin, and albumin from chemically cross-linked PVA gels.

Since the development of the semicrystalline PVA gels by Peppas, significant work has been done in characterizing of these systems. Peppas and Hansen (82) studied the kinetics of crystal formation during the freezing and thawing process. Subsequent work by Urushizaki et al. (83) evaluated the effects of the number of freezing and thawing cycles on the networks properties. The gels became more rigid with increasing number of cycles. Peppas and Stauffer (84) have also investigated the effects of crystallization conditions such as freezing temperature, number

of cycles, and freezing time on the structure and properties of the PVA networks.

Studies on the uses of PVA prepared by the freezing and thawing technique as controlled release devices have recently been reported. Peppas and Scott (85) and Ficek and Peppas (86) used PVA gels for the release of bovine serum albumin. In the work of Peppas and Scott, drug release occurred by classical Fickian diffusion. Ficek and Peppas (86) developed a method to prepare novel PVA microparticles containing bovine serum albumin by a freezing and thawing technique. In this work, they were able to release bovine serum albumin using these microparticles.

Other researchers have investigated the use of PVA gels as mucoadhesive delivery devices. The Tsutsumi et al. reported novel buccal delivery systems for ergotamine tartrate (87). Peppas and Mongia (88) have also considered PVA for mucoadhesive drug delivery applications. In this work, they investigated the mucoadhesive behavior of PVA gels prepared by the freezing and thawing technique. Additionally, they studied the release behavior of theophylline and oxprenolol from these materials. Additionally, the group of Peppas reported on the release behavior of ketanserin (89) and metronidazole (90) from these systems.

New phase erosion controlled release systems based on the semicrystalline phase have been reported by Mallapragada and Peppas (90,91). These systems exhibited an unusual molecular control of the drug or protein delivery by a simple dissolution of the carrier. Hydrophilic carriers pass through a process of chain unfolding from the semicrystalline phase to the amorphous one, eventually leading to complete chain disentanglement. It has been shown that PVA and PEG are the best systems for such release behavior, and that such devices have the potential to be used for a wide range of drug delivery applications release. A detailed mathematical analysis has been developed to analyze such swellable systems (91–93).

Poly(ethylene oxide) and Poly(ethylene glycol). Hydrogels of PEO and PEG have received significant attention in the last few years in biological drug delivery applications, especially because of their associated stealth characteristics and their protein resistance (94). Three major preparation techniques exist for the preparation of crosslinked PEG networks: (*1*) chemical crosslinking between PEG chains, (*2*) radiation cross-linking of PEG chains, and (*3*) chemical reaction of mono- and difunctional PEGs.

Some of the first chemically cross-linked PEG networks were prepared by McNeill and Graham (95). The crosslinked linear PEG chains used diisocyanates. These gels were used as reservoir devices for the controlled delivery of smaller molecular weight drugs. More recently, McNeill and Graham (96) have investigated the release behavior of small molecular weight solutes from PEG cross-linked with 1,2,6 hexanetriol. The release of proxyphylline from PEG spheres, slabs, and cylinders was studied. For each of the matrix devices, they observed non-Fickian release kinetics. Bromberg (97) also studied the release of chemically cross-linked PEG networks. In this work, PEG networks were cross-linked using tris(6-isocyanatohexyl)-isocyanurate. The kinetics of insulin release from PEG gels obeyed non-Fickian release kinetics.

The advantage of using radiation cross-linked PEO networks is that no toxic cross-linking agents are required. However, it is difficult to control the network structure of these materials. Stringer and Peppas (98) have recently prepared PEO hydrogels by radiation cross-linking. In this work, they analyzed the network structure in detail. Additionally, they investigated the diffusional behavior of smaller molecular weight drugs, such as theophylline, in these gels. Kofinas et al. (99) have prepared PEO hydrogels by a similar technique. In this work, they studied the diffusional behavior of two macromolecules, cytochrome C and hemoglobin, in these gels. They noted an interesting, yet previously unreported dependence between the crosslink density and protein diffusion coefficient and the initial molecular weight of the linear PEGs.

Peppas and coworkers (100–104) have presented exciting new methods for the preparation of PEG gels with controllable structures. In this work, highly cross-linked and tethered PEG gels were prepared from PEG dimethacrylates and monomethacrylates. The diffusional behavior of diltiazem and theophylline in these networks was studied. The technique presented in this work is promising for the development of a new class of functionalized PEG-containing gels that may be of use in a wide variety of drug delivery applications.

pH-Sensitive Hydrogels

Hydrogels that have the ability to respond to pH changes have been studied extensively over the years. These gels typically contain side ionizable side groups such as carboxylic acids or amine groups (105,106). The most commonly studied ionic polymers include polyacrylamide (PAAm), poly(acrylic acid) (PAA), poly(methacrylic acid) (PMAA), poly(diethylaminoethyl methacrylate) (PDEAEMA), and poly(dimethylaminoethyl methacrylate) (PDMAEMA).

Cationic copolymers based on PDEAEMA and PDMAEMA have been studied by the groups of Peppas and Siegel. The group of Siegel has focused on the swelling and transport behavior of hydrophobic cationic gels. Siegel and Firestone (107,108) studied the swelling behavior of hydrophobic hydrogels of PDMAEMA and PMMA. Such systems were collapsed in solutions of pH greater than 6.6. However, in solutions of pH less than 6.6, such systems swelled due to protonation of the tertiary amine groups. The release of caffeine from these gels was studied (109). No caffeine was released in basic solutions; however, in neutral or slightly acidic solutions steady release of caffeine was observed for 10 days. More recently, Cornejo-Bravo and Siegel (110) have investigated the swelling behavior of hydrophobic copolymers of PDEAEMA and PMMA. Additionally, Siegel (111) has presented an excellent model of the dynamic behavior of ionic gels.

The groups of Peppas has studied the swelling behavior of more hydrophilic, cationic copolymers of P(DEAEMA-*co*-HEMA) and P(DMAEMA-*co*-HEMA) (112,113). These gels swelled in solutions of pH less than 7 and were in the collapsed state in basic solutions. These materials swelled to a greater degree than those prepared by Siegel. These materials were used to modulate the release behavior of protein and peptide drugs (114). Schwarte and Peppas (115)

studied the swelling behavior of copolymers of PDEAEMA grafted with PEG. The permeability of dextrans of molecular weight 4,400 and 9,400 was studied. The membrane permeabilities in the swollen membranes (pH = 4.6) were two orders of magnitude greater than permeabilities of the collapsed membranes.

Anionic copolymers have received significant attention as well. The swelling and release characteristics of anionic copolymers of PMAA and PHEMA P(HEMA-*co*-MAA) have been investigated. In acidic media, the gels did not swell significantly; however, in neutral or basic media, the gels swelled to a high degree due to ionization of the pendent acid group (116,117). Brannon-Peppas and Peppas have also studied the oscillatory swelling behavior of these gels (118). Copolymer gels were transferred between acidic and basic solutions at specified time intervals. In acidic solutions, the polymer swelled due to the ionization of the pendent groups. In basic solutions, rapid gel syneresis occurred. Brannon-Peppas and Peppas (119) modeled the time-dependent swelling response to pH changes using a Boltzman superposition-based model. The pH-dependent release behavior of theophylline and proxyphylline from these anionic gels was also studied (120,121). Khare and Peppas (122) studied the pH-modulated release behavior of oxprenolol and theophylline from copolymers of P(HEMA-*co*-MAA) and P(HEMA-*co*-AA). In neutral or basic media, the drug release occurred rapidly by a non-Fickian mechanism. The release rate was slowed significantly in acidic media. In another study, am Ende and Peppas (123) examined the transport of ionic drugs of varying molecular weight in P(HEMA-*co*-AA). They compared experimental results to a free-volume–based theory and found that deviations occurred due to interactions between the ionized backbone chains and pendent acid groups. The swelling and release behavior of interpenetrating polymer networks of PVA and PAA was also investigated (124,125). These materials also exhibit strong pH-responsive swelling behavior. The permeability of these membranes was strongly dependent on the environmental pH and the size and ionic nature of the solute. Recent new studies have used ATR-FTIR spectroscopy to characterize the interactions between polyelectrolytes and solutes (125,126).

Heller et al. (127) studied the behavior of another type of pH-responsive hydrogel. In this work, they evaluated the pH-dependent release of insulin from degradable poly(ortho esters). Other researchers have used chitosan (CS) membranes for drug delivery applications. These materials exhibited pH-dependent swelling behavior due to gelation of CS upon contact with anions (128). Interpenetrating networks of CS and PEO have been proposed as drug delivery devices due to their pH-dependent swelling behavior (129,130). More recently, Calvo et al. (131) prepared novel CS-PEO microspheres. These systems were to provide a continuous release of entrapped bovine serum albumin for 1 week. In another study, methotrexate, an anticancer drug, was encapsulated in microspheres of pH-sensitive CS and alginate (132). Zero-order release of the drug was observed from the microspheres in pH = 1.2 buffer for greater than 1 week. The Kikuchi et al. (133) studied pH-responsive calcium-alginate gel beads. In such systems, modulated release of dextran was achieved by varying the pH and ionic strength of the environmental solution. Such systems may be promising for use in protein and peptide delivery applications.

Temperature-Sensitive Hydrogels

Some of the earliest work with temperature-sensitive hydrogels was done by the group of Tanaka (134). They synthesized with cross-linked poly(*N*-isopropylacrylamide) (PNIPAAm) and determined that the LCST of the PNIPAAm gels was 34.3°C. Below this temperature, significant gel swelling occurred. The transition about this point was reversible. They discovered that the transition temperature was raised by copolymerizing PNIPAAm with small amounts of ionic monomers. Beltran et al. (135) also worked with PNIPAAM gels containing ionic comonomers. They observed results similar to those achieved by Tanaka.

The earliest investigators studying PNIPAAm gels discovered that the response time of the materials in response to temperature changes was rather slow. Future studies focused on developing newer materials that had the ability to collapse and expand in a more rapid fashion. Dong and Hoffman (136) prepared heterogeneous gels containing PNIPAAm that collapsed at significantly faster rates than homopolymers of PNIPAAm. Kabra and Gehrke (137) developed new method to prepare PNIPAAm gels that resulted in significant increases in the swelling kinetics of the gels. They prepared gels below the LCST to produce a permanent phase-separated microstructure in the gels. These gels expanded at rates 120 faster and collapsed at rates 3,000 times faster than homogeneous PNIPAAm gels. The group of Okano (138,139) developed an ingenious method to prepare comb-type graft hydrogels of PNIPAAm. The main chain of the cross-linked PNIPAAm contained small molecular weight grafts of PNIPAAm. Under conditions of gel collapse (above the LCST), hydrophobic regions were developed in the pores of the gel resulting in a rapid collapse. These materials had the ability to collapse from a fully swollen conformation in less than 20 minutes, whereas comparable gels that did not contain graft chains required up to a month to fully collapse. Such systems show major promise for rapid and abrupt or oscillatory release of drugs, peptides, or proteins.

Thermoresponsive polymers may be particularly useful in a wide variety of drug delivery applications (62,140). Okano et al. (141) studied the temperature-dependent permeability of PNIPAAm gels. They were able to use these gels as "on-off" delivery devices in response to temperature fluctuations. This type of behavior was useful for controlling the release of insulin (142) and heparin (114). These gels were also used as "squeezing" systems (143). More recently, conjugates of PNIPAAm with trypsin have been developed (144). Such systems could be extremely targeted delivery of enzymes. Another promising application of these systems was explored by the Vernon et al. (145). In this work, islets of Langerhans were entrapped by thermal gelation of PNIPAAm for use as a rechargeable artificial pancreas.

pH- and Temperature-Sensitive Hydrogels

Over the last 10 years, researchers have developed a novel class of hydrogels that exhibit both pH- and temperature-

sensitive swelling behavior. These materials may prove to be extremely useful in enzymatic or protein drug delivery applications. Hydrogels were prepared from PNIPAAm and PAA that exhibited dual sensitivities (146,147). These gels were able to respond rapidly to both temperature and pH changes. The Kim et al. investigated the use of such systems for carriers for insulin (148) and calcitonin (149). In general, these hydrogels only exhibited strong temperature-sensitive swelling behavior with large amounts of PNIPAAm in the gel. Cationic pH- and temperature-sensitive gels were prepared using polyamines and PNIPAAm (150). These systems were evaluated for local delivery of heparin.

Chen and Hoffman prepared new graft copolymers of PAA and PNIPAAm that responded more rapidly to external stimulus than previously studied materials (151). These materials exhibited increased temperature sensitivity due to the presence of the PNIPAAm grafts. Such systems were evaluated for use in prolonged mucosal delivery of bioactive agents, specifically peptide drugs (152).

Brazel and Peppas (153) studied the pH- and temperature-responsive swelling behavior of gels containing PNIPAAm and PMAA. These materials were used to modulate the release behavior of streptokinase and heparin in response to pH and temperature changes (154). Baker and Siegel (155) used similar hydrogels to modulate the glucose permeability. However, only large amounts of PNIPAAm were needed to observe large temperature sensitivities. The group of Peppas developed novel pH- and temperature-sensitive terpolymers of PHEMA, PMAA, and PNIPAAm (156). These systems were prepared to contain PNIPAAm-rich blocks, and as a result, these materials were able to exhibit strong temperature sensitivity with only 10% PNIPAAm in the gel. Using these materials, they were effectively able to modulate the release kinetics of streptokinase (157).

Complexing Hydrogels

Another promising class of hydrogels that exhibit responsive behavior is complexing hydrogels. Osada studied complex formation in PMAA hydrogels (158). In acidic media, the PMAA membranes collapsed in the presence of linear PEG chains due to the formation of interpolymer complexes between the PMAA and PEG. The gels swelled when placed in neutral or basic media. The permeability of these membranes was strongly dependent on the environmental pH and PEG concentration (159). Similar results were observed with hydrogels of PAA and linear PEG (160). Interpenetrating polymer networks of PVA and PAA that exhibit pH- and weak temperature-sensitive behavior due to complexation between the polymers were prepared and the release behavior of indomethacin was studied (161,162).

The group of Peppas has developed a class graft copolymer gels of PMAA grafted with PEG, P(MAA-*g*-EG) (163–170; A.M. Lowman and N.A. Peppas, unpublished data). These gels exhibited pH-dependent swelling behavior due to the presence of acidic pendent groups and the formation of interpolymer complexes between the ether groups on the graft chains and protonated pendent groups. In these covalently cross-linked, complexing P(MAA-*g*-EG) hydrogels, complexation resulted in the formation of temporary physical cross-links due to hydrogen bonding between the PEG grafts and the PMAA pendent groups. The physical cross-links were reversible in nature and dependent on the pH and ionic strength of the environment. As a result, complexing hydrogels exhibit drastic changes in their mesh size over small changes of pH as shown in Figure 15. One particularly promising application for these systems is the oral delivery of protein and peptide drugs (170). As shown in Figure 16, these copolymers severely limited the release of insulin in acidic environments such as those found in the stomach. However, in conditions similar to those found in the intestines, insulin release occurred rapidly.

Glucose-Sensitive Systems

Major developments have been reported in the use of environmentally responsive hydrogels as glucose-sensitive systems that could serve as self-regulated delivery devices for the treatment of diabetes. Typically, these systems have have been prepared by incorporating glucose oxidase into the hydrogel structure during the polymerization. In the presence of glucose, the glucose oxidase catalyzed the reaction between water and glucose to form gluconic acid. The gluconic acid lowered the pH of the microenvironment of the gel.

The first such systems developed by Kost et al. (171) consisted of glucose oxidase immobilized in hydrogels based on PHEMA and PDMAEMA. These systems exhibited glucose-sensitive swelling behavior. In the presence of glucose, gluconic acid was formed resulting in a decrease in the local pH. As a result, the cationic-based hydrogels swelled to larger degrees in the presence of glucose due to the production of gluconic acid. The glucose-responsive swelling behavior allowed for control over insulin permeation in these membranes by adjusting the environmental glucose concentrations (172,173). The kinetics of gel swelling and insulin release from cationic, glucose-sensitive hydrogels was also studied (174).

Glucose responsive systems were proposed that were based on anionic hydrogels (175,176). Ito et al. (175) prepared systems of porous cellulose membranes containing an insulin reservoir. The pores of these devices were grafted with PAA chains functionalized with glucose oxidase. In the presence of glucose, the decrease in environmental pH caused the PAA chains to collapse, opening the pores and allowing for insulin release. More recently, glucose-sensitive complexation gels of P(MAA-*g*-EG) were developed by the group of Peppas (176). In these gels, as the pH decreased in response to elevated glucose concentrations, interpolymer complexes formed resulting in rapid gel syneresis. The rapid collapse resulted in insulin release due to a "squeezing" phenomenon.

Other glucose responsive systems have been developed that take advantage of the formation of complexes between glucose molecules and polymeric pendent groups. Lee and Park (177) prepared erodible hydrogels containing allyl glucose and poly(vinyl pyrrolidone). These systems were cross-linked by the noncovalent associations between concanavalin-A (Con-A) and the glucose pendent groups.

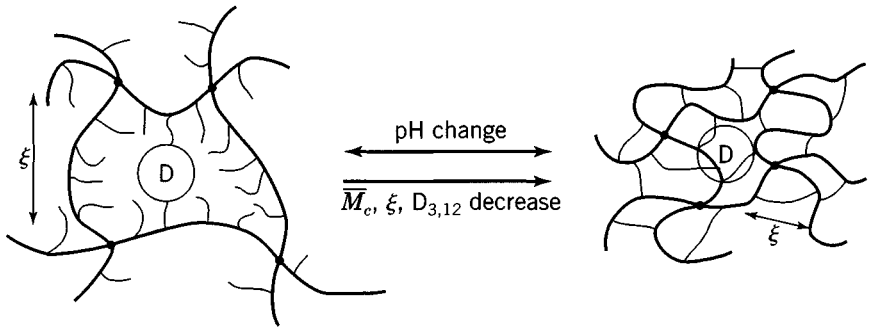

Figure 15. The effect of interpolymer complexation on the correlation length, ζ, and the effective molecular weight between cross-links, $\overline{M}_c$, in P(MAA-*g*-EG) graft copolymer networks with permanent, chemical cross-links (●).

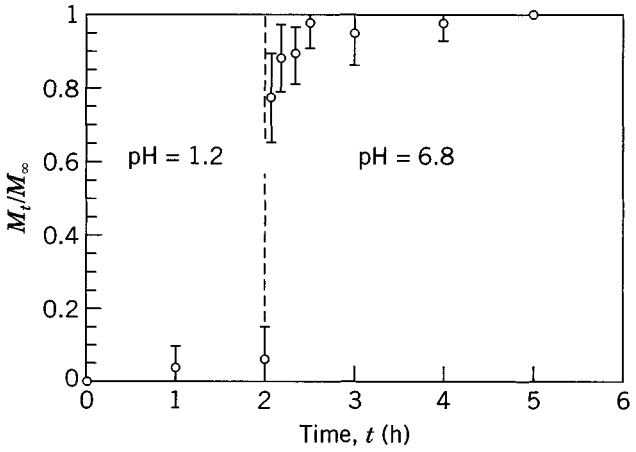

Figure 16. Controlled release of insulin in vitro from P(MAA-*g*-EG) microparticles simulated gastric fluid (pH = 1.2) for the first two hours and phosphate-buffered saline solutions (pH = 6.8) for the remaining three hours at 37°C (170).

In the presence of free glucose, the Con-A was bound to the free glucose, and the gels dissolved due to disruption of the physical cross-links. Newer materials developed by the group of Okano exhibited glucose responsive swelling behavior and insulin release (178–180). These gels were based on phenylboronic acid (PBA) and acrylamides. Another class of glucose-sensitive gels was prepared containing PBA, PNIPAAm, and PVA (181). These gels were designed to allow for the release of insulin at physiological pH and temperature.

Oral Insulin Delivery Systems

One of the major objectives of researchers working in the controlled release field is to design an effective, oral insulin delivery system. However, this is a difficult task due to the degradation of the drug in the upper gastrointestinal (GI) system barrier and the slow transport of insulin across the lining of the colon into the bloodstream (182–184). Numerous attempts have been made by researchers to use hydrogels as carriers for oral delivery of insulin in order to protect the drug in the stomach and release it into more favorable regions of the GI tract.

Touitou and Rubinstein (185) designed a reservoir system consisting of insulin encapsulated by a polyacrylate gel. The coating was designed to dissolve only in the colon. In this work, weak hypoglycemic effects were observed only with very high insulin doses and the addition of absorption enhancers. Saffran (186) developed a biodegradable hydrogel containing insulin. The device consisted of insulin dispersed in a terpolymer of styrene and PHEMA cross-linked with a difunctional azo-containing compound. The azo bond was cleaved by microflora present in the colon, and the polymer degraded, allowing for release of insulin into the colon. In this work, a hypoglycemic effect was obtained only with addition of absorption enhancers and protease inhibitors. However, the hypoglycemic effect obtained was not affected by the initial dosing.

Morishita et al. (187) administered insulin contained within Eudragit 100 gels. In these systems, the pH-responsive Eudragit® degraded in the upper small intestine, allowing for insulin release. They observed strong hypoglycemic effects in healthy and diabetic rats after the addition of absorption enhancers. Platé et al. (188) developed a hydrogel system containing immobilized insulin and protease inhibitors that was effective in lowering the blood glucose levels in rabbits. More recently, Mathiowitz et al. (189) have developed insulin containing poly(anhydride) microspheres. These materials adhered to the walls of the small intestine and released insulin based on degradation of the polymeric carrier. They observed a 30% decrease in the blood glucose levels of healthy rats. Lowman et al. (190) have developed a bioadhesive, complexation hydrogel system for oral delivery of insulin. This delivery system consisted of insulin-containing microparticles of crosslinked copolymers of P(MAA-*g*-EG). The P(MAA-*g*-EG) were more effective in delivering biologically active insulin than traditional enteric coating-type carriers because of the presence of the PEG grafts. The addition of PEG to the gels was critical because the PEG chains participate in the macromolecular complexes, function as a peptide stabilizer, and enhance the mucoadhesive characteristics of the gels. In this work, strong dose-dependent hypoglycemic effects were observed in healthy and diabetic rats following oral administration of these gels.

Other Promising Applications

Promising new methods for the delivery of chemotherapeutic agents using hydrogels have been recently reported. Novel bioreconizable sugar-containing copolymers have been investigated for the use in targeted delivery of anticancer drugs (191–193). Peterson et al. have used poly(*N*-

2-hydroxypropyl methacrylamide) carriers for the treatment of ovarian cancer (193).

In the last few years there have been new creative methods of preparation of novel hydrophilic polymers and hydrogels that may represent the future in drug delivery applications. The focus in these studies has been the development of polymeric structures with precise molecular architectures. Stupp et al. (194) synthesized self-assembled triblock copolymer, nanostructures that may have very promising applications in controlled drug delivery. Novel biodegradable polymers, such as polyrotaxanes, have been developed that have particularly exciting molecular assemblies for drug delivery (195). Dendrimers and star polymers (196) are exciting new materials because of the large number of functional groups available in a very small volume. Such systems could have tremendous promise in drug-targeting applications. Merrill (197) has offered an exceptional review of PEO star polymers and applications of such systems in the biomedical and pharmaceutical fields. Griffith and Lopina (198) have prepared gels of controlled structure and large biological functionality by irradiation of PEO star polymers. The new structures discussed in this section could have particularly promising delivery applications when combined with emerging new technologies such as molecular imprinting (199,200).

A number of investigators have concentrated on the development of environmentally responsive gels that exhibit biodegradability. This can be achieved by a number of synthetic methods. Kopecek and associates (201) have developed biodegradable hydrogels by incorporating azo compounds. Bae and associates (202) have synthesized very promising biodegradable carriers by preparing 8-arm, star-shaped, block copolymers containing PLA and PEO. Another potentially useful biodegradable system is a photo-cross-linked polymer based on poly(L-lactic acid-*co*-L-aspartic acid) (203), which could be prepared in situ for delivery of antiinflammatory drugs following surgery.

INTRODUCTION

In the late twentieth century, biomedical engineers and clinicians have increasingly adopted what may be termed the fundamental tenet of substitutive medicine: it is frequently the wiser choice to simply replace a failing organ than to struggle with attempts at repair and restoration. Such replacement can sometimes be accomplished with organ transplantation but more frequently relies upon man-made devices such as hemodialyzers, blood oxygenators, mechanical heart valves, pacemakers, and artificial hips or knees.

Transplanted organs more closely replicate natural function but are constrained in supply and require pharmacological immunosuppression. *Artificial organs* can be manufactured in large quantities and require no immunosupression but rarely offer the full functional capability of their natural counterparts. In the early seventies Dr. William Chick, who passed away in 1998, proposed a third approach to organ replacement: biohybrid organs, which combined living tissue and biomaterials into a single therapeutic device. Chick's primary interest was in the development of an artificial pancreas in which living cells were separated from the host by a selective membrane barrier. A satisfactory artificial pancreas still remains an elusive target, but immunoisolation, as this approach is now called, has provided the enabling technology for the development of a diverse collection of novel medical therapeutics. It has become a promising route to the delivery of gene therapy, and it offers the largest successful clinical experience thus far with the xenotransplantation of living animal-derived tissue into human hosts.

The concept of immunoisolation is illustrated in Figure 1. Living cells are ensconced in a supporting matrix and surrounded by a semipermeable membrane, which supports the transport of small molecules (oxygen, nutrients, and electrolytes) while restricting the passage of large molecules (immunoglobulins) and cells. The membrane is a mechanical analogue of pharmacological immunosupression. Both thwart the normally lethal response of a host immune system to foreign living tissue, albeit by different mechanisms. One important difference is that immunoisolatory membranes can often protect transplanted xenogeneic grafts (i.e., those originating in a different species than the recipient) whereas presently available immunosupressive drugs cannot. Table 1 lists some of the more important classes of membranes, matrices, and cells used in immunoisolation over the past two decades. As the therapy developed, membranes and matrices have steadily evolved, but the types and classes of cells have changed dramatically. These advances in exploitation of cell and molecular biology have transformed immunoisolation from a specialized approach to a bioartificial pancreas to a multifaceted technology of potential utility whenever long-term site-specific protein delivery is required.

BIOMATERIALS AND CELLS FOR IMMUNOISOLATION

Membranes

Membranes are simply thin barriers capable of providing selective transport between adjacent phases. Synthetic biocompatible membranes are widely used in today's hemodialyzers, blood oxygenators, and plasma filters. With over 100 million hemodialyzers produced each year, the technology of medical-grade membranes has become highly advanced. The membranes most often used for immunoisolation are open-cell foams cast in the form of thin capillaries or "hollow fibers." These structures are made from thermoplastics such as polysulfone or acrylic copolymers. Fiber diameter is typically 500 to 1000 μm and a wall

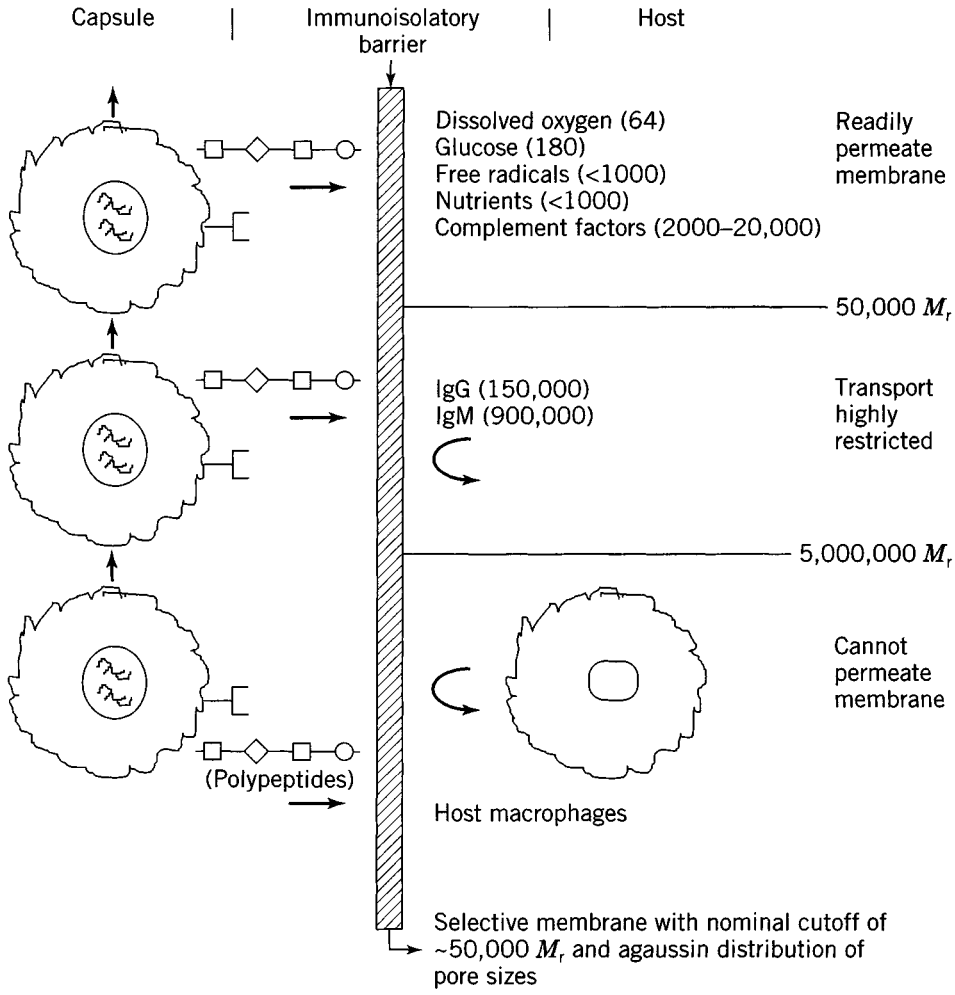

Figure 1. Immunoisolated cell therapy relies upon a membrane to separate foreign secretory cells from a host. Molecules secreted by the cells, usually proteins, can pass through the membrane if they are smaller than 50,000 M_r. In similar fashion, oxygen glucose and molecules such as insulin can diffuse from the host to the cells. However, the membrane blocks the passage of host cells and restricts transport of host immunoglobulins. Membranes allow passage of complement factors and free radicals that appear to be generated primarily when an implant containing xenogeneic cells is directly implanted into host tissue.

thickness of about 15% of the diameter. In recent years, the physical strength of membranes for immunoisolation has been increased by adding metallic or polymeric supports. The composite structures are several thousand times as strong as hemodialysis membranes with comparable dimensions. Some investigators prefer to use a different kind of membrane prepared by the interfacial polymerization of weak polyelectrolytes. Typically, cells are suspended in a droplet containing an aqueous solution of alginate. Alginate is a naturally occurring polymer derived from seaweed, which contains a slight positive charge. The droplet is then bathed in a solution containing polylysine, a synthetic, negatively charged polypeptide. The two polymers react and the resultant film encapsulates the cell in a droplet with a diameter of about 500 μm. A third approach, still in development, applies a conformal coating of photopolymerizable acrylic film on the surface of cells or clusters of cells.

Membranes formulated to allow permeation of molecules as large as proteins while preventing passage of cells are termed microporous. Membranes capable of discriminating between small and large molecules are called semipermeable. As a general rule, microporous membranes are used with allogeneic cells and semipermeable membranes with xenogeneic membranes. It is important to recognize that molecularly separative membranes contain a distribution of pore sizes and function as relative, rather than absolute, barriers to the transport of higher molecular species. A membrane with a nominal molecular weight cutoff of 50,000 daltons rejects well over 99% of IgG (60,000 daltons) or IgM (950,000 daltons) in a challenge solution but still permits passage of a very small fraction of the presenting immunoglobulins.

Matrix

Cells in a capsule are usually supported on a matrix. First-generation matrices were prepared from gelled versions of the same polymers used to coat tissue culture dishes: alginate, agarose, or collagen. Such matrices were weak with a jellylike morphology. More recently, matrices have been prepared not as gels but as scaffolds or macroreticulated foams made from plastic resins, which are sometimes coated with water-soluble polymers. These highly tailored materials are more stable and lead to mechanically stronger implants than earlier gels.

Cells

The first generation of cell technology for immunoisolation involved primary cells, which had been harvested from a

Table 1. Elements of an Immunoisolatory Implant

	Cells
Primary	Islets, hepatocytes, adrenal chromaffin cells
Dividing	Cell lines, such as PC-12 cells which secrete dopamine
Engineered	Cell lines which have received the gene for proteins like factor VIII or EPO
Tailored	Engineered cells which also contain complement restriction factors, antiapoptotic genes, and which may be conditionally immortalized to reduce immunogenicity.
	Matrices
Hydrogels	Natural polymers such as alginate or collagen
Scaffolds	Urethane foams
	Membranes
Hemodialysis membranes	Polysulfone, PAN-VC with cutoff around 50,000 daltons
Weak polyelectrolysis	Films of polylysine and alginate
Conformal	Adherent surface coating
Microporous	Freely permeable to proteins (allograft only)
Reinforced	Membranes cast on a reinforcing structure

donor, isolated, and purified. Since transplant-quality human cells, like human organs, are exceedingly scarce, investigators turned to porcine or bovine sources. Tissue was usually broken down into single-cell suspensions. For the pancreas, cells were maintained as islets, clusterlike organoids containing several thousand insulin-producing β cells. Primary cells were true transplants; the graft originated in a living donor. The second class of cells to be developed for encapsulation was dividing cells from immortalized cell lines. Here, grafted cells originated in tissue culture flasks or in bioreactors. For example, the well-established PC-12 cell line was used to form capsules that secreted dopamine for the treatment of experimental Parkinson's disease. Of course, dividing cells did not continue to multiply indefinitely inside a capsule. Rather they reached a numerically stable population set by the carrying capacity of the capsule. Dividing cell lines vastly simplified the procurement of uniform stable populations of cells and fit in well with cell-banking techniques in widespread use in the biopharmaceutical industry. But only a few cell lines producing therapeutically useful products were available. So the next step was to engineer dividing cells so by adding the genes necessary to produce a desired protein. Engineered cells could be selected for high output (upwards of 1,000 ng/24h-million cells) and could be engineered to produce virtually any protein whose gene was available. More recently, genetic engineering has been employed for a different purpose: cells are being fine-tuned at the molecular level for their future life inside an immunoisolatory capsule. Using strategies borrowed from whole organ xenotransplantation, restriction factors have been added to the surface of grafts reducing their susceptibility to host complement. And antiapoptotic genes have been incorporated into the cell genome to enhance both performance and survival under the low-oxygen and nutrient-scarce environment that awaits cells after encapsulation. Investigators are also attempting to develop cell lines with a simple chemical switch capable of turning on and off proliferation to allow large-scale expansion of a cell line, which would not subsequently divide, inside a capsule.

Implant Design

A wide variety of designs has been advanced to combine cell, matrix, and membrane into a device suitable for implantation. Designs vary widely but in all cases the maximum distance of a grafted cell from host is 200 to 500 μm. Cells further away from their ultimate source of nutrients and electrolytes simply fail to thrive. Several additional considerations apply to the selection of device design. Small beads or "microcapsules" have the optimal ratio of surface area to volume and require no redesign when scaling from small animal models to larger species. But once implanted they cannot be retrieved, and microcapsules do not conform readily to conventional medical-device or pharmaceutical quality assurance protocols. Larger implants or "macrocapsules" contain the entire therapeutic dose in a single device. These may be in the form of a sandwich of flat sheet membranes sealed at the periphery or a capillary sealed at the ends. These devices have the look and the feel of medical grade implants. They can be tested for membrane and seal integrity and some designs can be even be filled, or refilled, after implantation. All can be retrieved, and this feature facilitates the regulatory approval process. However, these designs are limited in the number of cells which can be contained in a practical design to around 5 million for a capillary device and around 100 million for a flat sheet device. Moreover, species scaling is complex. Consider the fact that a typical human weighs about 3,000 times more than a laboratory mouse, and it is problematic to make an implantable device 3,000 times larger, especially while not exceeding a thickness limitation of 500–1,000 μm. Flow-through designs, whether implantable or extracorporeal, draw heavily upon the technology already employed in available membrane devices such as hemodialyzers, blood oxygenators, and plasma filters. They have very large capacity and can hold several grams of foreign tissue if desired. Some designs incorporate a second set of fibers to provide oxygen to the mass of cells. Flow-through devices are well suited for use in extracorporeal circuits. But current flow-through implants are far more invasive than passive diffusion designs and require both surgical breaches of the host vasculature and lifelong, low-level anticoagulation.

THERAPEUTIC APPLICATIONS OF IMMUNOISOLATION

Serious preclinical and clinical evaluation of immunoisolation began early in the 1990s. Funding availability, investigative resourcefulness, and simple happenstance

have all contributed the relative rates of progress of the different applications, but the pacing item has usually been the type of cell required. Pain control and liver support both use primary cells; they have little else in common but both have moved into advanced clinical trials. In contrast, applications involving engineered cells and the delivery of gene therapy continue to offer enormous promise but remain earlier in their development. Engineered cells releasing ciliary derived neurotrophic factor (CNTF) have been studied in small-scale clinical trials for neurodegenerative diseases such as amyotrophic lateral sclerosis (ALS) and Huntington disease, but most gene therapy applications are still at the preclinical stage of development. And despite its formative role in the field, a clinically useful bioartificial pancreas remains an unfulfilled goal.

Alleviation of Chronic Pain

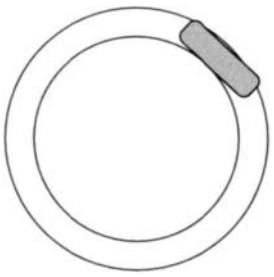
The implant used for chronic pain comprises a short length of hollow fiber is filled with chromaffin cells harvested from calf adrenal glands. Adrenal chromaffin cells, so called because of their affinity for certain dyes, secrete the body's natural analgesics. These natural biochemicals are known to moderate pain by a variety of mechanisms including a partial blockage of the presynaptic release of the neurotransmitters required to send pain impulses from one neuron to the next. Prior to human evaluation, encapsulated chromaffin cell implants were shown to be highly effective in animal models of both acute and chronic pain. Device design and implant technique, which is analogous to a spinal tap, were finalized in sheep. The spinal column was chosen as the implant site because it provides an ideal anatomical location to intercept nerve impulses travelling from the peripheral to the central nervous system. The site is immunopriviliged and further allows the implant to be bathed in cerebrospinal fluid. The safety of the implant and its ability to maintain cell viability and secretory function has been confirmed in detailed animal models, a preliminary clinical investigation, and a Phase I clinical trial. The more than 100 patients in these series represent the most extensive clinical experience to date with cross-species transplantation of living tissue. The effectiveness of this therapy is now being evaluated in pivotal clinical trial to evaluate efficacy in a randomized, placebo-controlled, double-blind, multicenter trial. An empty implant was used as the placebo. Results of this trial are expected around the year 2000.

Support of the Failing Liver

The liver is among the most biochemically complex organ of the human body and one of the few with a capacity for self-regeneration. Serious liver failure is a discouraging prognosis with the option of transplantation numerically limited to the fortunate few. The bioartificial liver is intended to maintain critical liver failure patients until a transplantable organ becomes available. The approach is simple in concept and more governed by the dictates of surgical pragmatism than the principles of pharmacological elegance. Hepatocytes are harvested from a porcine source and placed in the extraluminal chamber of a membrane exchange device designed along the principles of a hollow fiber hemodialyzer. Blood flows on one side of the membrane, the cells are on the other. In contrast to the pain implant, which contains a few milligrams of cells and is expected to last function months or years, the liver device contains between 20 and 200 g of purified hepatocytes, which are used for a very short period of 6 to 24 hours. Here, the mission of the membrane barrier is to prevent cell–cell contact while allowing protein traffic; hence, open microporous membranes are favored. Donor hepatocytes are believed to help clear substances normally removed by the liver and may even be active in synthesis. The procedure has been evaluated clinically in a Phase I trial involving just under 40 patients with diagnosed terminal liver failure. The device functioned as expected with no untoward safety problems; this has cleared the way for a larger multicenter randomized trial, which began with U.S. FDA approval late in 1998. Clinical response in the Phase I trial were very impressive indeed. However, the path to liver support systems is littered with a history of interventions that raised hopes in initial evaluation only to confound early enthusiasm in larger-scale application. The results of the Phase III trial, which will be conducted at several centers in the United States and Europe, are expected in 2002. Although the study design and stated goal is bridging patients to transplant, investigators will look carefully for signs of liver regeneration; the ultimate goal of liver support is recovery of liver function without transplantation.

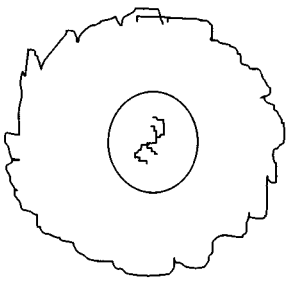
The question naturally arises whether it is reasonable and prudent to obtain living components of implants and other biological devices from bovine (chromaffin cells) and porcine (hepatocytes) sources. FDA regulations for good manufacturing procedures (cGMPs) are scrupulously observed in cell harvesting to assure purity, identity, and freedom from foreign microorganisms. Concern about endogenous retroviruses from porcine sources or other adventitious zoonotic agents is another matter. No infectious pathogens have been identified in extensive testing and monitoring to date. An intact membrane would provide a formidable barrier for viral or retroviral transmission from graft to host. The clinical course of all patients is being closely monitored. Investigators are neither cavalier or complacent and recognize that experience in xenogeneic cell therapy may well shape the equally as important area of whole organ xenotransplantation.

Parkinson's Disease



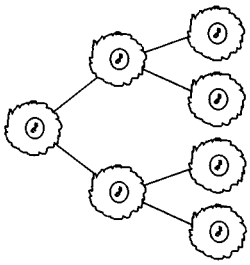
Parkinson's disease results from a deficiency of dopamine in the striatal region of the brain. Studies conducted in the early nineties used encapsulated PC-12 cell implants as a local source of dopamine in animal models of this condition. Although a naturally occurring mutant, PC-12 cells displayed most of the features of engineered cell lines including capacity for unlimited division and high constitutive release of a therapeutically useful product. Despite generally successful and widely published results in rodents and primates, the approach was never evaluated clinically. Numerous other avenues to treating Parkinson's disease are being investigated, including stem cell therapy, use of encapsulation to deliver growth factors to regenerate

the brain's own dopamine producing circuitry, and human fetal transplantation.

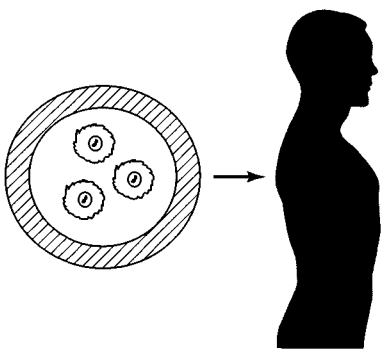


Delivery of Gene Therapy

Experience with PC-12 cells persuaded workers in the field of both the feasibility and practical benefits of dividing cell lines for encapsulation. Molecular biologists set about with characteristic enthusiasm to create multiple families of implantable cell lines producing medically useful proteins. In the broader sense, and as illustrated in Figure 2, this strategy amounted to use of immunoisolation as a pathway for delivery of gene therapy. Genes of interest were isolated and inserted into a carrier cell line using the conventional techniques of molecular biology. Cells were expanded, standardized, encapsulated, and implanted. The gene product was thereafter produced in situ. Because cells producing the gene were enclosed in a membrane capsule, investigators could reverse the experiment and remove the gene should this prove necessary or desirable. Some investigators preferred human-derived cell lines because allogeneic grafts do not normally secrete antigenic proteins and are thus easier to immunoisolate. Others advocated xenogeneic cell lines because they would be immediately destroyed in the event of escape from the capsule. Both approaches have merit and it is too early to tell which will prevail. A middle ground is also a possibility: xenogeneic cells can be humanized with complement restriction factors and other immune down-regulators. Alternatively, a variety of markers could be added to human cell lines to aid with their identification and destruction by the host immune system outside the capsule.



The first successful marriages of gene therapy and immunoisolation were reported in 1992 with cells transfected with the genes for neurotrophic factors and of lyosomal enzymes. Since that time a score of different protocols have been described in the literature (Table 2), and the number is likely to proliferate. In the first reported clinical trial, 6 patients diagnosed with ALS received implants containing a rodent cell line producing CNTF. Numerous preclinical studies and clinical trials not involving encapsulation had suggested that CNTF might be able to retard the deterioration of neurons that characterizes ALS and causes the eventual loss of peripheral motor activity. The device and implant protocol were very similar to that used for chronic pain; only the cells differed significantly from previous experience. In this trial, implanted cells survived and continued to release CNTF over the life of the experiment. The concentration of CNTF in monthly samples of spinal fluid averaged around 500 pg/mL. Progression of the disease was not markedly reduced relative to standard care although a much larger and longer trial would be needed to draw any firm conclusions about efficacy. Nevertheless, the intervention demonstrated production and delivery of the desired gene product at clinically useful concentrations and time frames. In this context the trial was at least as successful as the vast majority of clinical studies based upon ex vivo gene therapy. A second protocol has been initiated in Huntington patients, delivering the same product but this time with capsules implanted into the ventricles rather than into the cerebrospinal fluid. No results are yet available. Several additional applications are being evaluated in small and large animal models, as summarized in Table 2.



(a) Gene is added to viral vector.

(b) Vector implants gene into nucleus of carrier cells.

(c) Transfected cells are selected and proliferated.

(d) Cells are encapsulated and implanted in host.

Figure 2. Encapsulation has been used as a method of delivering gene therapy. (**a**,**b**) Conventional molecular biological techniques are employed to add a gene coding for a therapeutic protein to a dividing cell line. (**c**) Modified cells are grown divided and grown up in vitro. (**d**) A population of the modified cells are then encapsulated and implanted in a host. This approach has been successfully applied in animal models for delivery of erythropoietin, factor IX, several neurotrophic factors, and other proteins implicated in monogenetic diseases. It has also been used clinically to deliver the neurotrophic factor CNTF to patients with amyotrophic lateral sclerosis and Huntington disease.

Table 2. Encapsulation for Delivery of Gene Therapy

Target disease	Gene	Cell type	Status
ALS	*CNTF*	Hamster-BHK	Clinical, Phase I
Huntington	*CNTF*	Hamster-BHK	Clinical, Phase I
Hemophilia A	Factor VII	Murine	Preclinical, Rodent
Dwarfism	HGH	Murine myoblasts	Preclinical, Rodent
Anemia	EPO	Murine	Preclinical, Rodent
Type II diabetes	Glucagon-like peptide I	Murine	Preclinical, Rodent
Parkinson's	GDNF	Murine	Preclinical, Primate
Cancer	Cytochrome P450 2B1	Murine	Preclinical, Rodent

With its technical feasibility validated by the ALS trial, gene therapy is viewed by many as the most compelling application of immunoisolation. One practical problem is that biopharmaceutical firms owning rights to genes have usually invested massively in production facilities. Even a modest GMP level facility that produces a pharmaceutical product based upon recombinant protein costs upwards of $200 million. Such firms are understandably restrained in their enthusiasm for approaches that would render such facilities redundant. At the same time, the biotech start-ups with the technology for immunoisolation rarely have the resources to develop or acquire proprietary genes. For this reason commercial interest in encapsulation has tended to focus on therapeutic targets, such as the central nervous system, which remain beyond the reach of traditional drug development. Also favored are applications where cells release products in response to physiologic stimuli (e.g., the bioartificial pancreas) or metabolize circulating blood components (e.g., the bioartificial liver). Encapsulation may not fulfill its clinical promise of in situ drug delivery until the first round of gene products come off-patent.

The Artificial Pancreas

The bioartificial liver and cell therapy for chronic pain are in Phase III clinical trials. Immunoisolated gene therapy has reached the clinic and is fecund with promise. What then of the bioartificial pancreas? The path from first inspiration to clinical success takes many strange twists, and this is well illustrated by the history of the bioartificial pancreas. Successful demonstration of the reversal of induced diabetes in rodents in the mid-seventies by immunoisolated cells was the original defining moments in the origin of tissue engineering. By now similar results have been routinely obtained in dozens of laboratories around the world. In fact, so compelling is the treatment of induced diabetes in rodents that no fewer than five original reports on this subject have appeared in *Science* magazine. But attempts to obtain similar results in larger animals, canines and primates, have generally proven disappointing. There is simply no widely accepted set of large animal experiments demonstrating long-term satisfactory reversal of diabetes and normalization of glucose kinetics. Even marginal results in larger animals have often required supplementary use of immunosuppression or some level of injected insulin.

Much of the complexity with the bioartificial pancreas comes down to the fact that about 700,000 islets, containing about 2 billion β cells, would be required for transplantation. (This is two orders of magnitude more cells than have been successfully encapsulated in clinical implants to date.) Harvesting so many cells is one problem and housing them in a practical implant is another. Most successful rodent studies involve transplantation of about 500 rat islets to a mouse recipient. The 500 islets are usually handpicked from a partially digested rat pancreas. It is simply not practical to handpick the 700,000 islets required for a human graft, so investigators use semiautomated cell harvesting devices. Techniques for mass isolation have never reached the stage of consistently producing healthy batches of large islets given the natural variability in tissue sources and digestive enzymes. Furthermore, an islet is a not just a cluster of cells but a mini-organoid that enjoys its own vascular supply to distribute oxygen and nutrients to all of its constituent cells. In contrast, implants rely upon diffusion to provide adequate oxygenation and nutrition. The diffusion approach is manageable in small devices but very challenging in implants of the size required to house upwards of 10^9 cells. Perhaps the most satisfactory results to date have been achieved with flow-through designs but these are highly invasive and their use would be justified only in the most threatening of patient circumstances. Yet another complexity is the dose of soluble antigens released by the large quantity of cells needed to replace pancreatic function. The issue exists with all implants but is far more formidable when grams rather than milligrams of tissue are implanted. Over the past two decades, these and other difficulties have frustrated the efforts of several brilliant and dedicated investigative teams to reproduce in large hosts the tantalizing results obtained early on in rodents.

Fortunately, the resourcefulness of molecular biology has opened a second path to the bioartificial pancreas. At least three groups have set about to develop glucose-response, insulin-secreting cell lines. Because of the mass of tissue involved, cell lines of human origin, or at least highly humanized animal cells, seem preferred. Cells must not lose integrity of function over 25–50 passages. To make device size manageable, these cells should produce insulin at least on the order of 1 ng/10^6 cells-24 hours. They cannot be overly sensitive to hypoxia or other insults encountered by encapsulated cells. At the same time, such cells cannot threaten the patient should they escape the immunoisolatory implant. Ten years ago, development of such a cell line would have been considered a quixotic undertaking. Today, emboldened by increasing knowledge of glucose

regulation in the normal β cells and the emerging portfolio of antiapoptotic molecular technology, many investigators believe it to be within reach. We expect to see impressive large-animal results with manmade β cell lines within the next five years and hopefully, this time, a more rapid progression to clinical success.

CONCLUDING PERSPECTIVES

In 1955, the term *artificial organ* provoked skepticism, incredulity, and even hostility. Twenty years later in 1975 both transplantation and organ replacement were medically accepted and rapidly growing. Today, two score years later, multiple manifestations of high technology substitutive medicine accounts for about 7% of the total global health care enterprise. In like fashion, we fully expect over the next two decades that tissue engineering, including immunoisolated cell therapy, will emerge from its investigative origins and play a fulcral role in twenty-first-century medicine.

INTRODUCTION

Pharmaceutical companies rely heavily on the in vitro dissolution or release test to develop extended-release products and to ensure their performance in vivo. In 1971, Wagner (1) had already stated that "future research in dissolution rates should be directed mainly towards establishing correlations of the in vitro data with in vivo data." A strong correlation between the in vitro and the in vivo results means that the in vitro test results can predict the in vivo performance accurately and therefore indicates the test's usefulness as a tool for development and production control. To reach a valid correlation, one has to have valid methods to yield meaningful measurements, both in vitro and in vivo. It is also important that the scientific community reach a consensus about what it means by in vitro/in vivo correlation. The completion of these criteria was marked by the publication of "Stimuli" by the U.S. Pharmacopoeial Convention's (USP's) subcommittee on Biopharmaceutics in *Pharmacopeial Forum* in 1988 (2) and the workshop on in vitro and in vivo testing and correlation for oral controlled/modified-release dosage forms in De-

cember 1988 cosponsored by the American Association of Pharmaceutical Scientists, the U.S. Food and Drug Administration (FDA), the Federation Internationale Pharmaceutique, and the USP. The outcome of this workshop is documented in the workshop report (3).

This article discusses the accepted definition of correlation, the available methods for evaluating in vivo data, the commonly used in vitro testing methods, the currently accepted methods of establishing the correlation, and the possible applications of such a correlation. This article also includes many of the published works on the correlation of the in vivo and the in vitro results. The examples include the correlation between the in vivo human data and the in vitro data, the in vivo dog data and the in vitro data, and the human data and the dog data.

USP DEFINITION OF CORRELATION

The USP (4) defines three levels of in vitro and in vivo correlation: level A, level B, and level C. Level A is the highest category of correlation. It represents a point-to-point relationship between in vitro dissolution and in vivo input rate of the drug from the dosage form. Level B correlation examines the relationship between the mean in vitro dissolution time and the mean in vivo residence time or mean in vivo dissolution time. Like level A, level B utilizes all the in vitro and in vivo data but is not considered to be a point-to-point correlation because many different plasma drug concentration curves can give identical mean residence time values. Level C correlation examines the relationship between one dissolution time point (e.g., $t_{50\%}$) and one in vivo pharmacokinetic parameter (e.g., AUC, C_{max}, T_{max}). It represents a single-point correlation. It does not reflect the complete shape of the plasma drug concentration curve, the critical factor that defines the performance of modified-release products.

IN VIVO EVALUATION

Pharmacokinetic Study Design

To define the in vivo release profile of an extended-release product, one must include all necessary treatments in the study. Before discussing these treatments in the pivotal study, one should understand the drug kinetics over the dose and concentration range of interest, the mode of dosing (fed versus fasted), the time of dosing, the effect of body posture (5) or the influence of exercise (6), and many other details. It is beyond the scope of this article to enumerate what factors could affect the drug kinetics. In the simplest case when the drug kinetics is linear, time invariant, and not affected by any usual physiological activities or food, then the study needs minimally to include two treatments: the extended-release product and a reference product. Based on the concept of gastrointestinal (GI) bioavailability (7), the reference is ideally an oral solution. This reference can be modified without compromising the stated objective by using an oral suspension or an immediate-release dosage form, such as a tablet or a capsule. The basic idea is to have the reference readily available in the GI tract for absorption. For in vitro/in vivo correlation, one could use an intravenous dose as the reference as well. This reference defines the drug disposition function and hence a clear absorption profile. However, this absorption profile differs from the in vitro release profile by a bioavailability factor. Administered as a bolus, the reference gives a direct observation of the characteristic function. From a purely theoretical point of view, the reference product can be administered with any known input function (e.g., constant infusion). In such a case, the characteristic function is not directly observed but derived.

In most cases, not everything is known about the drug kinetics. In such cases, one should be conservative in the study design to guard against many aforementioned experimental factors that may affect the drug kinetics. Instead of a single administration of the reference at any dose, one would use the actual therapeutic dose/regimen of the immediate-release product that the extended-release product is trying to match. For example, a 240-mg pseudoephedrine extended-release product designed for once-daily administration can be compared to four 60-mg doses of an oral solution given at 6-h intervals (8). This approach gives a useful direct pharmacokinetic comparison between the extended-release product and a product given at a therapeutically effective regimen. It guards against any complications such as nonlinear kinetics, food effects, and diurnal effects, which can invalidate a simulation based on the data from the simpler design. This design can be further expanded to study both the extended-release product and the immediate-release product at several dose levels to account fully for possible dose dependence in the kinetics. As usual, the study is limited by the number of blood samples that can be withdrawn from healthy volunteers. This limitation unavoidably results in realistic compromises in study design and objectives. The overall goals can be reached only through many studies that individually address a piece of the puzzle.

Traditional Crossover Design. Intersubject variability in pharmacokinetic parameters is typically much larger than intrasubject variability. Therefore, it is more efficient to use a crossover study design to discover the subtle differences between formulations. In a typical randomized two-way crossover study, half the subjects receive extended-release product followed by the reference product; the other half receive these two treatments in the reverse order.

Stable Isotope-Labeled Drug As Reference. Although the intrasubject variability in pharmacokinetic parameters is small when compared with the intersubject variability, it may still be large and demand a large sample size, and it makes the results of a small pilot study unreliable. Intrasubject variability can be reduced by giving both treatments concurrently as long as the analytical method can differentiate between the two different drug sources. This differentiation can be accomplished by labeling both sources of drug with different isotopes or labeling one source of drug with an isotope. For example, the reversible metabolism of sulindac has been investigated using different radioactive isotopes to label sulfoxide and sulfide (9).

The use of stable isotope-labeled drug has been reviewed by Browne (10) and is an excellent approach to increase the reliability of the results when the basic assumptions are met. A middle-of-the-road approach is to give two treatments sufficiently apart such that the carryover drug from the first treatment can be properly modeled from the data (11).

Scintigraphic Monitoring. Scintigraphic monitoring technology has blossomed over the past 10 years. Today, a trace amount of lanthanides can be placed into a commercial formulation. These metals, when neutron activated, become radioactive, providing the means for following the dosage form in vivo. During earlier studies, researchers used this method to account for the bioavailability variations potentially caused by the dosage's short transit time (12). As we begin to realize that both the rate and the extent of drug absorption could be site dependent, the appropriate derivation of the in vivo release profile becomes almost impossible without the location information.

Mechanistic Considerations

After ingestion, the drug must be released from the dosage form and then dissolved. For some dosages, the release and dissolution can occur in one step rather than by two separate processes. The dissolved drug is simultaneously being degraded, emptied from any location, and absorbed through the GI membrane. The degradation, either chemically or microbially, can differ significantly from stomach to large intestine. The absorbed drug will then pass through the liver before appearing in the systemic circulation. The drug could be metabolized by the GI membrane and the liver, a process that is collectively known as first-pass metabolism because it happens before the drug's appearance in the systemic circulation. First-pass metabolism occurs for all drugs that undergo liver metabolism. The first-pass extraction ratio, E, accounts for part of the bioavailability loss. When the first-pass metabolism follows linear kinetics, then the extent of first-pass metabolism should remain unchanged regardless of the release rate from the dosage form. The impact of a nonlinear first-pass process is much more complex and has been discussed elsewhere (13).

Theory

This section defines the mathematics in the derivation of the in vivo release profile of an extended-release product from the pharmacokinetic data generated from a study as mentioned earlier. The methods generally derive from compartment models or linear system properties. Mathematically, the two approaches yield the same answer. The linear-system–based deconvolution method makes fewer assumptions about the system, giving a more robust derived answer; the compartment approach gives a conceptual picture of the process and allows scientists to derive the necessary equations with the comfort of a physical process instead of mathematical abstraction.

History. It is not surprising, given the long history of applying compartmental analysis techniques in endocrinology, that the early development of pharmacokinetics is mostly, if not completely, based upon the compartment analysis. In 1963, Wagner and Nelson (14) published their method of deriving the absorption profile from pharmacokinetic data for a drug with a one-compartment disposition model. When applied to an oral data set alone, the method implies that the function describing the entire plasma drug concentration profile can be described by the convolution of two functions: a staircase-step function for the absorption process and a single-exponential disposition function. The method also requires that the absorption is completed before the last plasma drug sample in order to have a clean elimination phase. Loo and Riegelman (15) reported a mathematical equation to calculate the amount of drug absorbed when the drug disposition follows a two-compartment model. The application of a linear-system–based deconvolution approach to the pharmacokinetic data seems to have originated with the publication by Benet and Chiang (16). However, the publication lacks an explicit mathematical expression and numerical algorithm. The application of a linear-system approach to pharmacokinetics was broadly addressed by Cutler (17) in 1978. That same year, the linear-system–based deconvolution methods were reported by Vaughan and Dennis (18) and Cutler (19) using staircase function and polynomials as input functions.

Compartment Models. The cumulative amount of drug absorbed at any time t, $A_a(t)$, is the sum of the amount present in the body and the cumulative amount eliminated. The cumulative amount eliminated from the body is:

$$Cl \int_0^t C(\tau)d\tau$$

where Cl is the body clearance for the drug and C is the plasma or serum drug concentration. The clearance always derives from the dose, D_{iv}, and the area under the curve, AUC_{iv}, after a dose of the drug is given intravenously. The equation defining the amount of drug present in the body at time t is disposition-model dependent. For a one-compartment disposition model, the amount of drug present in the body at time t equals $C(t)\ V$, where V is the distribution volume for the drug. Therefore, the cumulative amount of drug absorbed at any time t, $A_a(t)$, can be calculated from the following equation:

$$A_a(t) = VC(t) + Cl \int_0^t C(\tau)d\tau$$

If the drug-disposition model includes a peripheral compartment, compartment 2, then the equation defining the total amount of drug present in the body needs to include the amount of drug present in compartment 2. According to Wagner (20), the amount of drug in compartment 2 is given as $k_{12}e^{-k_{21}t}\int_0^t C(\tau)e^{k_{21}\tau}d\tau$. Thus, the cumulative amount of drug absorbed at any time t for a drug following a two-compartment disposition model is defined by the following equation:

$$A_a(t) = VC(t) + Cl\int_0^t C(\tau)d\tau + k_{12}e^{-k_{21}t}\int_0^t C(\tau)e^{k_{21}\tau}d\tau$$

The amount of drug absorbed is not a direct measurement of the in vivo performance of a dosage form. A theoretical purist would insist that the more appropriate measurement for the correlation to an in vitro release/dissolution measurement should be the corresponding in vivo measurement, such as the in vivo release/dissolution rate. This theoretical concern can be addressed by incorporating an absorption phase in the in vitro measurement to reflect the in vivo absorption process. The difference between the cumulative amount of drug released/dissolved, $A_r(t)$, and the cumulative amount absorbed is simply the amount of drug present in the GI tract (21), $G(t)$. When the GI absorption process is governed by a first-order process with a rate constant, k_a, and a bioavailability factor, F, then the amount of drug present in the GI tract is mathematically defined by the absorption rate.

$$G(t) = \frac{dA/dt}{Fk_a}$$

In this scenario, the cumulative amount of drug released/dissolved from an extended-release product is expressed as

$$A_r(t) = \frac{V}{k_aF}\left[\frac{dC}{dt} + (k + k_a)C + k_ak\int_0^t C(\tau)d\tau\right]$$

for a drug following the one-compartment disposition model, and

$$A_r(t) = \frac{V}{k_aF}\left[\frac{dC}{dt} + (k_{12} + k_{10} + k_a)C + k_{10}k_a\int_0^t C(\tau)d\tau + (k_a - k_{21})k_{12}e^{-k_{21}t}\int_0^t C(\tau)e^{k_{21}\tau}d\tau\right]$$

for a drug following the two-compartment disposition model.

Linear System. In a linear-system approach, one considers the body as a system that yields responses based on the input. One of the necessary and sufficient conditions for a linear system is a response proportional to the input. When the input function is an impulse that is equivalent to a bolus dose, the response of the system is a characteristic function, C*. For any input function, $in(\tau)$, the resulting plasma drug concentration, $C(t)$, is given as

$$C(t) = \int_0^t in(\tau)C^*(t - \tau)d\tau$$

The convolution integral is a simple multiplicative relationship in the Laplace domain, (i.e., $c(s) = in(s)c^*(s)$ where $c(s) = L\{C(t)\}$, and so on) and the derivation of the input function is a straightforward division, $in(s) = c(s)/c^*(s)$. When the impulse input is given intravenously, the characteristic function defines the disposition process, and the input function describes the input to the site where the impulse dose is given. This input to the impulse-administering site is commonly understood as the amount absorbed, although it is not an exact measurement of absorption across the GI-tract membrane unless the impulse input is given at the absorption site of interest (e.g., the portal vein). Although the mathematics are deceptively simple, numerical assumptions are necessary to make the convolution equation useful. Here we follow the work of Vaughan and Dennis to illustrate the application of the deconvolution method to pharmacokinetic data. First, assume that the input is a staircase function (i.e., it consists of a finite set of rectangular pulses of intensity, I_i, from time t_{i-1} to t_i, with $t_0 = 0$ and t_i corresponding to the plasma drug sampling time). The input function can be explicitly given as follows:

$$I_1 = \frac{C(t_1)}{\int_0^{t_1} C^*(\tau)d\tau}$$

$$I_2 = \frac{C(t_2) - I_1\int_{t_1}^{t_2} C^*(\tau)d\tau}{\int_0^{t_2-t_1} C^*(\tau)d\tau}$$

$$\vdots$$

$$I_n = \frac{C(t_n) - \sum_j I_j\int_{t_j}^{t_n} C^*(\tau)d\tau}{\int_0^{t_n-t_{n-1}} C^*(\tau)d\tau}$$

This approach uses all the data from the impulse input without imposing a model and simply assumes the input as constant between sampling intervals. It is simple and easy to understand. Unfortunately, the inaccuracy of the deconvolution output tends to be larger than desirable because this method accepts every data point as exact and passes all noise to the derived input function.

For drugs undergoing reversible metabolism, the input can be a combination of the drug and its metabolite(s). Mathematically, the input is a vector, and the deconvolution process discussed above has to be expanded into an n-dimensional problem. This case has been reported elsewhere (22).

Linear-System Basis in Compartment Model–Derived Equations. Any linear compartment model meets the definition of a linear system. Therefore, it should not be surprising that any equation that derives from linear-system properties alone should also be applicable to any linear compartment model. However, the reverse is not true because the equations may have been based on assumptions specific to the particular compartment model. A compartment-model–based absorption equation may be invalid if one doubts whether the compartment model truly describes the drug disposition regardless of how closely the model can describe the data. A good example is the presence of three two-compartment models to describe the same plasma drug-disposition profile (23). A more general discussion of the model identification issues is found in

other references (24). Interesting points related to the influence of the sampling site and lung metabolism on the derived pharmacokinetic parameters have also come up. Therefore, it is important to understand the deconvolution from the linear system perspective and determine how much of the derived information is independent of the model selection.

Any linear compartment model is a linear system with a multiexponential characteristic function

$$\sum_{i=1}^{n} A_i e^{-k_i t}$$

When the impulse dose is given intravenously, the multiexponential function is continuously declining and

$$\sum_{i=1}^{n} A_i > 0$$

The input function was derived by Veng-Pedersen (25). Wagner made the comparison between this approach and the compartment-model-derived absorption equations in 1983 (20). Specifically, the Laplace transformation of a monoexponential function, $a_1 e^{-k_1 t}$, is $a_1/(s + k_1)$, and the Laplace transformation of a biexponential function, $a_1 e^{-k_1 t} + a_2 e^{-k_2 t}$, is $a_1/(s + k_1) + a_2/(s + k_2)$. In the Laplace domain, the input function for a monoexponential characteristic function can be solved:

$$in(s) = \frac{c(s)}{a_1/(s + k_1)}$$

The solution for the cumulative input function is

$$A_a(t) = \frac{1}{a_1}\left[C(t) + k_1 \int_0^t C(\tau)d\tau\right]$$

When a one-compartment disposition model is imposed, then $1/a_1$ becomes the distribution volume of the compartment. However, one can derive this equation without imposing the compartment model. Similarly, the input function for a biexponential system can be derived:

$$in(s) = \frac{c(s)}{a_1/(s + k_1) + a_2/(s + k_2)}$$

$$\frac{in(s)}{s} = \frac{c(s)}{a_1 + a_2}\left(1 + \frac{\lambda_1\lambda_2}{Rs} + \left(\lambda_1 + \lambda_2 - R - \frac{\lambda_1\lambda_2}{R}\right)\frac{1}{s + R}\right)$$

where $R = a_1\lambda_2 + a_2\lambda_1/a_1 + a_2$.

The explicit cumulative-amount-absorbed equation can be solved by imposing inverse Laplace transformations on the previous equation:

$$A_a(t) = \frac{1}{a_1 + a_2}\left[C(t) + \frac{\lambda_1\lambda_2}{R}\int_0^t C(\tau)d\tau + \left(\lambda_1 + \lambda_2 - R - \frac{\lambda_1\lambda_2}{R}\right)Re^{-Rt}\int_0^t C(\tau)e^{R\tau}d\tau\right]$$

For the two-compartment model with elimination from the central compartment (1) only, the rate constants for the intercompartmental processes are commonly known as the following:

$$k_{21} = \frac{a_1\lambda_2 + a_2\lambda_1}{a_1 + a_2}$$

$$k_{10} = \frac{\lambda_1\lambda_2}{k_{21}}$$

$$k_{12} = \lambda_1 + \lambda_2 - k_{21} - k_{10}$$

Thus, the equation for calculating the amount absorbed based on a biexponential characteristic function is identical to that derived from a two-compartment model. Therefore, the equation is valid even when the particular disposition model is not consistent with the actual situation such as elimination from the peripheral compartment.

Numerical Algorithm

As mentioned previously, one way to approximate the input is to assume it is a staircase function. A polynomial function has been proposed by Cutler to approximate the input. Veng-Pedersen reported the use of a spline function (26) and a polyexponential function (27) to approximate the input function. One alternate approach is to assume the input function to be the solution of an mth-order ordinary differential equation (28), which is mathematically equivalent to a polyexponential function (29–32). The presence of physically impossible negative input caused by the data noise has been addressed by using a B-spline function (33) or a Fritsch-Butland nondecreasing cubic function to approximate the cumulative input function (34).

Deviation from Ideal

Despite the mathematical simplicity and beauty, the real world is full of complications that, in some cases, invalidate the mathematics. Here are some of the complexities.

In Vivo Dissolution. It has been stated that one should use a readily available dosage as the reference to define the characteristic function, which is relatively simple for drugs with reasonable solubilities—that is, the therapeutic dose can be dissolved in a reasonable amount of water. When the drug is not so soluble, the situation becomes much more complicated. One must choose among a suspension, a nonaqueous solution, and an immediate-release dosage form, such as a tablet or a capsule. Each choice has its drawbacks. The most difficult issue is the uncertainty related to the in vivo dissolution for each choice.

Absorption/Metabolism at Different GI Regions. Studies have used various techniques, such as intubation and high frequency (HF) capsules, to investigate the extent of absorption of drugs introduced directly to the colon. For colonically introduced glibenclamide (35), acetaminophen (36), ondansetron (37), and nifedipine (38), the extent of absorption appears to be similar to that administered orally and supports the assumption of a uniform absorption process throughout the GI tract. Contrary to these uniform-absorption examples, the colonically introduced

gepirone (39) has a higher bioavailability than an oral solution, and numerous drugs introduced into the lower GI tract have been reported to have a lower bioavailability than an oral solution—for example, ciprofloxacin (40), cimetidine, furosemide, hydrochlorothiazide (41), danazo (42), benazepril (43), isosorbide-5-mononitrate (44), amoxicillin (45), and sumatriptan (46). It seems prudent to investigate the absorption of the drug solution introduced into the lower GI tract experimentally. The usefulness of such information is demonstrated by an example—namely, the diminished bioavailability of an extended-release amoxicillin product that was published (47) after the publication of the amoxicillin intubation results. It is clear from these examples that useful information can be gained through independent experiment and that a simulation that takes account of location-dependent absorption, such as a model of n absorption sites (48), will be more realistic than the uniform absorption assumption. The diminished absorption of metoprolol in the lower GI tract has been demonstrated by comparing the plasma drug concentration profiles after the intragastric infusion and an oral administration of an OROS® metoprolol tablet (49). The presystemic metabolism of a drug could be site dependent as well. Researchers have measured selegiline and its metabolites—*N*-desmethylselegiline, L-methamphetamine, and L-amphetamine—in the plasma samples collected after giving selegiline to eight healthy young males by the oral route and direct infusion to the duodenum, jejunum, and terminal ileum through a nasoenteric tube (50). The plasma selegiline concentration profile was the highest after oral dosing and the lowest after dosing to the terminal ileum. The plasma *N*-desmethylselegiline concentration profiles followed a pattern similar to that of selegiline; plasma *L*-methamphetamine and *L*-amphetamine concentration profiles were essentially the same regardless of the site of administration. This example clearly demonstrates the complexity of the problem.

IN VITRO EVALUATION

Many methods exist for testing a dosage form for release/dissolution rate; more scientists are relying on the compendial methods. Typically, one uses USP apparatus 1, the basket method, and apparatus 2, the paddle method. The release/dissolution medium is typically aqueous, with surfactant if required. According to FDA guidance (51), the basket is run at 100 rpm, and the paddle is evaluated at 50 and 75 rpm. The dissolution medium (900 mL) of pH 1–1.5, 4–4.5, 6–6.5, and 7–7.5 is maintained at 37°C. The use of compendial equipment facilitates the across-laboratory comparison. However, this fact should not discourage scientists from exploring other methods to find a better-correlated test. Devane and Butler (52) gave a few examples of establishing in vitro/in vivo correlation where the adoption of initial dissolution method relies on the biopharmaceutical classification of the drug (53). The effect of food on the drug release from an extended-release product is a concern for the formulation scientists not just because of the regulatory agencies' requirement but also because of the realistic expectation that many patients may take the product with food. It is therefore of interest that one can evaluate the food effect in vitro. One study investigated the in vitro dissolution behavior of four theophylline extended-release products utilizing the rotating-dialysis-cell method (54). The effects of pH, oil, and enzymes on the dissolution profiles were studied. The in vitro observations of the oil effect were related to the in vivo food effect reported in the literature, and the authors concluded that the rotating dialysis cell can be a useful tool in studying factors that may be responsible for dissolution-related food effects on the absorption of controlled-release products.

CORRELATION BETWEEN THE IN VIVO AND THE IN VIVO PROFILES

In many examples, the correlation is established between the cumulative profiles. This practice may reflect

1. The way we measure the drug release/dissolution
2. The way Wagner and Nelson derived their equation
3. The fact that the cumulative profile is inherently stabler than the rate profile

A statistical concern exists with this approach: The observations at each time point are not truly independent. It is clear that the cumulative amount dissolved at time t_i equals the cumulative amount dissolved at time t_{i-1} plus the amount dissolved between t_{i-1} and t_i. Therefore, the first observation is used n times in the linear regression. It is statistically cleaner to use the incremental data rather than the cumulative data. Liu et al. (55) have demonstrated that the correlation of any two sets of cumulative fractions is inherently high. Even using randomly generated x–y pairs, the average correlation coefficient was 0.935. Therefore, a χ-square test using the incremental fraction data has been proposed to evaluate the correlation. It is more appropriate to show the correlation between the in vivo and the in vitro rates rather than the cumulative amounts.

In an example (56) of metoprolol tartrate extended-release tablet formulation, the authors evaluated several correlations' ability to predict the in vivo performance. This is an important criterion in selecting an in vitro method to control the in vivo performance of the extended-release product.

EXAMPLES

The examples are collected to show how the correlation between the in vitro and the in vivo data is done in actual practice. The first group are examples using human in vivo data. The second group are examples using dog pharmacokinetic data. The third group are examples trying to correlate the human and the dog pharmacokinetic data.

The interest in correlation between the in vitro and the in vivo performance is not limited to the extended-release product. Actually, it seemed to have started with the work by Levy and Hollister (57) with the immediate-release as-

pirin tablet. In the case of immediate-release product, the correlation is theoretically more difficult because it is more difficult to separate the dissolution and the absorption processes when both are rapid.

Two commercial cinnarizine capsules have been studied in a group of 12 healthy male volunteers (58). The formulations have similar in vitro dissolution rates as measured by amount dissolved at 30 min at pH 1 and at pH 6 but very different dissolution rates at pH between 1 and 6. These two capsules had no distinguishable AUC and C_{max} values in the subgroup of volunteers with high gastric acidity, whereas in the low-gastric-acidity group, they had statistically different AUC and C_{max} values with a twofold difference in mean. This finding clearly demonstrated the importance of measuring the dissolution rate over a wide range of pH and understanding the important physiology parameters. In a study of five sugar-coated metronidazole tablets in 10 healthy male volunteers (59), there was no significant correlation between the in vitro dissolution parameters and the pharmacokinetic parameters. The authors stated that "although the in vivo findings seem to agree well with the dissolution rate/pH relationship, the relative values and the ranking between the tablets tested did not agree with those of dissolution rates." Therefore, the correlation between the in vitro and the in vivo performance seems to be more drug specific and difficult to generalize.

The relationship between in vitro and in vivo drug release from OROS® oxprenolol systems have been examined by analyzing the plasma drug concentration data from two pharmacokinetic studies (60). An intravenous dose was used as the reference in the first study, and an oral bolus was used as the reference in the second study. The in vivo release drug-release rate was derived using a numerical deconvolution technique (61). The in vivo drug release from the product in most volunteers followed the same pattern as measured in vitro; only after 6–8 h was the decline in the in vivo release rate somewhat greater than expected. The same product was also investigated by Bradbrook et al. (62). The percentage of dose remained to be absorbed as derived from the Loo-Riegelman method was almost identical to the percentage of dose remained to be released over the first few hours. The difference between the in vivo and the in vitro measurements seemed to increase with time but disappeared at the end of sampling period.

Two extended-release formulations of etodolac have been studied (63). In the pilot pharmacokinetic study, these two formulations were studied in 14 healthy male volunteers with an oral solution of equal dose. The in vitro dissolution data were used to simulate the expected plasma drug concentration for each formulation. There appeared to be a good agreement between the simulation and the observed plasma drug concentrations. The simulation was further carried out for formulations of other strengths used in a steady-state study. The in vivo performance was accurately predicted by the in vitro dissolution data.

Four cellulosic polymer-based matrix tablet formulations of chlorpheniramine maleate were studied in 24 healthy male volunteers (64). The amount of drug absorbed at various times was calculated according to the Wagner-Nelson method. The dosages were also evaluated in vitro using USP apparatus 2 (50 rpm) and 1,000 mL of water. The plot of the amount released versus amount absorbed indicated a strong linear relationship for each formulation. The lines were approximately parallel with a different positive x-intercept for each formulation. After correcting for a lag time according to Levy and Hollister (57), a one-to-one correlation was established.

Three extended-release formulations of bromocriptine have been evaluated against an immediate-release capsule under fasting condition in a group of 14 healthy male volunteers (65). All extended-release formulations were based on a swelling hydrocolloid principle and contained hydroxypropylmethylcellulose (HPMC), microcrystalline cellulose, and cetyl palmitate but had quite different in vitro release profiles. The in vitro dissolution rate was measured in 500 mL of 0.1 HCl using USP apparatus 2 at 50 rpm. The dissolution profiles for all three extended-release formulations were essentially overlapping each other after normalizing to each formulation's mean dissolution time. For the three extended-release formulations, the in vitro and in vivo data are qualitatively in agreement with the bioavailability decreases with the prolonged in vitro release. However, this relationship breaks down when one considers the fastest dissolving extended-release formulation has a 123% bioavailability relative to the even faster-dissolving immediate-release capsule reference. Thus, this in vitro test seems to have only limited value in predicting the formulations' in vivo performance.

Six extended-release formulations of diltiazem HCl have been evaluated in 12 healthy volunteers (66). These included three multiple-unit dosage forms and one matrix tablet and two commercially available nondisintegrating tablets. The in vitro dissolution test used USP apparatus 2 and a distilled water medium with pH progression. The work demonstrated a linear relationship between the cumulative percentage released and the cumulative percentage absorbed for all three experimental multiple-unit dosages. There was also a statistically significant correlation between the pharmacokinetic parameter, mean residence time, and the in vitro dissolution parameter, mean dissolution time for all formulations studied.

Two theophylline extended-release formulations were compared with a solution under fasting condition in 12 healthy male volunteers (67). Both formulations consisted of the same spherical pellets but with different amounts of ethylcellulose/methylcellulose coating. Both formulations were demonstrated to have pH independent in vitro dissolution rates. The in vitro dissolution data were scaled using the Levy and Hollister technique to achieve a one-to-one correlation for each formulation. It is not clear from the publication whether one correlation equation can be established for both formulations. If the correlation is formulation specific, then it is of very little value for guiding further formulation work.

Five HPMC based extended-release formulations of diclofenac sodium have been evaluated in six healthy male volunteers (68). The release rate was controlled by the viscosity grade of the polymer and the amount of the polymer used. The authors reported a significant correlation between AUC, C_{max}, and the time for 50 or 80% drug to be released in vitro.

A marketed extended-release pseudoephedrine capsule and an experimental extended-release formulation of pseudoephedrine have been studied in six healthy volunteers (69). There was an evident linear relationship in the plot of cumulative fraction dissolved versus fraction absorbed. An extended-release OROS® formulation of pseudoephedrine HCl has been evaluated both in vitro and in 27 healthy male volunteers (8). The in vivo absorption profile was in good agreement with the in vitro release profile. There is a strong one-to-one relationship between the drug release rate and the absorption rate. Four cellulosic polymer-based matrix tablet formulations of pseudoephedrine sulfate were evaluated in 20 healthy male volunteers (70). The formulations were also evaluated in vitro using USP apparatus 2 at 50 rpm and 1,000 mL 0.1 N HCl. The results were essentially the same as what was observed for chlorpheniramine formulations, and a one-to-one correlation was established after correcting for the lag time and the difference in the first-order dissolution rate constant and the first-order absorption rate constant. The OROS nifedipine product, PROCARDIA XL, has been dosed to four mongrel dogs (71). The amount of drug released in the dog is in good agreement with the amount released in vitro.

A HPMC formulation of oxprenolol HCl has been evaluated in vitro and in five healthy mongrel dogs (72). A straight-line relationship was evident between the cumulative percent absorbed in vivo and the cumulative percent released in vitro. These results were somewhat disturbing because the more than twofold difference in the total AUC value reported between the conventional and the extended release formulations given at equivalent dose.

A series of seven 2-hydroxypropylcellulose (HPC)–based extended-release nifedipine formulations and one fast-release formulation were evaluated in gastric-acidity–controlled beagle dogs (73). The authors plotted the pharmacokinetic parameters, the absolute retarding parameter, mean residence time, and area under the plasma drug concentration curve against the mean in vitro dissolution time for each formulation. Although there is not a mathematical equation to describe the relationship, there are enough data points for interpolation. This approach clearly demonstrated the benefit of a well-designed experiment.

Three extended-release salbutamol products, Volmax®, and two HPMC-based matrix tablet formulations have been studied both in vitro and in vivo (74). An intravenous dose of salbutamol and an oral immediate-release product, Ventolin®, were also included in the in vivo study as the reference. The in vivo study used five mongrel dogs, and the in vitro study used USP apparatus 1 at 100 rpm and 500 mL of water as dissolution medium. The in vivo percentage of drug absorbed was calculated by numerical deconvolution using the KINBES® computer program. The in vitro dissolution profiles were generally faster than the corresponding in vivo absorption profiles for the three oral products; a good agreement between in vivo and in vitro results was evident for one of the HPMC formulations. In general, a higher amount dissolved in vitro than in vivo. This difference is at least partially due to the less than 100% bioavailability for oral salbutamol in dogs. A good linear relationship seems to exist between the amount absorbed in vivo and the amount dissolved in vitro, with a positive intercept on the axis for the amount dissolved. Both the incomplete bioavailability and the relatively slow absorption process ($t_{1/2}$ = 2 h) for the immediate-release oral product suggested that a better correlation might be achieved with the deconvoluted in vivo dissolution rate using the oral immediate-release product as the reference instead of the intravenous dose. Two ethylcellulose microsphere formulations of zidovudine were compared with zidovudine powder in four beagle dogs (75). The plasma drug concentration data were fitted to a first-order absorption/first-order elimination model. The observed in vitro release data were compared with the in vivo release profile generated from the best-fit absorption rate constant that, despite its name, actually reflected the drug-release process rather than the rapid-absorption process. Among three dissolution media, one was recommended on the basis of the agreement between the in vitro and in vivo results.

Two HPMC (Methocel® K4M) matrix tablets of zileuton were compared to an oral solution in nine beagle dogs using a single-dose design (76). The oral solution and immediate-release product plasma drug concentration profiles were fitted to polyexponential functions, and the matrix tablets' plasma drug concentration profiles were fitted to a smoothing cubic-spline function and then deconvoluted using the PCDON® software. The in vitro dissolution testing used USP apparatus 1 (100 rpm), 2 (100 rpm), and 3 (25 oscillations per min); and the dissolution medium was 10 mM sodium doecyl sulfate solution (900, 900, and 200 mL, respectively). The linear relationship was good between the in vitro and the in vivo data though the slope was approximately 2, indicating a much faster in vivo release rate. Despite the lack of a one-to-one correlation, a third HPMC (Methocel® K100LV) matrix tablet formulation was selected on the basis of the in vitro results and evaluated against an immediate-release tablet in eight beagle dogs using a multiple-dose design. The in vivo performance of the third formulation was consistent with that predicted from the in vitro dissolution data. Thus, the in vitro test method was a useful tool for selecting formulations despite the fact that it did not have a one-to-one correlation to the in vivo results.

Four theophylline extended-release formulations were evaluated in eight male beagle dogs under fasting condition (77). These formulations include theophylline/microcrystalline cellulose (Avicel® RC-581) beads, theophylline/microcrystalline cellulose (Avicel® PH-101) beads, Avicel® PH-101 beads coated with Surelease/HPMC, and a HPC/lactose/magnesium stearate matrix tablet. An intravenous dose of 80 mg theophylline, an oral theophylline solution, and an oral dose of theophylline syrup were included as references. The ratio of percentage cumulative released in vivo versus in vitro over time was evaluated as an indicator of the correlation. The in vivo release profiles for all four formulations are similar to the in vitro release profile in a pH 7.2 medium.

The GI physiology is quite different between dog and human. One notable difficulty is the relatively short GI transit time in dogs [reported to be between 6 and 12 h for four beagle dogs (78)]. The average gastric pH under fast-

ing condition was 1.8 ($n = 4$) for beagle dogs and 1.1 ($n = 10$) for human ($P < .05$); the average gastric-emptying time was 100 min for dogs and 60 min for human ($P > .05$). It was also reported that the average intestinal pH for dogs was higher and more variable than that for humans (79). The importance of such a difference is not exactly clear and is most likely to be drug and formulation specific. In a study of four griseofulvin tablet formulations, the ultramicrosize tablet showed a lower bioavailability in humans (80) but was the most bioavailable formulation in beagle dogs (81). On the other hand, the microsized formulations showed similar in vivo results to those in humans. Four brands of uncoated diazepam tablets have been studied in humans (82) and in beagle dogs (83). The correlation between the in vivo pharmacokinetic parameters (T_{max}, AUC, and the plasma metabolite concentration at 0.25 and 0.5 h) and the in vitro dissolution parameters (T_{30}, T_{50}, and T_{70}, where T_x is the time for X% of drug dissolved) were evaluated. Both the rate and the extent of the absorption in beagle dogs appeared to be correlated to the in vitro dissolution rate at pH 4.6 but not to the dissolution rate at pH 1.2. No statistically significant correlation existed in pharmacokinetic parameters between beagle dogs and humans. A consistent rank order was evident only between the serum drug concentration at 1 h in humans and the plasma drug concentration at 0.25 h in dogs; the rank order of other pharmacokinetic parameters was quite different between humans and dogs. In the study of fulfenamic acid (84) capsules, no significant correlation was evident between the dog and human results and the dissolution results, mainly because of the similar in vivo performance of all the products studied. Five tablet formulations of nalidixic acid have been studied in humans and beagle dogs (85). The rank order of tablets according to C_{max} was exactly the same between humans and beagles. The area under the plasma drug concentration curve also showed the same rank order between humans and beagles except for one formulation with a poor disintegrating ability. The bioavailability of five brands of sugar-coated metronidazole tablets has been evaluated in humans, as discussed earlier, and in beagle dogs (86). The in vitro dissolution rate of these five tablets showed a wide range of pH dependence. The gastric acidity was measured for each volunteer and each dog. The relative values of C_{max} and AUC_{0-24} ranked similarly between corresponding gastric acidity groups of beagle dogs and humans, and a statistically significant correlation was evident between AUC_{0-24} for beagle dogs and humans having low gastric acidity. It is also interesting to note that the tablet with a pH-independent dissolution rate had almost identical plasma drug concentration profiles between the low- and the high-gastric-acidity groups; the four formulations with pH-dependent dissolution rates had disparate plasma drug concentration profiles between the high-gastric-acidity and the low-gastric-acidity groups of dogs. Two commercial cinnarizine capsules, representing the extreme dissolution test results from 32 commercial capsules, were evaluated in 12 healthy beagle dogs (87). The gastric pH was quite variable from treatment to treatment and the between-dog variability in bioavailability cannot be statistically attributed to the gastric pH factor despite the statistically significant gastric pH effect on the bioavailability found in humans (88).

The food effect on the pharmacokinetics of two theophylline extended-release products has been evaluated in four male beagle dogs (89). The overall trends in relative bioavailability of these two products with and without food appeared to be similar to those reported in humans. A study of the food effect on a commercial theophylline extended-release product, Theo-24, in Hormel-Hanford miniswine (90) failed to reproduce the food effect observed in humans. Three extended-release theophylline matrix tablet formulations were evaluated with two commercial theophylline products in five mongrel dogs and six healthy male volunteers (91). Four formulations showed extended-release performance in both humans and dogs; one formulation showed incomplete absorption in both humans and dogs. For both human and dog data, the cumulative percent of dose absorbed appeared to be linearly related to the cumulative percent of dose released with a slope value close to one (92). Three extended-release theophylline capsule formulations with different in vitro dissolution rates were evaluated under fasting condition in 30 healthy male volunteers and six female beagle dogs (93). Although the agreement is not quantitative, the in vivo rate and the extent of absorption in both humans and dogs are in the same rank order as the in vitro dissolution rate. Qualitatively, the food exerted the same effect on the absorption profile for both humans and dogs. Four novel extended-release formulations of valproic acid have been studied in six healthy volunteers (94) and in five dogs (95,96). An apparent linear relationship existed between each formulation's absorption half-life for the human and that for the dogs (97). However, the relationship is not one-to-one implying that one cannot apply the dog absorption data directly to man and one needs to study a few formulations in both human and dog in order to establish the useful relationship. In addition, three extended-release formulations with diminished bioavailability in dogs were equally bioavailable as the immediate-release product in humans. For valproic acid, a wrong decision apparently could have been made if the formulation selection had been based on the dog pharmacokinetic data.

APPLICATION OF IN VITRO/IN VIVO CORRELATIONS

The ultimate objective of in vitro dissolution/release rate testing is to ensure the product's in vivo performance. In too many cases, the correlation between the in vitro and the in vivo performance has not been explicitly established. Even in these cases, the dissolution tests are still performed because it is unthinkable to release a lot of product without the dissolution test. Because we have established the in vivo meaning of an in vitro dissolution test, it is important for us to apply the correlation and rely on the in vitro results to make decisions that we used to make on the basis of the pharmacokinetic data. The resulted savings in the resources must be good for all, although the extent of benefit may be quite different for each societal subgroup. The following are just some possible applications of the in vitro/in vivo correlations assuming a level A correlation.

Dissolution/Release Rate Specifications

Without a correlation, the specifications of an in vitro test can be established only empirically. This approach is data driven but is valid only if all the batches have been extensively evaluated in clinical trials; furthermore, it probably can detect only relatively large differences between different batches. It is therefore more precise to set up the specification using the correlation to evaluate the in vivo consequences of the range. Clearly, the pharmacokinetic consequences alone are not sufficient to set up the specification. The pharmacodynamic knowledge is the key to making the specification clinically meaningful. In the absence of the information, some scientists may be willing to rely on the empirical bioequivalence range of ±20% as the first guidance. In the case of a one-to-one correlation, this automatically translates into a dissolution rate range of ±20%. If the empirically derived dissolution range is much wider than ±20%, then the companies invariably believe that the products have been punished by the presence of a one-to-one correlation. It is important for the regulatory agencies to recognize the scientific progress the industry has made in establishing the in vivo meaning of an in vitro test and reward the effort. Even though the batches may not be bioequivalent to each other, a product is still better controlled by an in vitro test with meaningful in vivo predictability than one without.

Manufacturing Control

The extended-release products are distinguished through their input rate to the absorption site. Therefore, the rate of the drug release from these products is an important feature and should be carefully controlled and evaluated. The in vitro dissolution/release test is meaningful only when the test results are correlated to the products' in vivo performance.

Process Change Assurance

The manufacturing processes of approved products are regulated by the regulatory agencies. The manufacturers are required to demonstrate that any kind of change, even an engineering improvement, does not cause changes in the finished product's in vivo performance. Consequently, many changes have to be supported by a bioequivalence study. With the availability of an in vitro test with a one-to-one correlation to the product's in vivo performance, a bioequivalence study should no longer be necessary. The dissolution/release tests measure only the rate process and cannot ensure the product performance for an excipient change. In such cases, the scientists and the regulatory agencies may consider a pilot pharmacokinetic study as an assurance that the new excipient does not inadvertently affect the absorption.

CONCLUSIONS

The methods for derivation of the in vivo release and absorption profile have been well established. There are many methods for measuring the drug products' in vitro release/dissolution rate. The scientific community has reached the consensus to define what we mean by in vitro/in vivo correlation. Therefore, all the necessary tools are available to make the in vitro dissolution test have in vivo meaning.

INTRODUCTION

Infectious diseases are caused by pathogenic organisms that enter the host, continue multiplying, and cause damage to the host tissue in many ways, resulting in symptoms and signs that may range from trivial to life threatening in nature depending on various host, agent, and environmental factors that facilitate growth and transmission. Many antiinfectious drugs have been developed since 1910, when Paul Ehrlich discovered salvarsan, and 1929, when Alexander Fleming discovered penicillin. Various antimicrobial drugs are available for the treatment of infectious diseases. β-Lactam antibiotics, such as penicillin and cephalosporin, are most commonly used because of their wide antimicrobial spectrum, increased selective toxicity, and potency. Third-generation cephems have wider spectra and more potent antimicrobial activities than second-generation cephems. These are still less active against methicillin-resistant *Staphylococcus aureus* (MRSA) and *Pseudomonas aeruginosa*.

Antimicrobial agents are the substances produced by some living organisms or prepared synthetically from naturally occurring substances that act on other living microorganisms and cause cell death or growth inhibition, resulting in inactivation of the pathogen and recovery from the disease. Thus, they are either microbiocidal or microbiostatic in action. The antimicrobial agents obtained from living organisms or semisynthetically prepared from naturally occurring substances are known as antibiotics. The principle of antimicrobial chemotherapy is based on the administration of the most strongly antimicrobial agents against the causative microorganisms. An ideal drug for treating infectious disease needs to be administered at a concentration above the minimum inhibitory concentration (MIC) of the microorganisms. Moreover, it is necessary for the drug to be safe and have minimum adverse effects. In the past few decades, many kinds of antimicrobial agents with broad efficacy against various kinds of microorganisms have been developed. Because antibiotic treatment of severe infections is not always successful, intensification of the treatment is needed. Targeting antibiotics to infected tissues or cells by encapsulation in liposomes is under investigation and may be of importance in the treatment of infections that prove refractory to conventional forms of antibiotic therapy. For these reasons, drug delivery systems can be utilized to enhance the efficacy of antimicrobial agents against infectious disease.

Liposomes are microvesicles composed of continuous bilayers of phospholipids surrounding an aqueous phase. Phospholipid, a component of the cell membrane, is amphipathic, consisting of hydrophilic heads and hydrophobic tails. Liposomes have been extensively used to deliver antibiotics, antifungal agents, and antiviral compounds for the treatment of infections in animal models. Three rationales have been invoked to justify the use of liposomes as carriers of antiinfectious agents: (*1*) passive targeting of compounds to the mononuclear phagocytic system (MPS) for enhanced effects at this site; (*2*) targeted drug delivery; and (*3*) site-avoidance delivery, wherein the rate of transfer of drug to the toxic site is reduced but not the drug-transfer rate to the active site. All strategies result in an increase in the therapeutic index of the drug; however, to obtain optimal drug therapy, the characteristics for a particular drug for site-specific delivery differ from those of site-avoidance delivery.

Future developments that will permit a larger variety of agents to be delivered in liposomes include the development of fusogenic liposomes and of liposomes that avoid the reticuloendothelial system. By modifying the lipid composition of the liposomes, it is possible to manipulate their intracellular degradation and thereby the intracellular release and therapeutic availability of the antibiotic. Efficacy of liposome-encapsulated antibiotics in the treatment of infectious diseases outside the mononuclear phagocyte system may be realized by manipulation of the liposome composition. Evidence for this is found in the treatment of systemic fungal infections, in which liposomes appear to be very effective as a carrier of amphotericin B (AmB). The most advanced application of liposome-based therapy is in this field, and clinical studies with liposome-encapsulated AmB have been in progress for several years.

Advanced liposomal therapeutic action has been attained by liposome surface modification, initially with specific glycolipids and subsequently with surface-grafted polyethelenglycol (PEG), reducing in vivo rapid recognition and uptake, and resulting in prolonged blood circulation and providing selective localization in pathological sites. The result is improved efficacy of encapsulated agents. The surface PEG may produce a barrier, as described for colloids. Reduced in vivo uptake may result from inhibition of plasma–protein adsorption, or opsonization, by the coating. Several physical studies support this mechanism, including those involving electrophoretic mobility. The dependence of blood circulation and tissue distribution on

PEG molecular weight correlates with ζ-potential estimates of PEG-coating thickness. Effects on tissue distribution are reported for liver and spleen, the major phagocytic organs. The biological properties of these liposomes depend on the surface polymer rather than the lipid bilayer, yielding important advantages for lipid-mediated control of drug interaction and release without affecting the biodistribution.

The recent developments of the drug delivery systems and their application in treating different types of infectious diseases are described in the following paragraphs.

LIPOSOMAL ANTIMICROBIAL AGENTS AGAINST THE CYTOZOIC MICROORGANISMS *SALMONELLA TYPHIMURIUM, LISTERIA MONOCYTOGENES*

Phagocytosis plays an important role in limiting invasion by pathogens. Several microorganisms can withstand the host cellular events after phagocytosis; thus, they can survive and multiply intracellularly. They are known as cytozoic microorganisms. The commonly believed mechanism is the altered production or inactivation of reactive oxygen metabolytes induced by the toxins or other substances from the pathogen. Intracellular infections involving the MPS (parasitic, fungal, bacterial, and viral infections), an improved therapeutic index and reduced toxicity resulting from encapsulation of the antibiotics in liposomes in animal models have been demonstrated. By manipulating the liposomal composition, rates of uptake and intracellular degradation can be influenced, and thereby the rates at which liposome-encapsulated agents are released and become available to exert their therapeutic action are also influenced. With respect to the targeting of macrophage modulators at the MPS by means of liposomes for maximal stimulation of the nonspecific antimicrobial resistance, experimental evidence is now available of the potential usefulness of liposomes as carriers of these agents. This approach may also be of importance for the potentiation of treatment of severe infections.

There are three varieties of drug transportation into cells: passive transport, active transport, and phagocytosis. Macrolides are actively transported into the polymorphonuclear leukocytes via the nucleoside transport system or glycolytic pathway. Aminoglycosides are not the choice for intracytoplasmic infections such as salmonellosis. However, liposome-encapsulated cephalothin or streptomycin was effective in intraphagcytic killing of *S. typhimurium* and experimental salmonellosis. Desiderio and Campbell used multilamellar liposomes, composed of phosphatidylcholoine, cholesterol, and phosohatidylserine, that entrapped an aqueous solution of cephalothin for in vitro experiments (1). Resident murine macrophages interiorized the liposome–antibiotics complex, and this event resulted in relatively high intracellular concentration of cephalothin. Treatment of infected macrophages with liposome-encapsulated cephalothin enhanced the intracellular killing of *S. typhimurium* compared with that of macrophages treated with free cephalothin. Tadakuma et al. reported its superior efficacy against experimental salmonellosis in mice; liposomal streptomycin was selectively delivered to the spleen and liver with concentrations in these organs about 100 times higher than those in mice receiving the free drugs (2).

Listeriosis is a severe disseminated infection in immunocompromized patients. Liposome-encapsulated ampicillin demonstrated efficacy for the treatment of murine disseminated listeriosis (3). All mice treated with liposome-encapsulated ampicillin survived. The in vitro susceptibility of *C. trachomatis* to liposome-encapsulated tetracycline was compared with that of free tetracycline. A chlamydia-infected mouse fibroblast monolayer was continuously exposed to varying concentrations of antibiotics. The MIC for anionic, cationic, and neutral liposomes containing tetracycline was approximately 2, 10, and 20 times smaller than that of free tetracycline (4).

Liposomal aminoglycosides showed excellent efficacy compared with free aminoglycosides or empty liposome. This therapeutic strategy should be developed for clinical application. Although the human defense mechanism against microbial infection is very complicated, biological response modifiers (BRMs) such as vaccination or cytokine therapy have been investigated. One of the most useful and protective vaccines for prevention of tuberculosis is the *Mycobacterium vaccae* vaccine, developed by Stanford et al. (5). As for the cytokines, interleukin 2, granulocyte macrophage-colony–stimulating factor, and tumor necrosis factor have very strong antimicrobial activity. Interferon alone, however, has weak efficacy and should be combined with other effective cytokines. These BRMs constitute an excellent strategy for antimicrobial chemotherapy.

LIPOSOMAL ANTIMICROBIAL (PIPERACILLIN OR TOBRAMYCIN) AGENTS AGAINST BACTERIA

Penicillin proved to be miraculous in its action against gram-positive and gram-negative bacteria, diminishing their roles as nosocomial pathogens, and this resulted in its promiscuous use in the following years. Subsequently, semisynthetic penicillins, such as methicillin, ampicillin, amoxycillin, and then cephalosporins, were developed. Unfortunately, several bacteria capable of producing β-lactamase (and thus resistant to penicillin) were isolated. Penicillinase-producing organisms such as *S. aureus* have caused the virtual elimination of penicillin from therapy against this organism. *S. aureus* has become resistant to methicillin and is known as a very refractile organism that causes opportunistic infections. Piperacillin itself is known to be inactive against β-lactamase–producing *S. aureus*. However, Nacucchio et al. reported the enhanced antibacterial activity of liposome-encapsulated piperacillin against *S. aureus* (6). The results, expressed as the percentage of bacterial growth inhibition at 50% MIC of piperacillin, demonstrated that growth inhibition was the highest when piperacillin was liposome encapsulated. Even adsorption of piperacillin to liposomes rendered significant enhancement of the antistreptococcal capacity when compared with the effect of piperacillin alone. Exogenous β-lactamase hydrolyzed piperacillin and eradicated its antistreptococcal activity. Encapsulation of piperacillin within liposomes conferred a high degree of

protection against hydrolysis. The enhanced antibacterial activity of liposome-encapsulated piperacillin was probably due to protection of the drug from hydrolysis by staphylococcal β-lactamase or stearic hindrance to the action of the β-lactamase by the lipid surface of liposomes.

Lower-respiratory-tract infections consisting of *P. aeruginosa* occur almost exclusively in patients with compromised local respiratory or systemic host defense mechanisms. Exposure to the hospital environment, particularly given in an intensive care setting, use of respiratory inhalation equipment, and prior antibiotic therapy, increases the likelihood of such infections. Lower-respiratory-tract colonization with mucoid strains of *P. aeruginosa* is a function of age in patients with cystic fibrosis. *P. aeruginosa* clearly plays a critical role in the progressive lung lesions and resulting disability observed in most patients with this disease. Under certain conditions *P. aeruginosa* produces a polysaccharide capsule, referred to as the *glycocalyx*. This material appears to form a matrix around the bacterium, anchoring it to its environment and protecting it from phagocytic cells and antibiotics.

Liposome-encapsulated anti-*Pseudomonas* agents were first developed in 1990 by Kotsifaki (7). The growth inhibition of four *P. aeruginosa* strains by liposome-trapped penicillin G indicated an association of its efficacy with the nature of the *O*-antigenic polymeric side chain. For instance, the P28-800 and PCF-95 strains, characterized by a rough polysaccharide chain, were the most susceptible, whereas strain P28-0, possessing an intact lipopolysaccharide, resisted the activity of the entrapped drug. Among the rough strains, P642, a β-lactamase producer, was not affected by the encapsulated drug. Lagace reported that ticarcillin- and tobramycin-resistant strains of *P. aeruginosa* were shown to have a markedly increased sensitivity to antibiotics enclosed in liposomes (8). The liposome-enclosed antibiotic was as effective against the β-lactamase–producing strain as against the non-β-lactamase–producing strain. The in vitro activities of encapsulated and free tobramycin were evaluated against *P. aeruginosa* by Poyner (9). The effects of free and liposome-encapsulated tobramycin on siderophore production by *P. aeruginosa* were examined and involved using MIC and sub-MIC quantities of tobramycin. Compared with free tobramycin, siderophore production was more effectively retarded in the presence of sub-MIC quantities of liposomal tobramycin, particularly at 0.5 MIC. Siderophore production was particularly reduced in the presence of positively charged phosphatidylcholine liposomes. Beaulac studied the efficacy of fluid liposome-encapsulated tobramycin against *P. aeruginosa* in an animal model of chronic pulmonary infection (10). Chronic infection in the lungs was established by intratracheal administration of a mucoid variant of *P. aeruginosa* prepared in agar beads, and antibiotic treatments were given intratracheally. Animals treated with encapsulated tobramycin in fluid liposomes had a number of colony-forming units (CFUs) less than the minimal CFUs of lungs for animals treated with encapsulated tobramycin in rigid liposomes, free antibiotic, or liposomes without tobramycin. Tobramycin measured in the lungs at 16 after the last treatment following the administration of encapsulated antibiotic was still active. Low levels of tobramycin were detected in the kidneys after the administration of encapsulated antibiotic, while a higher concentration was detected in the kidneys following the administration of free antibiotic. These results suggest that local administration of fluid liposomes with encapsulated tobramycin may offer advantages over free antibiotics, including sustained concentration of the antibiotic, minimal systemic absorption, reduced toxicity, and increased efficacy, and that it could greatly improve the management of chronic pulmonary infection in cystic fibrosis patients.

LIPOSOME-ENCAPSULATED ANTIMYCOBACTERIAL AGENTS

Mycobacteriosis, or mycobacterial infections, are caused by various species of the genus *Mycobacterium*. The most commonly encountered diseases are tuberculosis, caused by *Mycobacterium tuberculosis*, mycobacterial infections other than tuberculosis (MOTT), and leprosy, caused by *Mycobacterium leprae*. Antimycobacterial agents are those aimed at elimination or inactivation of infections caused by mycobacteria. The active drugs are expected to act on the agent within the cells or a caseous lesion. In recent years, the resurgence of multidrug-resistant (MDR) tuberculosis and the increased prevalence of atypical mycobacteriosis have been observed in immunocompromised patients, including those with AIDS or organ transplantation, and occasionally in immunocompetent patients as well. In the recent past, Rifampin-resistant strains have been on the increase. Strains of *Mycobacterium avium-intracellulare* complex (MAC) are common environmental organisms of low virulence. MACs have been frequently identified as the pathogen causing atypical mycobacteriosis in people with poor immune status. The disease differs in severity but is often debilitating and can be fatal. In addition to infections of the lung, fever, lymphadenopathy, weight loss, and so on, the disease may cause remote symptoms such as arthritis and osteomyelitis as a result of dissemination. A considerable number of patients with MAC infection do not respond to the conventional antimycobacterial agents. Thus, the quests for novel antimycobacterial drugs and modification of their cytotoxic potency by encapsulation in liposomes have been considered worthwhile.

Perhaps the most important recent advance in the field of infections due to MACs is the identification and development of more effective agents for the treatment and prevention of disseminated disease. These agents include clarithromycin, azithromycin, rifabutin and other rifamycins, ethambutol, clofazimine, fluoroquinolones, amikacin, and liposome-encapsulated gentamicin. Most clinicians currently use multidrug therapy to maximize efficacy and to minimize the emergence of resistance. Prospective clinical trials of multidrug regimens suggest that MAC colony counts in blood decline during therapy, usually accompanied by alleviation of clinical symptoms. The small size and short duration of these trials have not permitted an evaluation of survival or quality of life. Because the contribution of any single agent to multidrug trials is difficult to

assess, short-term trials of monotherapy have been conducted recently; clarithromycin, azithromycin, ethambutol, and liposome-encapsulated gentamicin have proved most active.

The earliest report of a successful treatment for mycobacterial infection involved the use of liposome-encapsulated streptomycin. Vladimirsky reported that intravenously injecting mice infected with *M. tuberculosis* H37 RV with liposome-encapsulated streptomycin led to the amount of mycobacteria decreasing significantly in the spleen but not in the lungs, as compared with an injection of a buffered solution of streptomycin (12). Several kinds of aminoglycosides encapsulated in liposomes were investigated for therapeutic efficacy against MAC infection. Duzgunes studied the therapeutic effects of free and liposome-encapsulated amikacin on MAC infection by using the beige-mouse model of the disease (13). The results showed reduction of the CFU counts in the spleen and kidneys treated with liposome-encapsulated amikacin compared with those of both untreated controls and free-drug-treated mice (14). Liposomal kanamycin injections led to a greater reduction in the degree of gross pulmonary lesions and the growth of the organisms in the visceral organs (lungs, liver, spleen, and kidneys) of MAC-infected mice than did either free kanamycin alone or free kanamycin mixed with empty liposomal vesicles (15). Nightingale reported that a liposome-encapsulated gentamicin was given intravenously twice weekly for 4 weeks to AIDS patients with MAC bacteremia, with MAC colony counts in blood subsequently falling by 75% or more in all treated groups (16).

Other antimycobacterial agents were encapsulated in liposomes and investigated for their efficacy against MAC. Saito estimated the in vitro efficacy of liposome-entrapped rifampin against MAC infection induced in mice. Intraperitoneal injections of liposome-entrapped rifampin led to a greater reduction in bacterial growth in the lungs and spleen of infected mice than did free rifampin alone. However, liposome-entrapped rifampin given to mice via the intramuscular or subcutaneous route failed to show such an increased therapeutic efficacy. It was concluded that entrapment of rifampin in liposomal vesicles increased incorporation of the drug into host peritoneal macrophages and the activity of the agent against MAC phagocytosed into the macrophages (17). Majumdar investigated the therapeutic efficacies of liposome-encapsulated ciprofloxacin against growth of the MAC inside human peripheral blood monocyte/macrophages. Liposome-encapsulated ciprofloxacin was at least 50 times more effective against the intracellular bacteria than was the free drug: At a concentration of 0.1 μg/mL, liposome-encapsulated ciprofloxacin had greater antimycobacterial activity than the free drug at 5 μg/mL (18). The therapeutic efficacies of liposome-encapsulated ciprofloxacin and clarithromycin against MAC in a model of intramacrophage infection were evaluated by Onyeji. Liposome entrapment of clarithromycin significantly enhanced the activities of the drugs when compared with the antimycobacterial effects of equivalent concentrations of the free drugs, and liposome-encapsulated clarithromycin plus ethambutol was more effective in organism eradication than each agent used singly (19). Mehta reported therapeutic efficacy of liposome encapsulation of clofazimine in the beige-mouse model of disseminated MAC infection. An equivalent dose of liposome-encapsulated clofazimine was more effective in eliminating the bacteria from the various organs studied, particularly from the liver. Moreover, because of the reduced toxicity of liposomal encapsulation of clofazimine, higher doses could be administered, resulting in a significant reduction in the numbers of CFU in the liver, spleen, and kidneys (20,21). In recent study, Deol investigated the therapeutic efficacies of isoniazid and rifampin encapsulated in lung-specific stealth liposomes against *M. tuberculosis* infection induced in mice. The efficacies of isoniazid and rifampin encapsulated in lung-specific stealth liposomes were higher than those of free drugs against tuberculosis, as evaluated on the basis of CFUs detected, organomegaly, and histopathology. Furthermore, liposomal drugs had marginal hepatotoxicities as determined from the levels of total bilirubin and hepatic enzymes in serum (22).

Aminoglycosides have been used for the treatment of mycobacterial infection (Fig. 1). Liposome-encapsulated amikacin showed significantly greater inhibitory activity against the survival of MAC inside mouse peritoneal macrophages than free drug (23). Liposome-encapsulated gentamicin significantly reduced the number of organisms in the spleen and liver of the infected beige mice, but it did not sterilize these organs (24). Liposome-encapsulated kanamycin was injected into mice infected with MAC once every week for up to 8 weeks, which led to a greater reduction in the degree of gross pulmonary lesions and in the growth of the organisms in the lung, liver, spleen, and kid-

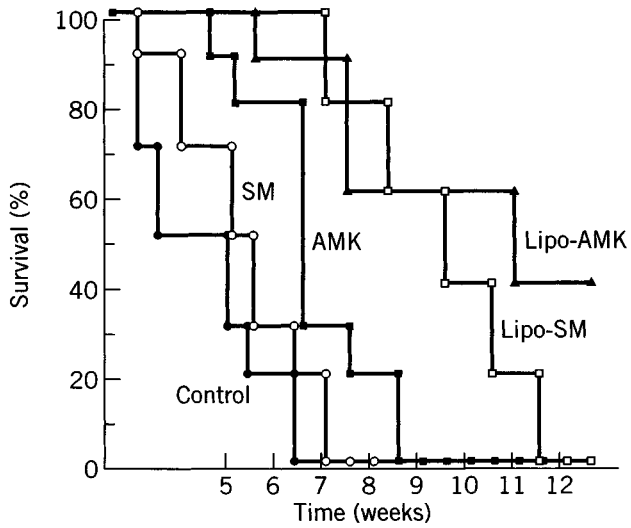

Figure 1. Survival rate over time in liposomal streptomycin and amikacin treatment for systemic *M. tuberculosis* infection in mice. *M. tuberculosis* (H37 Rv) (2×10^6 CFU/ml) was injected intravenously to BALB/c mice (5 weeks old, male). Treatment was started 24 h after infection. Streptomycin (SM), amikacin (AMK), liposomal amikacin (Lipo-AMK), and liposomal streptomycin (Lipo-SM) were injected intravenously on days 3, 5, 7, and 9. *Source:* Based on data from Ref. 11.

neys (15). The effect of liposome-encapsulated streptomycin against MAC infection in beige mice regarding the liposome was studied (25). At four weeks, liposome-encapsulated streptomycin reduced the colony-forming units in the liver and spleen to about the same extent as a 50- to 100-fold higher dose of free drug. These observations suggest that liposomes were taken up by the infected macrophages of the liver and spleen and that the encapsulated streptomycin was delivered to the intracellular compartments containing mycobacteria. The effects of unilamellar and multilamellar liposomes were similar in this model. This suggests that similar quantities of streptomycin may have been delivered to the intracellular sites of infection, although higher tissue levels were achieved with multilamellar liposomes. It is likely that not all of the streptomycin in multilamellar vesicles was released into the phagosome internalizing the liposome.

LIPOSOME-ENCAPSULATED ANTIFUNGAL AGENTS

Fungi are eukaryotic organisms that grow in a filamentous or yeastlike form or both. Fungi pathogenic to humans occur worldwide, some of which are common in defined geographic areas; in general, they can be divided into two basic groups, yeasts and molds. They are recognized as a significant and frequent cause of morbidity and mortality. Fungi may cause varying degrees of illnesses, starting from superficial to life-threatening, deep-seated mycosis. They are found to cause serious opportunistic infections in immunocompromised patients with, for example, leukemia, AIDS, and bone marrow transplants and in those treated for a long time with antineoplastic or immunosuppressive agents in particular. Frequent use of broad-spectrum antibacterial agents, intravenous catheters, and immunosuppressive therapies that are aimed at improving support to prolong survival, especially in critically ill patients, predisposes one to fungal infections.

Systemic fungal infections may arbitrarily be divided into two broad categories: endemic diseases such as blastomycosis, coccidioidomyosis, and histoplasmosis and opportunistic diseases such as aspergillosis, cryptococcosis, and candidosis, which occur almost exclusively in patient with impaired host defenses. Antifungal therapy is implemented according to several factors, such as the causative agent, the progression or invasion of the disease, and so on. Antifungal therapy may have to be administered empirically in febrile neutropenic patients who do not respond to treatment with an antibacterial drug (26).

Although newer pathogenic fungi causing deep-seated mycosis have emerged, antifungal agents have not substantially increased in number. There are few classes of agents that, in turn, have few mechanisms of action and limited response rates. The major groups of antifungal agents in clinical use are polyene antibiotics, azole derivatives, allylamine–thiocarbamates, morpholines, and miscellaneous compounds such as 5-fluorocytosin and griseofulvin. The polyenes and azoles are most widely used. Amphotericin B (AmB), nystatin and, natamycin are the polyene antifungal agents used for treatment of human diseases, with AmB being the only parenteral preparation with a broad range of antifungal activity. Over the past several years, increased efforts in both basic and clinical antifungal pharmacology have resulted in a number of entirely new reengineered or reconsidered compounds, that are at various stages of preclinical and early clinical development (27–29).

AmB is used to treat severe fungal infections. Its usefulness is compromised by a high incidence of adverse reactions, including fever, chills, nausea, vomiting, headache, and renal dysfunction with associated anemia, hypokalemia, and hypomagnesemia. Infrequently anaphylactic shock, thrombocytopenia, acute liver failure, flushing, vertigo, generalized seizures, and dose-related cardiac arrest or ventricular fibrillation have been reported. In children, overdose of AmB may cause cardiac arrhythmias and death. The damaging action of AmB to cells originates from its binding to sterols incorporated in cellular membranes (ergosterol in the case of fungal cells and cholesterol in mammalian cells); greater avidity for ergosterol-containing membranes than for cholesterol-containing membranes favors the clinical usefulness (30). Infusion-related side effects such as fever, rigors, and chills are common but not so alarming that AmB therapy should be discontinued, as would be recommended in the event of renal dysfunction. Renal insufficiency in association with azotemia, renal tubular acidosis, and impaired urinary concentrating ability resulting in electrolyte imbalance may be severe enough to lead to dose reduction or premature discontinuation of the drug (31).

Three ways have been suggested by which the therapeutic index of AmB might be improved: increasing the selectivity of drug-induced damage to fungal, as opposed to mammalian cells; decreasing toxicity to host cells bearing low-density lipoproteins (LDL) receptors; and decreasing toxicity for cells of the immune system. The lipid formulations of AmB are prepared with either phospholipids or detergents, and the resultant associations fall into two categories, liposomes and mixed micelles. Because only unbound AmB is active against cells, the damaging action of an AmB formulation depends on the ability of AmB to dissociate from complexes. At least three factors that can modify the distribution of AmB in vivo and affect the efficacy are suggested: its ability to bind to selected molecules found in plasma, its ability to bind to tissues and organs, and the ability of vesicles of differing sizes to traverse the epithelium. The lipid-based formulations are clearly less toxic, even at considerably higher doses; their pharmacokinetic properties and effectiveness differ in long-term assays because of different physicochemical characteristics (32). Adverse reactions to intravenous AmB are to some extent dependent on its mode of delivery. One potential problem with some of the new lipid formulations is their high manufacturing cost.

Three types of lipid-based formulations of AmB incorporated into liposomes, sheets, or discs are under intensive clinical investigation. The lipid-based formulations differ in size, structure, shape, lipid composition, and molar AmB content. Their physicochemical differences determine their thermodynamic stability, the distribution of AmB between the lipid formulation and lipoproteins, and their tissue distribution, levels in blood, uptake by macrophages, and pen-

etration to the site of infection. Despite all these differences, they are all less toxic than AmB to mammalian cells, animals, and humans.

Many of the newer lipid formulations including AmB–lipid complex (ABLC, Abelcet), AmB colloidal dispersion (ABCD, Amphocil), and liposomal AmB (L-AmB, AmBisome) have been found to be relatively less toxic in animals and in vitro studies as well, but lowered toxicity in vitro does not always predict lower toxicity in vivo. These formulations are described in Table 1. At equivalent concentrations of AmB, deoxycolate AmB (D-AmB) has been found more effective in fungal infections than the lipid-based formulations. The small amount of free AmB that dissociates from the complexes impairs their antifungal effectiveness.

Liposomes are biocompatible, biodegradable, microvesicular systems for drug delivery owing to their amenability to controlled release and site-directed delivery. The recent development of lipid formulations with longer half-lives opens new therapeutic avenues in treating infections, including those in non-MPS tissues. The passive targeting of liposomes to the sites of infection is of great value with respect to clinical application. Liposomal entrapment can exchange the pharmacokinetics and hence reduce the toxicity of AmB. Liposomal AmB is AmB incorporated into lipid bilayer; AmBisome is a formulation of AmB in unilamellar liposomes.

Studies with mice showed that liposome encapsulation of AmB reduced its toxicity and allowed higher doses to be administered, thus increasing the therapeutic efficacy of the compound in animal models of systemic mycosis, including candidiasis (33). The priorities of liposomes differ depending on the composition of the lipids constituting the membrane. AmBisome's lack of effect on immune system cells at high concentrations may explain the decrease in toxic phenomena observed in vivo when this form of the drug is tested. The decrease in toxicity might then allow for the demonstration of the more positive effects of AmB on the immune system. Macrophages may function as a reservoir of AmB for intracellular and extracellular antimicrobial action.

The lipophilic AmB is located within the lipid layers of the liposome. Because the affinity of AmB to ergosterol in the fungus membrane is the highest among the antifungal agents, and its affinity to the lipid carrier and cholesterol in human cell membranes is the lowest, a selective transfer of AmB from the lipid carrier to its target, the fungus membrane, can be expected. The result is a great reduction in toxicity, which allows the administration of much higher doses of AmB. Although the antifungal activity of most lipid formulations is reduced to some extent, the use of much higher dosages might lead to an increased therapeutic index compared with conventional AmB. AmBisome, Amphocil, and ABLC share the advantage of low nephrotoxicity (34).

One trial involved sequestration of AmB from some host tissues while delivering the drug to the rethiculoendotherial cells where various intracellular pathogens, including *Cryptococcus neoformans*, reside. Mice were challenged intraperitoneally, intratracheally, or intracerebrally, and the course of infection in untreated control mice was compared with that of mice given D-AmB or L-AmB. Over six times more AmB in L-AmB than D-AmB could be delivered in mice without any acute toxicity. In murine pulmonary cryptococcosis, L-AmB–treated mice survived significantly longer than control mice; thus, L-AmB was found to be effective against pulmonary cryptococcosis. AmB from liposomes is readily available to the cryptococci. L-AmB may permit efficient delivery of much larger doses than are feasible with D-AmB. However, it is possible that the adjuvancy of either the AmB or the liposomes activates macrophages to kill more cryptococci and thus prolongs survival. Intracranially challenged mice treated with L-AmB had significantly reduced cell counts in brain and spleen; thus, it was suggested that effective intracranial concentrations of AmB were delivered in the liposomes and that liposomes may offer a way to protect at least some organs against the toxic effects of AmB (35).

In a controlled, randomized trial, a short antifungal prophylaxis course of AmBisome was found to reduce the incidence of proven invasive fungal infections significantly during the first month following liver transplantation surgery. AmBisome was well tolerated, although backache, thrombocytopenia, and renal function impairment were reported in a few patients (36). Aerosolized liposomal AmB deposited aerosolized form may be advantageous. This would provide delivery of the AmB to the lung tissue, but the drug would probably also get into systemic circulation. Because liposomal AmB is rapidly cleared by the reticuloendothelial system (RES), administration of higher doses is often required to obtain sufficient levels of drug in lung lead to side effects, in a murine model of pulmonary and systemic cryptococcosis, aerosolized liposomal AmB could be delivered to target and was found effective (37).

Table 1. Characteristics of Some Lipid Formulation of AmB

Lipid formulation	Composition	Shape	Size
AmB–lipid complex (ABLC)	Dimyristoyl phosphatidylcholine Dimyristoyl phosphatidyl glycerol	Sheets	1.6–11 μm
AmBisome	Hydrogenated phosphatidylcholine Cholesterol Distearoyl phosphatidylglycerol	Unilamellar Vesicles	0.06 μm
AmB colloidal dispersion (ABCD)	Cholesteryl sulfate	Discs	0.12 μm
Lipid nanosphere AmB	Soybean oil Egg lecithin Maltose	Vesicles	25–50 nm

Micelles are colloid particles formed by an aggregation of detergent molecules. Special drug career systems and dosage forms, such as nanoparticles and liposomes, hold the promise of overcoming the pharmacokinetic limitations. Nanoparticles are stable, solid colloidal particles of various sizes that consist of macromolecular material. Nanoparticles represent an interesting carrier system for specific enrichment in macrophage-containing organs like the liver and the spleen. Injectable nanoparticle carriers have important potential applications, as in site-specific drug delivery. Conventional carriers are generally eliminated by the RES. Although in deep mycoses, efforts to lower the toxicity of AmBisome, Abelcet, and Amphocil showed comparable efficacies, studies on the efficacies of NS-718, AmB encapsulated in lipid nanospheres are in progress in Japan. Lipid nanospheres are composed of equal amounts of egg lecithin and soybean oil. The carrier potentials of lipid nanosphere are characterized by lower uptake by the RES and good distribution to the sites of inflammation (38).

NS-718 was found to more effective than D-AmB or L-AmB against clinical isolates of *Candida albicans* and *Aspergillus fumigatus*. NS-718 was well tolerated and improved survival markedly at equivalent doses in treating pulmonary aspergillosis in rats. Increased activity was also supported by pharmacokinetic study (Fig. 2) (39). In another study, NS-718 was found to have better in vitro efficacy against clinical isolates of *C. neoformans* than other AmB formulations; it was well tolerated, and its efficacy was much higher than that of D-AmB or L-AmB in treating pulmonary cryptococcosis in mice (40) (Fig. 3).

The development of immunoliposomes is an important step in the pursuit for an effective cellular targeting system. Upon binding to the specific cellular receptor via an antibody–antigen link, the immunoliposomes cluster into the coated pits and are subsequently internalized into cellular vacuoles. The immunoliposomes are then processed through the endosome–lysosome system. Trials of their in vitro and in vivo antifungal activity, toxicity, and efficacy against systemic candidiasis in murine models showed prolonged circulation, reduced toxicity, and improved efficacy by PEG conjugated to L-AmB (41). In murine models of invasive pulmonary aspergillosis, PEG- and 34A monoclonal antibodies conjugated to L-AmB were found to have higher efficacy than those of L-AmB and PEG conjugated to L-AmB (Fig. 4). Conjugation of PEG could reduce uptake by the RES and prolong circulation time, and conjugation of 34A-monoclonal antibody to L-AmB could deliver the drug to the target tissue, that is, the endothelia of mouse pulmonary capillaries. Thus, it was suggested that functional liposomes encapsulating AmB could have great potential against refractory fungal infections because

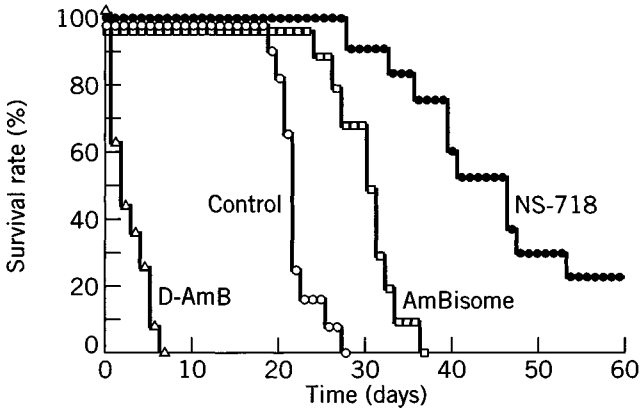

Figure 3. Survival rate over time of mice with pulmonary cryptococcosis, treated with NS-718. NS-718 (2mg/kg), AmB sodium deoxycholate (D-AmB) (2mg/kg), and AmBisome (2mg/kg) were injected intravenously once a day for 5 days after infection. *Source:* Based on data from Ref. 40.

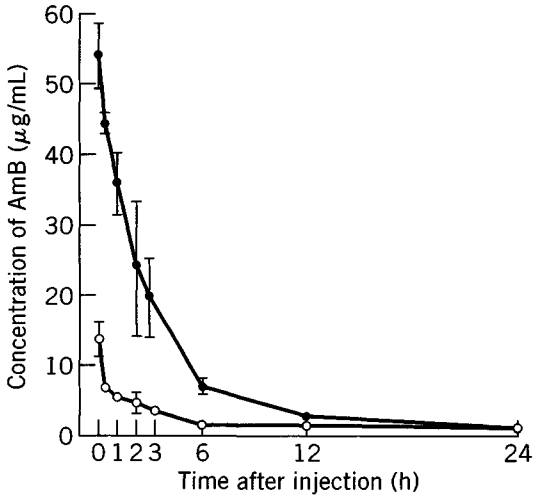

Figure 2. The concentrations of AmB in plasma after a single administration of 3mg/kg NS-718 and AmB sodium deoxycholate (D-AmB) in rats with invasive pulmonary aspergillosis. *Source:* Based on data from Ref. 43.

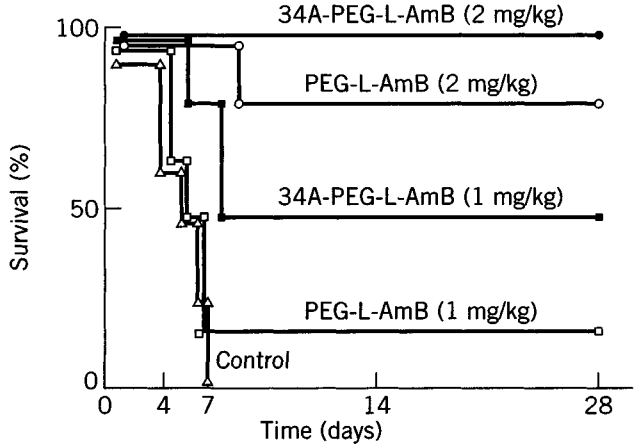

Figure 4. Effects of an immunoliposome, 34A-polyethylene glycol-liposomal-AmB (34A-PEG-L-AmB), on the survival rate over time in mice experimentally infected with invasive pulmonary aspergillosis. Liposomal AmB was injected intravenously in once a day for 5 days after infection. *Source:* Based on data from Ref. 43.

extended-circulation immunoliposomes are well tolerated and show comparable efficacy to other AmB formulations in murine invasive pulmonary aspergillosis (42,43).

ABLC is a formulation of lipid aggregates of dimyristoyl phosphatidylcholine (DMPC) and dimyristoyl phosphatidylglycerol (DMPG), and it has an unusual ribbonlike lipid structure that may attenuate the toxicity of AmB (44). Biological characteristics of ABLC were investigated in murine model of a variety of systemic mycoses such as candidiasis, aspergillosis, cryptococcosis, and histoplasmosis; ABLC was effective against all model infections studied, though comparable or a little lower in efficacies than D-AmB, but improved therapeutic index was noted. LD_{50} of ABLC was more than 40 mg/kg compared to that of D-AmB, 3 mg/kg. Putatively, AmB is released gradually only in the infection site, most likely because yeast lipase disrupted the drug lipid interaction. Therefore, ABLC can be given at much higher doses, and therapeutic benefits can be achieved (45). In vitro antifungal activity and in vivo efficacy and acute toxicity in murine model of candidiasis were studied; ABLC was well tolerated and was found as effective as AmB (46).

In a multicenter (although not well-established) study, ABLC was found to have apparently better clinical and microbiological activity in patients with AIDS-associated cryptococcal meningitis and was significantly better tolerated than a standardized regimen of AmB but was not free from toxicities (47). Internalization of low-density-protein (LDL)-bound AmB into cells may result in toxicity, which may be minimized by a career like ABLC. In a patient with disseminated zygomycosis including renal lesions, the combined use of ABLC and granulocyte-colony-stimulating factor was successful; the patient's condition remained stable, and no relapse occurred after 1 year of follow-up (48).

AmB colloidal dispersion (ABCD) consists of a cholesteryl sulfate complex of AmB and is a disklike stable complex of the constituents in a 1:1 molar ratio. There is no free drug in this type of arrangement and low lipoprotein binding in serum or other milieu, suggesting that the drug moiety lipid-binding sites are minimally exposed and the preparation is in lyophilized form. In animal models, the half-life of ABCD is longer than that of D-AmB, which suggests that once lipid binding of ABCD occurs, dissociation occurs much slowly. AmB in ABCD reaches the antifungal target, but activity is variable. ABCD has been found effective in different animal models of systemic mycosis including coccidioidomycosis, candidiasis, and aspergillosis, and much higher doses could be administered safely (49). Efficacy and safety of ABCD was compared with that of a D-AmB suspension in a murine model of disseminated cryptococcosis, and improved therapeutic index was suggested (50). In a murine model of systemic cryptococcosis, the efficacies of commercially available lipid-based formulations and D-AmB were evaluated. The lipid-based formulations showed efficacy in prolongation of survival. ABCD and L-AmB showed equivalent potencies and were superior to ABLC; ABCD was better in clearing infections other than in the brain (51). Measurement of plasma concentration of AmB for 4 weeks after a single intravenous infusion of ABCD administered to healthy volunteers indicated that the pharmacokinetics of AmB following infusions do not differ significantly from those of D-AmB. Acute side effects reported were similar to those of D-AmB and were dose dependent. But no clinically significant changes in biochemical parameters in renal or liver function tests were noticed (52).

Four patients with cryptococcal meningitis were assessed clinically and were treated with ABCD, and it was suggested that despite having undetectable levels in the cerebrospinal fluid (CSF), ABCD is an efficacious alternative form of therapy for cryptococcal meningitis for patients intolerant to D-AmB (53). In an open-label multicenter study in hospitalized patients with invasive fungal infections and impaired renal function, ABCD was found to be effective and well tolerated in immunocompromised patients with invasive fungal infections and was safe for those with underlying renal impairment (54). In another multicenter study, ABCD was administered in patients with invasive mycoses, and clinical response and adverse effects were evaluated. The conditions of patients were also monitored by biochemical parameters, blood counts, routine urinalysis, culture, microscopy, radiography, and serologic findings. ABCD was found active and less nephrotoxic than AmB, particularly in patients nonresponsive or intolerant to D-AmB. It was also suggested that the colloidal particles of ABCD remain intact after intravenous injection and are rapidly cleared by hepatic reticuloendothelial cells, resulting in low intrarenal concentrations of AmB, which appeared to be the cause of reduction of nephrotoxicity (55). There are some noncommercially developed lipid-based formulations, such as multilamellar liposomal AmB, small unilamellar liposomal AmB, and AmB-intralipid.

Nystatin, another polyene derivative antibiotic, is to some extent similar to AmB in action, but parenteral administration being toxic, it should be used as a topical preparation. Incorporation of nystatin into multilamellar liposome was found to retain the in vitro antifungal activity and protected human erythrocytes from toxicity (56). Liposomal formulation of nystatin was well tolerated and improved survival at equivalent doses as compared to free nystatin; it showed markedly increased activity at higher doses in treating systemic candidiasis in mice. Clinical trials are under way to evaluate its efficacy and rational application (57). Fluconazole, a bis-triazole antifungal agent encapsulated in a biodegradable scleral implant, was studied in vitro and also in pigmented rabbits. Periodic measurement of released fluconazole and effects on ocular tissue by ophthalmoscopy, histology, and electrophysiological studies were done. Concentration of fluconazole in rabbit vitreous remained within 99% of MIC for *C. albicans* for 3 weeks, and no toxicity was noticed. Thus, usefulness of biodegradable, polymeric scleral implants containing fluconazole was suggested (58).

LIPOSOME-ENCAPSULATED ANTIVIRAL AGENTS

Viruses are very small, "filterable" submicroscopic organisms, characterized by only a core of DNA or RNA in their genomes; they are surrounded by a protein coat and can

replicate only in living cells. In some of the well-known viral infections, viral receptors are detected on host cells, which has been proposed to be important in causing disease. Many viral infections are self-limiting in nature and produce low-grade illness for short periods; others may cause prolonged suffering and at times life-threatening infections. Antiviral agents are aimed at suppression of viral replication; many of the currently available antiviral agents have therapeutic and prophylactic effects. However, viral containment or elimination is extremely difficult in individuals with impaired immune status.

In a murine model of respiratory Influenza A virus infection, improved therapeutic and prophylactic efficacies of the antiviral antibody were noted when liposomes were used as carriers for it. Thus, it was suggested that liposomes facilitated specific delivery and that targeting the antibodies to the infection site could enhance the in vivo protective efficacies of the antibody (59). In experimental Influenza A virus infection in mice, intranasal administration of 5,7,4′-trihydroxy-8-methoxyflavone solution in hydroxypropyl cellulose showed significant inhibition of virus proliferation in both nasal and bronchoalveolar cavities, which suggested potential for drug delivery by hydroxypropyl cellulose (60).

Human serum albumin (HSA) and negatively charged *cis*-aconitic anhydride–reacted HSA were found to covalently couple to liposome. After conjugation with polyethyleneglycol prolonged activity and dual attack on human immunodeficiency virus type 1 (HIV-1) life cycle in vitro and in vivo as a result of an effective drug delivery system it was suggested that the attachment of an anti-CD4 monoclonal antibody to the outer surface of liposomes resulted in their interaction with both monocytes and lymphocytes (61). Thus, it was suggested that immunoliposome targeting to CD4+ cells in human blood might provide a means of targeting antiviral agents in cells at risk of HIV infection (62). Nanoparticles prepared by emulsion polymerization from polyhexylcyanoacrylate were loaded with nucleoside analog zalcitabine or the HIV protease inhibitor saquinavir and then tested for antiviral activity in primary human monocytes/macrophage cells in vitro, showing comparable results to those of free drugs. The delivery of antiviral agents to the monocyte phagocytic system was enhanced by nanoparticulate formation of saquinavir and could also overcome pharmacokinetic problems; thus, improved activities of the drugs by enhancing cellular uptake and in HIV target cells and tissues were suggested (63).

A single intravitreal injection of liposome-encapsulated (*S*)-1-(3-hydroxy-2-phosphonylmethoxypropyl) cytosine (cidofovir) in a rabbit model of focal nonlethal *Herpes simplex* virus (HSV) type 1 viral retinitis was found to have remarkably protective and prolonged antiviral effect. The slow rate of release of cidofovir was considered responsible for the long-term effect (64). Intravitreal injection of acyclovir diphosphate dimystoylglycerol in a rabbit model of focal nonlethal HSV type 1 viral retinitis resulted in reduction of severity of infection and rapid clearing of vitreous and optical media as compared to the effects of gancyclovir, acyclovir, and buffer. The drug delivery system modified the antiviral effects and the duration of activity as well, and treatment for cytomegalovirus retinitis and other retinal diseases was suggested (65).

LIPOSOME-ENCAPSULATED ANTIPARASITIC AGENTS

Parasites are living organisms that grow, feed, and are sheltered on or in different organisms while contributing nothing to the survival of the host. Parasitic diseases comprise a large portion of health problems in underdeveloped or developing countries in tropical and subtropical areas. In developed countries, parasitic diseases occur infrequently, though contamination of water supplies, improperly cooked meat, or worldwide travel are important factors to consider. Some parasitic infections have been found in association with impaired immune status, such as results from AIDS.

The use of drug delivery systems in parasitic diseases other than lipid formulations of AmB in leishmaniasis are not well known and lag behind use against other infectious diseases. In experimental leishmaniasis, pentamidine isethionate and its methoxy derivative, encapsulated in mannose-grafted liposomes, showed improved therapeutic effects over pentamidine isethionate, though the methoxy derivative was less toxic. Sugar-grafted liposomes were suggested to have better carrier potential than liposomes or free drug (66). Colloidal carrier potential and the targeted and controlled delivery of albendazole encapsulated in polyhexylcyanoacrylate nanoparticle was evaluated in vitro and also in murine models of hepatic alveolar echinococcosis. Cytotoxicity study showed no toxicity for peritoneal macrophages but reduced viability of the parasites. In vivo, no acute toxicity of albendazole-loaded nanoparticles was observed, and the injectable form showed equivalent parasitostatic effect (67).

The ideal drug delivery system should provide therapeutics in response to physiological requirements, having the capacity to "sense" changes and alter the drug-release process accordingly. The basic approach that drug concentration–effect relationships are significantly invariant as a function of time in humans has led to the development of constant-rate drug delivery systems (1). Nevertheless, there are a number of clinical situations where such an approach may not be sufficient. These include the delivery of insulin for patients with diabetes mellitus, antiarrhythmics for patients with heart rhythm disorders, gastric acid inhibitors for ulcer control, and nitrates for patients with angina pectoris as well as selective β-blockade, birth control, general hormone replacement, immunization, and cancer chemotherapy. Recent studies in the field of chronopharmacology indicate that the onset of certain diseases exhibits strong circadian temporal dependency. Thus, drug delivery patterns can be further optimized by pulsed or self-regulated delivery, adjusted to the staging of biological rhythms (2).

Modulated drug delivery systems are devices that are implanted or injected into the body and are capable of releasing drugs in response to external stimuli such as magnetic fields, heat, ultrasound, pH, or concentration of a specific molecule. These "intelligent" delivery systems can be classified as open- or closed-loop systems. Open-loop control systems are those in which information about the controlled variable is not automatically used to adjust the system inputs to compensate for the change in the process variables, whereas in closed-loop control systems, the controlled variable is detected, and as a result the system output is adjusted accordingly. In the controlled drug delivery field, open-loop systems are known as *pulsatile* or *externally regulated*, and the closed-loop systems as *self-regulated*. The externally controlled devices apply external triggers for pulsatile delivery such as magnetic, ultrasonic, thermal, electric, and electromagnetic irradiation, whereas in the self-regulated devices, the release rate is controlled by feedback information without any external intervention. The self-regulated systems utilize several approaches as rate-control mechanisms: pH-sensitive polymers, enzyme–substrate reactions, pH-sensitive drug solubility, competitive binding, antibody interactions, and metal concentration–dependent hydrolysis.

This article outlines the fundamental principles of both pulsatile and self-regulated systems for drug delivery.

PULSATILE SYSTEMS

Magnetically Modulated Systems

An early approach to pulsatile delivery involved incorporating magnetic beads in elastic polymers. When an oscillating magnetic field was applied, more drug was released (Fig. 1). Studies demonstrated that insulin and other molecules could be continuously released by embedding the hormone in a carrier such as ethylene-vinyl acetate copolymer (EVAc) (3). In vitro studies were then conducted characterizing the critical parameters affecting release rates (4). This information was utilized to design subcutaneous implants of EVAc–insulin, which decreased the glucose levels of diabetic rats for 105 days (5). The next step in designing a delivery system for use in diabetes was to develop a system that would be capable of releasing insulin at a higher rate upon demand. In vitro studies were conducted showing that EVAc–protein matrices containing magnetic beads exhibit enhanced release rates when placed in an oscillating external magnetic field (6–8). In vivo studies (9) showed that when polymeric matrices containing insulin and magnetic beads were implanted in diabetic rats, glucose levels could be repeatedly decreased on demand by application of an oscillating magnetic field.

The systems consists of drug powder dispersed within a polymeric matrix together with magnetic beads. One method of formulating this system is to add approximately 50% of the drug–polymer mixture to a glass mold that has been cooled to $-80°C$ using dry ice. The magnetic particles are added, followed by the remaining drug–polymer mixture (7). In addition to the experimental polymer matrices containing both magnets and insulin, controls, including polymer matrices that contained a magnet but no insulin and that contained insulin but no magnet, were made.

When a polymer matrix containing insulin and a magnet was implanted into a diabetic rat (9), the blood glucose

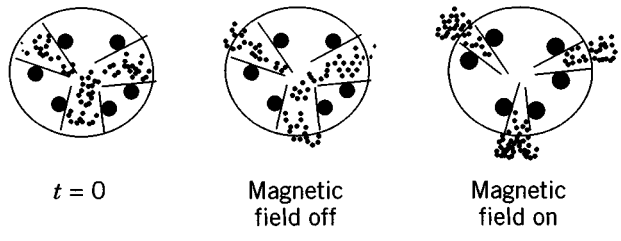

Figure 1. Schematic presentation of a magnetic-triggered controlled-release system. Large dots are magnetic beads; small dots represent drug (1).

level fell from over 400 mg % to nearly 200 mg %. In the absence of the magnetic field, the blood glucose level remained near this value over the 51-day implantation period. However, every time the magnetic field was applied, the blood glucose level decreased. The average decrease for the three rats in the experimental group, which were triggered a total of 26 times, was 29.4%. The difference in glucose changes between the experimental group and the controls (14 rats, 97 triggers) was highly significant. These results were confirmed by an insulin radioimmunoassay (RIA).

The factors that are critical in controlling the release rates in these systems can be characterized by two main groups: (*1*) magnetic field characteristics and (*2*) mechanical properties of the polymer matrix. It was found that the extent of release enhancement increases as the magnetic field amplitude rises. When the frequency of the applied field was increased from 5 to 11 Hz, the release rate of bovine serum albumin (BSA) from EVAc copolymer matrices rose in a linear fashion (7). Saslavski et al. (10) investigated the effect of magnetic field frequency and repeated field application on insulin release from alginate matrices and found that with repeated applications, inverse effects can occur: High frequencies gave a significant release enhancement for the second magnetic field application, after which the enhancement level decreased owing to faster depletion at these frequencies.

The mechanical properties of the polymeric matrix also affect the extent of magnetic enhancement (6). For example, the modulus of elasticity of the EVAc copolymer can be easily altered by changing the vinyl acetate content of the copolymer. The release-rate enhancement induced by the magnetic field increase as the modulus of elasticity of EVAc decreases. A similar phenomenon was observed for the cross-linked alginate matrices: higher release-rate enhancement for less rigid matrices. Edelman et al. (11) also showed that enhanced release rates observed in response to an electromagnetic field (50 G, 60 Hz) applied for 4 min were independent of the duration of the interval between repeated pulses.

Ultrasonically Modulated Systems

Kost et al. (12) suggested the feasibility of ultrasonic-controlled polymeric delivery systems in which release rates of substances can be repeatedly modulated at will from a position external to the delivery system. Both bioerodible and nonerodible polymers were used as drug carrier matrices. The bioerodible polymers evaluated were polyglycolide, polylactide, poly(bis(*p*-carboxyphenoxy) alkane anhydrides and their copolymers with sebacic acid. The releasing agents were *p*-nitroaniline, *p*-aminohippurate, bovine serum albumin, and insulin.

Enhanced polymer erosion and drug release were observed when the bioerodible samples were exposed to ultrasound. The systems response to the ultrasonic triggering was rapid (within 2 min) and reversible. The enhanced release was also observed in nonerodible systems exposed to ultrasound where the release is diffusion dependent. Release rates of zinc bovine insulin from EVAc matrices were 15 times higher when exposed to ultrasound compared with the unexposed periods. It has also been demonstrated that the extent of enhancement can be regulated by the intensity, frequency, or duty cycle of the ultrasound (12).

To assess the effect of ultrasonic energy on the integrity of the releasing molecules, insulin samples were evaluated by high-pressure liquid chromatography (HPLC). No significant difference was detected between insulin samples exposed to ultrasound and unexposed samples, suggesting that the ultrasound is not degrading the releasing molecules (12).

In vivo studies have suggested the feasibility of ultrasound-mediated drug release enhancement (12). Implants composed of polyanhydride polymers loaded with 10% para-aminohippuric acid (PAH) were implanted subcutaneously in the back of catheterized rats. When exposed to ultrasound, a significant increase in the PAH concentration in urine was detected (400%) (Fig. 2). The Rats' skin histopathology of the ultrasound-treated area after an exposure of 1 h at 5 W/cm^2 did not reveal any differences between treated and untreated skin.

It was proposed (12) that cavitation and acoustic streaming are responsible for this augmented degradation and release. In experiments conducted in a degassed buffer, where cavitation was minimized, the observed enhancement in degradation and release rates was much smaller. It was also considered that several other parameters (temperature and mixing effects) might be responsible for the augmented release due to ultrasound. However, experiments were conducted that suggested that these parameters were not significant. A temperature rise of only 2.5°C was recorded in the samples during the triggering

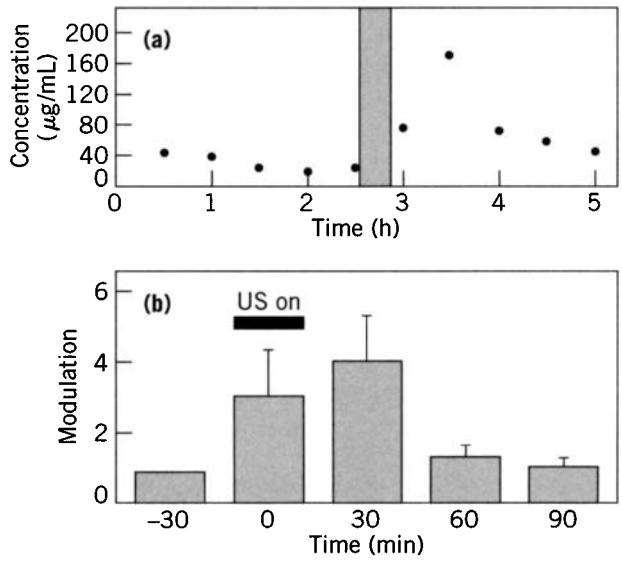

Figure 2. (**a**) Para-amino hippuric acid (PAH) concentration in the urine of Sprague-Dawley rats as a function of time before, during, and after a 20-min exposure to ultrasound (shaded area). (**b**) Modulation versus time expressed as a mean and standard deviation of four experimental rats. (Modulation was defined as the ratio of PAH concentration during and after the ultrasound [US] exposure to the mean of the PAH concentration before the exposure) (12).

period. A separate release experiment done at 40°C instead of 37°C showed that the rate increase was below 20%. To evaluate the ultrasound effect on the diffusion boundary layer, release experiments were performed under vigorous shaking. The increase of the release rates due to shaking were always below 20%. Therefore, it was concluded that the effect of the ultrasound on the augmented release cannot be due to mixing or temperature only.

Similar phenomena were observed by Miyazaki et al. (13) who evaluated the effect of ultrasound (1 MHz) on the release rates of insulin from ethylene-vinyl alcohol copolymer matrices and reservoir-type drug delivery systems. When diabetic rats receiving implants containing insulin were exposed to ultrasound (1 W/cm^2 for 30 min), a sharp drop in blood glucose levels was observed after the irradiation, indicating a rapid rate of release of insulin in the implanted site. The authors speculate that the ultrasound caused increased temperature in the delivery system, which may facilitate diffusion.

Over the past 40 years, numerous clinical reports have been published concerning phonophoresis (14). The technique involves placing the topical preparation on the skin over the area to be treated and massaging the area with an ultrasound probe. In the last decade, with the development of transdermal delivery as an important means of systemic drug administration, researchers investigated the possible application of ultrasound into transdermal delivery systems. Kost et al. (14–16) studied in rats and guinea pigs the effect of therapeutic ultrasound (1 MHz) on skin permeability of D-mannitol, a highly polar sugar alcohol; insulin, a high-molecular-weight polysaccharide; and physostigmine, a lipophilic anticholinesterase drug. Ultrasound nearly completely eliminated the lag time usually associated with transdermal delivery of drugs. Three to five minutes of ultrasound irradiation (1.5 W/cm^2 continuous wave or 3 W/cm^2 pulsed wave) increased the transdermal permeation of inulin and mannitol in rats by 5–20-fold within 1–2 h following ultrasound application. Ultrasound treatment also significantly increased the inhibition of cholinesterase during the first hour after application in both physostigmine-treated rats and guinea pigs.

Miyazaki et al. (17) performed similar studies evaluating the effect of ultrasound (1 MHz) on indomethacin permeation in rats. Pronounced effect of ultrasound on transdermal absorption for all three ranges of intensities (0.25, 0.5, and 0.75 W/cm^2) was observed. Bommannan et al. (18) examined the effects of ultrasound on the transdermal permeation of lanthanum nitrate, an electron-dense tracer. The results demonstrate that exposure of the skin to ultrasound can induce considerable and rapid tracer transport through an intercellular route. Prolonged exposure of the skin to high-frequency ultrasound (20 min, 16 MHz), however, resulted in structural alterations of epidermal morphology. Tachibana and Tachibana (19–21) have reported use of low-frequency ultrasound (48 KHz) to enhance transdermal transport of lidocaine and insulin across hairless mice skin. Low-frequency ultrasound has also been used by Mitragotri et al. (22,23) to enhance transport of various low-molecular-weight drugs including salicylic acid and corticosterone as well as high-molecular-weight proteins including insulin, γ-interferon, and erythropoeitin across human skin in vitro and in vivo.

Mitragotri et al. (24) also evaluated the role played by various ultrasound-related phenomena, including cavitation, thermal effects, generation of convective velocities, and mechanical effects. The authors' experimental findings suggest that among all the ultrasound-related phenomena evaluated, cavitation plays the dominant role in sonophoresis using therapeutic ultrasound (frequency, 1–3 MHz; intensity, 0–2 W/cm^2). Confocal microscopy results indicate that cavitation occurs in the keratinocytes of the stratum corneum upon ultrasound exposure. The authors hypothesized that oscillations of the cavitation bubbles induce disorder in the stratum corneum lipid bilayers, thereby enhancing transdermal transport. The theoretical model developed to describe the effect of ultrasound on transdermal transport predicts that the sonophoretic enhancement depends most directly on the passive permeant diffusion coefficient in water and not on the permeant diffusion coefficient through the skin.

Electrically Regulated Systems

Electrically controlled systems provide drug release by the action of an applied electric field on a rate-limiting membrane and/or directly on the solute, thus controlling its transport across the membrane. The electrophoretic migration of a charged macrosolute within a hydrated membrane results from the combined response to the electrical forces on the solute and its associated counterions in the adjacent electrolyte solution (25). Grimshaw et al. (26) reported four different mechanisms for the transport of proteins and neutral solutes across hydrogel membranes (*1*) electrically and chemically induced swelling of a membrane to alter the effective pore size and permeability, (*2*) electrophoretic augmentation of solute flux within a membrane, (*3*) electrosmotic augmentation of solute flux within a membrane, and (*4*) electrostatic partitioning of charged solutes into charged membranes.

Electrically controlled membrane permeability has also been of interest in the field of electrically controlled or enhanced transdermal drug delivery (e.g., iontophoresis, electroporation) (27,28).

Kwon et al. (29) studied the effect of electric current on solute release from cross-linked poly(2-acrylamido-2-methylpropane sulfonic acid-*co*-*n*-butylmethacrylate). Edrophonium chloride, a positively charged solute, was released in an on–off pattern from a matrix (monolithic) device with electric field. The mechanism was explained as an ion exchange between positive solute and hydroxonium ion, followed by fast release of the charged solute from the hydrogel. The fast release was attributed to the electrostatic force, squeezing effect, and the electroosmosis of the gel. However, the release of neutral solute was controlled by diffusion effected by swelling and deswelling of the gel.

Anionic gels as vehicles for electrically modulated drug delivery were studied by Hsu and Block (30). Agarose and combination of agarose with anionic polymers (polyacrylic acid, xanthan gum) were evaluated. The authors conclude the use of carbomer (polyacrylic acid) in conjunction with agarose enables the formulator to achieve zero-order re-

lease with electrical application. Increased anisotropicity of a gel system due to the application of electrical current could alter the effectiveness of a drug delivery system.

D'Emanuele and Staniforth (31) proposed a drug delivery device that consists of a polymer reservoir with a pair of electrodes placed across the rate-limiting membrane. By altering the magnitude of the electric field between the electrodes, the authors proposed to modulate the drug release rates in a controlled and predictable manner. A linear relationship was found between current and propanolol hydrochloride permeability through poly(2-hydroxyethyl methacrylate) (PHEMA) membranes cross-linked with ethylene glycol dimethacrylate (1% v/v). Buffer ionic strength and drug reservoir concentration as well as electrode polarity were found to have significant effects on drug permeability (32).

Labhasetwar et al. (33) propose similar approach for a cardiac drug delivery modulation. The authors studied a cardiac drug implant in dogs that is capable of electric current modulation. Cation-exchange membrane was used as an electrically sensitive rate-limiting barrier on the cardiac-contacting surface of the implant. The cardiac implant demonstrated in vitro drug-release rates that were responsive to current modulation. In vivo results in dogs have confirmed that electrical modulation resulted in regional coronary enhancement of the drug levels with current responsive increase in drug concentration.

A different approach for electrochemical-controlled release is based on polymers that bind and release bioactive compounds in response to an electric signal (34). The polymer has two redox states, only one of which is suitable for ion binding. Drug ions are bound in one redox state and released from the other. The attached electrodes serve to switch the redox states, and the amount of current passed can control the amount of ions released.

Photoresponsive Systems

Photoresponsive gels change their physical or chemical properties reversibly upon photoradiation. A photoresponsive polymer consists of a photoreceptor, usually a photochromic chromophore, and a functional part. The optical signal is captured by the photochromic molecules, and then the isomerization of the chromophores in the photoreceptor converts it to a chemical signal. Photoinduced phase transition of gels was reported by Mamada et al. (35). Copolymer gels of *N*-isopropylacrylamide and a photosensitive molecule, bis(4-dimethylamino)phenyl)(4-vinylphenyl)methyl leucocyanide, showed a discontinuous volume-phase transition upon ultraviolet irradiation, caused by osmotic pressure of cyanide ions created by the ultraviolet irradiation. Suzuki and Tanaka (36) reported on phase transition in polymer gels induced by visible light, where the transition mechanism is due only to the direct heating of the network polymer by light. Yui et al. (37) proposed photoresponsive degradation of heterogeneous hydrogels comprising cross-linked hyaluronic acid and lipid microspheres for temporal drug delivery. A visible light–induced degradation of cross-linked hyaluronic acid gels by photochemical oxidation using methylene blue as a photosensitizer. (The hyaluronic acid gels were also proposed by the authors to be inflammation responsive [38].)

RESPONSIVE SYSTEMS

Polymers that alter their characteristics in response to changes in their environment have been of great recent interest. Several research groups have been developing drug delivery systems based on these responsive polymers that more closely resemble the normal physiological process. In these devices, drug delivery is regulated by means of an interaction with the surrounding environment (feedback information) without any external intervention. The most commonly studied polymers having environmental sensitivity are either pH or temperature sensitive (Fig. 3).

Temperature-Sensitive Systems

Temperature-sensitive polymers can be classified into two groups based on the origin of the thermosensitivity in aqueous media. The first is based on polymer–water interactions, especially specific hydrophobic/hydrophilic balancing effects and the configuration of side groups. The other is based on polymer–polymer interactions in addition to polymer–water interactions. When polymer networks swell in a solvent, there is usually a negligible or small positive enthalpy of mixing or dilution. Although a positive enthalpy change opposes the process, the large gain in the entropy drives it. In aqueous polymer solutions, the opposite is often observed. This unusual behavior is associated with a phenomenon of polymer-phase separation as the temperature is raised to a critical value, known as the lower critical solution temperature (LCST). *N*-alkyl acrylamide homopolymers and their copolymers, including acidic or basic comonomers show this LCST (39,40). Polymers characterized by LCST usually shrink, as the temperature is increased through the LCST. Lowering the temperature below LCST results in the swelling of the polymer. Bioactive agents such as drugs, enzymes, and antibodies may be immobilized on or within the temperature-sensitive polymers. Responsive drug-release patterns regulated by temperature changes have been recently demonstrated by several groups (39,41–52).

Systems Sensitive to pH

The pH range of fluids in various segments of the gastrointestinal tract may provide environmental stimuli for responsive drug release. Studies by several research groups (53–65) have been performed on polymers containing weakly acidic or basic groups in the polymeric backbone. The charge density of the polymers depends on pH and

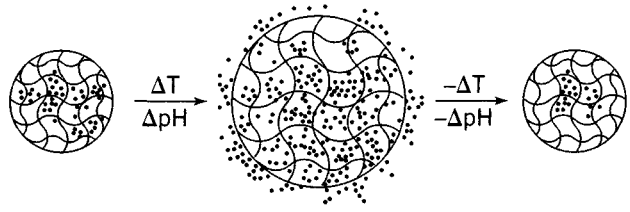

Figure 3. Schematic presentation of pH- or temperature-controlled drug delivery systems. Small dots represent drugs; lines represent polymer chains (1). (Δ can be positive or negative.)

ionic composition of the outer solution (the solution into which the polymer is exposed). Altering the pH of the solution will cause swelling or deswelling of the polymer. Thus, drug release from devices made from these polymers will display release rates that are pH dependent. Polyacidic polymers will be unswollen at low pH, because the acidic groups will be protonated and hence unionized. With increasing pH, polyacid polymers will swell. The opposite holds for polybasic polymers, because the ionization of the basic groups will increase with decreasing pH. Siegel et al. (66) found the swelling properties of the polybasic gels are influenced also by buffer composition (concentration and pK_a). A practical consequence proposed is that these gels may not reliably mediate pH-sensitive swelling-controlled release in oral applications, because the levels of buffer acids in the stomach (where swelling and release are expected to occur) generally cannot be controlled. However, the gels may be useful as mediators of pH-triggered release when precise rate control is of secondary importance.

Annaka and Tanaka (54) reported that more than two phases (swollen and collapsed) can be found in gels consisting of copolymers of randomly distributed positively and negatively charged groups. In these gels, polymer segments interact with each other through attractive or repulsive electrostatic interactions and through hydrogen bonding. The combination of these forces seems to result in the existence of several phases, each characterized by a distinct degree of swelling, with abrupt jumps between them. The existence of these phases presumably reflects the ability of macromolecular systems to adopt different stable conformations in response to changes in environmental conditions. For copolymer gels prepared from acrylic acid (the anionic constituent) and methacryl-amidopropyl-trimethyl ammonium chloride (460 mmol/240 mmol), the largest number of phases was seven. A similar approach was proposed by Bell and Peppas (64); membranes made from grafted poly(methacrylic acid-*g*-ethylene glycol) copolymer showed pH sensitivity due to complex formation and dissociation. Uncomplexed equilibrium swelling ratios were 40 to 90 times higher than those of complexed states and varied according to copolymer composition and polyethylene glycol graft length.

Giannos et al. (67) proposed temporally controlled drug delivery systems, coupling pH oscillators with membrane-diffusion properties. By changing the pH of a solution relative to the pK_a, a drug may be rendered charged or uncharged. Because only the uncharged form of a drug can permeate across lipophilic membranes, a temporally modulated delivery profile may be obtained with a pH oscillator in the donor solution.

Heller and Trescony (68) were the first to propose the use of pH-sensitive bioerodible polymers. In their approach, described in the section on systems utilizing enzymes, an enzyme–substrate reaction produces a pH change that is used to modulate the erosion of a pH-sensitive polymer containing a dispersed therapeutic agent.

Bioerodible hydrogels containing azoaromatic moieties were synthesized by Ghandehari et al. (69). Hydrogels with lower cross-linking density underwent a surface erosion process and degraded at a faster rate. Hydrogels with higher cross-linking densities degraded at a slower rate by a process where the degradation front moved inward to the center of the polymer.

Recently recombinant DNA methods were used to create artificial proteins that undergo reversible gelation in response to changes in pH or temperature (70). The proteins consist of terminal leucine zipper domains flanking a central, flexible, water-soluble polyelectrolyte segment. Formation of coiled-coil aggregates of the terminal domains in near-neutral aqueous solutions triggers formation of a three-dimensional polymer network, with the polyelectrolyte segment retaining solvent and preventing precipitation of the chain. Dissociation of the coiled-coil aggregates through elevation of pH or temperature causes dissolution of the gel and a return to the viscous behavior that is characteristic of polymer solution. The authors suggest these hydrogels have potential in bioengineering applications requiring encapsulation or controlled release of molecules and cellular species.

Inflammation-Responsive Systems

Yui et al. (38) proposed an inflammation-responsive drug delivery system based on biodegradable hydrogels of cross-linked hyaluronic acid. Hyaluronic acid is specifically degraded by hydroxyl radicals, which are produced by phagocytic cells such as leukocytes and macrophages, locally at inflammatory sites. In their approach, drug-loaded lipid microspheres were dispersed into degradable matrices of cross-linked hyaluronic acid.

Glucose and Other Saccharide-Sensitive Polymers

The basic principle of competitive binding and its application to controlled drug delivery was first presented by Brownlee and Cerami (71), who suggested the preparation of glycosylated insulins, which are complementary to the major combining site of carbohydrate-binding proteins such as Concavalin A (Con A). Con A is immobilized on sepharose beads. The glycosylated insulin, which is biologically active, is displaced from the Con A by glucose in response to, and proportional to, the amount of glucose present, which competes for the same binding sites. Kim et al. (72–79) found that the release rate of insulin also depends on the binding affinity of an insulin derivative to the Con A and can be influenced by the choice of saccharide group in glycosylated insulin. By encapsulating the glycosylated insulin-bound Con A with a suitable polymer that is permeable to both glucose and insulin, the glucose influx and insulin efflux would be controlled by the encapsulation membrane (Fig. 4).

It was found (73) that the glycosylated insulins are more stable against aggregation than commercial insulin and are also biologically active. The functionality of the intraperitoneally implanted device was tested in pancreatectomized dogs by an intravenous glucose tolerance test (IVGTT). The effect of an administered 500 mg/kg dextrose bolus on blood glucose level was compared with normal and pancreatectomized dogs without an implant. Figure 5 shows the results of this study (78). In addition, the blood glucose profile for a period of 2 days demonstrated that a diabetic dog, implanted with the self-regulating insulin

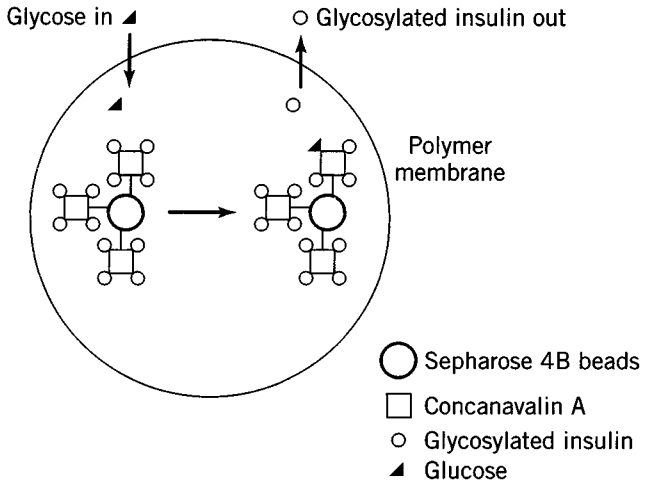

Figure 4. Schematic presentation of a self-regulated insulin delivery system based on competitive binding (79).

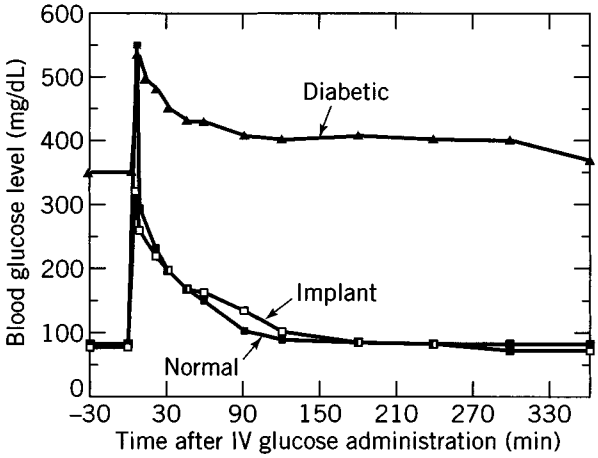

Figure 5. Peripheral blood glucose profiles of dogs administered bolus dextrose (500 mg/kg) during an intravenous glucose tolerance test. Blood glucose levels at $t = -30$ min show the overnight fasting level 30 min prior to bolus injection of dextrose (79).

delivery system, was capable of maintaining acceptable glucose levels (50–180 mg/dL) for the majority of the experiment (40 h) (75–77). Makino et al. (72) proposed a modification based on hydrophilic nylon microcapsules containing Con A and succinil-amidophenyl-glucopyranoside insulin.

Kokufata et al. (80) reported on a gel system that swells and shrinks in response to specific saccharides. The gel consists of a covalently cross-linked polymer network of *N*-isopropylacrylamide in which the lectin, Con A, is immobilized. Con A displays selective binding affinities for certain saccharides. For example, when the saccharide dextran sulphate is added to the gel, it swells to a volume up to 5 times greater. Replacing dextran sulphate with nonionic saccharide α-methyl-D-mannopyranoside brings about collapse of the gel back to almost its native volume. The process is reversible and repeatable.

Taylor et al. (81) proposed similar approach for the delivery of insulin. The self-regulating delivery device, responsive to glucose, has been shown to operate in vitro. The device comprises an reservoir of insulin and a gel membrane that determines the delivery rates of insulin. The gel consists of a synthetic polysucrose and a lectin, Con A. The mechanism is one of displacement of the branched polysaccharide from the lectin receptors by incoming glucose. The gel loses its high viscosity as a result but reforms on removal of glucose, thus providing the rate-controlling barrier for the diffusion of insulin or any other antihyperglycemic drugs.

A similar approach was also presented by Park et al. (82–84), who synthesized glucose-sensitive membranes based on the interaction between polymer-bound glucose and Con A.

Kitano et al. (85) proposed a glucose-sensitive insulin-release system based on a sol–gel transition. A phenylboronic acid (PBA) moiety was incorporated in poly(*N*-vinyl-2-pyrrolidone) by the radical copolymerization of *N*-vinyl-2-pyrrolidone with *m*-acrylamidophenylboronic acid (poly [NVP-*co*-PBA]). Insulin was incorporated into a polymer gel formed by a complex of poly(vinyl alcohol) with poly(NVP-*co*-PBA) (Fig. 6). PBA can form reversible covalent complexes with molecules having diol units, such as

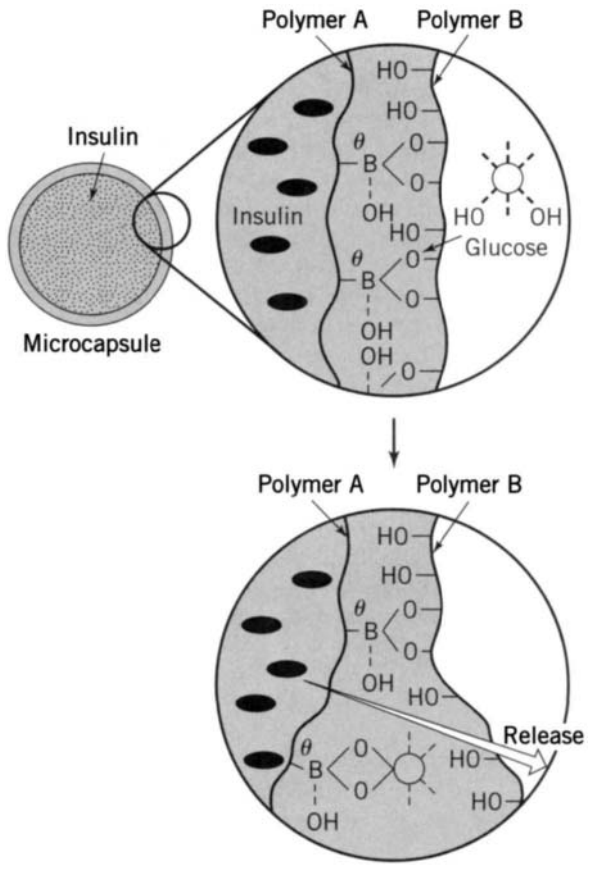

Figure 6. Schematic presentation of glucose-sensitive insulin-release system using PVA–poly(NVP-*co*-PBA) complex system (85).

glucose or PVA. With the addition of glucose, PVA in the PVA–boronate complex is replaced by glucose. This leads to a transformation of the system from gel to sol state, which facilitates the release of insulin from the polymeric complex. The same group (86) modified the approach suggesting glucose-responsive gels based on the complexation between polymers having PBA groups and PVA. The introduction of an amino group into PBA polymers was effective for increasing the complexation ability and the glucose responsivity at physiological pH.

SYSTEMS UTILIZING ENZYMES

In this approach, the mechanism is based on an enzymatic reaction. One possible approach studied is an enzyme reaction that results in a pH change and a polymer system that can respond to that change.

Urea Responsive Delivery

Heller and Trescony (68) were the first to attempt using immobilized enzymes to alter local pH and thus cause changes in polymer erosion rates. The proposed system is based on the conversion of urea to NH_4HCO_3 and NH_4OH by the action of urease. As this reaction causes a pH increase, a polymer that is subjected to increased erosion at high pH is required.

The authors suggested a partially esterified copolymer of methyl vinyl ether and maleic anhydride (Scheme 1). This polymer displays release rates that are pH dependent. The polymer dissolves by ionization of the carboxylic acid group (87).

A schematic presentation of the experimental device is shown in Figure 7. The pH-sensitive polymer shown in Scheme 1 containing dispersed hydrocortisone is surrounded with urease immobilized in a hydrogel prepared by cross-linking a mixture of urease and bovine serum albumin with glutaraldehyde. When urea diffuses into the hydrogel, its interaction with the enzyme leads to a pH increase, therefore enhancing erosion of the pH-sensitive polymer with concomitant changes in the release of hydrocortisone.

Figure 8 shows release of hydrocortisone from the described device. Although the device has no therapeutic relevance, it established the feasibility of creating self-responsive delivery system.

Ishihara et al. (89,90) suggested a nonerodible system based on a similar idea. The system is comprised of a pH-sensitive membrane prepared by copolymerizing 4-carboxyacrylanilide with methacrylate, sandwiched within a membrane containing urease immobilized in free radically crosslinked *N,N*-methylenebisacrylamide. The permeation of a model substance (1,4-bis(2-hydroxyethoxy) benzene varied with the urea concentration in the external solution.

Glucose-Responsive Insulin Delivery

Glucose-responsive delivery systems utilizing enzymes are based on the enzymatic reaction of glucose oxidase with glucose shown in Scheme 2. Several approaches have been devised.

Insoluble Soluble

Scheme 1. Solubilization of a partially esterified copolymer of methyl vinyl ether and maleic anhydride by ionization of pendent carboxylic acid functions (87).

$$\text{Glucose} + O_2 \xrightarrow[\text{oxidase}]{\text{Glucose}} \text{Gluconic acid} + H_2O_2$$

Scheme 2. Glucose oxidase catalyzes the conversion of glucose to gluconic acid and hydrogen peroxide.

Systems based on pH-sensitive polymers consist of immobilized glucose oxidase in a pH-responsive hydrogel, enclosing a saturated insulin solution or incorporated with insulin (91–99). As glucose diffuses into the hydrogel, glucose oxidase catalyzes its conversion to gluconic acid, thereby lowering the pH in the microenvironment of the hydrogel and causing swelling (Fig. 9). Because insulin should permeate the swelled hydrogel more rapidly, faster delivery of insulin in the presence of glucose is anticipated. As the glucose concentration decreases in response to the released insulin, the hydrogel should contract and decrease the rate of insulin delivery.

Horbett and coworkers (91–98) immobilized glucose oxidase in a cross-linked hydrogel made from *N,N*-dimethylaminoethyl methacrylate (DMA), hydroxyethyl methacrylate (HEMA), and tetraethylene glycol dimethacrylate (TEGDMA). Membranes were prepared at −70°C by radiation polymerization, previously shown to retain the enzymatic activity (100). To obtain sufficient insulin permeability through the gels, porous HEMA/DMA gels were prepared by polymerization under conditions that induce a separation into two phases during polymerization: one phase rich in polymer and the other rich in solvent plus unreacted monomer. When gelation occurs after the phase separation, the areas where the solvent/monomer phase existed become fixed in place as pores in the polymer matrix. The authors used a dilute monomer solution to obtain porous gel, typically 1–10 μm in diameter (92).

The rate of insulin permeation through the membranes was measured in the absence of glucose in a standard transport cell; then glucose was added to one side of the cell to a concentration of 400 mg/dL while the permeation measurement was continued. The results indicated that the insulin transport rate is enhanced significantly by the addition of glucose. The average permeability after addition of 400 mg/dL glucose was 2.4 to 5.5 times higher than before glucose was added. When insulin permeabilities through the porous gels were measured in a flowing system in which permeabilities were measured with fluid flowing continuously past one side of the membrane, no effect of glucose concentration on insulin permeabilities could be detected. The authors propose that inappropriate design of the membranes used in the experiments is the explanation for their lack of response to glucose concentration (91).

A mathematical model describing these glucose-responsive hydrogels demonstrates two important points (91,92). (*1*) Progressive response to glucose concentration over a range of glucose concentrations can be achieved only with a sufficiently low glucose oxidase loading; otherwise, depletion of oxygen causes the system to become insensitive to glucose; and (*2*) a significant pH decrease in the membrane, with resultant swelling, can be achieved only if the amine concentration is sufficiently low that pH changes are not prevented by the buffering of the amines.

Although the great advantage of reservoir systems is the ease with which they can be designed to produce constant release-rate kinetics, their main disadvantage are leaks, which are dangerous because all the incorporated

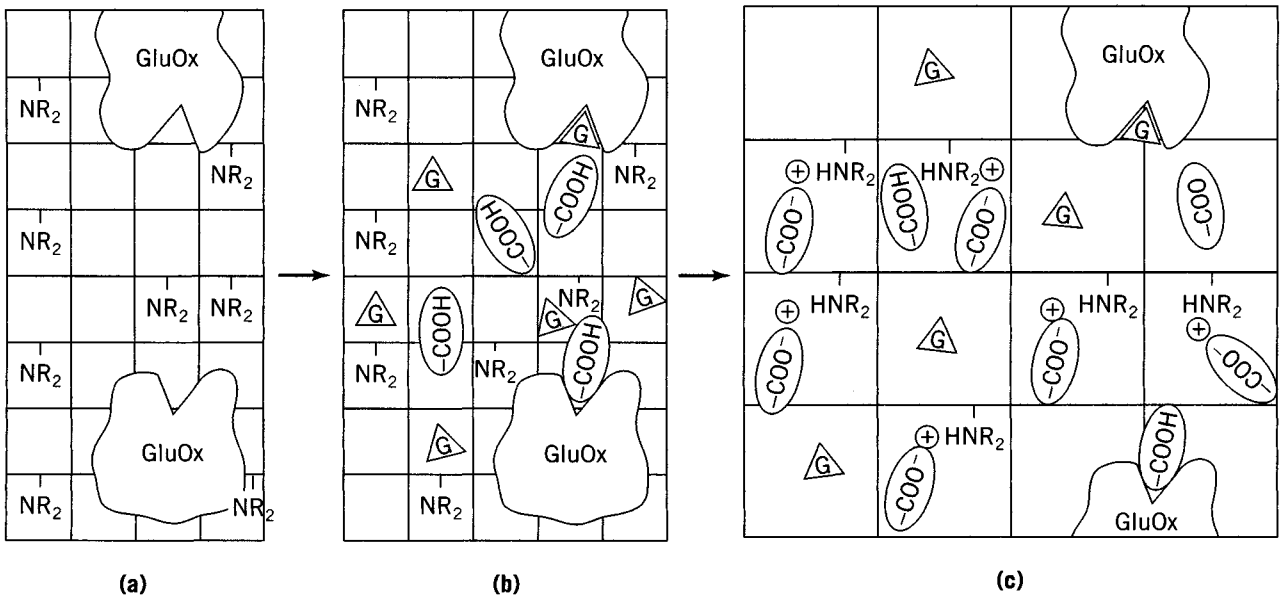

Figure 9. Mechanism of action of glucose-sensitive polymeric hydrogel. (**a**) In the absence of glucose, at physiologic pH, few of the amine groups are protonated. (**b**) In the presence of glucose, the glucose oxidase produces gluconic acid that can (**c**) protonate the amine groups. The fixed positive charge on the polymeric network led to electrostatic repulsion and membrane swelling and therefore enhanced insulin release (98).

drug could be rapidly released. In attempt to overcome this problem, Goldraich and Kost (99) proposed to incorporate the drug (insulin) and the enzyme (glucose oxidase) into the pH-responsive polymeric matrices.

Ishihara et al. (89,90,101–104) investigated two approaches for glucose-responsive insulin delivery systems; one approach is similar to that investigated by Horbett et al. (97). The polymers were prepared from 2-hydroxyethyl acrylate (HEA)-DMA and 4-trimethylsilystyrene (TMS) by radical polymerization of the corresponding monomers in dimethylformamide (DMF). The mole fractions of HEA, DMA, and TMS in the copolymer were 0.6, 0.2, and 0.2, respectively. Membranes were prepared by solvent casting. Capsules containing insulin and glucose oxidase were prepared by an interfacial precipitation method using gelatin as an emulsion stabilizer. The average diameter of the polymer capsules obtained was 1.5 mm (101,104). The water content of HEA–DMA–TMS copolymer membranes increased with a decrease in the pH of the medium. An especially drastic change was observed in the pH range of 6.3 to 6.15. The permeation of insulin through the copolymer membrane increased in response to pH decreases. The permeation rate of insulin at pH 6.1 was greater than that at pH 6.4 by about 42 times. The permeation of insulin through the copolymer membranes was very low in buffer solution without glucose. Addition of 0.2 M glucose to the upstream compartment induced an increase in the permeation rate of insulin. When glucose was removed, the permeation rates of insulin gradually returned to their original levels (101) (Fig. 10).

A similar approach for glucose-responsive insulin release based on hydrogels of poly(diethyl aminoethyl methacrylate-*g*-ethylene glycol) containing glucose oxidase and catalase was also proposed by Podual et al. (105).

The other approach proposed by Ishihara et al. (103) is based on an immobilized glucose oxidase membrane and a redox polymer having a nicotinamide moiety. The device consists of two membranes. One membrane, with the immobilized glucose oxidase, acts as a sensor for glucose and forms hydrogen peroxide by an enzymatic reaction; the other membrane is a redox polymer having a nicotinamide moiety that controls the permeation of insulin by an oxidation reaction with the formed hydrogen peroxide. The oxidation of the nicotinamide group increases hydrophilicity and therefore should enhance the permeability to water-soluble molecules such as insulin. The results showed relatively small increases in insulin permeability.

Iwata et al. (106,107) pretreated porous poly(vinylidene fluoride) membranes (average pore size of 0.22 μm) by air plasma, and subsequently acrylamide was graft-polymerized on the treated surface. The polyacrylamide was then hydrolyzed to poly(acrylic acid). In the pH range of 5 to 7, grafted poly(acrylic acid) chains are solvated and dissolved but cannot diffuse into the solution phase because they are grafted to the porous membrane. Thus, they effectively close the membrane pores. In the pH range of 1 to 5, the chains collapse and the permeability increases. To achieve the sensitivity of the system toward glucose, glucose oxidase was immobilized onto a poly(2-hydroxyethyl methacrylate) gel.

Ito et al. (108) adopted the approach proposed by Iwata et al. (107) using a porous cellulose membrane with surface-grafted poly(acrylic acid) as a pH-sensitive membrane. By immobilization of glucose oxidase onto the poly(acrylic acid)-grafted cellulose membrane, it became responsive to glucose concentrations (Fig. 11). Figure 12 shows the change in permeability of insulin through poly(acrylic acid)-grafted cellulose membranes following the addition of 0.2 M glucose to the buffered solution. The permeation coefficient after glucose addition was about 1.7 times that before the addition of glucose. The authors suggest to improve the proposed system (sensitivity of insulin

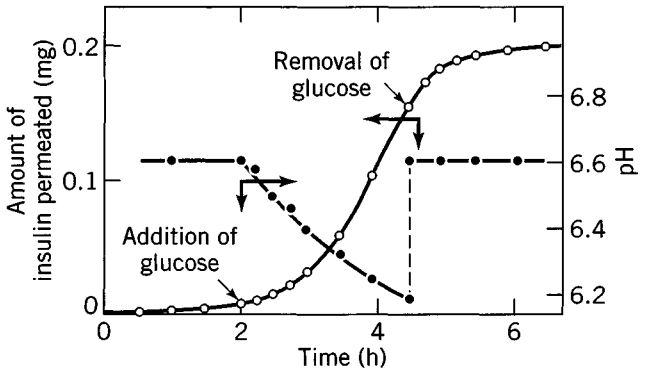

Figure 10. Effect of the addition and removal of glucose on insulin permeation through the HEA–DEA–TMS copolymer membrane and on the pH of the feed-side solution at 30°C. (HEA is 2-hydroxyethyl acrylate; DEA is *N,N*-diethylaminoethyl methacrylate; and TMS is 4-trimethylsilystyrenel; [●] pH; [○] insulin permeated [104]).

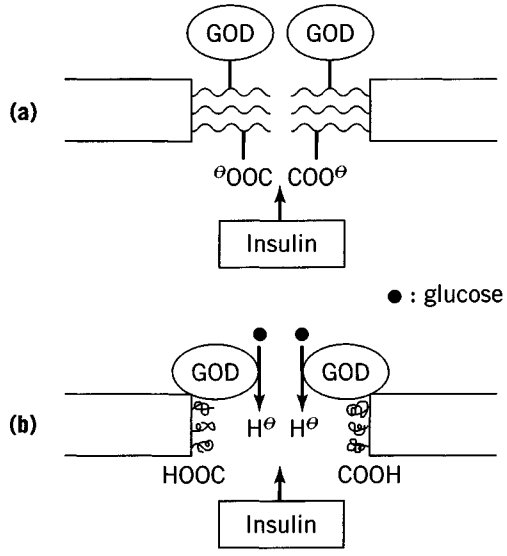

Figure 11. Principle of the controlled-release system of insulin. (**a**) In the absence of glucose, the chains of poly(acrylic acid) grafts are rodlike, lowering the porosity of the membrane and suppressing insulin permeation. (**b**) In the presence of glucose, gluconic acid (COOH) produced by glucose oxidase (GOD) protonates the poly(acrylic acid), making the graft chains coillike and opening the pores to enhance insulin permeation (108).

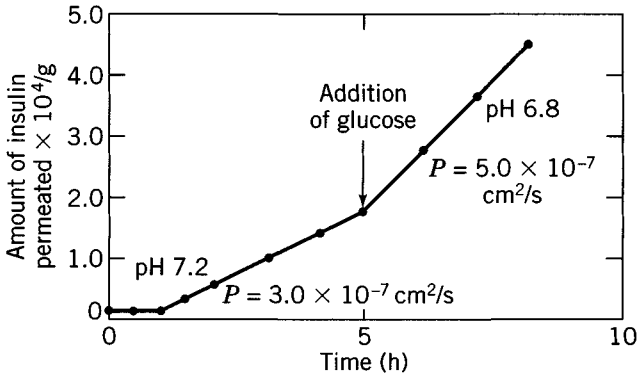

Figure 12. Permeation of insulin through poly(acrylic acid)-grafted membrane in 0.1 M tris-HCl–buffered solution. The concentration of added glucose is 0.2 M (108).

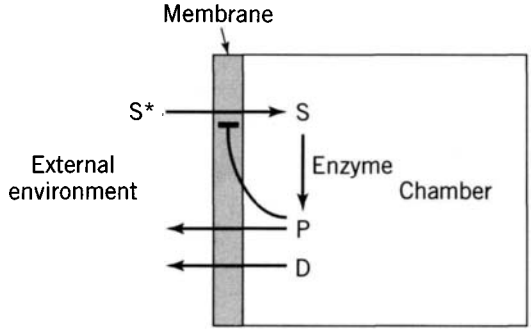
permeability to glucose concentrations) by modification of the graft chain: density, length, and size or density of pores.

Siegel and Firestone (109,110) proposed an implantable "mechanochemical" pump that functions by converting changes in blood glucose activity into a mechanical force, generated by the swelling polymer that pumps insulin out of the device.

More recently Siegel (111) proposed self-regulating oscillatory drug delivery based on a polymeric membrane whose permeability to the substrate of an enzyme-catalyzed reaction is inhibited by the product of that reaction. This negative feedback system can, under certain conditions, lead to oscillations in membrane permeability and in the levels of substrate and product in the device. Any one of these oscillating variables can then be used to drive a cyclic delivery process. Figure 13 illustrates a possible scheme for such drug delivery systems. The device consists of a chamber containing the drug to be delivered (D), plus an enzyme. The chamber is partially bounded by a membrane that controls solute influx and efflux. The substrate (S) for the enzyme is present externally at constant concentration and diffuses through the membrane into the chamber and is converted by the enzyme to a product (P). The product in turn diffuses out of the membrane. However, the product concentration in the chamber inhibitorily affects the permeabilities of the membrane to the substrate. That is, increasing product concentration causes decreasing flux of substrate into the device. Siegel propose several means to control drug delivery based on the presented scheme. Drug solubility could be affected by substrate or product concentration, which will be seen to oscillate. Alternatively, the permeability of the membrane to drug can oscillate with time along with the substrate permeability.



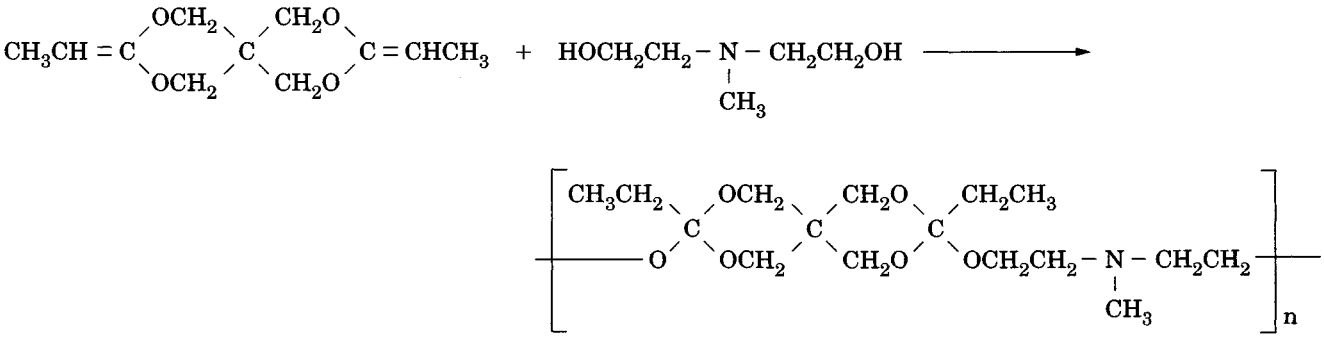


Figure 13. General scheme for proposed drug delivery oscillator (111).

Heller et al. (88,112,113) suggested a system in which insulin is immobilized in a pH-sensitive bioerodible polymer prepared from 3,9 bis (ethylidene 2,4,8,10-tetraoxaspirol(5,5)undecane and *N*-methyldiethanolamine (Scheme 3), which is surrounded by a hydrogel containing immobilized glucose oxidase. When glucose diffuses into the hydrogel and is oxidized to gluconic acid, the resultant lowered pH triggers enhanced polymer degradation and release of insulin from the polymer in proportion to the concentration of glucose. The response of the pH-sensitive polymers containing insulin to pH pulses was rapid. Insulin was rapidly released when the pH decreased from 7.4 to 5.0. Insulin release was shut off when the pH increased (Fig. 14). The amount of insulin released showed dependents on the pH change. However, when the in vitro studies were repeated in physiologic buffer, response of the device was only minimal. The authors found the synthesized amine containing polymer (Scheme 3) undergoes general acid catalysis where the catalyzing species is not hydronium ion but rather the specific buffer molecules used. Therefore, further development of this system will require the development of a bioerodible polymer that not only has adequate pH sensitivity but also undergoes specific ion catalysis.

Glucose-dependent insulin release was proposed by Langer and coworkers (114–116) based on the fact that insulin solubility is pH dependent. Insulin was incorporated into EVAc matrices in solid form. Thus, the release was governed by its dissolution and diffusion rates. Glucose oxidase was immobilized to sepharose beads that were incorporated along with insulin into EVAc matrices. When glucose entered the matrix, the produced gluconic acid caused a rise in insulin solubility and consequently enhanced release. To establish this mechanism in the physiological pH of 7.4, the insulin was modified by three additional lysine groups so that the resultant isoelectric point was 7.4. In vitro and in vivo studies demonstrated the response of the system to changes in glucose concentration. In the in vivo experiments, a catheter was inserted into the left jugular vein, and polymer matrices containing insulin and immobilized enzyme were implanted subcutaneously in the lower back of diabetic rats. Serum insulin concentrations were measured for different insulin matrix implants. A 2 M glucose solution was infused, 15 min into the experiments, through the catheter. Rats that received trilysine insulin/glucose oxidase matrices showed a 180% rise in serum insulin concentration that peaked at 45 min into the experiment. Control rats that received matrices containing no insulin or insulin but no glucose oxidase or diabetic rats without implants showed no change in serum insulin.

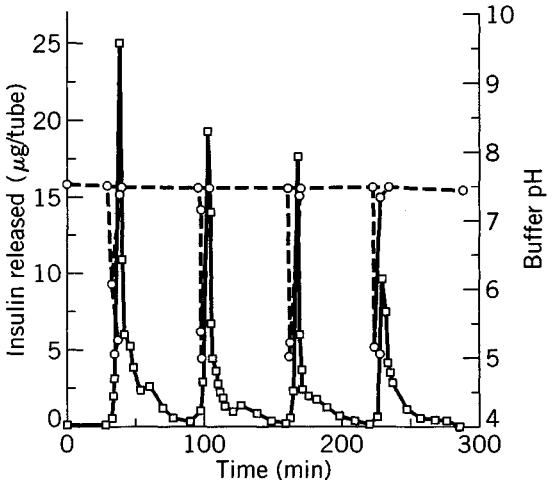

Figure 14. Release of insulin from a linear polymer prepared from 3,9-bis(ethylidene)-2,48,10-tetraoxaspiro [5,5] undecane and *N*-methyldiethanolamine as a function of external pH variations between pH 7.4 and 5.0 at 37°C: disks, 3 × 0.55 mm; insulin loading, 10 wt %; nonrecycling media was continuously perfused at a flow rate of 2 mL/min; total efflux was collected at 1–10 min intervals; (○) buffer pH; (□) insulin release (122).

Morphine-Triggered Naltrexone Delivery Systems

Heller and coworkers (88,112,117–122) have been developing a naltrexone drug delivery system that would be passive until drug release is initiated by the appearance of morphine external to the device. Naltrexone is a long-acting opiate antagonist that blocks opiate-induced euphoria, and thus the intended use of this device is in the treatment of heroin addiction. Activation is based on the reversible inactivation of enzymes achieved by the covalent attachment of hapten close to the active site of the enzyme–hapten conjugate with the hapten antibody. Because the antibodies are large molecules, access of the substrate to the enzyme's active site is sterically inhibited, thus effectively rendering the enzyme inactive. Triggering of drug release is initiated by the appearance of morphine (hapten) in the tissue and dissociation of the enzyme–heptan–antibody complex rendering the enzyme active. This approach is being developed by incorporating the naltrexone in an bioerodible polymer (Fig. 15). This polymer matrix is then covered by a lipid layer that prevents water entry into the polymer matrix and therefore prevents its degradation and the release of naltroxane. The system is placed in a dialysis bag. The bag contains lipaze (enzyme) that is covalently attached to morphine and reversibly inactivated by antimorphine complexation. Thus, when morphine is present in the tissues surrounding the device, morphine diffuses into the dialysis bag and displaces the lipase–morphine conjugate from the antibody, allowing the now-activated enzyme to degrade the protective lipid layer, which in turn permits the polymeric core degradation and release into the body of the narcotic antagonist, naltrexone.

A key component of this morphine-responsive device is the ability to reversibly and completely inactivate an enzyme and to be able to rapidly disassociate the complex with concentrations as low as 10^{-8} to 10^{-9} M. To achieve this sensitivity, lipase was conjugated with several morphine analogs and complexed with affinity chromatography–purified polyclonal antimorphine antibodies. In vivo studies (118) suggest that the concentration of morphine in a device implanted in a typical heroin-addicted patient is estimated to be about 10^{-7} to 10^{-8} M. Recent studies have shown that reaching such sensitivity is possible (88).

SYSTEMS UTILIZING ANTIBODY INTERACTIONS

Pitt et al. (123) proposed utilizing hapten–antibody interactions to suppress enzymatic degradation and permeabil-

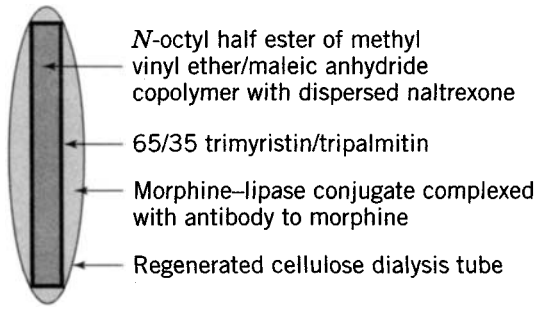

Figure 15. Schematic representation of triggered naltrexone delivery device (88).

ity of polymeric reservoirs or matrix drug delivery systems. The delivery device consists of naltrexone contained in a polymeric reservoir or dispersed in a polymeric matrix configuration. The device is coated by covalently grafting morphine to the surface. Exposure of the grafted surface to antibodies to morphine results in coating of the surface by the antibodies, a process that can be reversed by exposure to exogenous morphine. The presence of the antibodies on the surface or in the pores of the delivery device will block or impede the permeability of naltrexone in a reservoir configuration or enzyme-catalyzed surface degradation and concomitant release of the drug from a matrix device. A similar approach was proposed for responsive release of a contraceptive agent. The β-subunit of human chorionic gonadotropin (HCG) is grafted to the surface of the polymer, which is then exposed to antibodies to β-HCG. The appearance of HCG in the circulatory system (indicative of pregnancy) will cause release of a contraceptive drug. (HCG competes for the polymer-bound antibodies to HCG and initiates release of the contraceptive drug.)

Pitt et al. (123,124) also proposed a hypothetical reversible antibody system for controlled release of ethinyl estradiol (EE). EE stimulates biosynthesis of sex-hormone-binding globulin (SHBG). High serum levels of EE stimulate the production of SHBG, which increases the concentration of SHBG bound to the polymer surface and reduces the EE release rate. When the EE serum level falls, the SHBG level falls, as does binding of the SHBG to the polymer surface, producing an automatic increase in the EE release rate.

The polymers evaluated by Pitt and coworkers for covalent attachment of haptens were poly(ethylene vinyl acetate) copolymers for reservoir devices and hydroxylated polyester urethanes where the release is enzymatic degradation dependent. The polymers were prepared from ϵ-caprolactone and δ-valerolactone, lightly cross-linked with 1,6-hexanediisocyanate. The residual hydroxyl groups of the elastomer were shown to be suitable sites for hapten derivatization by treatment with chloroacetic anhydride. Biodegradability studies of the cross-linked polymers were conducted by implanting films subdermally in rabbits and measuring weight loss and dimensional changes with time. No weight loss was observed after 4 weeks of implantation. This results were in contrast with the immediate and rapid surface erosion of polymers prepared from ϵ-caprolactone and δ-valerolactone cross-linked with bis-2-2-(ϵ-caprolactone-4-yl)propane in which weight loss was detected within 2 weeks and increased thereafter in an approximately linear fashion (125).

SYSTEMS UTILIZING CHELATION

Self-regulated delivery of drugs that function by chelation was also suggested (126). These include certain antibiotics and drugs for the treatment of arthritis as well as chelators used for the treatment of metal poisoning. The concept is based on the ability of metals to accelerate the hydrolysis of carboxylate or phosphate esters and amides by several orders of magnitude. Attachment of the chelator to a polymer chain by a covalent ester or amide link serves to prevent its premature loss by excretion and reduces its toxicity. In the presence of the specific ion, a complexing with the bound chelating agent will take place, followed by metal-accelerated hydrolysis and subsequent elimination of the chelated metal. Measurement of the rates of hydrolysis of polyvinyl alcohol coupled with quinaldic acid chelator (PVA-QA) in the presence of CO(II), Zn(II), Cu(II), and Ni(II) confirmed that it is possible to retain the susceptibility of the esters to metal-promoted hydrolysis in a polymer environment.

CONCLUDING REMARKS

During the last three decades, polymeric-controlled drug delivery has become an important area of research and development. In this short time, a number of systems displaying constant or decreasing release rates have progressed from the laboratory to the clinic and clinical products. Although these polymeric-controlled delivery systems are advantageous compared to the conventional methods of drug administration, they are insensitive to the changing metabolic state. To more closely control the physiological requirements of the specific drugs, responsive mechanisms must be provided. The approaches discussed represent attempts conducted over the past two decades to achieve pulsatile release. It should be pointed out that these drug delivery systems are still in the developmental stage, and much research will have to be conducted for such systems to become practical clinical alternatives. Critical considerations are the biocompatibility and toxicology of these multicomponent polymer-based systems, the response times of these systems to stimuli, the ability to provide practical levels of the desired drug, and addressing necessary formulation issues in dosage or design (e.g., shelf life, sterilization, and reproducibility). A key issue in the practical utilization of the pulsatile, externally triggered systems (i.e., those that are magnetic, ultrasound, electrically regulated, and photoresponsive) will be the design of small portable trigger units that the patient can easily use. Ideally, such systems could be worn by the patient, as in a wristwatch-like system, and could be either preprogrammed to go on and off at specific times or turned on by the patient when needed. A critical issue in the development of responsive, self-regulated systems such as those containing enzymes or antibodies is the stability and/or potential leakage and possible immunogenicity of these bioactive agents. The successful development of responsive polymer delivery systems will be a significant challenge. Nevertheless, the considerable pharmacological benefit these systems could potentially provide—particularly given ongoing research in biotechnology, pharmacology, and medicine, which may provide new insights on the desirability and requirements for pulsatile release—should make this an important and fruitful area for future research.

INTRODUCTION

The evolution of the science and technology of liposomes as a drug carrier has passed through a number of distinct phases. Lamellar structures in lipid–water systems had previously been studied as models of biomembranes and interpreted in terms of dynamic properties, solute sequestration, and release characteristics (1). The latter prompted the development of the liposome drug carrier concept (2), and in 1970 animals were, for the first time, injected with liposomes containing a variety of potentially therapeutic agents (3–6). This has now culminated in several injectable liposome-based drug formulations licensed for clinical use (5).

It has often been asked why it has taken so much time and effort to bring a liposomal drug onto the market. On the surface, this appears to be a legitimate question. However, the issue here is not the development of a new drug (which itself can take many years) but rather, the development of a whole approach (i.e., the use of a delivery system) to improve the efficacy of a great number of existing drugs. The liposome was adopted as a promising delivery system because its organized structure could accommodate drugs, depending on their solubility characteristics, in both the aqueous and lipid phases. In retrospect, it is not surprising that following initial work in vivo with liposomes containing therapeutic agents, several potential problems became apparent. First, although it was encouraging to note that entrapped enzymes, proteins, and lipid-

soluble agents by and large acquired the pharmacokinetics of the carrier, water-soluble drugs of low molecular weight leaked extensively into the circulating blood. Secondly, there was rapid and quantitative interception of liposomes and their contents by the cells of the reticuloendothelial system (RES) through endocytosis, an event that appeared to limit the use of the system to, at best, the treatment of intralysosomal diseases or metal storage conditions. Equally disconcerting were the low levels of drug entrapment, vesicle size heterogeneity, and poor reproducibility and instability of formulations. Yet interest in liposomes, especially among academic workers, spread rapidly. We attribute this to the remarkable structural versatility of the system, which enables the design of countless liposome versions to satisfy particular needs in terms of both technology and optimal function in vivo.

In the ensuing years, great strides (5) were made toward understanding the way in which liposomes interact with the biological milieu at the molecular and cellular level. As a result, ways were found to improve liposomal stability in biological fluids so that drugs would not leak significantly, vesicle presence in the circulation would be extended, and targeting to alternative sites would be made possible. At the same time, important advances in liposome technology provided indications that many of the difficulties with entrapment and stability during storage could be overcome. Indeed, optimism generated by such progress led to the foundation of at least three liposome-based companies in the early 1980s, forcefully encouraging ideas and enthusiasm into the path of the realities of industrial research and development, and leading eventually to useful products. However, the contribution that liposome research has made (and will make) to targeted drug delivery is not just the happy prospect of additional liposome-based drugs. Of greater importance is the wealth of information that has become available on the ways that the body interacts with drug carriers and the harnessing of such information to circumvent anatomical and physiological barriers to optimal performance of the carrier. This cannot but prove instrumental in our efforts to ensure that old and new drugs act effectively.

MOLECULAR ASPECTS OF LIPOSOME FORMATION

Self Assembly of Lipids

Liposomes are microscopic aggregates of highly ordered lipid molecules which are normally dispersed in a hydrophilic solvent, typically water. This description applies to various types of microparticles, but the distinguishing feature of liposomes is that their lipid components are in a lamellar arrangement. When any molecule is dispersed in a solvent, its fate is dependent on the polarity of the molecule, which reflects the distribution of the electron clouds surrounding it. Polar molecules tend to dissolve in polar solvents such as water, whereas nonpolar ones are generally hydrophobic and only dissolve in nonpolar organic solvents. However, it is common to have both polar and nonpolar residues on the same molecule, in which case it is described as amphiphilic and its solvent dispersion characteristics are more complicated. Transient structuring of the hydrogen bonds between water molecules allows very small amounts of amphiphile to dissolve in the free form, but at more appreciable concentrations, the hydrophobic residues must be masked from the polar environment. This is achieved by reorientation of the amphiphile molecules into ordered structures in which the hydrophobic regions are brought into proximity with each other while the polar groups are juxtaposed between them and the water continuum. How this is accomplished depends on the way in which adjacent amphiphile molecules are able to align with each other, and this is in turn dependent on their spatial geometry (1).

When the cross-sectional areas of the polar and nonpolar regions are approximately equal, the molecule is effectively cylindrical in shape and adjacent cylinders then align in a parallel arrangement to form a two-dimensional monolayer, with the polar head groups forming one surface of this monolayer and the fatty acid acyl chains the other. (Fig. 1). Two of these monolayers are organized back-to-back to form a bilayered sheet or lamella in which the hydrophobic regions are sandwiched between the polar groups and segregated from the bulk water. Such an arrangement is typical of naturally occurring phospholipids such as the phosphatidylcholines (lecithins), which form the major component of cell membranes.

On the other hand, if there is a significant difference between the cross-sectional areas of the polar and nonpolar regions, the amphiphile molecules approximate to the shape of a wedge rather than a cylinder and are unable to align in a planar arrangement (7). These differences may be due to steric factors such as head group size, or variation in the number of fatty acyl chains, or to electrostatic effects arising from attractive or repulsive forces between adjacent head groups. In these situations, the aligning amphiphiles are forced to form curved structures, the most common of which include hexagonal phases (cylinders) and micelles (ranging from spheres to elongated rods). Depending on which end of the molecule is widest, each of these structures adopts a normal or reverse (inside out) configuration. Thus, if the polar head group is broader than the nonpolar region, curvature will be "positive," with the polar group forming the outer surface of the curve (e.g., micelles [L_1 phase] and normal hexagonal [H_I] phase). Conversely, if the nonpolar tail is broader than the head group, curvature will be "negative," with the fatty acyl chains forming the outer surface (reverse micelles [L_2] or reverse hexagonal [H_{II}] phase). Another important nonbilayer phase is the cubic phase, alternative forms of which can resemble close-packed micelles or bicontinuous structures. It is quite normal to accommodate non-bilayer-forming amphiphiles into lipid bilayers by including amphiphiles of opposite shape tendency to compensate. Thus mixtures of wedges, inverse wedges, and cylinders can be formulated which still favors a planar arrangement.

Lipid Polymorphism

This capability of amphiphiles to form a variety of structures and phases is known as polymorphism, and is of the utmost importance in normal biological processes such as cell trafficking, digestion, absorption, and fusion. An im-

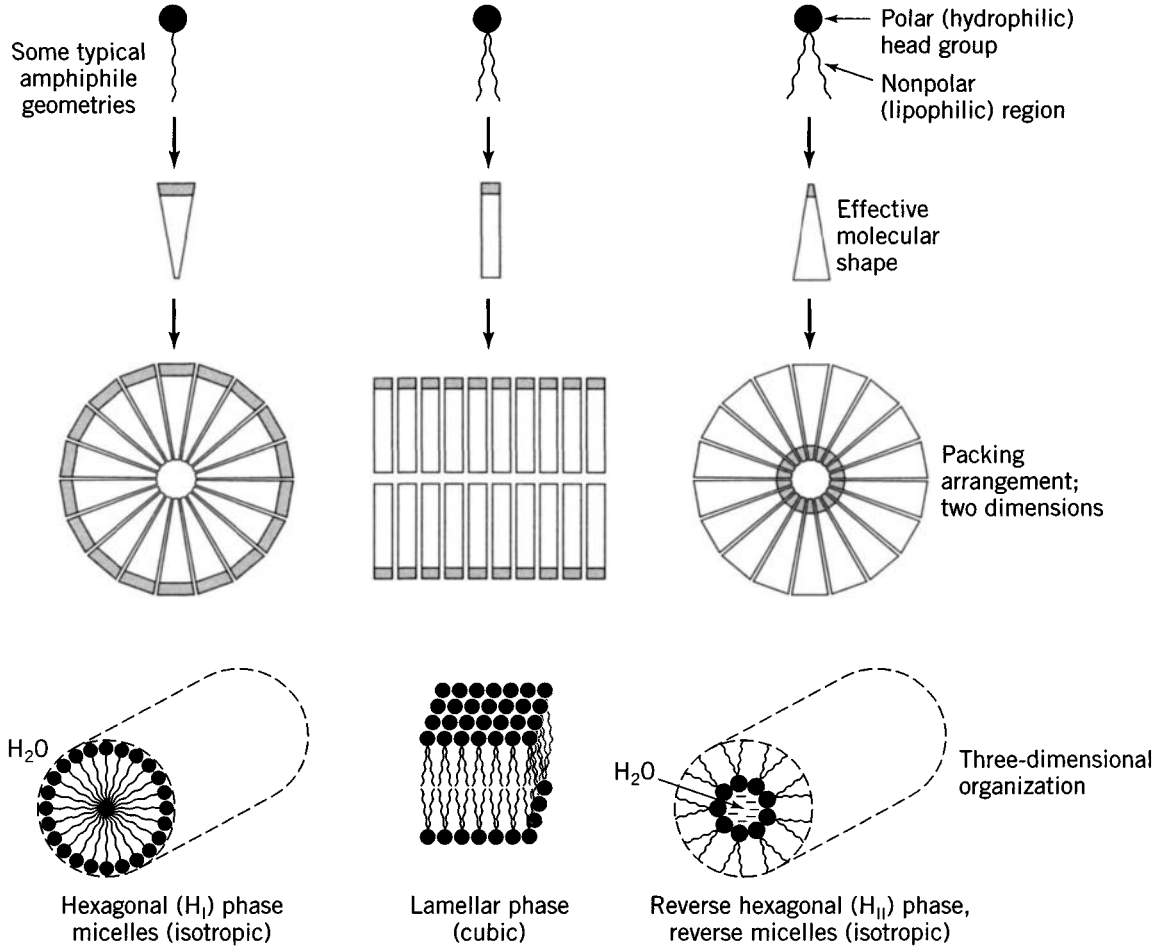

Figure 1. Dependence of phase behavior on the molecular geometries of the individual amphiphile molecules. *Source:* Adapted from Ref. 7, with permission.

portant aspect is that different phases can interconvert, either by inward or outward migration of particular amphiphiles, or by individual amphiphiles changing their shape. For example, increased temperature can increase the dynamic motion of the hydrocarbon chains, effectively broadening the nonpolar region. Changes in pH can affect ionization of polar head groups and so alter their diameter, as can changes in their level of hydration. Thus, bilayer to nonbilayer transitions can take place, resulting in loss of membrane barrier function or increased fusogenicity. These transitions can be exploited to design lipid-based carrier systems with predetermined release properties which are triggered by changes in their microenvironment or in the local ambient conditions.

Aqueous Dispersions of Lamellar Phase Lipid: Liposomes

Normal micelles, which show only short-range order, form spontaneously when the appropriate amphiphiles are added to water and dilute freely in excess water. For liquid crystalline phases, which also exhibit *long-range* order, the situation is different. Cubic and normal hexagonal phases do not disperse spontaneously, but procedures have been developed by which they can be converted into a colloidal form without loss of short-range order, producing "cubosomes" and "hexasomes," respectively. When lamellar phase lipid is diluted with excess aqueous phase, areas of lamellae are able to detach from the bulk lipid and round off to form sealed spherical liposomes (Fig. 2), thereby ensuring that hydrophobic chains at the bilayer "edges" are not exposed to the aqueous phase. In practice, detachment of lamellae from uncharged bilayer lipid is extremely slow unless the mixture is agitated, in which case all of the lipid eventually becomes dispersed in the form of liposomes. Such structures were first described in the early 1960s (1) and within a short time led to intense activity by a large number of research groups throughout the world.

LIPOSOMES AS DRUG DELIVERY SYSTEMS

The Drug Delivery Concept

The common structural features shared by liposome bilayers and biological membranes led to their widespread early use as membrane models for investigating the structural and functional relationships of natural cell membranes and their components. For example, integral membrane

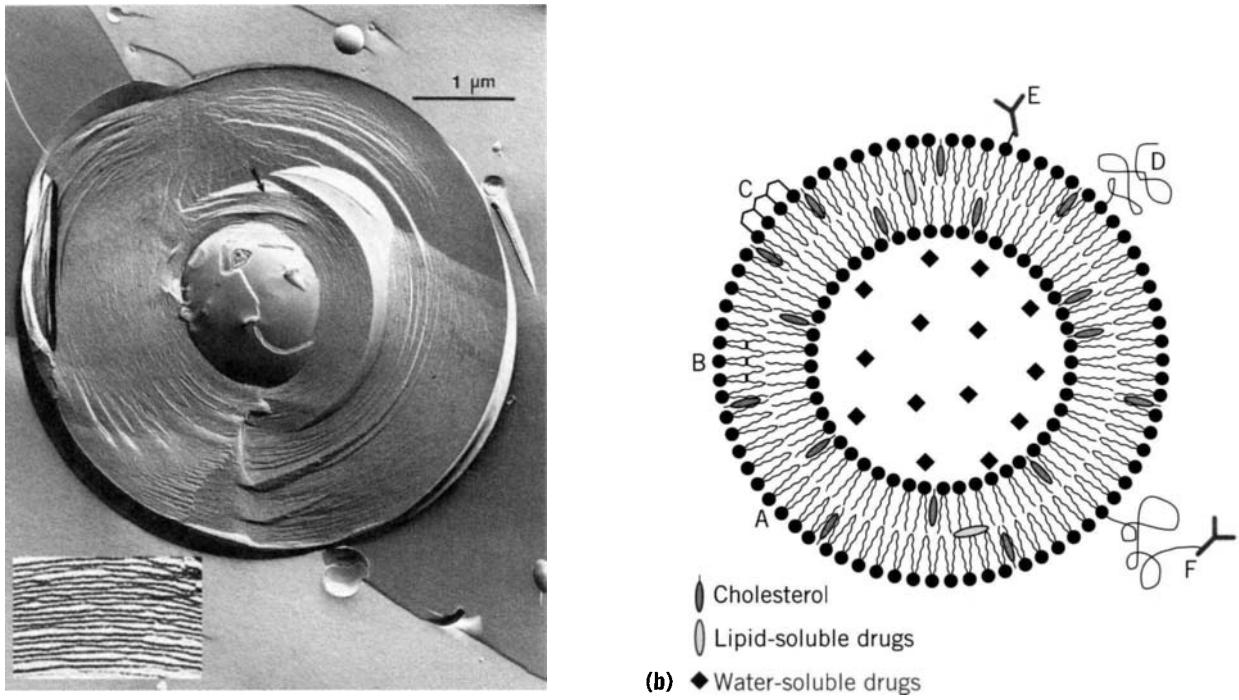

Figure 2. (**a**) Freeze-fracture electron micrograph of a multilamellar liposome prepared in water. The inset shows the area indicated by the arrow, magnified a further 6.7 times, to show the detail of the lamellae. *Source:* Micrograph courtesy of Mr. B. E. Brooker. (**b**) A diagrammatic representation of a unilamellar liposome showing the molecular structure of the lipid bilayer. The diagram also shows some of the modifications that can be made in order to tailor liposomes for specific applications, as discussed later in this article. Thus, A, B, and C are amphiphiles polymerized at the terminal and central regions of the fatty acyl chain, and at the polar head group, respectively. D denotes a poly(ethylene glycol) (PEG) modified phospholipid for preparing sterically stabilized liposomes, whereas E and F indicate ligand (antibody)-targeted amphiphiles with the targeting moiety attached to the head group and to the terminal region of a PEG chain, respectively.

proteins could be reconstituted into lipid bilayers to allow characterization in their natural state or to study their vectorial transport properties. However, their potential use as carriers for drugs, cosmetics, and many other types of active agent has excited a much greater volume of interest and led to their eventual commercialization (5). Such applications are dependent on the fact that liposomes are sealed structures, so that water-soluble substances dissolved in the internal aqueous phase are entrapped and isolated from the external environment. Many nonpolar compounds, as well as other amphiphiles, can also be included. For example, smaller alkanes partition into the central hydrocarbon region of the bilayer, whereas larger ones and amphiphilic molecules align themselves between and in parallel with the phospholipid chains. Insoluble substances such as colloidal metal particles have also been incorporated. Once inside, labile substances are protected from external conditions that might otherwise lead to their degradation. The liposomes themselves can be constructed with widely different physical structures, lipid composition, and surface properties, thus enabling a great deal of control over the fate of their contents. For these reasons, they have been explored very widely as delivery vehicles, particularly of drugs and other biologically active materials (5,8). The basic aspects of the drug delivery concept are briefly summarized as follows.

- *Protection*. Both the active material and the host are protected by virtue of the membrane barrier function and the possibility of coencapsulation of protective agents.
- *Sustained release*. Such release is dependent on the ability to vary the permeability characteristics of the membrane by control of bilayer composition and lamellarity.
- *Controlled release*. Drug release is enabled by exploiting lipid phase transitions in response to external triggers such as changes in temperature or pH.
- *Targeted delivery*. Such delivery can be achieved by relying on natural attributes such as liposome size and surface charge to effect passive delivery to body organs or by incorporating antibodies or other ligands to aid delivery to specific cell types. At the same time, drugs can be directed away from vulnerable or unintended targets.
- *Internalization*. This occurs by encouraging cellular uptake via endocytosis or fusion mechanisms; for example, to deliver genetic materials into cells.

Examples of these control mechanisms are discussed later in this text.

Because the basic unit of liposome structure, the lipid bilayer, is itself formed spontaneously, this makes incorporation of additional levels of sophistication much more straightforward, thereby enabling the tailoring of liposomes for many different situations and applications. Their tremendous versatility, ease of construction, and similarity to natural membranes has given them many advantages over other systems that have been developed for use in drug delivery.

Incorporation of Solutes

The amount of solute incorporated into the liposomes is defined both in terms of the encapsulation efficiency, which is the percentage of the starting material that becomes encapsulated, and the encapsulation capacity, which is the amount incorporated per unit amount of bilayer lipid. When material becomes encapsulated during liposome manufacture it is said to be passively entrapped, whereas if it is incorporated at a subsequent stage, it is described as actively loaded, or alternatively remotely loaded to indicate that incorporation has taken place at a site other than where manufacture took place. As already indicated, both hydrophilic and lipophilic materials may be incorporated, the former in the internal aqueous spaces and the latter within the lipid bilayer. The usual method of incorporating lipophilic substances is to dissolve them together with the amphiphile(s) in an organic solvent and then to remove the solvent so that the different bilayer components are left behind in a homogeneous, molecularly dispersed form. If an appropriate amount of the substance is added, then encapsulation efficiencies of 100% normally are achieved. However, the encapsulation *capacity* is likely to be much lower, and if added at greater than 5 mol % of the total lipid, it may well have adverse effects on the normal bilayer properties. On the other hand, water-soluble materials are able to partition between the internal and external water phases of the liposome, and encapsulation efficiencies generally are much lower than 100%, and dependent on the nature of the solute, the liposome components and the preparation method employed. These variables are discussed in the forthcoming sections.

Morphology and Nomenclature of Liposomes

Lamellar-forming lipids, like other amphiphiles, normally exist in a densely packed crystalline form when in the dry state. Below a certain characteristic temperature, the nonpolar hydrocarbon chains are fully extended and rigid, but above this temperature thermal excitation is increased and the chains enter a more disordered, liquid-like state. If water is added to the lipid above this *transition temperature* (T_c), the polar head groups at the surface of the exposed amphiphile become hydrated and start to reorganize into the lamellar form. The water diffuses through this surface bilayer causing the underlying lipid to undergo a similar rearrangement, and the process is repeated until all of the lipid is organized into a series of parallel lamellae, each separated from the next by a layer of water. Once this liquid crystalline phase is fully swollen and in equilibrium with excess water, mild agitation allows portions of close-packed, multilamellar lipid to break away (1). The resulting large spherical liposomes, each consisting of numerous concentric bilayers in close apposition, alternating with layers of water, are known as multilamellar vesicles (MLV). These are heterogeneous in size, varying from a few hundreds of nanometers in diameter to around ten μm, in the latter case representing some hundreds of lamellae thick.

The main advantage of MLV is that they are simple to make and have a relatively rugged construction. However, because the interior is largely occupied by the internal lamellae, the volume available for solute incorporation is very limited, and under normal condition only a small percentage of the available material is taken up. Their large size range is generally considered to be a drawback for many medical applications requiring parenteral administration, because it leads to rapid clearance from the bloodstream by the cells of the RES. On the other hand, this effect has been exploited for passive targeting of substances to the fixed macrophages of the liver and spleen; e.g., for delivery of antimicrobial agents to microorganisms which are otherwise refractive to treatment because of their localization within these cells (9), chelating agents to remove accumulated metal ions (10), and exogenous enzymes to treat inherited enzyme deficiency conditions such as Gaucher's disease (5).

If the lipid contains a component of negatively charged amphiphile, then at low ionic strengths of the hydration media, the interlamellar distance is increased substantially due to charge-charge repulsive forces between adjacent lamellae. When the lipid is allowed to hydrate undisturbed followed by gentle swirling, individual lamellae are able to detach to form large unilamellar vesicles (LUV) (11). In practice, it is generally more convenient to use one of a variety of methods developed specifically for manufacturing this type of liposome. LUV vary in size from around 100 nm up to tens of micrometers in diameter, and because the interior is not occupied by internal lamellae, there is ample space for incorporation of "drug." This also means that any cells taking up LUV are less subject to lipid overload. However, the absence of additional lamellae means that they are more fragile than MLV and have increased permeability to small solutes.

The lower limit of liposome size is fixed by the maximum curvature that the lipid bilayer is able to achieve, around 21 nm in the case of unsaturated, natural phospholipids such as egg and soy lecithin. These single-layered liposomes are known as small unilamellar vesicles (SUV), and the upper limit of size is designated as 100 nm. Because of their small size, clearance from the systemic circulation is significantly reduced, so they remain circulating for longer and thus have a better chance of exerting the desired therapeutic effect in tissues other than those of the RES. However, the small size also decrees that they have a much lower capacity for drug entrapment, typically less than 1% of the material available.

SUV, together with MLV and LUV are the three major morphological categories of liposomes, and these may be subdivided further. For example, several types of MLV are known. Oligolamellar (or paucilamellar) vesicles have in-

termediate lamellarity between LUV and MLV, and their formation is favoured under certain conditions. Multivesicular liposomes (MVL) can also be prepared, in which several separate compartments are present within a single MLV (12). On the other hand, stable plurilamellar vesicles (SPLV) have a similar appearance to classical MLV under the microscope, but have different physical and biological properties owing to the fact that the latter appear to be in a state of osmotic compression (13). LUV and SUV are often subdivided according to their size. It is also common to classify liposomes according to the various manufacturing procedures, as described in the following section.

PREPARATION OF LIPOSOMES IN THE LABORATORY

Early developments in liposome methodology were aimed particularly at achieving good solute entrapment (8). The move toward commercialization has placed increasing emphasis on such needs as stability, scale-up, reproducibility, and process validation (8). Numerous methods have been developed to meet widely different requirements. These can be broadly divided into two categories, those involving physical modification of existing bilayers and those involving generation of new bilayers by removal of a lipid solubilizing agent. The various methods available are discussed here from the perspective of the different structural types of liposome that they produce. Due to lack of space, this article can offer no more than a brief qualitative description of the more widely known procedures. For more in-depth details, the reader is referred to the various reviews, original papers, and manuals that are available (8,14,15).

Oligo- and Multilamellar Vesicles

Physical Methods. ***Simple "Hand-Shaken" MLV.*** MLV may be prepared from single-source natural or synthetic lipids, by suspending the latter (1), preferably in a finely divided form, in an aqueous solution maintained at a temperature greater than the T_c of the lipid. For unsaturated phospholipids such as egg and soy phosphatidylcholine (PC), which have T_c values below 0°C, this is conveniently done at room temperature. Stirring or swirling considerably speeds up lipid hydration and liposome formation, and the possibility of lipid oxidation can be minimized by working in an inert atmosphere of nitrogen or argon. As the liposomes form, a small proportion of the solution and its associated solute becomes entrapped within the interlamellar spaces. Uptake may continue over several hours, though in practice two hours of gentle stirring is normally adequate to achieve near-maximal incorporation. At the end of this period, the loaded liposomes can be separated from nonencapsulated solute using a process such as centrifugation or dialysis.

It is often desirable to prepare liposomes from mixtures of amphiphile, for example to improve their stability or to impart functional properties such as charge. In this case it is essential that the different lipids be thoroughly mixed at the molecular level. This has traditionally been achieved in the laboratory by codissolving them in a common solvent such as a 2:1 (v/v) mixture of chloroform and methanol and then removing the solvent. If done using a rotary evaporator, the lipid can be deposited as a thin film, which aids solvent removal and subsequent dispersion of the lipid. Hydration, separation, and harvesting can then be carried out as already described.

A major drawback of conventional MLV is their low efficiency for incorporation of water-soluble solutes, which is partly due to the fact that much of the volume is occupied by the internal lamellae. Thus, in neutral liposomes, only a few percent of the starting material may become entrapped. The encapsulation efficiency can be increased in several ways. Inclusion of a charged amphiphile, such as phosphatidyl glycerol or phosphatidic acid at a molar ratio of 10–20%, causes electrostatic repulsion between adjacent bilayers, leading to increased interlamellar separation, thus allowing more solute to be accommodated. However, if the solute itself is charged, entrapment may be increased or decreased depending on the relative sign, and may lead to solute association with the external surface. Freeze-drying of the lipid from solution in an organic solvent tends to form an expanded foam with an increased surface area, which increases the amount of aqueous phase that can be incorporated (16). A solvent with a high freezing point such as tertiary butanol should be used, so that it becomes deposited in the condenser rather than dissolving in the pump oil. Drying of the lipid onto an inert support, whether water-insoluble such as glass beads, or water-soluble such as sorbitol, also increases lipid surface area and may increase the level of solute entrapment.

It has been found that solute concentration in the interior of hand-shaken MLV is less that that in the external aqueous phase (13). This is because, as the phospholipid is hydrating, water passes across the semipermeable lamellae more rapidly than does the solute, and so the liposomes are correspondingly depleted. This can be alleviated by subjecting the suspension to cycles of freezing and thawing, which causes transient defects in the lamellae through which solute redistribution can take place.

Dehydration/Rehydration Vesicles (DRV). The DRV method was designed to achieve high levels of entrapment, particularly of sensitive biological molecules such as proteins and nucleic acids, using simple, mild conditions (17,18). The conventional MLV method described at the beginning of this section satisfies the latter two criteria, but since the multilayers form and seal off with the vast majority of the lipid never having come into contact with the solute, encapsulation efficiencies are extremely low. The intention of the DRV method is to maximize exposure of solute to the lipid before its final lamellar configuration has been fixed, so that the liposomes ultimately form around the solute. This is achieved by first preparing MLV in distilled water and then converting these to SUV using established procedures (to be described later), so that the phospholipid achieves the highest possible level of dispersion within an aqueous phase. Lipid packing constraints resulting from the high curvature of SUV mean that up to 70% of the total phospholipid will be present in the outer leaflet of the lamella. Thus when SUV are mixed with a solution of the material to be entrapped (again in distilled water), the majority of the amphiphile is directly exposed to the solute. At this stage the water is removed, most pref-

erably by freeze-drying, to produce an intimate mixture of the dry components. The original vesicles are now in a metastable state, with the phospholipid head groups in close proximity and oriented toward the active component (Fig. 3). A small, defined amount of water is added (17–19), initiating fusion of the vesicles surrounding the active, and formation of larger liposomes, which now encapsulate a large proportion of the solute. The amount of water added at this stage is critical to achieving the optimal level of entrapment, a point that has been missed by some workers. Following the hydration step, the liposomes are diluted with an isotonic buffer such as phosphate-buffered saline (17), and washed to remove nonencapsulated material using a process such as centrifugation or dialysis. At the rehydration stage, there is an increase in the overall solute concentration (e.g., 10-fold) because of the reduced amount of water added (e.g., 10 times less than the original amount). Subsequent dilution with isotonic buffer produces a large osmotic gradient between the internal and external phases, which leads to a redistribution of solute, both within the forming liposome and with the external aqueous phase. This may be aided by increased permeability to solute as a result of bilayer stretching caused by hyperosmotic inflation. At this stage, liposome formation is completed and equilibration achieved.

A wide variety of active materials have been incorporated into DRV, ranging from small ionic compounds and cyclodextrin–drug complexes to proteins and DNA (17–21). Encapsulation efficiencies are high, typically 40–50% under the standardized conditions described, and these levels can be increased substantially by using additional lipid. For solutes that are used in small amounts, much higher proportions can be encapsulated, e.g., values greater than 70% are normally achieved for DNA. Retention of encapsulated carboxyfluorescein dye during incubation with mouse plasma at 37°C was found to be substantially higher than for SUV or reverse phase evaporation vesicles (REV). DRV may be oligo- or multilamellar depending on the conditions used to prepare them. Thus, when ascorbic acid was encapsulated at an initial concentration of 23 mM, freeze-fracture microscopy showed a normal multilamellar appearance. However, when a concentration of 115 mM was used, followed by equilibration in isotonic buffer, many were oligolamellar, with regions of multilayer alternating with broad expanses of aqueous phase (20) (Fig. 4). Liposomes retained 40% of the original solute, which in view of the high concentration at the rehydration stage (more than 1 M), represents a particularly high loading of ascorbic acid. This is presumably due to the increased internal aqueous volume available for solute entrapment. Increas-

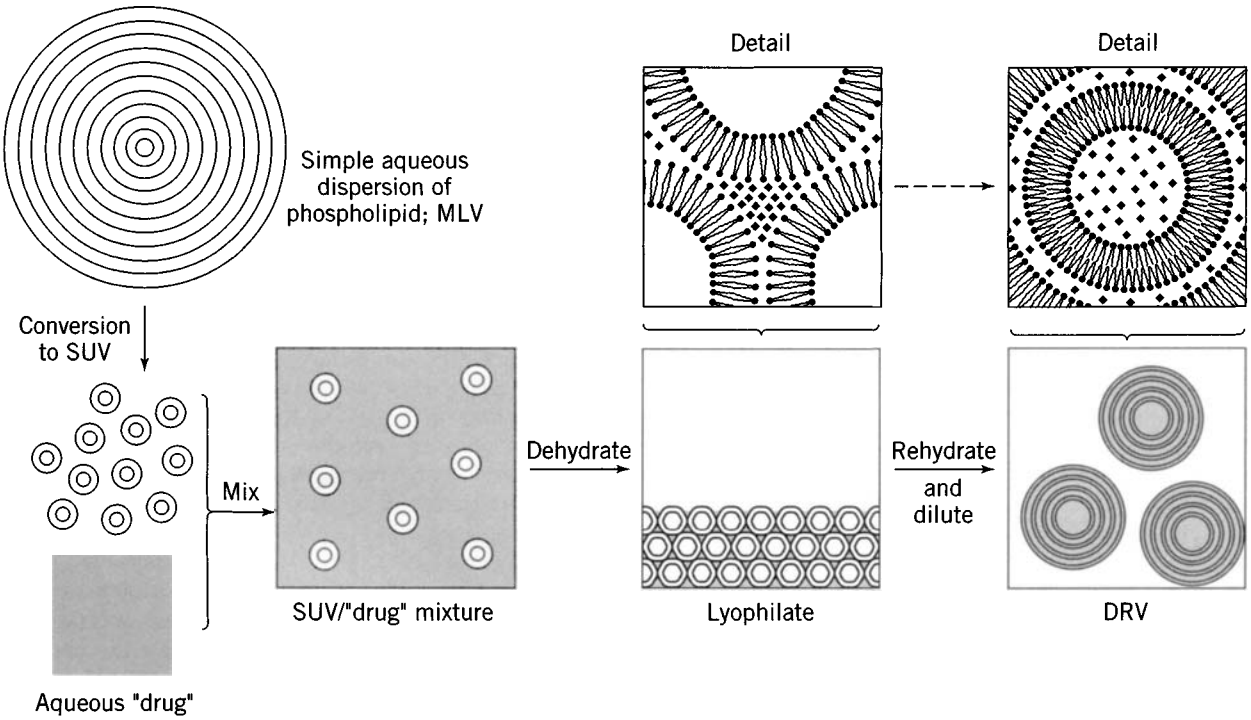

Figure 3. Manufacture of liposomes by the dehydration-rehydration method. A more detailed description of the individual steps is given in the text. The diagram is purely descriptive and no attempt has been made to draw any of the vesicles and other components to scale. During the freezing process, some deformation of the SUV is likely to occur as a result of osmotic shrinkage, caused by increasing external solute concentration arising from progressive formation of ice crystals. Further destabilization of the bilayer during dehydration facilitates rearrangement/fusion to form DRV during the subsequent rehydration step. The relative alignment of the individual drug and phospholipid molecules in the lyophilate (detail) is essentially similar to that in the final product.

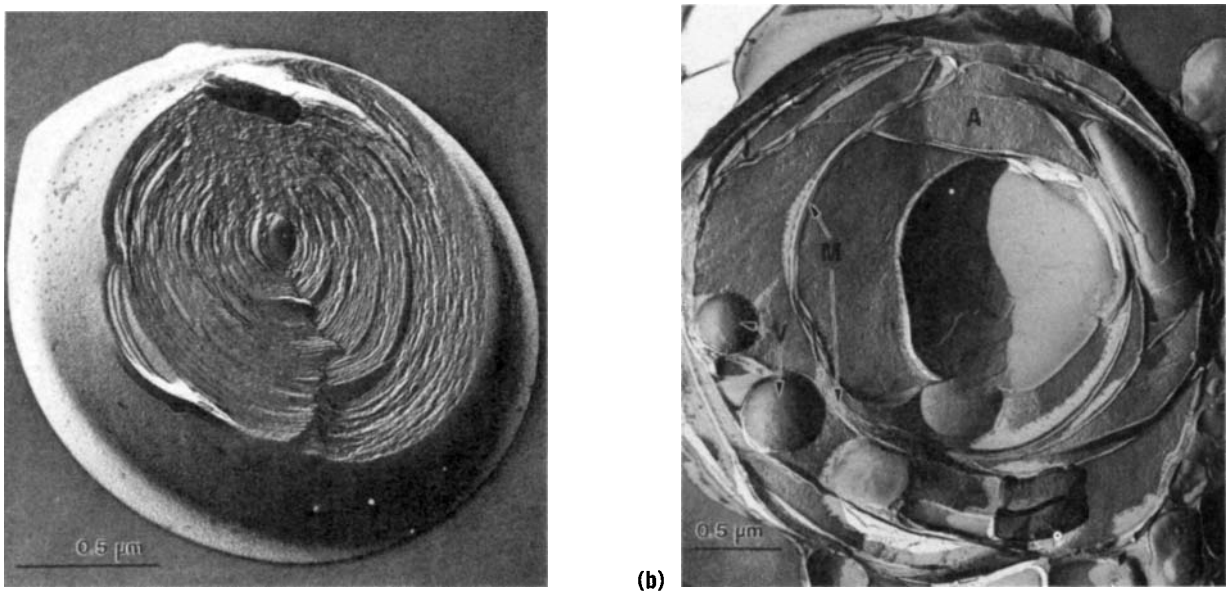

Figure 4. Freeze-fracture electron micrographs of liposomes containing ascorbic acid. DRV prepared in the presence of (**a**) 23 mM and (**b**) 115 mM ascorbic acid. ing levels of entrapment at increased solute concentration have also been seen with sodium and potassium chloride, and it may be possible to harness controlled osmotic inflation to achieve still higher loading of other coencapsulated solutes such as macromolecules. These liposomes contained a number of internal vesicular structures, perhaps related to a heterogeneous solute distribution during the dehydration stage, and the particularly high osmotic gradient during rehydration.

The DRV procedure remains one of the most efficient methods for direct loading of drugs into liposomes. Unlike other high entrapment methods, it avoids the use of potentially damaging conditions such as sonication and the use of organic solvents or detergents, which might cause damage to sensitive biological materials. Its simplicity means that scale-up is relatively straightforward.

Resizing of Liposomes. For some applications, the large size and size heterogeneity of multilamellar liposomes is a disadvantage. Both parameters can be reduced by various physical processes that, when used to their full capability, result in the formation of unilamellar liposomes, and so are described more fully in the relevant section. Many of these procedures can be used under less extreme conditions to reduce size, lamellarity, and polydispersity while maintaining the essential oligo- or multilamellar nature of the liposomes. Such processes inevitably lead to reduced entrapment due to redistribution of solute molecules between the liposomes and the external aqueous phase, though losses can be reduced if processing is carried out in the presence of the mother liquor. Bath sonication, microfluidisation and membrane extrusion have been widely used in this respect. Of these, microfluidization (22) and membrane extrusion (C.J. Kirby, unpublished results) have been used to reduce the size range of DRV while still retaining substantial proportions of the encapsulated solutes.

Removal of Lipid-Solubilizing Agents. In practice, the only commonly used agents during preparation of MLV are organic solvents (Fig. 5).

Simple Hydration of Solvent-Solubilized Lipids. Single- or mixed-source amphiphiles dissolved in organic solvents can be hydrated in solution without prior solvent removal. If the solvent is water-miscible such as ethanol or propylene glycol, it can be removed at the end of the procedure (e.g., by dialysis or filtration) or else allowed to remain. The *ethanol injection* procedure discussed later (23) was originally developed for producing SUV, but when the lipid is dissolved at increased concentration and added to the aqueous phase by simple admixture, the resulting liposomes are largely multilamellar. These might then be used to produce feedstock for further processing into other types of liposomes such as DRV. Alternatively, water-immiscible solvents such as ether, chloroform, or methylene chloride may be employed, removing them during processing by evaporation. As with hand-shaken MLV, solute encapsulation is generally very poor. More complex variations of this approach, designed to give improved encapsulation efficiencies, are be discussed later.

Stable Plurilamellar Vesicles. This is a variant of the REV method, which had been developed previously for preparing LUV. As with the DRV procedure, it aimed to increase the level of encapsulation of drugs in MLV by including them before the final lamellar configuration had been fixed. An aqueous phase containing the drug is emulsified together with excess of an ethereal solution of lipids, using bath sonication to form an oil-in-water type emulsion, while evaporating the solvent under a stream of ni-

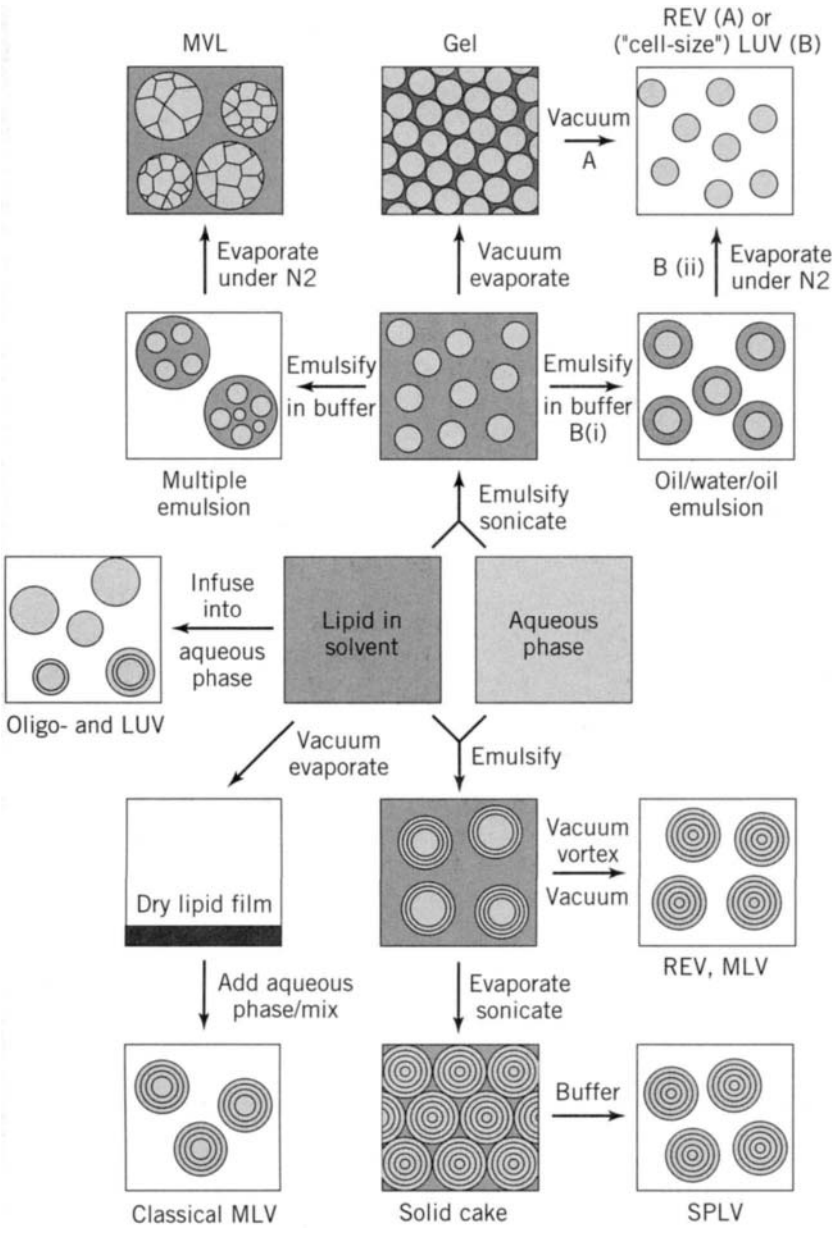

Figure 5. Solvent evaporation processes for liposome preparation. This scheme shows a considerably simplified summary of the different methodologies that are dependent on solvent evaporation, i.e., entailing the use of volatile solvents. No attempt is made at drawing to scale and various steps have been omitted. For convenience, steps A and B (i) and (ii) are shown as producing a similar product, whereas the "cell-sized" LUV derived from B (i) and (ii) may be considerably larger than the REV from step A. In addition, different processes require different solvents, but no such distinctions are made here.

trogen. The resulting cake is then suspended in buffer and washed. The important differences from the parent method are that the amount of lipid is proportionately higher and sonication is used throughout. Whereas the continuous water phase of REV is derived from the original disperse phase of the emulsion, in SPLV it is added later. It has been suggested that toward the end of the process, the aqueous cores collapse and are occupied by lamellae, with the solute load becoming distributed throughout the interlamellar spaces. Maximum levels of entrapment were reported to be 37%, but in terms of the amount of drug incorporated per unit amount of lipid, that level is about 10 times less than the typical value for DRV. In comparison with conventional MLV, SPLV were found to have improved physical stability and biological efficacy. This was claimed to be related to the fact that, unlike MLV, they are not solute-depleted and are in a state of osmotic equilibrium with the surrounding media. The main drawbacks of the SPLV procedure are the need to use volatile organic solvents and sonication, both of which are serious obstacles to potential scale-up and incorporation of sensitive materials such as proteins.

Multilamellar Reverse Phase Evaporation Vesicles (MLV-REV). This is another derivation of the REV method, again differing from the latter in that more lipid and less water are used in order to encourage the formation of multilamellar liposomes (24). The main difference from the SPLV method is that the solvent is removed under vacuum in two stages, and the aqueous continuous phase for the liposomes is derived from the disperse phase of the emulsion (as with the parent REV method). The initial phase of evaporation leads to formation of a gel consisting of aque-

ous cores surrounded by multilayers of lipid. The gel is removed from the vacuum, vortexed, and then reevacuated. During the final stage, phase inversion occurs, wherein a proportion of the cores release their aqueous content, and this is used to form a continuous phase for the newly formed liposomes. Up to 91% of the solute was encapsulated within these MLV-REV, but again from the point of view of mass loading, this is only 50% of that which is typically achieved with DRV. As with the SPLV approach, a major drawback is the need for volatile organic solvents and the implications for safety and scale-up potential.

Multivesicular Liposomes. This approach involves the use of multiple, water-in-oil-in-water type emulsions (12). These are created by first dispersing the aqueous drug solution into a chloroform–ether organic phase containing dissolved amphiphile, thus forming a fine water-in-oil type emulsion, and then dispersing this in turn into a second aqueous phase to form the multiple emulsion. Compositions and conditions are chosen such that each droplet of organic disperse phase contains multiple droplets of the initial aqueous solution. The solvents are removed under a stream of nitrogen, wherein the amphiphile is deposited around the internal aqueous, drug-containing microdroplets, which end up as separate aqueous compartments within a single liposome. Therefore, these are actually multicompartment vesicles in which adjacent, nonconcentric compartments are separated by a single, common unilamellar boundary. The method can achieve very high encapsulation efficiencies of up to 89%, but requires specialized lipids and rather complex conditions. Again, limitations are imposed by the need to use volatile organic solvents, but it is noteworthy that the method has been successfully scaled-up for commercial use.

Small Unilamellar Vesicles

Most of the commonly used methods for preparing SUV involve size-reduction of preexisting bilayers using procedures that have already been referred to in the previous section. The earliest, and probably still the most widely used approach at the bench scale, is by ultrasonic irradiation (25). SUV can be formed rapidly and conveniently by high-power probe sonication but are vulnerable to oxidative damage of unsaturated lipids. This can be reduced by maintaining them in an inert atmosphere during processing and by using a cooling bath to dissipate the large amounts of heat produced. Ideally the equipment should be fitted with an electronic controller to allow the sonic energy to be delivered in short pulses interspersed with longer cooling intervals (for example, 1 s sonication and 3–4 s cooling). Small particles of titanium shed from the probe are removed at the end of the process by centrifugation. A more gentle approach is to use bath sonication, where it is easier to control temperature and to maintain an inert atmosphere, and metal contamination is avoided. Unfortunately, processing time is substantially longer than when a probe sonicator is used.

Many of the literature reports describing preparation of SUV by probe sonication entail the lipid being processed at relatively low concentration. Interestingly, we have noted that when lipid concentration is increased progressively, up to a maximum of around 250 mg/mL, there is a substantial reduction in the time required to form clear SUV using probe sonication (C.J. Kirby, unpublished results, 1992). By this means, gram quantities can be processed in a relatively short time. This suggests that there is less chance of damage to the lipid when working at higher concentrations, a surprising observation because one would instinctively expect the opposite to be true. The reason may be that the high lipid concentration results in an increased likelihood of bilayer fragments being able to reanneal after high power sonication to form SUV. Whatever the reason, the phenomenon allows a certain level of increased throughput in what is otherwise a convenient but notoriously difficult procedure to scale up.

Alternative ways of preparing SUV by sizing make use of high pressure homogenization or extrusion. High-pressure homogenization devices include the French Pressure Cell (26), the Microfluidiser™ (27), and the Gaulin homogenizers (28). The latter two can have particularly high throughputs and employ high shear and cavitation effects to ultimately convert MLV to SUV. The Gaulin range can be used to forcibly hydrate a suspension of dry lipid and convert this to SUV in a single-step process. More impressively, differential scanning calorimetry (DSC) studies indicated that separate amphiphiles could be combined at the molecular level to form SUV having a homogeneous lipid distribution without the involvement of organic solvents (28). To our knowledge, no other mechanical procedure has been reported to be able to achieve this.

High-pressure extrusion involves forcing multilamellar liposomes at high pressure through membranes having "straight-through," defined size pores (29). The liposomes have to deform to pass through the small pores, as a result of which lamellar fragments break away and reseal to form small vesicles of similar diameter to that of the pore. Polycarbonate membranes are manufactured with pore diameters ranging from 8 μm down to 0.03 μm, and ceramic or stainless steel membranes are also available. Repeated cycling through small-diameter pores at temperatures greater than the T_c of the lipid produces a homogeneous population of SUV. A particular advantage of the method is that the disruptive effects of sonication are avoided.

Rapid injection of an ethanolic solution of lipid into an aqueous solution produces a dispersion of vesicles of 30 to 110 nm in diameter depending on the concentration of lipid used (23). Compared with sonicated SUV, these have a relatively heterogeneous size range and have added disadvantages in that a dilute suspension of liposomes is formed, the method is restricted to using ethanol-soluble lipids, and the ethanol may need to be removed afterwards. However, a modification of this method, used to incorporate a lipid-soluble antifungal drug into liposomes, has been successfully scaled up to a batch size of hundreds of kilograms and regulatory approval obtained (30).

Dispersions of the acidic phospholipids, phosphatidic acid, or phosphatidylglycerol, either alone or mixed with other phospholipids, can be induced to form unilamellar liposomes simply by transiently increasing the pH. SUV can be favored by adjusting the experimental conditions (31). However, despite its apparent simplicity, the method

is very restrictive in terms of the lipid compositions that can be used and the conditions of preparation. The vesicles tend to be of a heterogeneous size range, which is influenced by factors such as the nature of the other lipids present, ionic strength, cholesterol content, and the rate and extent of titration.

Large Unilamellar Vesicles

LUV occupy the size range following on from SUV, but unlike the smaller SUV are not subject to lipid packing constraints. Their single bilayer membrane makes them well suited as model membrane systems whereas the large internal aqueous volume:lipid mass ratio means that the efficiency of drug encapsulation for both small and large molecules can be maximized. As with the liposome types already discussed, methods for preparing LUV fall into two categories, the first involving generation of new bilayers by removal of a lipid solubilizing agent, whereas the second involves physical modification of preformed bilayers. For LUV preparation, the solubilizing agents include detergents and chaotropic ions as well as organic solvents.

Removal of Detergents and Chaotropic Agents. For procedures involving detergent removal (32), the lipid is initially dissolved by an aqueous solution of the detergent to form mixed lipid–detergent micelles, and the detergent is then removed by a diffusion-based process such as dialysis, diafiltration, or gel chromatography. The method produces almost exclusively uni- or oligolamellar vesicles ranging in diameter from SUV size up to several micrometers depending on the conditions used. Ionic detergents, such as cholate and deoxycholate or nonionic detergents such as Triton × 100 and octylglucoside, have been used. Detergent removal methods have been especially useful for functional reconstitution of membrane proteins. Many of these proteins retain their activity better in the presence of the nonionic species but these often have a relatively low critical micellar concentration making them difficult to remove by the aforementioned procedures. Use of hydrophobic adsorbent beads has proved particularly useful in these cases. The principle of detergent removal was applied in the first commercially available apparatus for laboratory production of liposomes, the Lipoprep™, which relied on a fast flow dialysis cell to remove detergent (33). The approach has the considerable advantage of allowing close control of the final size of the liposomes, which have a homogeneous size range. Disadvantages are that encapsulation efficiency is low compared with most other methods of LUV preparation, and detergent removal by ordinary dialysis techniques is a time-consuming process that can take several days to reduce residual detergent to a negligible level. Even traces of detergent can have pronounced effects on liposome permeability and can greatly increase the transmembrane movement of phospholipids. Detergents may also have deleterious effects on the material being encapsulated. Giant liposomes have been prepared by solubilizing phospholipids in a micellar form, in solutions of chaotropic ions such as trichloroacetate, and then removing the latter by dialysis or dilution (34). The liposomes, which are uni- or oligolamellar have diameters in the region of 10–20 μm.

Removal of Organic Solvents. Solvent vaporization liposomes tend to be of a larger size range than those prepared by detergent removal. Three distinct types of process have been described, each involving addition of a solution of lipid in organic solvent, to an aqueous solution of the material to be encapsulated (see Fig. 5).

Solvent Infusion. Solvent such as diethyl ether, petroleum ether, ethylmethyl ether, or dichlorofluoromethane-containing dissolved lipid(s), is infused slowly into the aqueous phase, which is maintained at a temperature above the boiling point of the solvent so that bubbles are formed (35). The lipid is deposited as a multilayer around the vapor–water interphase, and as the solvent evaporates off, uni- and oligolamellar liposomes remain in solution. High encapsulation efficiencies (up to 46%) were reported when high concentrations of lipid (15 mM final concentration) were used, and most of the vesicles were in the size range 0.1–0.4 μm. The major disadvantage is the need for exposure of the active to organic solvents, with the possibility of damage to labile materials such as proteins.

Reverse Phase Evaporation. Modifications of this method aimed at preparing MLV have already been described (36). Those approaches proceed via the formation of a water-in-oil (diethyl ether) emulsion containing excess lipid. In the parent case, the amount of amphiphile used is greatly reduced such that, when all of the solvent has been removed (by rotary evaporation), there is just enough lipid to form a monolayer around each of the microdroplets of aqueous phase. At this stage emulsion inversion takes place. This involves collapse of a proportion of these inverted micelles so that their aqueous contents now form the new continuous phase, while their lipid components go to form an outer leaflet around the remaining structures, thus converting them from inverted micelles to a vesicular form. In the absence of cholesterol, these uni- and oligolamellar vesicles have diameters in the range of 0.05–0.5 μm, while with 50 mol % cholesterol, mean diameters are about 0.5 μm. High encapsulation efficiencies of up 65% can be achieved using hydrophilic solutes. Particular drawbacks of the method include the need to work with volatile organic solvents and to expose potentially labile solutes (e.g., proteins) to these, and the need to use sonication to form a stable emulsion.

Double Emulsion Evaporation. A variant of this procedure has already been described for the preparation of MVL (12). In fact, the original method (37) was used to prepare cell-sized liposomes of average diameter about 9 μm. There are again formed by preparing a multiple, water-in-oil-in-water type emulsion followed by solvent evaporation as described for MVL. However, the conditions differ in terms of lipid concentration, solvent composition, and duration of shaking, such that each droplet of organic phase contains only a single microdroplet of drug solution, and the final product is an aqueous suspension of LUV. Although only a small proportion (about 30%) of the lipid present actually becomes incorporated into liposomes, the captured volume is very high at around 52 liters per mole of lipid used. The main disadvantages are that the procedure is quite complex and that specialized lipid mixtures are required. As in the two preceding methods, the pres-

ence of organic solvents may prohibit its use for encapsulation of labile materials.

Physical Modification of Existing Bilayers. Extrusion procedures have already been referred to in the context of downsizing of MLV and ultimately of forming SUV. If MLV are repeatedly extruded under moderate pressure (<500 lb/in^2) through membranes containing straight-through, defined size pores, smallish LUV are formed, with diameters between 60 and 100 nm, depending on the pore size. These have trapped volumes of up to 3 μL/μmol lipid. Where appropriate, drugs can be actively loaded after liposome formation via transmembrane gradients. Alternatively, solute incorporation can be facilitated by prior intermixing with the lipid using freeze-thaw cycles or by using the DRV procedure. This may be particularly useful for entrapping macromolecules.

Exposure of sonicated phospholipid mixtures to alternate cycles of freezing and thawing followed by a brief sonication results in fusion of the SUV and can be used to prepare large, mainly unilamellar liposomes with a relatively large trapping capacity (38). This method was based on a procedure that had previously been used for reconstitution of membrane proteins and is mild in that it avoids the use of detergents and organic solvents, and the period of sonication is quite brief. Disadvantages are that sugars, divalent cations, and high concentrations of ions and proteins all inhibit the membrane fusion process, and the liposomes are heterogeneous in size.

Another procedure employing fusion to produce LUV makes use of electrostatic effects. SUV composed of negatively charged phospholipids are mixed with calcium ions which cause the vesicle to aggregate and then fuse (39). This results in the formation of "cochleate cylinders," which are rolled-up portions of lipid bilayer. Chelation of calcium by adding ethylene diamine tetraacetic acid (EDTA) results in conversion of the cochleates to large uni- and oligolamellar vesicles having a relatively large encapsulation capacity. The main limitation is that the method is only applicable to negatively charged lipids.

SCALE-UP AND INDUSTRIAL MANUFACTURE OF LIPOSOMES

As in many areas of technology, the transition from an optimized research laboratory process to liposome manufacture at the production level is likely to be a daunting prospect, particularly because commercialization of liposome-based products is a relatively recent occurrence. In this context it is reassuring that many of the procedures discussed already have been successfully scaled up, and some are in commercial production. The preparation method chosen at the research phase is likely to have depended on the nature of the material being encapsulated and on the liposome type perceived to be optimal for its intended application. The latter is defined by parameters such as liposome size, lamellarity, permeability, fluidity, hydrophilicity, and other surface properties. Some methodologies are certainly more amenable to scale-up than others, and hopefully some thought will have been given at that stage toward potential future requirements. The subject has been reviewed by various authors (40–42) and so is dealt with only briefly here.

When discussing the implications of scale-up, it is convenient to break down liposome manufacture into the different components of the process which are directly affected. The most important of these are the achievement of a molecular dispersion of different lipid species, hydration of the amphiphiles (wherein actual formation of the liposomes takes place), solute entrapment, and sizing. The first two are interdependent and so are discussed together.

Lipid Intermixing and Hydration

Liposomes are often composed of lipid mixtures (e.g., to increase stability and to provide functionality) and organic solvents are commonly used to enable different lipids to be combined as a homogeneous molecular dispersion. Volatile solvents such as chloroform, methylene chloride, and diethylether have been widely used in this respect because they have high solubilizing capacity for lipids and are easy to remove by evaporation. On the other hand, for large-scale use they are difficult to work with and rigorous safety measures must be in place to guard against fire and toxicity hazards. Moreover, stringent regulations govern the levels of any trace residues that may be present in pharmaceutical products. Some of the methodologies that use them tend to be complex and so pose additional problems for large-scale production. However, volatile solvents have additional roles such as promoting lipid hydration via thin film formation and, in the case of the emulsion methods, in helping to configure liposome structure. In this context it is noteworthy that the MVL method (12), which involves the preparation of multiple, chloroform-containing emulsions, has been used for commercial scale production of Depotfoam™, which has been proposed as a sustained release depot system for localized injection via various routes. In this case however, the liposomal product has a unique configuration which has not been achieved using other methodologies, and as a general rule it is advisable to avoid large-scale use of procedures based on volatile solvents where a similar product can be prepared by other means.

Intermixing of lipid components is also achieved using water-miscible solvents with relatively low volatility such as ethanol, methanol, and propylene glycol, and these are easier to work with than volatile solvents. They also enable rapid hydration of the dissolved amphiphiles. An ethanol-based procedure has been applied for large-scale commercial production of a lipid-soluble antifungal drug econazole into liposomes, enabling 450-kg batch sizes to be produced (30). Ethanol is a pharmaceutically acceptable solvent and, in this case, was left in place at the end of the procedure, helping to maintain the sterility of the formulation. However in other situations its presence may be undesirable, necessitating its removal from the final product. Another disadvantage is the limited capacity of these solvents to dissolve certain liposome components such as certain other phospholipids and cholesterol, thus increasing the amount of solvent which has to be added. If necessary, removal can often be achieved using procedures such evaporation or di-

alysis and, in the case of larger liposomes, by centrifugation or ultrafiltration. Evaporation of smaller amounts of methanol or ethanol can be carried out rapidly and conveniently using a freeze-drier, but a cold trap of liquid nitrogen is needed to prevent contamination of the pump oil. A good compromise is to use a high boiling point solvent such as tertiary butanol which is readily deposited in the freeze-drier condenser.

Detergent removal methods have also been scaled up to produce larger volumes of liposomes, particularly containing bilayer-associated drugs. A range of lipophilic cytostatic drugs were incorporated in volumes of 0.1 to 5 liters for use in clinical trials (43), achieving incorporation efficiencies ranging from 85 to 100% compared with only 1.6% for a hydrophilic drug. Further scale-up to batches exceeding 10 liters was carried out using a topical steroid β-methasone (44), and a production unit capable of producing batches of between 100 and 200 L was reported. In this case, the methodology was chosen in order to produce monodisperse liposomes of defined size distribution. In all cases the initial association between lipid and drug was achieved by dissolution in organic solvents followed by evaporation to form a thin film, and where mixed lipid components are required, the same procedure would have to be followed. Apart from the likelihood of small amounts of residual detergent remaining in the product, a further drawback of this method for large-scale use is the relatively long time periods involved.

Entrapment

For successful commercial usage of liposomes it is vital that sufficient material can be incorporated for the intended application and that it is retained by the vesicles until their subsequent use. This is particularly important for pharmaceutical applications where a shelf life of two years is often required. Both aspects are readily achievable for bilayer-associated substances but are much more of a problem for water-soluble ones and largely dictated by the properties of the latter. If low encapsulation efficiencies are acceptable, then it may be sufficient to use one of the mechanical procedures already described. On the other hand, various approaches have been used to increase the level of encapsulation and retention of hydrophilic substances. Interaction with the bilayers can be increased by including lipids of opposite charge, by preparing lipophilic derivatives (45), or in certain cases, by incorporating lipophilic chelating agents for the solute into the bilayer (46). Otherwise, manufacturing procedures that enable high encapsulation efficiencies can be used. If it is deemed appropriate to use volatile organic solvents, REV, or one of its derivative methods might be considered feasible. An alternative possibility is to use the DRV method, if necessary using extrusion or microfluidization to reduce the size of the resulting liposomes. This method has added advantages in that sensitive biological molecules can be incorporated with high efficiency, and also the lyophilized intermediate can, in theory, be stored indefinitely before being reconstituted as and when needed. This second point could help to alleviate the problems of leakage of smaller molecules during long-term storage.

Another approach to achieving high encapsulation efficiencies while eliminating the consequences of leakage during storage is to use the active loading principle (47,48) by means of which a drug can be remotely loaded into liposomes at the time it is needed, for example at the patients' bedside. This approach is dependent on the fact that small charged molecules have a very low ability to diffuse across lipid membranes, whereas if their charge is neutralized, many become lipophilic and able to cross much more readily. By passively incorporating ionizable substances into liposomes, and then adjusting the external pH, transmembrane pH or concentration gradients can be established and used to load certain drugs into the liposome. For example, a weakly basic drug such as doxorubicin added to liposomes with a relatively high external pH becomes deprotonated and thence lipophilic, enabling it to partition across the membrane. Once inside, it becomes protonated due to the low internal pH, preventing its exit and enabling more of the uncharged drug to enter. Other approaches can result in precipitation of the loaded drug by interaction with encapsulated cations, thus promoting further drug entry.

Sizing

The suitability of high-pressure homogenization systems for scale-up of the sizing stage has already been discussed. In particular, the claimed ability of the Gaulin Micron range to be able to convert highly concentrated particulate suspensions of lipids directly to SUV by forced hydration, to achieve homogeneous lipid intermixing, and to be operated continuously (28) suggests that it is well fitted for effective scale-up of the earlier stages. The possibility of enabling incorporation of proteins and peptides with good retention of activity is also worthy of further investigation. One reported drawback is that the cavitational effects can result in mechanical erosion and contamination of the product with metal particles, but these could presumably be removed using appropriate filters. Also, because SUV are formed, the entrapped volumes are rather low. The Microfluidiser has also been widely used for preparing large volumes of small vesicles and has proved useful for producing empty SUV for scaling up of the DRV procedure.

Sizing by extrusion through polycarbonate membranes can be conveniently carried out in the laboratory using small, compact apparatus, resulting in liposomes with well-defined size characteristics (49). In earlier studies, the technique was limited due to clogging of the membrane resulting in reduced throughput, but it has now been successfully scaled up to enable processing of multiliter volumes. Initial improvements were achieved in batch mode by increasing the surface area of the membranes and using stirring to prevent clogging (43). More recently a continuous flow device was introduced which employed higher pressures and achieved flow rates of up to 500 mL/min. High lipid concentrations of up to 400 mg/mL could be processed, and no signs of membrane clogging were seen after using a range of lipid compositions (50).

Other Issues

The major drive to develop liposomes has come from the pharmaceutical industry, and so particular emphasis has

been placed on factors such as sterility, apyrogenicity, stability, and reproducibility. Sterility is normally achieved either by ultrafiltration of the final product through 0.2 μm filters in the case of smaller oligo- and unilamellar liposomes, or by carrying out the whole manufacturing process in a sterile environment. Both approaches have been successful for a range of liposome-based products and so should pose no problems with forthcoming ones. Other approaches have been discussed (51). The adoption of good quality control procedures and the use of high-quality raw materials from approved suppliers should help to minimize problems of poor stability and pyrogenicity. If a solvent solubilization step is present, dissolved lipids can be ultrafiltered to remove pyrogenic substances. Antioxidants can be included to minimize oxidative degradation, particularly where unsaturated lipids are used. In some cases it might be feasible to freeze-dry the product in order to improve stability during storage, but this is generally most appropriate in the case of bilayer-soluble drugs.

CHARACTERIZATION

There are numerous methods for the characterization of liposomes, depending on the aspect of the system under investigation (52). Such aspects include those that are related to the overall structure of liposomes, for instance vesicle size, lamellarity (i.e., number of bilayers), surface potential, and morphology. Others relate to the stability of liposomes in terms of either changes in vesicle size and other general characteristics on storage, or ability of vesicles to retain entrapped drugs in a given medium (e.g., buffer, biological fluids). Finally, it is often necessary to determine the extent, if any, of component modification during the production of liposomes or storage, especially in the case of unsaturated phospholipids that can be easily peroxidised or degraded.

Overall Structure of Liposomes

Vesicle size can be determined either by hydrodynamic methods (53) (e.g., gel exclusion chromatography using Sepharose 4B or 2B, Sephacryl S500, and S1000) or by photon correlation spectroscopy (54–56) using instrumentation that is appropriate for the size range of the vesicles. Values are expressed as z average mean in nanometers or micrometers. A polydispersity index provides information on the range of vesicle size distribution. Size measurements can also be made in a z sizer which, in addition, also determines the z-potential (zP) of vesicles. zP values range from negative to positive and reflect the surface charge of the vesicles. The latter is particularly useful in formulations where the drug incorporated in liposomes is charged and thus able to modify the overall surface charge. The lamellarity of liposomes is determined by small-angle X-ray scattering (57,58) which can reveal whether bilayers are arranged nonconcentrically (multivesicular structures).

Morphological observations of liposomes can be carried out by light microscopy (53) and electron microscopy (EM) (58) under a variety of conditions. For instance, bright field and phase contrast microscopy are used extensively, especially in conjunction with fluorescent dyes. However, light microscopy is only suitable for large (e.g., LUV and MLV) and giant liposomes (53). With transmission electron microscopy, liposome samples in suspension are firstly negatively stained (e.g., with OsO_4, UO^{2+}) and then directly examined (58). The technique can reveal unilamellar, oligolamellar, or multilamellar structures. Alternatively, a three-dimensional image of liposomes is obtained by freeze-fracture electron microscopy (FFEM) where samples of liposome suspensions are quickly frozen, fractured at very low temperature (e.g., -150°C) and immediately replicated by appropriate means (59). Replicas are then examined by EM. In some cases, to facilitate identification of liposomes (e.g., in tissues where local structures can be mistaken for liposomes) these are labelled with gold particles which can be either entrapped within the vesicles or attached onto the vesicle surface using immunogold labeling (58). This, however, requires the presence of a protein on the liposomal surface. In cryoelectron microscopy a thin aqueous film on a specimen grid is formed by dipping the grid in and withdrawing it from the liposomal suspension (58). The film is rapidly vitrified, cooled to its melting point, and then examined by EM. As with FFEM, confirmation of vesicle images with entrapped gold particles or immunogold labeling is often necessary when biological samples are examined.

Other methods for the characterization of liposomes include spectroscopy, which can be used to measure the turbidity of a liposomal suspension (52). Sets of calibration curves are then employed to devise semiquantitative estimates of vesicle size or concentration. On the other hand, the structure and dynamics of the acyl chains of liposomal phospholipids can be determined by infrared or Raman spectroscopy, and the hydration of phospholipid polar heads (and their interaction with counterions) by Fourier transformation methods (60). Liposomal parameters such a liquid-crystalline transition temperature (T_c), or diffusion constants within bilayers can be measured by NMR and electron paramagnetic resonance (EPR) (60). In addition, electron resonance techniques can provide information on vesicle size and number of lamellae (60), and EPR spin labeling coupled with the addition of paramagnetic ions is a particularly useful method for the estimation of vesicle internal volumes. Finally, thermodynamic methods are useful in the study of T_c energetics (DSC), or liposome dissolution heat (isothermal calorimetry) (60).

Liposomal Stability

Changes in the structural characteristics of liposomes on storage can be monitored by one or more of the techniques already mentioned. These techniques, however, cannot detect subtle structural changes (e.g., vesicle porosity) that lead to the leakage of drugs entrapped in the aqueous phase of liposomes. Drug retention by liposomes on storage or in the presence of a biological fluid can be determined by a variety of techniques (60,61).

It is always appropriate that in designing the lipid composition of liposomes for the entrapment of a drug within their aqueous phase, the stability of the bilayers within a given milieu is monitored. A typical example is the effect of blood components on the ability of a liposomal formu-

Next Page

lation to retain entrapped solutes (61). To that end, one of the easiest and most effective methods is the use of calcein or carboxyfluorescein as marker solutes. Calcein and carboxyfluorescen self-quench at high concentrations (e.g., above 0.05 M) but acquire a green fluorescent colour on excessive dilution. Suspended liposomes containing quenched dye appear as brown or orange. However, destabilization of the vesicles leads to the leakage of some of the dye and its excessive dilution into the medium. Measurement of the resulting fluorescence by spectrofluorimetry reveals the extent of leakage. For liposomal formulations containing drugs, drug leakage on storage or in the biological milieu can be monitored by techniques that separate entrapped from leaked drug. This can be achieved by ultracentrifugation, dialysis, molecular size chromatography, or ion exchange chromatography.

FATE OF LIPOSOMES IN VIVO AND ITS CONTROL

Following work in the early 1970s (2–6,62–67) with drug-containing MLV, several basic aspects of their behavior in vivo became apparent. For instance, rate of clearance of vesicles from the blood of intravenously injected rats was rapid, dose-dependent, and biphasic. It was subsequently observed that neutral MLV (68) and SUV (69) exhibit a slower rate of clearance than negatively and (more recently) positively charged MLV, and that SUV had a longer residence time than MLV (69). Another observation was that small, water-soluble drugs (e.g., 5-fluorouracil and penicillin G) leaked considerably from circulating MLV (6). In view of what we know today, this is hardly surprising as the MLV used contained little cholesterol. On the other hand, larger entrapped solutes such as albumin and amyloglycosidase did not appear to leak (3,4,68). Finally and perhaps more importantly, liposomes with entrapped materials were shown to end up in the fixed macrophages of the RES, mainly in the liver and spleen, through the lysosomotropic pathway (4,66,67). Within lysosomes, vesicles were seen (67) to lose their organized structure (presumably through the action of phospholipases) and to release their contents. Depending on their molecular size and ability to withstand the hostile milieu of the organelles, drugs could then act either locally (e.g., hydrolysis of stored sucrose by liposomal fructofuranosidase) (62) or, after diffusion through the lysosomal membrane, in other cell compartments (e.g., inhibition of DNA-directed RNA synthesis by liposomal actinomycin D in partially hepatectomized rats) (66). Such understanding of liposomal fate and behaviour led to a number of proposed applications, including the treatment of certain inherited metabolic disorders (4,62,70), intracellular infections (6,9), cancer (6,71), gene therapy (4), and because of antigen-presenting cell involvement in vesicle uptake in vivo, immunopotentiation and vaccine delivery (72).

The demonstration in the early 1970s that liposomes coated with cell-specific ligands (e.g., antibodies and asialoglycoproteins), can interact with, and be internalized by, alternative (other than macrophages) cells expressing appropriate receptors, both in vitro (73) and in vivo (73,74) culminated in the concept (73) of vesicle targeting and to novel avenues of liposome research and potential use. Perhaps more encouraging were indications that even ligand-free liposomes could enhance the delivery of drugs to solid tumors in vivo (74). It was soon realized (63), however, that success in this area would require not only quantitative retention of entrapped drugs by the vesicles (also needed for "passive" targeting to fixed macrophages), but also a sufficient time period for circulating (targeted, ligand-bearing) vesicles to encounter and associate with the target. Because vesicle behavior in vivo, resulting from a given structural feature of the system, must be closely related to the particular environment in which that system exists, knowledge of the influence of the biological milieu on both drug leakage and vesicle clearance rates appeared essential.

Retention of Drugs by Liposomes

Initial indications as to why liposomes might become permeable to entrapped drugs, or destabilized in the presence of blood, thereby allowing drugs to leak out, came from the finding (75,76) that plasma high density lipoproteins (HDL) remove phospholipid molecules from the vesicle bilayer. It appeared logical to assume (77) that prevention of such HDL action, for instance by increasing the packing of the lipid components in the bilayer, would enable the vesicles to remain intact. Experiments to test this assumption were thus carried out, initially using MLV (77) and later with SUV (78). In both cases, additional cholesterol (e.g., a phospholipid: cholesterol molar ratio of 1:1) increased the bilayer stability in the presence of blood components (77–80) with very little loss of phospholipid or of an entrapped water-soluble marker, either in vitro (78) or after intravenous (78,79), intraperitoneal (78), or subcutaneous (81) injection. A role for HDL in the destabilization of liposomes was further substantiated by (*1*) the demonstration (82) that cholesterol-free SUV exposed to blood plasma from lipoprotein-deficient mice or a patient with congenital lecithin-cholesterol acyltransferase deficiency (characterized by low HDL levels) were more stable than when incubated with plasma from normal mice or humans; (*2*) the identification (82) of HDL as the only lipoprotein, among a number of lipoprotein species added to lipoprotein-deficient plasma, that could restore vesicle-destabilizing activity.

It was thus of interest to see whether reduction of vesicle leakage to solutes by cholesterol-induced bilayer packing could also be achieved with bilayers made rigid by substituting egg PC with high-melting phospholipids. As anticipated (77,80), SUV or MLV made of hydrogenated lecithin, distearyl phosphatidylcholine (DSPC) or sphingomyelin (SM) were less permeable to entrapped solutes in the presence of blood plasma, with bilayer stability becoming even greater when additional cholesterol was present (81–86). Thus, liposomes composed of equimolar DSPC and cholesterol were able to completely retain their marker solute (carboxyfluorescein) content, even after 48 hours of exposure to plasma at 37°C (84).

Vesicle Clearance Rates: The Role of Lipid Composition

In the course of work on liposomal stability it was observed (83) that solute retention by cholesterol-rich SUV, al-

lation to retain entrapped solutes (61). To that end, one of the easiest and most effective methods is the use of calcein or carboxyfluorescein as marker solutes. Calcein and carboxyfluorescen self-quench at high concentrations (e.g., above 0.05 M) but acquire a green fluorescent colour on excessive dilution. Suspended liposomes containing quenched dye appear as brown or orange. However, destabilization of the vesicles leads to the leakage of some of the dye and its excessive dilution into the medium. Measurement of the resulting fluorescence by spectrofluorimetry reveals the extent of leakage. For liposomal formulations containing drugs, drug leakage on storage or in the biological milieu can be monitored by techniques that separate entrapped from leaked drug. This can be achieved by ultracentrifugation, dialysis, molecular size chromatography, or ion exchange chromatography.

FATE OF LIPOSOMES IN VIVO AND ITS CONTROL

Following work in the early 1970s (2–6,62–67) with drug-containing MLV, several basic aspects of their behavior in vivo became apparent. For instance, rate of clearance of vesicles from the blood of intravenously injected rats was rapid, dose-dependent, and biphasic. It was subsequently observed that neutral MLV (68) and SUV (69) exhibit a slower rate of clearance than negatively and (more recently) positively charged MLV, and that SUV had a longer residence time than MLV (69). Another observation was that small, water-soluble drugs (e.g., 5-fluorouracil and penicillin G) leaked considerably from circulating MLV (6). In view of what we know today, this is hardly surprising as the MLV used contained little cholesterol. On the other hand, larger entrapped solutes such as albumin and amyloglycosidase did not appear to leak (3,4,68). Finally and perhaps more importantly, liposomes with entrapped materials were shown to end up in the fixed macrophages of the RES, mainly in the liver and spleen, through the lysosomotropic pathway (4,66,67). Within lysosomes, vesicles were seen (67) to lose their organized structure (presumably through the action of phospholipases) and to release their contents. Depending on their molecular size and ability to withstand the hostile milieu of the organelles, drugs could then act either locally (e.g., hydrolysis of stored sucrose by liposomal fructofuranosidase) (62) or, after diffusion through the lysosomal membrane, in other cell compartments (e.g., inhibition of DNA-directed RNA synthesis by liposomal actinomycin D in partially hepatectomized rats) (66). Such understanding of liposomal fate and behaviour led to a number of proposed applications, including the treatment of certain inherited metabolic disorders (4,62,70), intracellular infections (6,9), cancer (6,71), gene therapy (4), and because of antigen-presenting cell involvement in vesicle uptake in vivo, immunopotentiation and vaccine delivery (72).

The demonstration in the early 1970s that liposomes coated with cell-specific ligands (e.g., antibodies and asialoglycoproteins), can interact with, and be internalized by, alternative (other than macrophages) cells expressing appropriate receptors, both in vitro (73) and in vivo (73,74) culminated in the concept (73) of vesicle targeting and to novel avenues of liposome research and potential use. Perhaps more encouraging were indications that even ligand-free liposomes could enhance the delivery of drugs to solid tumors in vivo (74). It was soon realized (63), however, that success in this area would require not only quantitative retention of entrapped drugs by the vesicles (also needed for "passive" targeting to fixed macrophages), but also a sufficient time period for circulating (targeted, ligand-bearing) vesicles to encounter and associate with the target. Because vesicle behavior in vivo, resulting from a given structural feature of the system, must be closely related to the particular environment in which that system exists, knowledge of the influence of the biological milieu on both drug leakage and vesicle clearance rates appeared essential.

Retention of Drugs by Liposomes

Initial indications as to why liposomes might become permeable to entrapped drugs, or destabilized in the presence of blood, thereby allowing drugs to leak out, came from the finding (75,76) that plasma high density lipoproteins (HDL) remove phospholipid molecules from the vesicle bilayer. It appeared logical to assume (77) that prevention of such HDL action, for instance by increasing the packing of the lipid components in the bilayer, would enable the vesicles to remain intact. Experiments to test this assumption were thus carried out, initially using MLV (77) and later with SUV (78). In both cases, additional cholesterol (e.g., a phospholipid: cholesterol molar ratio of 1:1) increased the bilayer stability in the presence of blood components (77–80) with very little loss of phospholipid or of an entrapped water-soluble marker, either in vitro (78) or after intravenous (78,79), intraperitoneal (78), or subcutaneous (81) injection. A role for HDL in the destabilization of liposomes was further substantiated by (*1*) the demonstration (82) that cholesterol-free SUV exposed to blood plasma from lipoprotein-deficient mice or a patient with congenital lecithin-cholesterol acyltransferase deficiency (characterized by low HDL levels) were more stable than when incubated with plasma from normal mice or humans; (*2*) the identification (82) of HDL as the only lipoprotein, among a number of lipoprotein species added to lipoprotein-deficient plasma, that could restore vesicle-destabilizing activity.

It was thus of interest to see whether reduction of vesicle leakage to solutes by cholesterol-induced bilayer packing could also be achieved with bilayers made rigid by substituting egg PC with high-melting phospholipids. As anticipated (77,80), SUV or MLV made of hydrogenated lecithin, distearyl phosphatidylcholine (DSPC) or sphingomyelin (SM) were less permeable to entrapped solutes in the presence of blood plasma, with bilayer stability becoming even greater when additional cholesterol was present (81–86). Thus, liposomes composed of equimolar DSPC and cholesterol were able to completely retain their marker solute (carboxyfluorescein) content, even after 48 hours of exposure to plasma at 37°C (84).

Vesicle Clearance Rates: The Role of Lipid Composition

In the course of work on liposomal stability it was observed (83) that solute retention by cholesterol-rich SUV, al-

though always high during relatively short (e.g., up to 2 h) periods of exposure to blood plasma, was significantly reduced when some formulations (e.g., those made of PC) were incubated for longer periods, whereas with others (e.g., SM) remained unchanged. It turned out (84) that this phenomenon correlated with the residence time in the blood circulation of the corresponding vesicles, i.e., the greater the vesicle stability, the longer the half-life (Figs. 6, 7; Table 1). However, this relationship between stability and clearance observed for neutral SUV (of size up to about 80 nm diameter) did not apply to very stable negatively charged SUV (85) or, more importantly (because of the higher drug load they can accommodate), to larger neutral vesicles (85). In the latter case, clearance rates were found to increase progressively with increasing size, even though bilayer stability remained high for prolonged periods during incubation with plasma (85). It thus appeared that vesicle size and surface charge both override the state of bilayer stability in determining vesicle clearance from the circulation.

On the basis of such findings, a tentative hypothesis was put forward (87) to unify observations concerning the role of liposomal phospholipids and cholesterol in promoting bilayer stability in vitro and (for neutral vesicles) circulatory half-life in vivo. Figure 8 proposes that, for liposomes that survive attack and complete disintegration by HDL, destabilization of the bilayer facilitates the adsorption onto, or insertion into it, of plasma proteins (opsonins) thought to be responsible (88) for the presentation of vesicles and other particles in a form recognizable by macrophages. The hypothesis predicts that the lower the destabilization of the bilayer, the fewer or smaller the "gaps" on

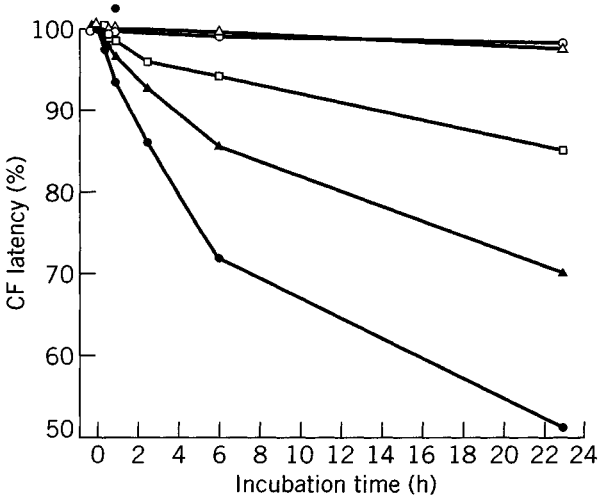

Figure 6. The effect of phospholipid composition of liposomes on their permeability in plasma. In a typical experiment shown here, small unilamellar liposomes containing quenched carboxyfluorescein (CF) and composed of SM (○), 77% SM, 23% egg phosphatidylcholine (PC) (△), 47% SM, 53% PC (□), 23% SM, 77% PC (▲) and PC (●) were incubated in the presence of mouse plasma at 37°C. All liposomal preparations contained cholesterol, equimolar to the total phospholipid. CF latency values (indicative of liposomal stability) at time intervals are % of total CF present *Source:* From Ref. 84, with permission.

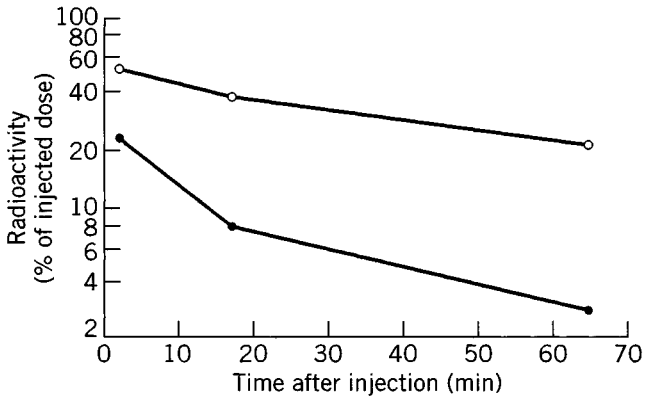

Figure 7. Entrapped drug clearance after intravenous injection of mice with vincristine-containing liposomes. Cholesterol-free (●) and cholesterol-rich (○) egg PC liposomes containing [^{3}H]vincristine were injected intravenously into mice. Animals were bled at time intervals and plasma samples chromatographed on Ultrogel AcA 34 columns. Radioactivity eluting in the fractions corresponding to the liposomal peak was then estimated and expressed as % (mean) of the total radioactivity injected per total mouse plasma. *Source:* From Ref. 98, with permission.

Table 1. Half-Lives of Liposomes After Intravenous Injection

	Half-life in vivo (h)	
Liposomes	Quenched CF	[s1^{4}C]SM
SM	11.0	10.0
77% SM, 23% PC	11.0	10.7
47% SM, 53% PC	7.0	7.0
23% SM, 77% PC	4.5	3.6
PC	2.1	2.3

Note: Liposomes as described in Fig. 6 containing CF and ^{14}C-labeled SM were injected intravenously into mice. Animals were bled at time intervals and plasma samples assayed for latent (quenched) CF and ^{14}C radioactivity. Half-lives were estimated from the linear clearance patterns plotted on a logarithmic scale.

it (and the lower the leakage of solutes) and, therefore, the smaller the amount of opsonins capable of associating with the vesicles. Thus, vesicles with decreasing amounts of opsonin on their surface would be expected to exhibit a proportionally reduced uptake by the RES. However, the scheme in Figure 8, although probably valid in general terms, is too simple to reflect real events. Indeed, since 1976 a number of workers have shown that a variety of plasma components (including α_2-macroglobulin (89), blood coagulation factors (90), components of the complement cascade (91), C reactive protein (92), and fibronectins (93) can, depending on their lipid composition and surface properties, bind to liposomes. More recent work (94) has revealed that liposomes interact (or fail to interact) with tissue-specific opsonins that are capable of facilitating or inhibiting (dysopsonins) uptake of vesicles with differing lipid compositions by the macrophages of the liver, spleen, or bone marrow. The ways by which the bilayer surface in its varying states of fluidity or destabilization encourages

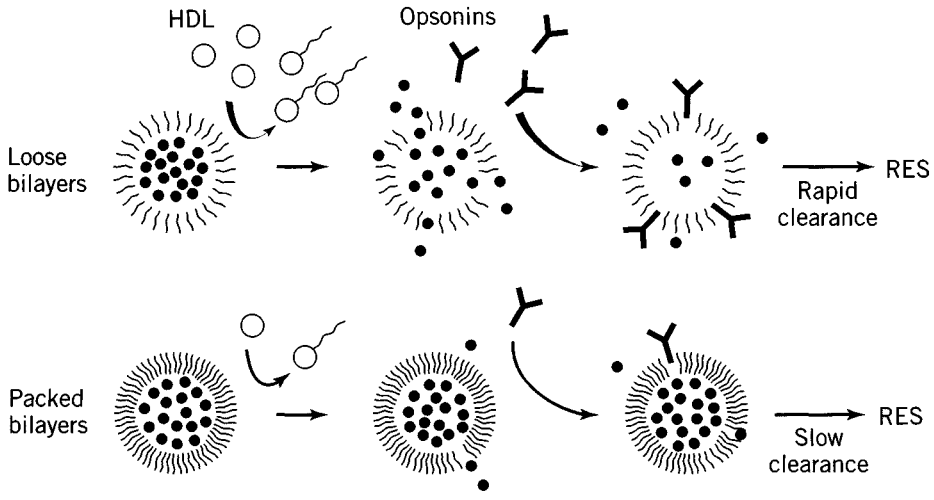

Figure 8. Correlation between stability of liposomes and clearance from blood circulation. In proposed scheme, extent of bilayer porosity and leakage of solutes in blood is dependent on the facility with which HDL remove phospholipid molecules from the bilayer. Loose bilayers are attacked by HDL more effectively than packed bilayers. The greater the gaps after HDL attack, the more extensive the opsonin adsorption on vesicles and uptake by the RES.

or discourages interaction with specific opsonins is not clear at present. Nonetheless, the failure (94) of a liver-specific opsonin to enhance uptake of liposomes rich in cholesterol or composed of "high melting" phospholipids by Kupffer cells is compatible with the sequence of events in Figure 8.

TAILORING OF LIPOSOMES

The properties of the basic liposome types and procedures for preparing them have been outlined in the previous section, illustrating the enormous diversity of structure and compositions that can be achieved. The versatility of the system means that additional refinements can be added and the scope broadened so that existing applications are optimized and new ones can be developed. The aspects of further development that have made the greatest impact are discussed here.

Long-Circulating Liposomes

For many years, a major obstacle to the use of liposomes for drug delivery via the parenteral route was the rapid clearance from the blood circulation by the RES before they had had the chance to exert their intended effect. Clearance is slower in the case of SUV, particularly when their composition is based on mixtures of SM (83) or DSPC (84) together with cholesterol, where increased lipid packing makes the bilayer more rigid and less likely to be opsonized by blood proteins (see Fig. 8). In these cases, the rate of clearance is also dose-dependent in that a larger amount of lipid saturates the sites of uptake in the mononuclear phagocytes. It was subsequently found that liposome clearance could also be substantially reduced in a manner which was less dependent on size or dose by inclusion of monosialoganglioside (GM_1) or hydrogenated phosphatidylinositol (HPI) in the bilayer lipid (95). This is related to the more hydrophilic nature of the head groups of these amphiphiles, which made it easier for the resultant vesicles to evade detection by the RES, and led to their being termed Stealth™ liposomes. It was later found that the same effects could be achieved by incorporating PEG groups at the liposome surface (95,96), usually by including a PEG-substituted phosphatidylethanolamine (PE) as a bilayer component. The liposomes so formed are often described as sterically stabilized, and are now used more widely than those based on GM_1 or HPI since the lipids are less expensive (and more clinically acceptable than GM_1). Moreover, the clearance pattern was less governed by lipid content, enabling greater flexibility in terms of the bilayer composition of the liposomes.

The reduced rate of clearance of liposomes (as a result of the choice of lipid composition or PEGylation) has important implications for the application of liposomes in drug delivery. One such application is to use the liposomes as circulating drug reservoirs, e.g., to give improved pharmacokinetic control of phase-specific cytostatic agents (97,98) and/or to increase the stability of vulnerable substances in the blood. This is achieved by a combination of increased control over the rate of drug release from the carrier and of the rate of clearance of the carrier from the bloodstream. Such effects are made increasingly possible by being able to prolong the circulation time of the liposomes while (in the case of PEGylated vesicles) being less reliant on liposome size and lipid composition. Prolonged circulation time also gives increased opportunity for liposomes to interact with non-RES target sites in the body, both by passive and by ligand-mediated targeting. These examples are discussed in greater detail later in this article, particularly under the heading of "Cancer."

Targeted Liposomes

One of the major tenets of the drug delivery concept is control of the physiological distribution of the administered carrier in the body, so that the effects of the associated drug are focused at the intended site of action and its therapeutic index is maximized. This aspect has been avidly explored throughout most of the period since liposomes were first proposed as drug delivery vehicles almost three decades ago (3,4). Some progress was gained by harnessing the structural variability of normal, unmodified liposomes to achieve so-called *passive* targeting. Thus the larger size

range of MLV, which predisposes them to removal from the RES, has been exploited to deliver various therapeutic agents to these cells, e.g., to replace genetically deficient enzymes (70) and to target antimicrobial agents to intracellular pathogens (9). By the same token, the small-size of SUV makes them more able to extravasate from leaky vasculature (95). However, passive targeting is limited in its scope, and tremendous effort has been directed toward the development of more universal levels of control by associating molecules with recognition properties with the liposome surface. The essential requirements (95) of this *active* targeting approach are summarized as follows:

- Characteristics of the target cell population must be identified which are qualitatively and/or quantitatively different from other cells that might be encountered by the delivery vehicle, and which are appropriate as recognition features for a targeting mechanism. Typical examples are antigenic determinants, including various types of membrane receptor, which are unique or overexpressed (by virtue of the aggressive growth rate of the cell).
- It must be possible to generate targeting ligands that are able to interact with some degree of exclusivity with these epitopes. Examples include antibodies (either intact or as active fragments), other proteins and peptides, lipoproteins, glycoproteins, and growth factors. Specific examples will be given later.
- The ligand must be capable of being attached stably and accessibly to the drug carrier so that interaction with the target epitope brings the liposome into close proximity with the cell surface.
- The liposome–ligand construct must be stable within the biological milieu and present for sufficient time to maximize the chances of it interacting with the target cell population.
- Binding should increase the chances of the drug reaching the cell interior, for example, by receptor-mediated endocytosis or membrane fusion events or by local diffusion across the cell membrane. Also, once internalized, the drug must retain its stability (e.g., against damage from lysosomal processing) and be available to exert its intended action.

Ligand Coupling Strategies. The general strategy of this approach is exemplified by the developments achieved with antibodies and what are now known as immunoliposomes. The earliest report of antibody-mediated liposome targeting appeared 24 years ago (73). In that first report, liposomes containing a radiolabeled antitumor drug, bleomycin, were associated with a series of polyclonal antibodies and then incubated with a range of cells against which the various antibodies had been raised. In all cases, radioactivity was higher in those cells incubated with the corresponding antibody than in the same cells incubated with the other, nonspecific antibodies, thus confirming an in vitro targeting effect. In the same study, asialofetuin, which is known to bind to galactose receptors on the liver parenchymal cells, was associated with doubly labeled liposomes and then administered to rats, some of which had first been injected with free asialofetuin. The latter group of animals showed reduced association of the two radiolabels with the liver, thereby providing the first evidence of targeting of liposomes in vivo. A little later (74), in vivo targeting of liposomes was also demonstrated by the use of tumor-specific antibodies.

Many different coupling strategies have been used to associate the targeting ligands and the liposomes. The aforementioned study used a relatively crude approach whereby the two components were sonicated together, presumably enabling hydrophobic portions of the proteins to insert into the perturbed bilayers, and a similar approach by another group confirmed the targeting ability of the resulting vesicles (99). Others have used targeting moieties loosely bound to the liposome surface. Thus a hapten-specific antibody was used to bring about interaction between liposomes and cells, both of which were coated with the hapten (100), whereas in a separate study, liposomes opsonized with antibody were targeted to tumor cells resulting in their internalization by receptor-mediated endocytosis (101). The majority of the subsequent studies have used chemical coupling methods to link a targeting moiety to an amphiphilic molecule inserted into the liposome bilayer. Early approaches included immunoglobulin G (IgG) cross-linked to liposomal PE using glutaraldehyde (102), or to aldehyde groups formed by periodate-oxidation of liposomal glycosphingolipids (103). Another early method which became very popular involved covalent coupling of fatty acid chains directly to IgG using cross-linking agents, and then incorporation of the resultant molecules into liposomes by detergent dialysis (104). However, by far the most widely used approach to date involves the use of heterobifunctional cross-linking reagents for introducing thiol-based linkages between the lipid anchor and the ligand, thereby minimizing the chances of formation of homopolymers.

In the original method, thiol-reactive derivatives were prepared, both of the antibody (via free amino groups) and the PE anchor; the latter was incorporated into liposomes, and then free thiol groups were formed by reduction. Interaction of the two species resulted in coupling of the immunoglobulin molecule to the liposome surface via a thiol linkage (86,105). An alternative approach is to use the thiol groups generated when a $F(ab')_2$ fragment of IgG is reduced to form two Fab′ fragments (106). A particular drawback with the thiol linkage is its limited stability in blood, and an important improvement was to replace this with the much more stable thiol–ether linkage (107). This is achieved by using maleimido-based thiol reagents to derivatize either the lipid anchor or the ligand so that subsequent interaction produces a stable thiol–ether bond. The same approach can of course also use Fab′ fragments as already discussed (106). Over the years, many modifications and improvements have been made to this technique and are now widely used in many different targeting applications.

An alternative to the strategy of coupling the ligand directly to the liposome surface has been to make use of the high affinity avidin–biotin interaction (108). Avidin and streptavidin are glycoproteins with molecular weights of 67 and 60 kDa, respectively, either of which can tightly

bind four molecules of low molecular weight biotin, and the components can be configured in different ways to achieve ligand binding. Biotinylation of the bilayer anchoring molecule and the ligand can be readily achieved via free amino groups and then bridged together by addition of (strept)avidin to form a tightly bound complex. Alternatively, (strept)avidin can be covalently bound to the bilayer using one of the aforementioned procedures and then complexed to a biotinylated ligand. Either approach provides a flexible way of enabling the separate components to be prepared and stored in advance and then put together on a "mix and match" basis as required.

Progress in the development of ligand-based liposome targeting has been held up by numerous obstacles that can affect various stages of the targeting process. During construction of the carrier, the ligand may be damaged or lose activity as a result of the conjugation process. Formation of IgG fragments may result in reduced affinity. On the other hand, binding of intact antibody has been observed to result in rapid clearance of the construct, probably as a result of the affinity of the Fc portion of the antibody for the Fc receptors in the liver. Moreover, chronic use of antibody-coated liposomes may lead to immune responses against the (foreign) proteins. This can be approached by preparing chimeric or else wholly humanized antibodies. Once in the bloodstream, exposure to blood components may lead to cleavage of the ligand from the carrier or else to drug leakage. On the other hand, if the liposome is too stable, it might not release its contents once its destination has been reached. Early attempts to combine the immunoliposome and Stealth approaches were problematic because the PEG chains obstructed access of antibody to the liposome surface during the conjugation procedure and to the cell surface epitope during the targeting procedure. This was eventually resolved both by using an avidin–biotin approach similar to that already described, or by conjugating the antibody to the terminal region of the PEG moiety.

At the level of the target cell, it has proved difficult to identify truly tumor-specific markers, in addition to which there may be considerable surface heterogeneity between different cells in a given tumor cell population. Moreover, it was demonstrated quite early that the simple fact of a carrier binding to its target epitope does not in any way guarantee its internalization (109), and other mechanisms for drug entry into the cell (e.g., passive diffusion or fusion) may well be ineffective. Different antibodies may themselves vary in their ability to be internalized. Reliance on overexpression of ubiquitous antigens known to internalize (e.g., transferrin, folate, and low density lipoproteins) is still accompanied by nonspecific binding to normal cells expressing these receptors. However, despite the gloomy picture that this may present, sound progress has been made such that positive results are now being achieved in vivo. These is discussed in more detail in the section "Applications for Liposomes".

Polymerized Liposomes

The concept of liposome polymerization has been around for about 20 years but may still be some way from becoming a viable proposition. For a recent review, see Bonte et al. (110). The basic premise is that polymerizable amphiphiles can be used to form lipid vesicles and then made to polymerize using conventional triggers. The ideal outcome is a liposome of high but controllable stability with fluid, liquid crystalline properties. A variety of polymerizable phospholipids have been synthesised, with the reactive groups in different regions of the molecule as shown in Table 2. Thus, the polymer backbone can be in the head group region, through the midchain hydrocarbon region, or through the end of the hydrocarbon chains.

Polymerized liposomes are very stable in the presence of blood components and have been widely studied as potential drug delivery vehicles, where they have been seen as a possible solution to the instability of natural phospholipid liposomes. Their use in this respect would require that they be only partially polymerized to permit eventual drug release when required. To achieve this goal, windows of normal or trigger-responsive lipids would need to be included. In fact, by using mixtures of normal and polymerizable lipids, different domains can be formed, the size and distribution of which are dependent on the preparation conditions. This was well demonstrated in a study using a mixture of polymerizable octadecadienoyl phosphatidylcholine and nonpolymerizable dipalmitoyl phosphatidylcholine, where treatment of the resultant liposomes with solvents removed the normal lipids to leave "skeletonized" porous liposomes which could be observed by scanning electron microscopy. However, various technical hurdles must be overcome before polymerized liposomes are ready for use as drug delivery vehicles, and concerns remain about the possibility of toxic residues. Inert fragments of polymer backbone are known to accumulate in the body and biodegradable amphiphiles have been proposed as a way of overcoming this. Of the limited in vivo studies that have been carried out, one showed rapid clearance of methacrylate-derived liposomes from the blood of injected mice, by the liver and spleen.

A related potential application is the use of polymerized liposomes as an artificial blood substitute for transporting hemoglobin or synthetic oxygen carriers around the body. For example, synthetic hemoglobin embedded by copolymerization into the bilayer of imadazole dienoylphospholipid liposomes formed oxygen carriers which were stable for several months and were similar to human blood in terms of their oxygen-carrying capacity and binding affinity. Polymerized liposomes have also been used for studying membrane dynamics during various processes of cell biology. These include molecular recognition phenomena such as occur between membrane receptors and lectins, between cells and the extracellular matrix, and between phospholipase and other enzymes with the lipid bilayer. In addition, they have provided valuable information regarding the localized membrane changes that occur during processes such as endo- and exocytosis and membrane budding.

pH- and Temperature-Sensitive Liposomes

These modifications were developed in order to increase the selectivity of drug action in the body via controlled re-

Table 2. Reactive Groups for Liposome Polymerization

Functional group	Link region	Polymerization method
Methacrylic	Head group, acyl chain	Chemical or UV
Thiol–disulphide bonds	Head group, acyl chain (end)	Chemical or UV
Dienoate	Acyl chain	Chemical or UV
Vinyl	Acyl chain	UV
Diacetylinic	Acyl chain	UV, γ radiation

lease from the carrier. The former originated from attempts to design liposomes that would become leaky and release their contents in the low pH environment surrounding anoxic tumor cells (111), but it was subsequently realized that the same strategy could be used to exploit the changes occurring during endosomal acidification (112). The approach is dependent on the use of an amphiphile that under physiological conditions does not normally exist in a lamellar phase, but can be induced to do so in the presence of a second titratable amphiphile that conditionally stabilizes the bilayer in a *pH dependent* manner. The nonlamellar amphiphile used in virtually all cases to date has been PE. Except under conditions of high pH and low ionic strength, or at temperatures well below its transition temperature, unsaturated PE preferentially adopts the inverted hexagonal (H_{II}) phase, which as discussed at the beginning of this article, has considerable fusogenic character. Several different stabilizing amphiphiles have been used, the most common being oleic acid and cholesterol hemisuccinate. Under neutral or mildly alkaline conditions, each of these will be deprotonated and hence negatively charged. When present with PE under these conditions, the latter is unable to form the H_{II} phase and favors a lamellar phase whereupon liposomes can be formed. If, however, the pH is subsequently reduced, the titratable amphiphile becomes protonated and the loss of charge results in a transition to the H_{II} phase, thus destabilizing the liposome structure.

When conventional liposomes are taken up by receptor-mediated endocytosis, the endosomal pH is sequentially reduced to reach 5.0 or lower at the lysosome stage, where the combined effects of low pH and enzymic action generally result in degradation of the liposome and its contents. If, on the other hand, pH-sensitive liposomes are used, the nonbilayer transitions take place between the early and late endosomal stages, resulting in destabilization of the endosome and delivery of its contents into the cytoplasm. Such effects are particularly important in gene delivery (see the following section) and are referred to again in the section "Applications for Liposomes." A major drawback in the exploitation of pH-sensitive liposomes is their poor stability in vivo, such that larger ones based on dioleoyl phosphatidyl ethanoldiamine (DOPE) and oleic acid leaked most of their contents in the presence of plasma at 37°C, and were rapidly cleared by the RES. This was found to be due to loss of oleic acid to plasma components. To approach this problem, a double chain amphiphile, 1,2-dipalmitoyl *sn*-3-succinylglycerol, was synthesized and used to prepare liposomes which were found to remain stable and to retain their pH sensitivity after prolonged plasma incubation (113). Immunoliposomes of this composition were able to deliver their contents into the cytoplasm of L929 cell cultures.

The concept of temperature-sensitive liposomes was also developed with the aim of selective drug delivery to tumors. In this case, the liposomes are prepared using phospholipid mixtures which have transition temperatures a few degrees higher than body temperature (114). It is known that liposomes show increased permeability at temperatures in the vicinity of the transition temperature, due to formation of defects in the bilayer. By injecting drugs containing cytotoxic drugs into the systemic circulation and then applying localized heat externally to the target area, e.g., to the vicinity of a tumor, the liposomes can be induced to release their payload of drug in that region.

Cationic Liposomes

This term has become synonymous with gene transfection. In fact it is somewhat confusing because although the starting material is liposomal, electrostatic interaction with DNA leads to extensive loss of the original morphology. In early studies, encapsulation was assumed to be a prerequisite for successful transfection but this idea had to be revised when it was found that lipid–DNA complexes formed by simple mixing of DNA, and cationic SUV were much more effective (115). The basis of the approach is that positive charge in the form of cationic lipid is used to neutralize the considerably extended, polyanionic nucleic acid chain to form a highly compact microstructure, which has become known as a lipoplex. Each of these particles carries a small net positive charge, which enables it to approach and interact with the negatively charged cell membranes and perhaps ultimately gain entry by receptor-mediated endocytosis (Fig. 9). There is still conjecture concerning the fine structure of the lipoplex. Examination by FFEM typically shows a heterogeneous mixture that includes the presence of aggregated spherical structures together with elongated fibrils (116) forming what has been described as the "spaghetti-meatball" appearance. The spherical units are believed to comprise condensed DNA associated with cationic lamellar lipid, whereas the fibrils appear to be strands of DNA surrounded by lipid bilayer in tubular form. It has proved difficult to confirm any structure–transfection activity relationship in the various morphological variations that have been observed.

A large and diverse range of cationic lipid transfection agents have been synthesized, not only to improve the efficiency of transfection, but also to increase biodegradability, decrease toxicity, and increase stability during storage

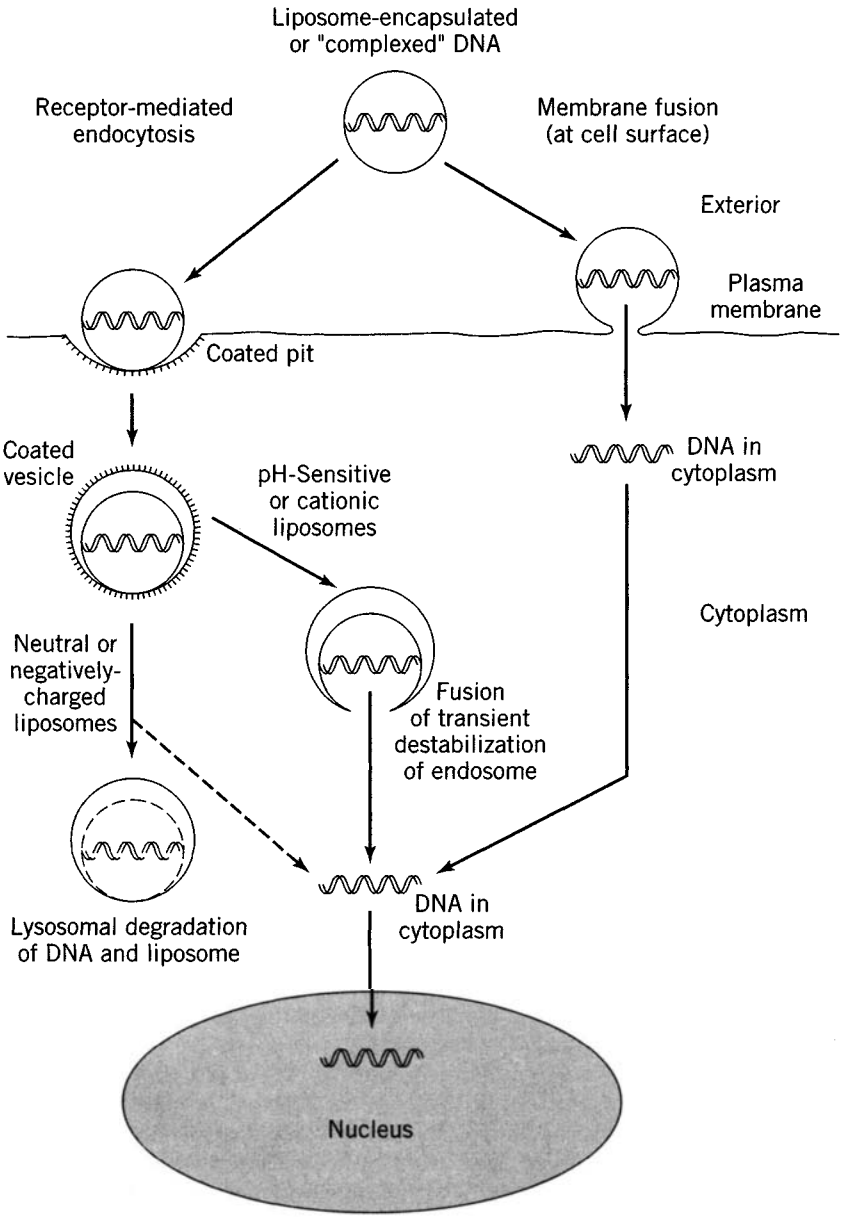

Figure 9. Proposed modes of cellular uptake of liposome-associated nucleic acid. The membrane fusion pathway remains putative. *Source:* From Ref. 118, with permission.

and in the presence of blood components. These have been the subject of recent reviews (117,118) and are not discussed in any detail here. The standard was set by dioleoyloxypropyl-trimethylammonium chloride (DOTMA) in 1989 (115) and was rapidly followed by many others. Cationic lipids vary widely with respect to their polar head group, hydrophobic tail, and the interlinking region of the molecule. All are dependent on amine-containing head groups for their positive charge, and in the majority the lipophilic region consists of two fatty acyl chains as in conventional phospholipids. Of the others, a few have used single acyl chains, but better results have been achieved using the cholesterol backbone, as in 3β*N*-(*N*′,*N*′-dimethylaminoethane)-carbamoyl) cholesterol (DC-Chol) (119), which formed the basis of the first cationic liposome system to be tested in human trials. The great majority have been used together with a neutral helper lipid which has usually been DOPE, though in some cases cholesterol has also been useful in this respect. The function of the helper lipid is thought to be due to its propensity to form the fusogenic hexagonal (H_{II}) phase and hence to promote endosomal disruption and release into the cell cytoplasm (see previous section). In the case of cationic amphiphiles based on the cholesterol moiety, DOPE is also required for these to form liposomes, whereas the double chain species form liposomes on their own.

Cationic amphiphiles with monovalent head groups have a limited capacity to condense DNA, but this can be increased by substitution for a multivalent group such as one based on spermine, to form lipopolyamines (120) such as dioctadecyl-amidoglycyl-spermine and dipalmitylphosphatidylethanolamidospermine. The greater charge density means that the resultant structures are smaller and more compact, and therefore better able to bind to the

coated pits and be taken up by endocytosis. In addition their greater buffering capacity can give increased protection against low intralysosomal pH. In a related approach, protamines, which are natural polyamine components of sperm, have been included together with DC-Chol/DOPE, providing effective transfection of Chinese hamster ovary (CHO) cells (121). These natural cationic peptides may also have nuclear localization signals that might help them to gain entry into the nucleus. A similar system using 1,2-dioleoyloxy-3-(trimethylammonium) propane (DOTAP) liposomes together with protamine was injected intravenously into mice, showing expression of the luciferase gene in all organs, particularly in the lung (122).

APPLICATIONS FOR LIPOSOMES

Cancer

This application has been widely reviewed in recent publications (5,95,123–126). Possibilities for using liposomes for the treatment of cancer have been approached from several different directions. Chemotherapeutic agents, including conventional low molecular weight cytotoxic drugs as well as peptides and proteins, have been administered in undirected and in ligand-targeted liposomes. Cytokines and other immunomodulators have been encapsulated in MLV and used to activate macrophages and make them tumoricidal. Genetic material, including DNA, antisense molecules, and ribosomes, has been presented in liposomes to bring about different antitumor effects. Many of these approaches have given promising results and two formulations based on cytotoxic anthracyclines are now in commercial use.

A variety of cytotoxic drugs have been administered in liposomes via various routes to a range of animal tumor models (95,123–126). Much of this work has focused on the anthracyclines. Although for certain cytotoxic drugs encapsulation into liposomes was found to cause increased toxicity, early studies indicated that for others, including the anthracyclines, toxicity was reduced. This appears to be due to the fact that rapid uptake and sequestration of liposomes by the macrophages of the RES reduces the peak plasma levels of the drug and their associated toxicity, particularly to the myocardium. The macrophage-associated drug is ultimately released back into the circulation to produce an effect akin to continuous infusion. However, although the therapeutic benefits of conventional infusion are well known, the significance of such an effect in the context of liposomal delivery remains controversial, and certainly in some cases reduced toxicity is accompanied by reduced efficacy.

One effect that is clearly beneficial is the fact that many rapidly growing tumors have poorly formed, leaky vasculature through which liposomes of appropriate diameter can pass, and because of ineffective lymphatic drainage, will then accumulate. The longer the liposomes are able to circulate in the blood, the greater the level of accumulation. This effect is the basis of three different liposomal anthracycline products (Table 3) which have given successful results in clinical trials, two of which are on the market. Of these, TLC® D-99 (The Liposome Company), which is still in Phase III, comprises doxorubicin actively loaded into egg PC–cholesterol liposomes of around 150 nm in diameter using a pH gradient (5,126). Comparative studies of dogs treated with TLC D-99 or with the same amount of free drug showed retention and occasionally increased antitumor activity in the former group, without the histological evidence of myocardial toxicity that was seen with the free drug. Several Phase III trials are ongoing in U.S. and Europe to evaluate TLC D-99 alone and in combination therapy in metastatic breast cancer.

Daunosome® (NeXstar, Inc.) consists of daunorubicin incorporated by a remote loading technique into 40–50 nm-diameter SUV composed of DSPC and cholesterol and is supplied as a ready to use aqueous liposome suspension (5,127) (see Table 3). This composition forms a particularly rigid bilayer which inhibits opsonization by the plasma lipoproteins, and this together with their small size results in an extended circulation time of 24 hours in the blood. It is also claimed that a substantial portion of the extravasated liposomes are taken up intact by the tumor, where they then release their contents over a prolonged period of time to produce sustained drug action within the tumor. The product has so far been approved for first-line therapy of AIDS-related Kaposi's sarcoma in the U.S. and other countries. Promising results against a variety of other tumors have led to Phase II clinical trials, which are currently underway to look at its utility for treating lymphoma, leukemia, and myeloma, as well as solid tumors in breast, ovary, and brain (127).

The third product, Doxil® (Sequus Pharmaceuticals) (see Table 3) is based on doxorubicin, which is again incorporated by active loading, this time into sterically stabilized liposomes comprising hydrogenated soy PC, PEG-DSPE (distearyl phosphatidylethanolamine) and cholesterol, and having an approximate diameter of 85 nm (5,95,128). The drug is in the form of a gel-like precipitate which enables high concentrations to be encapsulated and retained within the liposomes. The slightly increased size compared with DaunoXome (and hence increased loading), is achieved by virtue of the fact that sterically stabilized liposomes are less size dependent with respect to their clearance rate. Thus, circulation times of 15 to 30 hours in rodents and dogs and 40 to 60 hours in humans can be achieved with consequently increased accumulation in the vicinity of the tumor. The steric stabilization also results in decreased contact with other tissues such as the myocardium while circulating in the blood, with the drug remaining sequestered inside the liposomes during this time. Once localized in the tumor tissue, various mechanisms have been proposed to account for liposome breakdown and drug release, including low pH, the action of lipases and other released enzymes, and the consequences of engulfment by tumor-resident macrophages. Once released, doxorubicin is sufficiently lipid soluble to diffuse into the tumor cells, leading to their destruction (128). Doxil was the first liposomal drug approved by the FDA and has been on the market for treatment of AIDS-related Kaposi's sarcoma since 1995. It has also shown very promising results in a range of solid tumors including ovarian and breast carcinoma for which advanced clinical trials are underway (128). Sequus Pharmaceuticals is also developing cisplatin

Table 3. Liposome-Based Products Developed or Under Development (UD)

Product	Drug	Target disease
	Aronex Pharmaceuticals, The Woodlands, TX	
Liposomal nystatin (trademark not yet given; intravenous) (UD)	Nystatin	Systemic fungal infections
Liposomal tretinoin (trademark not yet given; intravenous) (UD)	All-trans retinoic acid	Leukemia
Liposomal annamycin (trademark not yet given; intravenous) (UD)	Annamycin	Kaposi's sarcoma Retractory breast cancer
	IGI, Vineland Laboratories, Vineland, NJ	
Newcastle disease vaccine (intramuscular) (Novasomes)	Newcastle disease virus (killed)	Newcastle disease (chicken)
Avian Rheovirus vaccine (intramuscular) (Novasomes)	Avian rheovirus (killed)	For vaccination of breeder chickens; for passive protection of chicks against rheovirus infection
	NeXstar Pharmaceuticals (formerly Vestar), Boulder, CO	
AmBisome (intravenous)	Amphotericin B	Systemic fungal infections; visceral leishmaniasis
DaunoXome (intravenous)	Daunorubicin	First line treatment for advanced Kaposi's sarcoma. Breast cancer and other solid tumors
MiKasome (intravenous) (UD)	Amikacin	Serious bacterial infections
VincaXome (intravenous) (UD)	Vincristine	Solid tumors
	Novavax, Rockville, MD	
E. coli 0157:H7 vaccine (oral) (Novasomes) (UD)	*E. coli* 0157:H7 (killed)	*E. coli* 0157 infection
Shigella flexneri 2A vaccine (oral) (UD)	S. flexneri 2A (killed)	S. flexneri 2A infection
	SEQUUS Pharmaceuticals (formerly Liposome Technology), Menlo Park, CA	
Doxil (intravenous)	Doxorubicin	Kaposi's sarcoma. Refractory ovarian, recurrent breast, prostate and primary liver cancers
Amphotec™ (intravenous)	Amphotericin B	Systemic fungal infections
	The Liposome Company, Princeton, NJ	
D99 (intravenous) (UD)	Doxorubicin	Metastatic breast cancer
ABELCET™ (intravenous) (Ribbons)	Amphotericin B	Systemic fungal infections
C53 (intravenous) (UD)	Prostaglandin E_1	Systemic inflammatory diseases
	Swiss Serum and Vaccine Institute, Berne, Switzerland	
Epaxal-Berna vaccine (intramuscular) (IRIV[a] liposomes)	Inactivated hepatitis A virions (HAV) (antigen; RG-SB strain)	Hepatitis A
Trivalent influenza vaccine (intramuscular) (UD)	Hemagglutinin and neuraminidase from H_1N_1, H_3N_2, and B strains according to recommendations by WHO	Influenza
HAV/HB_s-IRIV combined[b] vaccine (intramuscular) (UD)	HAV, genetically engineered hepatitis B antigens (HBs)	Hepatitis A and B
Diphtheria/tetanus/hepatitis A combined vaccine (intramuscular) (UD)	Diphtheria and α and β tetanus toxoids; inactivated HAV virions	Diphtheria, tetanus, hepatitis A
Hepatitis A and B/diphtheria/tetanus/influenza supercombined vaccine[a] (intramuscular) (UD)	Inactivated HAV virons, HB_s, diphtheria, and α and β tetanus toxoids, hemagglutinin and neuraminidase from influenza strains as in trivalent influenza vaccine	Hepatitis A and B, diphtheria, tetanus, and influenza

[a]IRIV, immunopotentiating reconstituted influenza virosomes.
[b]Combined vaccines denote the presence of up to three antigens in the formulation.
[c]Supercombined vaccines denote the presence of more than three antigens.

in sterically stabilized liposomes, which may be effective in combination therapy with Doxil. Other companies are incorporating different cytotoxic drugs into liposomes, some of which are currently in Phase II clinical trials (5).

The beneficial effects of steric stabilization of liposomes using PEG are not completely clear cut. The accumulation efficiencies of long circulating (by virtue of their rigid bilayers) liposomes by a series of mouse tumors were investigated in the absence and presence of a surface coating of PEG. By comparing the area under the curve (AUC) for plasma drug levels with that of the tumor, it appeared that PEGylation actually reduced the proportion of drug that accumulated in the tumor (129). This occurred despite the fact that the sterically stabilized liposomes circulated for longer in the blood than did the corresponding conventional ones. Steric stabilization also tends to mediate against uptake of liposomes by the tumor cells in the same way that it prevents interaction with other cells. Given these facts, the conflict between the need to design liposomes which fully retain their drug content while circulating in the blood and the need to make this drug available to tumor cells after extravasation remains a difficult issue (129). Its resolution may ultimately depend on controlled release strategies such as the use of pH-sensitive liposomes that respond to reduced pH within the tumor microenvironment or of the combination of temperature-sensitive liposomes and localized hypothermia. Exciting possibilities have also been raised by the recent development of liposomes that can be made highly fusogenic by loss of PEG groups, which potentially enable them to fuse with adjacent cells (130).

The use of ligand-mediated targeting to increase the specificity of drug transfer to tumor cells is still at an early stage, but since the emergence of long-circulating liposomes, promising results in vivo are starting to appear. Early studies (131) reported substantial therapeutic effects when PEG-stabilized or GM_1-stabilized immunoliposomes, containing doxorubicin and a lipophilic prodrug, respectively, were used to treat newly established lung cancers in mice. In the former case, attempts to treat more advanced tumors were unsuccessful. Effective treatment involving receptor-mediated internalization was also achieved using immunoliposomes targeted against malignant cells within the vasculature (132). More recently a comprehensive series of studies has been carried out (133) using sterically stabilized, doxorubicin-containing liposomes targeted against cancers overexpressing the HER2/neu proto-oncogene. HER2 is an internalizing receptor, highly expressed in a wide range of tumors where it plays an important role in aggressive growth and so is unlikely to be down-regulated. It also has other important advantages as a target in that it is a readily accessible cell surface protein with infrequent expression in a limited range of normal cells. A highly reactive antibody is available which has been fully humanized to reduce the chances of immunogenicity, and in these studies was generally conjugated as the Fab′ fragment to the terminal region of liposome-grafted PEG chains. After in vitro optimization, the system was tested against subcutaneous xenografts of different tumors showing various levels of HER2 expression. Interestingly, similar levels of gross uptake were seen in tumors with high and very low expression levels, whereas the antitumor effect was substantially higher in the former (134). This correlated with electron microscopic evidence using colloidal gold-labeled liposomes that in nontargeted systems (low HER2 expression or antibody-free liposomes), the label was concentrated in tumor-resident macrophages and in intercellular spaces, whereas in positively targeted systems it was present both between and *within* the tumor cells (133). This latter distribution presumably accounted for the superior antitumor effects of the targeted systems, whereas the observed gross similarities in tumor distribution using targeted and nontargeted systems agrees with earlier indications that extravasation is the rate-determining step (133).

A completely different strategy for anticancer therapy is to use liposomes to deliver activating factors, such as cytokines to macrophages, so that they become tumoricidal (135). Because the total number of available macrophages in the body is limited, the major indication is for the treatment of metastatic disease after surgical removal of the primary tumor. Activated macrophages ignore normal cells but selectively kill tumor cells, regardless of the numerous levels of biological heterogeneity that normally make metastases so difficult to treat. A widely used method of activation is to expose the macrophages to muramyl dipeptide (MDP), the minimal structural unit of Mycobacterium cell wall. By incorporating lipid soluble derivatives of MDP into MLV enriched with phosphatidylserine, these are preferentially taken up after intravenous injection by macrophages residing in the lung, which is one of the major sites of metastatic disease. Promising studies in mice were followed by successful treatment of dogs after surgical removal of osteosarcoma (135). The approach has progressed through Phase I and Phase II trials, where it was evaluated in combination with chemotherapy and is currently in Phase III for newly diagnosed osteosarcoma patients, where it is hoped that the treatment will destroy residual tumor cells that were not eliminated by chemotherapy. Adults and children have been treated with minimal side effects, and an added attraction is that activation of alveolar macrophages can be achieved by oral administration of liposomal MDP.

Antimicrobial Agents

Liposomes have been widely investigated as delivery systems for treatment of bacterial, fungal, viral, and parasitic diseases, and the topic has been reviewed in recent publications (5,135–137). Therapeutic benefits can be brought about in various different ways. The use of liposomes for passive delivery of immunomodulators to macrophages has been discussed already with respect to cancer treatment, but this approach can also be used to bring about nonspecific resistance to infections in general (135). Thus a wide range of infectious diseases have been shown to respond to treatment by macrophages activated by MDP or cytokines such as interferon γ (IFN-γ) associated with liposomes. Phagocytosed microorganisms often take up residence and multiply in the host cells, making them refractory to treatment by antimicrobial agents due to poor penetration or reduced intracellular activity of the drug.

However, this same phagocytic activity can be used to passively deliver particulate drug carriers such as liposomes to the interior of the cell while at the same time masking the toxicity of the drug to the host. Early studies (9) involved treatment of protozoal Leishmania infections using liposome-encapsulated antimonial drugs and produced substantial increases in therapeutic index due both to improved delivery and reduced toxicity. Similar effects have subsequently been shown in a wide range of bacterial, viral, and fungal infections (123,127).

In recent years there has been a dramatic increase in the incidence of potentially fatal, systemic fungal infections, particularly in patients who are immunocompromised as a result of treatment for diseases such as cancer, diabetes, and AIDS; as a result of organ transplantation; or due to various other factors. Amphotericin B is the drug of choice for treating such infections because its spectrum of activity is much larger than any other clinically acceptable drug (137). It is a lipophilic drug whose mode of action is to interact with ergosterol in plant and fungal membranes (the equivalent of cholesterol in mammalian cells), thereby causing membrane disruption and cell death. The drug does interact with cholesterol but to a lesser extent, and this partial specificity can be amplified by administering it in a particulate form so that it is taken up by the macrophages, which may themselves be hosts to the fungi but can also carry the drug to other sites of infection. Appropriate dosage forms can also reduce the rate of clearance from the bloodstream, enabling increased chance of extravasation through leaky vasculature due to inflammation of diseased tissue. While complexed within these formulations, amphotericin B is unavailable to interact with cell membranes in the body. Thus incorporation into liposomes and other lipidic complexes resulted in substantial reductions in toxicity compared with free drug or with the established formulation Fungizone™ (a deoxycholate-containing micellar dispersion), enabling doses up to five times larger than the latter to be given (127). Three such lipid formulations are now available (see Table 3). AmBisome™ (NeXstar Pharmaceuticals, Inc.) (5,127) is the only truly liposomal form, consisting of SUV composed of hydrogenated soy PC, distearoyl phosphatidylglycerol and cholesterol, stored as a lyophilized powder. Molecules of drug are believed to align in parallel to form cylindrical structures, two of which fit end to end to form a bilayer-spanning pore across which ions and other solutes can pass. These pores can be inserted into the fungal cell membrane, allowing rapid loss of cell contents. In vitro studies have shown binding of AmBisome liposomes to fungal cells, followed by liposome disintegration and subsequent cell disruption (127).

Amphotec™ (Sequus Pharmaceuticals) (5,138) is a non-liposomal form of amphotericin B. Instead it is a stable, disk-shaped complex of drug together with cholesterol sulphate, 115 nm in diameter and 4 nm thick. As with the previous formulation, it is stored in a lyophilized form and reconstituted for use. Comparative studies have indicated that its efficacy is approximately similar to that of AmBisome (138). The third formulation, known as ABELCET™ (The Liposome Company), is also not a true liposome, but is an interdigitated complex of lipid and drug, the lipid components comprising dimyristoyl phophatidylcholine and dimyristoyl phosphatidylglycerol (5,126). Numerous studies at the research level have looked at the use of liposomal drugs to treat bacterial and viral infections and again the main focus has been on intracellular pathogens, particularly in immunocompromised patients. These have included targeting of the HIV virus itself, and of *Mycobacterium* species such as *M. avium*, which causes serious opportunistic infections in AIDS sufferers, and *M. tuberculosis*, which reflects the recent resurgence of multidrug resistant forms of TB. The MiKasome™ system (NeXstar) where the antibiotic amikacin is encapsulated in SUV composed of HSPC, DSPG and cholesterol is currently in Phase I clinical trials (127). Genetic approaches to cancer treatment are discussed in the following section.

Gene Therapy

Liposome-based gene transfection systems have been promoted as a means of achieving the transfection efficacy of viral constructs without the associated risks. The earliest attempts at liposome-based gene transfer in vivo involved conventional entrapment in negatively charged vesicles, and transfection efficiencies were accordingly low. A plasmid containing the preproinsulin gene was injected intravenously into rats, a transient hypoglycaemic response was noted, and increased levels of insulin were detected in the blood, liver, and spleen (139). Improvements arose when increased insights into the mechanisms of uptake prompted the development of pH-sensitive liposomes (111), which could exploit the cellular endocytic mechanisms, and these were rapidly followed by the concept of cationic lipid delivery systems. However, the reactivity of cationic liposomes within the blood, and their rapid removal by the RES (after opsonization) (88), has meant that their application in vivo has generally been limited to localized delivery by various routes. For example, plasmids complexed with Lipofectin™ (DOTMA/DOPE) were injected into specific areas of the brain of Xenopus embryos to study gene function in the developing embryo, whereas expression in mammals was achieved in later studies after injection into mouse brain (140).

DNA–liposome complexes have been used to stimulate immunogenic responses against malignant tumors in vivo. Initial studies carried out in mice (141) involved direct injection into the tumor of the genes for foreign major histocompatibility complex proteins associated with DC-Chol cationic liposomes. The treatment resulted in complete tumor regression in many of the animals, and tumors remote from the injection site and not expressing the transfected gene product also underwent rejection. Based on these positive results, a human clinical trial was carried out whereby the human *HLA-B7* gene in the same type of complex was injected into cutaneous tumors in human melanoma patients (142). Antigen expression, with generation of cytotoxic *T*-lymphocytes specific for *HLA-B7* was seen in the tumors of all 5 patients, and in 1 case, complete regression of the primary tumor occurred.

Site-specific delivery within the vasculature was demonstrated by using a double balloon catheter to isolate a

segment of artery, then injecting into this segment a plasmid associated with either DOTMA/DOPE liposomes or a retroviral vector. Transfection was confirmed histochemically and shown to be limited to the treated segment (143). Such selective transfection in vivo might be applicable for treatment of diseases such as atherosclerosis or cancer. A similar approach involving the use of antisense oligonucleotides was carried out for treatment of neointimal hyperplasia, which frequently occurs after balloon angioplasty, with neointima formation being completely inhibited for 2 weeks after treatment.

The lung is an ideal target for in vivo gene therapy because it is a discrete compartment that is directly accessible via the respiratory airways. Though it has been successfully targeted both by the intravenous and intratracheal routes, the latter is undoubtedly the most convenient, and expression of different reporter genes was readily demonstrated, initially by instillation of DOTMA/DOPE-gene complexes, and subsequently using aerosols. A major impetus for these model studies has been the need for a treatment for cystic fibrosis, which is one of the most common lethal hereditary diseases. After initial studies in mice, a placebo-controlled, human clinical trial was carried out using a cystic fibrosis transmembrane conductance regulator (CFTR) plasmid complexed with DC-Chol/DOPE in the form of an aerosol, administered intranasally to CF patients (144). This resulted in a partial restoration of 20% of normal CFTR activity persisting for up to 7 days, and with no evidence of adverse clinical or histological effects. It was concluded that such a result might be an acceptable clinical outcome, though the duration of effect would need to be extended. Similar studies carried out recently, using DOTAP and DC-Chol liposomes, have shown similar clinical results.

Despite the significant progress so far, there is still a long way to go before the ideal vector becomes a reality. Some headway has been made in improving stability within the bloodstream, and Stealth technology might eventually enable ligand-conjugated complexes to be delivered to specific cell types within the body (130). The rate-limiting step of gene transfer from the cell cytoplasm to the nucleus needs to be solved in order to obtain substantially increased expression levels. Other major goals include the achievement of long-term expression and the ability to regulate transcription of newly introduced genes to permit external control over their expression. Mechanisms for achieving these goals are being developed in the field of viral genetics and may eventually be applied in the liposome field.

Liposomes as Immunological Adjuvants

Immunization against microbial infections and cancer is an attractive alternative to chemotherapy. However, vaccines consisting of attenuated organisms, although efficacious in producing diverse and persistent immune responses by mimicking natural infections usually without the disease, can be potentially unsafe. On the other hand, the extracellular localization of killed virus vaccines and their subsequent phagocytosis by professional antigen presenting cells (APC) or antigen-specific B cells, lead to MHC-II class restricted presentation and to T helper cell and humoral immunity but not to significant cytotoxic T cell (CTL) responses. Moreover, subunit vaccines produced from biological fluids may not be entirely free of infectious agents (145).

New-generation vaccines that are based on recombinantly made subunit and synthetic peptide antigens are usually nonimmunogenic and the need for immunopotentiation is well recognized (146). Although a great variety of structurally unrelated agents (immunological adjuvants) are capable of inducing immune responses to vaccine antigens, most of them are toxic (146). Surprisingly, for over 70 years the only immunological adjuvant licenced for use in humans was, until recently, aluminium salts or hydroxide (alum) (146). Alum, however, is far from ideal, fails to induce cell-mediated immunity and is often unsuitable for a variety of antigens. Twenty years after the discovery of the immunological adjuvant properties of liposomes (72) and a multitude of related animal immunization studies carried out in between (147,148), liposomes as adjuvants have come of age, with the first liposome-based vaccine (Epaxal-Berna; against hepatitis A) (5,149) licensed for use in humans (see Table 3). Epaxal-Berna is based on virosomes produced from the influenza virus (IRIV; immunopotentiating reconstituted influenza virosomes) (149). Vaccines based on novasomes (nonphospholipid biodegradable paucilamellar vesicles formed from single chain amphiphiles with or without other lipids) have also been licensed for the immunization of fowl against Newcastle virus disease and avian rheovirus (5). Other novasome-based (oral) vaccines against bacterial infections are under development (see Table 3) (5).

The way in which liposomes induce immune responses to antigens associated with them is not clear but has been attributed to a depot (slow antigen release) mechanism and the ability of vesicles and antigen content to migrate to regional lymph nodes after local injection (or, when given orally to be endocytozed by M cells which then provide antigen to the lymphoid cells in the Peyer's patches). In the case of liposomes, further improvement of adjuvanticity has been achieved by the use of coadjuvants such as lipopolysaccharide, positively charged lipids, and interleukin-2, and also by ligand-mediated targeting to antigen-presenting cells (147).

The approach adopted for the IRIV vaccines is of particular interest as it has been claimed (149) to combine several components that are known to contribute to immunostimulation and are, at the same time, harmless (e.g., egg PC). Thus, PE serves as a binding site for the hepatitis A virions (HAV). HAV attachment to host cells occurs by binding to the PE regions of their membrane, an appropriate feature of PE for Epaxal-Berna. It is also known to directly stimulate (in the form of liposomes) B cells and to generate antibodies without T-cell help. The inclusion of the influenza virus envelope phospholipids contributes to vesicle stability. Moreover, a key role is played by the haemagglutinin (HA) component: HA (the major antigen of the influenza virus) through its HA_1 epitope containing sialic acid, is expected to mediate IRIV binding to its receptors on macrophages and other antigen-presenting cells and subsequent receptor-mediated endocytosis, thus initiating

a successful immune response. On the other hand, the HA_2 subunit of HA causes fusion of viral and endosomal membranes. The essential feature of IRIVs is that, in addition to the antigen they carry, they are also endowed with the fusion-inducing HA component that, presumably, mediates rapid release of the antigen into the target cell membranes. This proposed (149) mechanism for IRIV adjuvanticity is thought to account for the results obtained with the hepatitis A vaccine and the promising outlook of the trivalent influenza and "combined" or "supercombined" vaccines.

Genetic Immunization

A novel and exciting concept (150) developed recently, namely de novo production of the required vaccine antigen by the host's cells in vivo, promises to revolutionize vaccination, especially where vaccines are either ineffective or unavailable. The concept entails the direct injection of antigen-encoding plasmid DNA which, following its uptake by cells, finds its way to the nucleus where it transfects the cells episomally. Antigen so produced is recognized by the host as foreign and is then subjected to pathways similar to those undergone by the antigens of internalized viruses (but without their disadvantages) leading to protective humoral and cell-mediated immunity.

It was initially observed (151) that intramuscular injection of DNA vaccines leads to such types of immunity as CTL response. This was surprising because antigen presentation requires the function of professional APCs. However, myocytes which were shown to take up the plasmid, albeit only to a small extent and with only a fraction of cells participating in the uptake, are not professional APCs. Although myocytes carry MHC class I molecules and can present endogenously produced viral peptides to the $CD8^+$ cells to induce CTLs, they do so inefficiently as they lack vital costimulatory molecules such as the B7-1 molecule (151). It has thus been difficult to accept that antigen presentation leading to a CTL response occurs via myocytes. Instead, it was reported that CTL responses are, at least in part, the result of transfer of antigenic material between the muscle cells and professional APC. It is also likely that plasmid secreted by the myocytes or as such is taken up directly by APC (including dendritic cells) infiltrating the injection site. Moreover, the extent of DNA degradation by extracellular deoxyribonucleases is unknown but, depending on the time of its residence interstitially, degradation could be considerable. It follows that approaches to protect DNA from the extracellular biological milieu, introduce it into cells more efficiently, or target it to immunologically relevant cells, should contribute to optimal DNA vaccine design (152). One such approach is the use of liposomes.

The interaction of cationic SUV with DNA to form a condensed lipoplex has been discussed in an earlier section ("Cationic Liposomes"). The pathway to transfection is thought to commence with the binding of the positively charged complex to the negatively charged cell membranes followed by endocytosis. This leads to destabilization of the endosomal membrane whereupon, through lateral diffusion of anionic lipids from the cytoplasm-facing endosomal monolayer, DNA is thought to be displaced from the complex and released into the cytosol (153). Intravenous application of the complexes has met with only modest success. Contributing causes include the formation of large aggregates between complexes and anionic plasma proteins leading to the neutralization of the cationic charge and rapid removal of the aggregates by the RES, and hence to reduction or even abolition of transfection activity. So far, results from a few reported studies on genetic immunization with SUV–plasmid DNA complexes have been rather disappointing in that immune responses were either similar to or modestly higher than those achieved with naked DNA (154). Therefore, conventional liposome entrapment procedures may offer an alternative approach.

Liposome-Entrapped DNA. It was recently proposed (155,156) that, as APC are a preferred alternative to muscle cells as targets for DNA vaccine uptake and expression, liposomes would be a suitable means of delivery of entrapped DNA to such cells. Locally injected liposomes are known (147) to be taken up avidly by APC, either after these have infiltrated into the site of injection or else within the lymphatics, and this event has been implicated in their immunoadjuvant activity. Liposomes would also protect their DNA content from deoxyribonuclease attack (152). Because of the structural versatility of the system, its tranfection efficiency could be further improved by the judicious choice of vesicle surface charge, size and lipid composition, or by the coentrapment of cytokine genes and other adjuvants (e.g., immunostimulatory sequences), together with the plasmid vaccine (152).

It has been shown that a variety of plasmid DNAs can be quantitatively entrapped into the aqueous phase of multilamellar liposomes by the mild dehydration-rehydration procedure. Incorporation values were, as expected, higher (57–90% of the amount used; about 10–500 μg) when a cationic lipid was present in the bilayers (152). The possibility that DNA was not entrapped within the bilayers of cationic liposomes but was rather complexed with their surface was examined by gel electrophoresis of cationic liposomes entrapping the DNA and of similar liposomes complexed with externally added DNA, in the presence of sodium dodecylsulphate (SDS). Whereas most of the complexed DNA was dissociated from the vesicles, presumably because of its displacement by the anionic SDS, there was very little dissociation of the entrapped DNA (157).

Plasmid-containing liposomes were tested in immunization experiments (155) using a plasmid (pRc/CMV HBS) encoding the S region of the hepatitis B surface antigen (HBsAg; subtype ayw). Figure 10 illustrates how mice (Balb/c) injected repeatedly by the intramuscular route with 5 or 10 μg plasmid entrapped in cationic liposomes elicited, at all times tested, much greater (up to 100-fold) antibody (IgG_1) responses against the encoded antigen than animals immunized with the naked DNA. This was also true for IFN-γ and interleukin 4 (IL-4) levels in the spleens of immunized mice (155). In a more recent study, the role of the route of injection of the pRc/CMV HBS plasmid was examined for both humoral and cell-mediated immunity, using Balb/c mice and an outbred strain (T.O.) of the same species. Results (152) comparing responses for

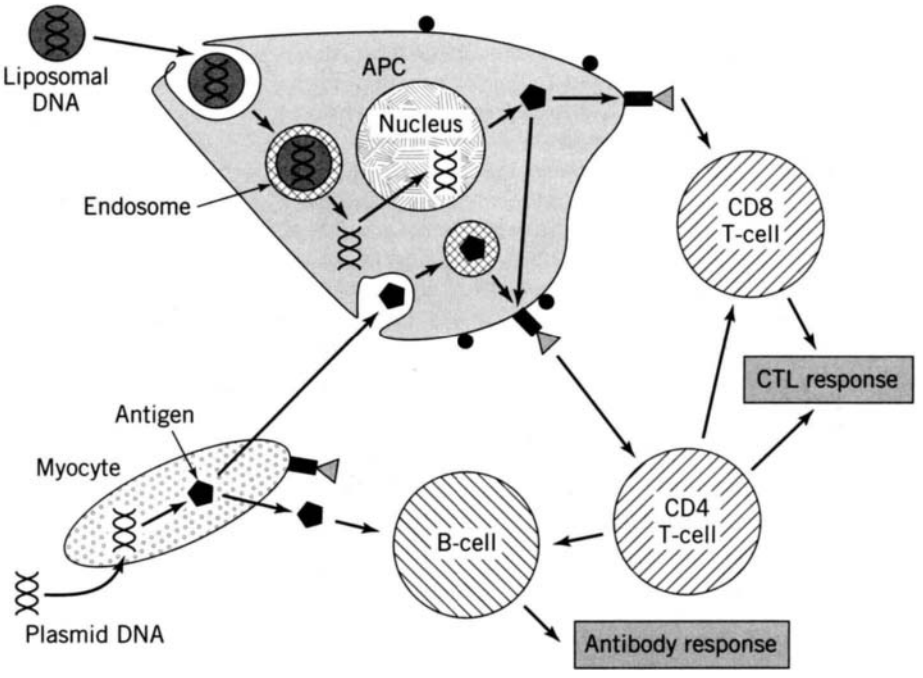

Figure 10. Schematic representation of proposed mechanisms of DNA immunization. Naked plasmid DNA is taken up by a small number of myocytes after intramuscular injection which are then transfected episomally. The produced antigen is released from the cells to interact with APC and thus induce immunity. In contrast, liposomal plasmid DNA interacts with APC directly. The way by which naked DNA enters the muscle cells to localize in the nucleus is unknown at present. For a proposed intracellular pathway of the liposomal DNA, see text. *Source:* Scheme designed by Dr. Yvonne Perrie, Centre for Drug Delivery Research.

liposome-entrapped and naked DNA indicate greater antibody (IgG_1) responses for the former not only by the intramuscular route but also after subcutaneous and intravenous injection. Interestingly, there was not much difference in the titers between the two strains, suggesting that immunization with liposomal pRc/CMV HBS is not MHC restricted. A similar pattern of results was obtained with IFN-γ and IL-4 in the spleen (152). The ability of liposomes to mediate immune responses to entrapped, plasmid encoded antigens has recently been demonstrated with another plasmid encoding the *Mycobacterium leprae* heat shock protein 65 (158).

The way by which liposomal plasmid promotes immunity to the encoded antigen is not likely to involve muscle cells. Although cationic liposomes could in theory bind to the negatively charged myocytes and be taken up by them, protein in the interstitial fluid would neutralize the liposomal surface and thus be expected to interfere with such binding (152). Moreover, vesicle size (about 800 nm average diameter) would render access to the cells difficult if not impossible. It is more likely then that cationic liposomes are endocytosed by APC (see Fig. 10), possibly including dendritic cells. As discussed earlier, it appears that the key ingredient of the DNA liposomal formulations in enhancing immune responses is the cationic lipid. It is conceivable that some of the endocytosed DNA escapes the endocytic vacuoles prior to their fusion with lysosomes to enter the cytosol for eventual episomal transfection and presentation of the encoded antigen. It is perhaps at this stage of intracellular trafficking of DNA, spanning its putative escape from endosomes and access to their nucleus, that the cationic lipid (possibly together within the fusogenic phosphatidylethanolamine component), plays a significant but yet unravelled role (152). However, the question still remains as to why liposome-entrapped DNA is more efficient in inducing immunity to the encoded antigen than complexed DNA.

Other Applications

Various other applications for liposomes have been explored or actively pursued but due to lack of space have not been discussed earlier. Among these, their use as carriers for radioisotopes or contrast agents for use in diagnostic imaging has received considerable attention over many years (159–161). A range of different imaging modalities have been used, the major ones being gamma scintigraphy (γ S), computed tomography (CT), and magnetic resonance (MR), the basis behind all of these being to measure a signal difference between the target (e.g., a tumor) and the surrounding tissues. Carriers such as liposomes are used to amplify the signal differential, i.e., to apply contrast, with the contrast agents used for γ S, CT, and MR being γ-emitting radionuclides, radiopaque materials, and paramagnetic metal ions, respectively. Imaging can be approached either by applying the contrast to the target or to the background, and the best results to date using liposomal systems have used the second approach, based on the fact that tumor cells generally have reduced phagocytic function compared with surrounding tissues. Thus the latter has an increased inclination to accumulate particle (liposome)-associated contrast and tumors register as holes within this background. Caution must be exercised due to the fact that areas of inflammation will also give a positive signal, and in fact good results have been obtained for imaging of arthritic areas. Because liposomes have a natural tendency to be cleared by the RES, they have been widely used for imaging hepatosplenic tumors and metastases and may be the systems of choice for CT and MR imaging in that application (159). However for γ S, they

are not significantly better than conventional colloidal systems, and their main promise is for imaging of non-RES tumors. Application of long-circulating, sterically stabilized liposomes may broaden the scope for tumor imaging due to their increased ability to extravasate from the tumor vasculature, and further developments in targeting will give additional potential. They are also useful for imaging the blood-pool, in order to detect vascular abnormalities such as atherosclerotic lesions, thrombi, tumors, and intravascular shunts (159). Another imaging technique that is giving promising results is ultrasound.

The first, large-scale commercial application for liposomes was in the field of cosmetics, and that industry remains by far the most prolific user, with over 200 different liposome-based products (161). These include a multitude of product types, ranging from humectants and tanning agents to hair restorers and antiaging products. Active components may be in the aqueous phase, including moisturizers, vitamins, plant extracts, and hydrolyzed proteins, or in the membrane bilayer, including lecithin itself, α-tocopherol, retinoids, and carotenoids. In general, intact liposomes do not penetrate beyond the outermost layers of the stratum corneum, though some of their constituents may reach more deeply, by mechanisms which are as yet unclear. Notable exceptions are *transfersomes*, which seem to allow enhanced penetration and have been shown to permit entry of encapsulated peptide drugs into the systemic circulation (162).

It has been suggested that the various aspects of the drug delivery approach, in other words, increased stability of the encapsulant, passive (and active) targeting to different phases, and delayed and/or controlled release, can be used to enhance the activity of functional food ingredients in complex foods (163,164). For example, food enzymes could be used in a more selective and efficient manner, antioxidant vitamins could be used more effectively and various synthetic food additives (e.g., antimicrobial agents) could be replaced by safer naturally occurring ingredients (e.g., nisin or egg white lysozyme). As an illustration, hard cheeses, which can take over a year to ripen, can be produced in a fraction of the normal time using liposome-encapsulated enzymes, with retention of their normal properties and without the damaging consequences of the alternative approaches (165). This could potentially lead to considerable savings in terms of the costs of prolonged, controlled temperature storage and various other risk factors. Unfortunately, raw material and process costs currently outweigh these savings. In addition to the applications already discussed, many others have been developed and undoubtedly many more will emerge in the future. Experience to date suggests that some at least will have a major impact.

INTRODUCTION

Microencapsulation is one of the most intriguing fields in the area of drug delivery systems. It is an interdisciplinary field that requires knowledge of the field of pure polymer science, familiarity with emulsion technology (1), and an in-depth understanding of drug and protein stabilization (2). In the early 1970s this area was considered more of an art than a science because most of the research was developed in pharmaceutical companies and very little information was discussed in scientific meetings. Today, the topic of microencapsulation is extensively studied inside major pharmaceutical companies and universities as well as research institutes. Some journals are now solely dedicated to the area of microencapsulation (e.g., *Journal of Microencapsulation*). Although scientists at the beginning of the 1970s were primarily concerned with the encapsulation of dyes to produce carbonless paper, scientists today have mastered the technology to such a level that cells as well as delicate proteins and genes can be encapsulated. Because two entries in this encyclopedia are dedicated to liposomes and nanoparticles, they are not going to be discussed in this article. In addition, traditional methods such as coating are discussed in a separate article related to coatings. This article is divided into three main sections. In the first section we discuss general aspects of polymer topics related to microencapsulation. Then we describe in more detail the main methods of preparing microcapsules and microspheres, and we end with a general summary of the different fields of application of microencapsulation.

BACKGROUND

Classification of Microencapsulation Techniques

Microencapsulation is a technology devoted to entrapping solids, liquids, or gases inside one or more polymeric coat-

ings (3–43). Two major classes of encapsulation methods have evolved, chemical and physical. The first class of encapsulation involves polymerization during the process of preparing the microcapsules. Examples of this class are usually known by the name of interfacial polymerization or in situ polymerization (44–49). The second type involves the controlled precipitation of a polymeric solution wherein physical changes usually occur. Several books examine the different processes of microencapsulation, and readers are strongly recommended to consult them (2,5,19,30,39, 42,49–58). Perhaps one of the best courses on the fabrication of microcapsules is given at the University of Washington by Dr. Thies.

There are a huge and increasing number of encapsulation processes. In addition, many new patents evolve solely on the basis of novel ways to produce microspheres. Thus, many scientists try to develop a systemic nomenclature for encapsulation classification. In Table 1 we classified the different types of methods according to published literature. It is sometimes difficult to classify encapsulation methods because specific techniques can be hybrids of two or more methods or can use different mechanisms simultaneously. Also, many names have changed throughout the years (e.g., solvent evaporation has been called water drying and double emulsion), and this can create confusion.

Interfacial polymerization involves the condensation of two monomers at the interface of the organic and aqueous phases. Polyamide capsules are a great example of this system and are discussed later in this article (44–48).

Complex coacervation was the process used to make the microcapsules in the first successful encapsulated product, carbonless copy paper (11,14,22,27,29,32,59–66). Complex coacervation encapsulation processes use the interaction of two oppositely charged polyelectrolytes in water to form a polymer-rich coating solution called a coacervate (68). This solution (or coacervate) engulfs the liquid or solid being encapsulated, thereby forming an embryo capsule. Cooling the system causes the coacervate (or coating solution) to gel via network formation. Gelatin is a primary component of most complex coacervation systems.

Coacervation uses the common phenomenon of polymer–polymer incompatibility to form microcapsules. The polymer that is to become the capsule wall material is dissolved in a solvent and to this solution a second polymer (called the phase inducer) is introduced. Because the two polymers are incompatible, two polymer-rich phases form. If drug particles are then introduced, one phase, rich in the desired coating polymer, engulfs the drug being encapsulated thereby forming embryo capsules. In principle, the range of polymers that can be used in this process is essentially infinite. In practice, the number of polymers that have been used successfully is relatively small, for reasons that will be discussed later.

The precipitation and/or gelation processes listed in Table 1 cover many techniques. One example is the precipitation of water-soluble polymers such as gelatin with water-miscible solvents such as isopropanol. Other examples include the precipitation of ethyl cellulose from cyclohexane by cooling, the gelation of sodium alginate with aqueous calcium salt solutions (41,68–74), and the thermally induced precipitation of proteins to form microspheres. In all cases, the objective is to precipitate a preformed polymer around the core (sometimes a multiparticulate core) to cause encapsulation.

Salting-out also listed in Table 1, involves the addition of salt to an aqueous polymer solution ultimately causing the polymer to phase separate from solution. One potential problem with this process is the possibility of incorporating a relatively high concentration of salt in the final capsule wall, as these salts may have an adverse effect on capsule release behavior.

Solvent evaporation (18,36,75–80) is the most popular way to accomplish encapsulation. A core material and capsule wall material are briefly dissolved in a water-immiscible, volatile organic solvent and the resulting solution is emulsified in an aqueous solution. The solvent is allowed to evaporate, thereby producing solid microcapsules or microparticles. Another version involves forming a double emulsion where an aqueous core material solution is emulsified in a polymer–volatile organic solvent solution. The resulting emulsion is emulsified in water giving a double emulsion. Evaporation of the volatile solvent yields a solid microcapsule with an aqueous core. Much of the effort on encapsulation in the pharmaceutical field has concentrated on using biodegradable polymers. A recent review by Brannon-Peppas (43) describes some of these advances with both microparticles and nanoparticles.

Hot melt encapsulation was developed to avoid the use of solvents throughout the process (81). Solvent removal (82,83) was developed as a modification of the solvent evaporation technique, using organic solvents as the extracting medium. In spray-drying, the evaporation of the

Table 1. Classification of Microencapsulation Methods

Process	Coating material	Suspended medium
Interfacial polymerization	Water-soluble and insoluble monomers	Aqueous/organic solvent
Complex coacervation	Water-soluble polyelectrolyte	Water
Coacervation	Hydrophobic polymers	Organic solvent
Thermal denaturation	Proteins	Organic
Salting-out	Water-soluble polymer	Water
Solvent evaporation	Hydrophilic or hydrophobic polymers	Organic or water
Hot melt	Hydrophilic or hydrophobic polymers	Aqueous/organic solvent
Solvent removal	Hydrophilic or hydrophobic polymers	Organic solvents
Spray-drying	Hydrophilic or hydrophobic polymers	Air, nitrogen
Phase separation	Hydrophilic or hydrophobic polymers	Aqueous/organic

solvent is achieved in a special, temperature-controlled cyclone. And finally, phase separation is a new method in which a one-step precipitation of two polymers or more produces double-walled microspheres (84).

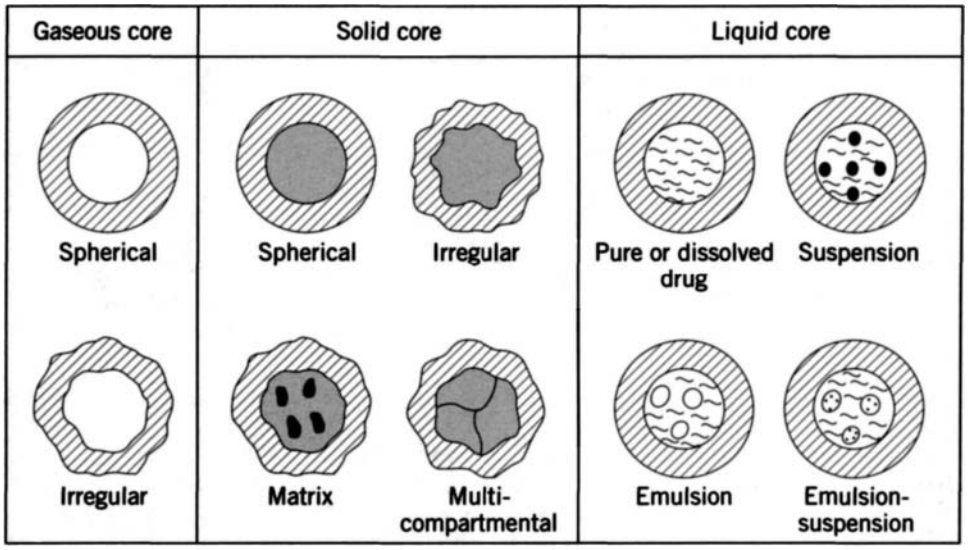
When someone is faced with the challenge of encapsulating a substance, the first question should be, "What is the final application of the product?" As examples, if the final target is pesticide encapsulation, one must first choose polymers that are stable and nonerodible, or if one is to encapsulate therapeutic drugs such as proteins, the choice of polymers becomes more restricted to bioerodible ones. Once the polymer system is chosen, the next step is to select an appropriate encapsulation method. This can undertaken by either reviewing the relevant literature or developing new methods of encapsulation. Once the correct method of encapsulation has been determined the next step is to prepare the microcapsules, ensuring reproducibility, high encapsulation efficiency, and preservation of the activity of the encapsulated substance. This is achieved by thorough characterization, both before and after microsphere fabrication. It is an integral component, necessary for replication and optimization, and is discussed later in this article.

Classification of Microspheres and Microcapsules

Two general structures exist: microcapsules and microspheres. A microcapsule is a system that contains a well-defined core and a well-defined envelope: the core can be solid, liquid, or gas; the envelope is made of a continuous, porous or nonporous, polymeric phase. Figure 1a shows the different microcapsule configurations; the drug can be dispersed inside the microcapsule as solid particulates with regular or irregular shapes. Other forms may consist of a pure or dissolved solution, suspension, emulsion, or a combination of suspension and emulsion. Specific applications sometimes require modifications, e.g., when proteins are encapsulated they may contain stabilizers as well as the active ingredient (2). Also, the core can be something other than a chemical meant for release. An interesting application is the encapsulation of gases for the use of ultrasonic imaging (85–87). Alternatively, a microsphere is a structure made of a continuous phase of one or more miscible polymers in which particulate drug is dispersed, at either the macroscopic (particulates) or molecular (dissolution) level (Fig. 1b). However, the difference between the two systems is the nature of the microsphere matrix, in which no well-defined wall or envelope exists. Different methods of encapsulation result, in most cases, in either a microcapsule or a microsphere. For example, interfacial polymerization almost always produces a microcapsule, whereas solvent evaporation may result in a microsphere or a microcapsule, depending on the amount of loading. Yet, one can use solvent evaporation twice to create a sphere within a sphere, or as we discuss later, novel methods have been designed to use solvent evaporation to create in one step a double-walled microsphere, which is essentially a microcapsule (84).

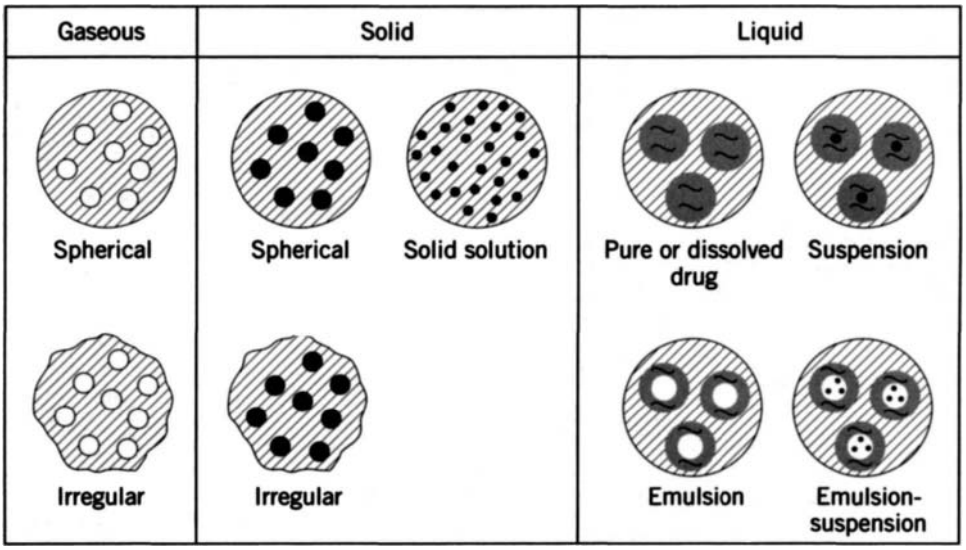
Classification of Polymeric Membranes

Polymeric films and membranes can be classified in various ways. One such classification is based on porosity, with the following categories:



1. Macroporous membranes, which have large pores (0.1–1 μm)
2. Microporous membranes, in which the pores are appreciably smaller (100–500 Å)
3. Nonporous (gel, solution-diffusion) membranes. In the last category the "pores" are of the order of molecular dimensions. They are formed by entanglement and/or cross-linking of the molecular chains and mesh size refers to the space between these chains.

Release Characteristics of Microspheres and Microcapsules



Release of core material from a nonerodible microcapsule can occur in several ways. Figure 2 contains four theoretical curves (A, B, C, and D) that describe four types of release behavior. All curves are plotted as percent drug released versus time. The mathematical descriptions of these release processes have been given (88–90).

Curve A represents the release behavior of a perfect, nonerodible, spherical microcapsule which releases the encapsulated material by steady-state diffusion through a coating of uniform thickness. The rate of release remains constant as long as the internal and external concentrations of core material and the concentration gradient through the membrane are constant. If a finite time is needed to establish the initial, constant concentration gradient in the capsule wall membrane then there is a time lag in core material release. Curve A in Figure 2 displays a system with no time lag. If some of the encapsulated material migrates through the microcapsule membrane during storage, a burst effect occurs, as represented by Curve B. If the microcapsule acts as an inert matrix particle in which core material is dispersed (a microsphere), the Higuchi model is valid up to 60% release (91). In this case, a plot of percent drug released versus square-root time is linear, as shown by Curve C in Figure 2. First-order release is represented by Curve D. The curve is linear if log percent core material left in the capsule is plotted versus time.

Actual capsule release data have been plotted for all of the described ways and analyzed in terms of the appropriate model. Good agreement between actual results and assorted model release curves may exist for some portion of the release curve, but significant deviations occur often, either during initial states of release or after most of the core material carried by a capsule sample has been released. Many capsule samples experience an unusually rapid rate of release when first immersed in an in vitro release medium, i.e., they have a large burst effect. First-order release plots tend to fit a broader range of capsule release data than other plots. It is relevant to note that proper adjustment of the release constant in the first-order release equation can make a first-order release curve approximate, within a few percent, the release curve calculated from the Higuchi equation up to 60% release. If microcapsule release data are linear with square root of time and also fit a first-order release plot, the expression most accurately describing the release behavior can be determined by plotting the total amount of drug released (Q′)

(a)

(b)

Figure 1. Various configurations of (**a**) microcapsules and (**b**) microspheres.

and 1/Q′ versus release rate. For the first-order release, Q′ is directly proportional to release rate whereas for square root of time release, 1/Q′ is directly proportional to release rate.

The desire to fit capsule release data to various models is worthwhile. However, it must be recognized that the actual release kinetics of microcapsules and microspheres can vary greatly from those developed to describe release from macroscopic controlled release delivery devices. Microcapsules are small particles and even small doses contain many microcapsules. The release behavior of a microcapsule formulation is the sum of the release of a population of microcapsules (38,39). This population consists of individual microcapsules that differ from each other in the quality of their walls. Some capsule walls are more permeable than others because of irregularities, which may appear as pits or craters under a scanning electron microscope. Dappert and Thies (38,39,47) discussed the release behavior of microcapsule populations. One capsule population considered contained microcapsules that individually released their contents at a constant rate, but the individual release rate constants fit a log-normal distribution. For such a capsule population, the predicted release curve will approximate first-order release kinetics.

All microcapsule release behaviors reported in the literature represent microcapsule populations and not individual microcapsules. Therefore, the successful replication of microcapsule preparations and confirmation of reproducible release rates is an optimal result. The Lupron Depo™, a product already in the marketplace, demonstrates that these milestones can be achieved. In the following section, we discuss the specific releases as relevant to the specific encapsulation methods.

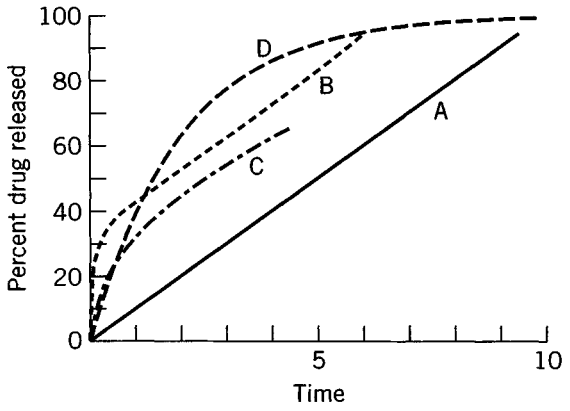


Figure 2. Theoretical release curves expected for different types of nonerodible delivery systems. A, Membrane reservoir-type free of lag time and burst effects; B, same as A, with burst effects; C, matrix or monolithic sphere with square root time-release; D, system with first-order release.

Emulsion Formation

The first step in almost any encapsulation technique (described in Table 1) involves the formation of an emulsion, usually of a polymeric solution inside a continuous phase (1). Similarly, in order to disperse the drug inside this polymeric solution (assuming a nonsoluble drug), emulsions must be created. Thus, an understanding of the properties of emulsions is extremely important. The emulsion formation determines the resulting particle size in the final process of encapsulation. An emulsion is achieved by applying mechanical energy which deforms the interface between the two phases to such an extent that droplets form. These droplets are typically large and are subsequently disrupted or broken up into smaller ones. The ability to disrupt the larger droplets is a critical step in emulsification and in encapsulation where an emulsion is prepared. When considering dyes as the main encapsulate, the problems involved at this stage can be minor because most dyes are quite stable. However, drugs (e.g., labile proteins) or cells may be destroyed by the application of mechanical shear and, if necessary, preventive measures should be taken to stabilize these, even at this stage of the process.

A suitable surfactant is needed to produce a stable emulsion, a result achieved by lowering the surface tension (γ, usually from 40 to 5 mN/m^{-1}). For pharmaceutical applications surfactants must acceptable for therapeutic use (92).

Many devices have been designed to produce emulsions. Depending on the desired particle size, a range of devices from simple overhead stirrers or impellers to more sophisticated devices such as homogenizers, ultrasonic power generators, or ball and roller mills are available. The following is a list of techniques and equipment used to form emulsions. Also, an excellent reference is Chapter 2 in Becher (1).

1. *Shaking.* Shaking is self-evident but in many encapsulation techniques countertop shakers or agitators are used.
2. *Pipe flow: laminar and turbulent.* Pipe flow may include constriction on the flow baffles on which the liquid can infringe to increase the velocity gradient or turbulence.
3. *Injection.* The dispersed phase is injected into a continuous phase as a cylindrical jet, where it is broken up into fairly large droplets.
4. *Stirring: simple stirrer, rotor-stator, scraper, and vibrator.* Many types of stirring exist, e.g., for pumps revolution rates up to 300/s. Rotor-stator machines exist in great variety and are described under the name of homogenizers. In the laboratory the name "Ultra Turrax" is often used.
5. *Colloid mill.* This is a rotor-stator device as well, with the exception of having a very narrow slit (e.g., 0.1 mm) and is designed to achieve very high (simple) shear up to $10^7 s^{-1}$.
6. *Ball and roller mills.* These are more suited for disruption of solid particles or very viscous emulsion droplets.
7. *High-pressure homogenizer.* In the homogenizer the liquid is brought under a high pressure p_h (e.g., 10 to 40 MPa) by a positive pump and is forced through a narrow (e.g., 0.1 mm) valve slit; owing to the pressure, the valve opens against a spring. The potential energy is converted into kinetic energy as the liquid obtains a high velocity u ($p_h = _u^2/2$; u is, e.g., 200 m s^{-1}). The kinetic energy is dissipated into heat during passage through the valve. This takes a very short time (0.1 ms); so energy density is very high (up to 10^{12} Wm^{-3}).
8. *Ultrasonic: vibrating knife and magneto-striction.* Ultrasonic waves can be generated in many ways. A common one is the "liquid whistle" or Pohlmann generator. The liquid stream impinges on a knife or blade, which is then brought to vibrate at high frequency (6–40 kHz); the liquid is forced through a narrow slit at speeds over 50 m s^{-1}, which requires a pressure of some 1 MPa or more. Magneto-striction devices often work at a frequency of 20 kHz.
9. *Aerosol to liquid: mechanical and electrical.* One may atomize the dispersed phase in air and let the droplets be taken up by the continuous phase.
10. *Foaming or boiling.* Some oils spread over a water–gas interface. If air is beaten in or the water boiled, the thinly spread oil layer is disrupted, and very small droplets may result. This may happen as an additional mechanism during various stirring operations. Also by steam injection, droplets can be disrupted to very small ones, though at high cost of steam.

Some of the methods are exclusively used in laboratories such as shaking, vibrator stirring, magneto-striction ultrasonic systems, and aerosol to liquid systems. For large-scale production of emulsions, rotor-stator stirring, colloidal mills, and high-pressure homogenizers are most often used, with some newer processes also using ultrasonic techniques.

Evaluation of Emulsions

Three types of characteristics are critical in evaluating an emulsion procedure, each with its own methods of evaluation (1). They can easily be adapted to encapsulation techniques such as solvent evaporation or interfacial polymerization. The parameters that should be studied are:

1. *Emulsion capacity.* The maximum amount of dispersed phase that can be emulsified under specific conditions without causing aggregation.
2. *Emulsion stability.* The amount of phase separation taking place, mostly by the sedimentation rate, which is estimated either under by gravity or by centrifugation. The governing theory is that sedimentation rate depends on droplet size. This relation, however, may not be so simple because sedimentation rate depends on fluctuation of the droplets and their apparent viscosity at very low velocity gradients of the continuous phase. This condition may also be affected by the variables studied, leading to misinterpretation. In microcapsules this first step is important because once the emulsion is stabilized the next step of hardening the capsules follows.
3. *Droplet size.* This may be some kind of average or full distribution. Sometimes the number of drops is determined, or some characteristic, depending on the drop size, such as turbidity under specific conditions. Droplet size distribution may change after emulsification. This can be due to coalescence but it also may be due to isothermal distillation, unless the dispersed phase is completely insoluble in the continuous one. Again, the initial size of the emulsion may differ from the final size of the microspheres or microcapsules.

Determination of droplet size distribution as function of the process and product variables is by far the best method to study emulsification, particularly in microencapsulation where the process does not stop at the point of making the emulsion, but continues to the further steps of formation of hard particles. Particle comparison between the original size of the emulsion and the final size of the microsphere is beneficial.

Phase Properties of Emulsion: Hydrophilic-Lipophile Balance

One of the important parameters in studying emulsions is the selection of a surfactant which satisfactorily emulsifies the different phases. For this, the hydrophilic-liphophile balance (HLB) is a useful index. The concept of HLB in its early stage was qualitative; however, schemes designed to put this concept on a quantitative basis have been advanced and a new method, which takes into consideration the temperature and the kind of oil used, has been introduced. Around 1950 Griffin [see also Schick (93)] found that it was possible to define the polarity for nonionic agents in terms of an empirical quantity which he called the HLB. This is represented by an arbitrary scale, in which the least hydrophilic materials have low HLB numbers and increasing HLB corresponds to increasingly hydrophilic character. Broadly, these HLB numbers can be used to characterize the applicability of particular surfactant. In a given homologous series of surfactants there is a range in which the HLB is optimal for a particular application. Table 2 lists the HLB ranges suitable for various applications.

In many cases the HLB number may be calculated from composition data. For example, for fatty acid esters of many polyhydric alcohols,

$$HLB = 20\left(1 - \frac{S}{A}\right) \tag{1}$$

where S is the saponification number of the ester and A is the acid number of the fatty acid. In another example, for glyceryl monostearate, $S = 161$ and $A = 198$; hence, its HLB is 3.8.

For some fatty acid esters it is not practical to obtain good saponification-number data, e.g., esters of tall oil and rosin, beeswax, and lanolin fatty acids. However, for these, the HLB may be calculated from the relation

$$HLB = \frac{E + P}{5} \tag{2}$$

where E is the weight percent of oxyethylene content and P is the weight percent of polyol content.

For materials where only ethylene oxide is used to produce the hydrophilic moiety, e.g., fatty-alcohol ethylene oxide adducts, this equation reduces to

$$HLB = E/5 \tag{3}$$

where E has the same meaning as above.

The use of weight percent in these equations is quite significant, because a better dependence of micellar properties on chain length is found when this quantity is used rather than the ethylene oxide mole ratio.

Davies devised a method for calculating HLB numbers for surfactants directly from their formulae using empirically derived group numbers. Thus, a group number is assigned to various component groups in emulsifiers, e.g., CH_3-CH_2-COO-, -CH_2CH_2O, etc., and the HLB is then calculated from the following relation (94):

$$HLB = 7 + \Sigma(\text{hydrophilic group numbers}) - \Sigma(\text{lipophilic group numbers}) \tag{4}$$

For a number of cases, Davies (94) has shown that the HLB numbers calculated from the previous equation and

Table 2. HLB Ranges and Applications

Range	Application
3–6	W/O emulsifier
7–9	Wetting agent
8–15	O/W emulsifier
13–15	Detergent
15–18	Solubilizer

Source: From Ref. 93.

those experimentally determined are in satisfactory agreement. However, this equation contains the implicit assumption that all ethylene oxide groups make the same hydrophilic contribution, which is manifestly incorrect (94), and the equation fails with increasing poly(oxyethylene) content.

Additional techniques can be used to determine HLB. These include water titration, algebraic addition of contribution from various groups making up the chemical structure from spreading, and by measurements of such properties as dielectric constant, and behavior as a substrate in gas-liquid chromatography [see Schick (95), pp. 607–613].

A rough estimate of HLB can frequently be made on the basis of water solubility or dispersibility. Table 3 shows the ranges of HLB numbers indicated by various types of dispersibility. An up-to-date listing of HLB numbers for a large range of emulsifying agents (including a few ionic species) is given in Schick (95).

A valuable attribute of the HLB scale is that the HLB of mixtures of surfactants can be calculated (to a good first approximation, at least) by algebraic addition. For example, a blend containing 4 parts of Span® 20 and 6 parts of Tween® 60 would have an effective HLB of:

$$0.4 \times 8.6 + 0.6 \times 14.9 = 12.3 \qquad (5)$$

It has recently been shown that this algebraic additivity is not strictly obeyed, but the deviation is usually sufficiently small so that the system is insensitive to the discrepancy. In a few cases, the requirements may be more stringent, but this merely requires final adjustment of the composition of the emulsifier.

As a corollary to the previous discussion, each nonaqueous phase to be emulsified has a *required* HLB, which is of course different depending on whether water or oil is to be the continuous phase. The required HLB for a particular oil is usually determined by preparing emulsions over a range of HLB values (obtained, for example, by blending Span® and Tween® emulsifiers in various proportions) and observing the HLB at which maximum stability occurs. A list of required HLB values for a variety of oil phases is given in Table 4.

Using a particular emulsifier pair, the HLB corresponding to maximum stability may result, however, in an emulsion insufficiently stable for the purpose desired. In this case, it may be necessary to examine the effect of the *chemical type* of the emulsifying agent, i.e., substituting an oleate for a stearate, or an ether-type nonionic for an ester.

Table 3. HLB by Dispersibility

In each case, however, the required HLB is equal to (or nearly equal to) the required HLB determined in the initial experiment.

Geiger et al. (96) studied the behavior of a W/O/W multiple emulsion formulation as potential controlled delivery system. The authors were interested in understanding the release due to a swelling-breakdown phenomenon. The breakdown was caused by the water flow from the external aqueous phase to the internal aqueous phase. Various experimental analyses, such as granulometry, rheology, and conductimetry, as well as a micropipette aspiration method, were used to study the stability of W/O/W emulsions. The predominant role of the lipophilic surfactant during the swelling phase was confirmed. Two different mechanisms were proposed and both imply that the migration of the lipophilic surfactant from one interface to another takes place successively. The lipophilic surfactant could diffuse from the first to the second interface, thus rigidifying the membrane, or from the oily phase to the first interface, resulting in delayed coalescence of the aqueous droplets during swelling. Thus, the more lipophilic the surfactant, the more the oil globule capacity increases and the more the release is delayed.

Polymer Characterization

A broad range of polymers can be used to form microcapsules. However the list of polymers approved for used in

oral and/or parenteral drug formulations is limited. This list includes proteins, polysaccharides, cellulose derivatives, synthetic polyesters developed as synthetic suture materials, polyanhydrides, and polyphosphazene. Characterization data for candidate polymer wall materials can play an important role in the development of a successful and reproducible encapsulation procedure. Thus, considerable attention should be paid to obtaining meaningful characterization data for polymer samples being used to form microcapsules. All the physical properties allow better fit of individual polymers to the correct encapsulation techniques. For example, it is not recommended to use polyanhydrides in solvent evaporation because the polymer may degrade during the process of encapsulation. Once the microcapsules are made, a new series of characterizations are required because morphological changes occur during encapsulation.

Phase Separation of Polymers

A wide range of polymer phase separation can be used to encapsulate materials: interfacial coacervation, binary polymer/solvent systems, polymer/solvent/nonsolvent systems, polymer/polymer/solvent systems, complex coacervation, and salting-out.

All these processes provide a way to surround each discrete internal phase droplet or particle of drug with homogeneous and reliably concentrated polymeric layers which can be later solidified in some manner to form a stable capsule. Thus, the next section addresses the general concepts of phase separation relevant to microencapsulation.

Interfacial Coacervation. The first example of a suitable phase separation process is the case of polymer adsorption, which Chang (49) has used to prepare small capsules. In this process, polymer dissolved in an organic phase migrates to the water–organic liquid interface where it precipitates spontaneously from solution to form a membrane. Chang calls this interfacial coacervation. Phase separation occurs spontaneously. An example of this process is the emulsification of an aqueous protein solution in diethyl ether using an oil-soluble nonionic surfactant. Span® 85, sorbitan trioleate, is preferred because it does not denature the protein. Chang used collodian nitrocellulose as the wall structure.

The emulsification process gives microcapsules that can be separated from much of the ether suspending medium and resuspended in *n*-butyl benzoate. *n*-Butybenzoate was selected because it is a poor solvent for collodian, a water-immiscible solvent, and a solvent with a density of 1.0. The suspension is left uncovered in order to allow evaporation of ether.

Chang often uses collodian (i.e., nitrocellulose) as the wall material, but stresses that microcapsules (or membranes) also can be formed in interfacial coacervation or precipitation of other polymers using different solvents (e.g., polystyrene in benzene). The success of this procedure depends on having a sufficiently high initial protein concentration in the aqueous phase. Microencapsulation usually is not possible with a very dilute solution of protein. Nothing more was noted about the mechanism whereby the protein (and probably the emulsifying agent in the system) influences the oil/water interfacial tension ($\gamma_{o/w}$) or how changes in $\gamma_{o/w}$ influences precipitation of the oil phases' polymer.

Phase Separation in Binary Polymer/Solvent Systems. The most conventional phase equilibria involving nonionic polymers dissolved in organic solvents have been discussed extensively by Flory (97). Flory's book focused on systems where all phases formed are completely liquid in nature and several systems of this nature play a key role in microencapsulation. The simplest case is of a binary system containing polymer and solvent. Figure 3 is a phase diagram of this system. Temperature changes alone are used to induce phase separation. Assuming a monodisperse polymer, phase separation is characterized by formation of two distinct phases, one rich in polymer and the other containing little polymer. Under equilibrium conditions, chemical potentials of the solvent (μ_1) and polymer (μ_2) in Phase I equals that in Phase II (i.e., $\mu_1^{I} = \mu_1^{II}$; $\mu_2^{I} = \mu_2^{II}$). Furthermore, at some critical temperature (T_c), incipient phase separation will take place:

$$\left(\frac{\partial^2 \mu_1}{\partial v_2^2}\right)_{T,P} = 0; \left(\frac{\partial \mu_1}{\partial v_2}\right)_{T,P} = 0 \tag{6}$$

and from these relations it can be shown that:

$$v_{2C} = \frac{1}{1 + \sqrt{X}}; \; X_{1C} = \frac{1}{2} + \frac{1}{\sqrt{X}} \tag{7}$$

where v_2 = volume fraction of polymer, v_{2C} = critical volume fraction of polymer, X = number of segments in a given polymer molecule, and X_{1C} = critical value of polymer–solvent interaction free energy. For this simplest case, theoretical binodials can be calculated and compared with experimental values. Such binodials have some important features. First, v_{2C} is predicted to be small, and this is confirmed by experimentation. In addition, at temperatures well below T_c, the dilute phase may retain an unappreciable amount of solute (especially true at higher

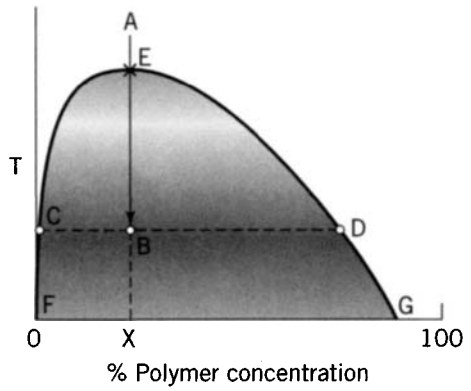

Figure 3. Phase separation in a two-phase system (polymer/solvent) induced by temperature.

M_w values). However, even the so-called concentrated phase contains a large amount of solvent which means that the system is still liquid in nature and thus could flow and engulf the core.

Thus, lowering the temperature (T) of a polymer–solvent mixture at constant v_2 and M_w often is a simple method of inducing phase separation and thereby obtaining a "polymer-rich" phase which can form a capsule wall. This could, in principle, be accomplished at constant T and v_2 by increasing M_w (i.e., continuing polymerization of the polymer). Alternately, at constant T and M_w, v_2 could be varied. Of course, if encapsulation is to occur, the polymer-rich phase must engulf at the internal phase. That is, formation of a concentrated polymer-rich phase having a low total volume does not necessarily mean adsorption and encapsulation occurs. Adsorption of this polymer-rich phase is a prerequisite for wall deposition (see next section) and may not be achieved in many cases.

Phase Separation in Polymer/Solvent/Nonsolvent Systems. A second method to produce phase separation involves addition of nonsolvent to a polymer–solvent system (Fig. 4). In such a case one moves from a two- to a three-component system (polymer/solvent/nonsolvent), thereby grossly complicating theoretical calculations. Nevertheless, it still is true that at equilibrium, chemical potentials of each component must be equal in the two phases:

$$\mu_1^{I} = \mu_1^{II}; \mu_2^{I} = \mu_2^{II}; = \mu_3^{II} \qquad (8)$$

where subscripts 1, 2, and 3 refer to nonsolvent, solvent, and polymer, respectively. If it is assumed:

$$V_1 = V_2; X_{23} = 0; X_{12} = X_{13} = 1.5 \qquad (9)$$

(V_1 = molar volume solvent; V_2 = molar volume nonsolvent; X_{23} = polymer–solvent interaction free energy; X_{12} = solvent–nonsolvent interaction free energy; and X_{13} = polymer–nonsolvent interaction free energy), a special case which can be solved is obtained and theoretical binodials can be calculated. Binodials calculated in this manner have critical points which occur at low polymer concentrations. This concentration decreases as M_w increases. As the binodial merges with the solvent–nonsolvent axis, at point D in Figure 4, the polymer concentration in the dilute phase becomes negligible (i.e., approaches zero) if the nonsolvent just slightly exceeds that required at the critical point. Thus, a two-phase system is formed with one phase relatively rich in polymer and the other containing relatively little polymer and mostly solvent. Provided the polymer molecules in the polymer-rich phase adsorb at the internal phase–solution interface, encapsulation occurs. A possible problem with systems of this type is that the nonsolvent could be of such a nature that it is preferentially absorbed by the internal phase and thereby prevents encapsulation even though phase separation occurs. An additional important point is that a mixed solvent system usually cannot be treated like a single solvent system. Generally speaking, the nonsolvent–solvent ratios differ markedly for the two phases in equilibrium whose compositions are indicated by the ends of the tie line. Only if $\mu_{12} \cong \mu_{23}$ will the solvent compositions in each phase be similar (they are equal if $\mu_{13} = \mu_{23}$). A large difference between μ_{13} and μ_{23} favors absorption of the better solvent in the polymer-rich phase and this undoubtedly contributes to serious aggregation problems when efforts are made to prepare microcapsules by encapsulation processes involving polymer solvent–nonsolvent mixtures.

Phase Separation in Polymer/Polymer/Solvent System. A third type of phase separation occurs in systems containing mixtures of two chemically different polymers, as seen in Figure 5. In such cases, formation of true polymer-in-polymer solutions is rarely observed. This is particularly true for polymer mixtures free of solvent. In the presence of solvent, two phases are generally formed under all but dilute solution conditions. The inability of two polymers to mix has led to the general rule of polymer–polymer incompatibility. This incompatibility has proved to be a problem in many cases where homogeneous mixtures of two poly-

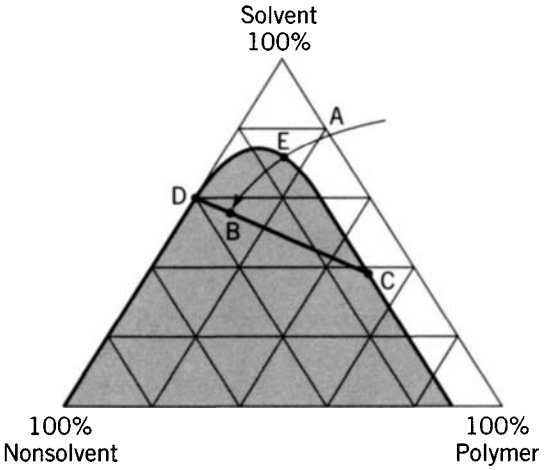

Figure 4. Phase separation diagram for a polymer/solvent/nonsolvent system.

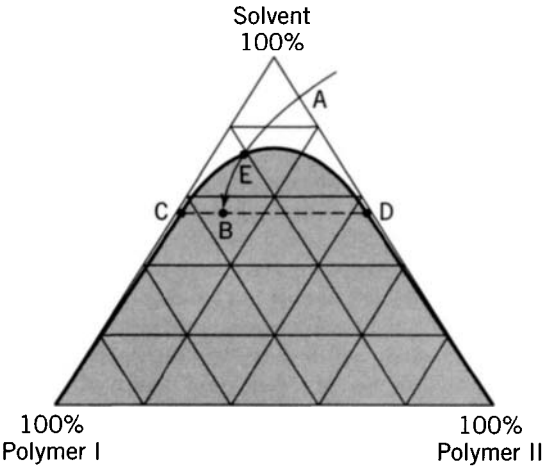

Figure 5. Phase separation diagram for a polymer/polymer/solvent system.

mers are desired (e.g., polymer blends, cases of plasticization), but it is a very important phenomena for use as an encapsulation technique; particularly, our group has used it to make double-walled microspheres in one step (84).

Polymer–polymer incompatibility is a widely encountered phenomenon because the free energy change occurring when the two polymers are mixed is generally >0. The free energy of mixing (ΔG_m) can be described by:

$$\Delta G_m = \Delta H_m - T\Delta S_m \quad (10)$$

For two polymers: ΔS_m is small.

ΔH_m generally is >0 (i.e., endothermic mixing). ΔS_m is so small that even if the heat of mixing (per segment) is just greater than zero, polymer–polymer incompatibility would occur. Thus, the widespread nature of incompatibility is attributable to the small contribution of the ΔS_m term and the tendency for polymer–polymer mixing processes to be endothermic in nature (i.e., $\Delta H_m > 0$).

It was originally predicted that polymer–polymer incompatibility is not influenced by the solvent used. That is, polymer pairs incompatible in one solvent are incompatible in all solvents. This often has been found to be the case, provided that the same molecular weight of polymer is used, but exceptions do exist. Theoretical phase diagrams developed for specific monodisperse model systems also revealed that polymer/polymer/solvent phase separations are characterized by formation of two phases, each of which contains essentially only one of the two polymers involved. Figure 5 is a phase diagram of such a system. The higher the M_w, the sharper the separation of the two polymers. These features have been confirmed experimentally by numerous workers and by our group. The actual phase separation process is influenced by such factors as solvent, temperature, nature of the two polymers involved, and their initial concentrations and the molecular weights. Complete separation of two polymers is not always achieved by polymer–polymer incompatibility. In most cases of encapsulation by phase separation, the low molecular weight polymers commonly used to induce phase separation become entrapped in the microcapsule wall, thereby affecting properties of the wall. Our experience with polymers such as polylactide and polystyrene with M_w in the range of 20,000 to 50,000 always showed complete solubility of 15% W/W, where used with polymer ratios of 1:1.

The importance of polymer–polymer phase separation in encapsulation is its capability to consistently form a distinct, relatively concentrated polymer phase which, if the polymer is adsorbed by the internal drug phase, readily wraps it completely thereby forming a capsule.

These methods are theoretically applicable to encapsulation of both water-soluble and water-insoluble substances. However, when water-insoluble solids or liquids must be encapsulated, an additional useful form of polymer phase separation phenomena is encountered, complex coacervation.

Complex Coacervation. Complex coacervation is the spontaneous liquid–liquid phase separation that frequently occurs when solutions of oppositely charged polyelectrolytes are mixed in the same solvent (usually water). It is encountered in biological systems and differs fundamentally from the polymer–polymer incompatibility mentioned earlier in that one phase contains most of the two polymers whereas the second phase is a dilute polymer solution. Figure 6, a phase diagram for the gelatin–gum arabic–water complex coacervation system, illustrates this point. Polymer–polymer incompatibility yields two phases with each containing predominately one of the two polymers.

Significantly, complex coacervation is truly a complex phenomenon. Polyelectrolytes useful for coacervation come in all shapes and forms with varying numbers and types of charged sites distributed along the polymer chains. The polyelectrolytes may have charged sites that are fully ionized at all pH values (e.g., SO_3) or sites where the group is weakly ionized (e.g., COOH), and the degree of ionization varies strongly with pH. Both positively and negatively charged sites can be on the same molecule (polyampholytes). Furthermore, many useful polyelectrolytes are natural gums, biopolymers, etc., and they often (usually) have complex structures which are not fully resolved. These factors grossly complicate matters, especially when rigorous analyses of such processes are desired.

The best known example of complex coacervation is the gelatin-gum arabic (GGA) system studied by Bungenberg de Jong and co-workers (57). Additional studies by Veis (98) have shown that the interaction of two gelatins of differing ionic points (pI = 5.0 and pI = 9.0) also provides an example of complex coacervation. Each polymer pair (under proper pH conditions) interacts to form a complex which appears as a concentrated, separated phase (i.e., coacervate). Temperatures of 40°C are used in order to obtain the so-called coacervate in a liquid state. These complexes are not the precipitated complexes formed by interacting oppositely charged polyelectrolytes of high charge density. For proper encapsulation, it is preferred to have liquid coacervates which can flow around or completely wrap the internal phase particles or droplets. Of course, the coacervate must wet the internal phase (i.e., be adsorbed by it) if it is to form the capsule wall. As mentioned before, a key

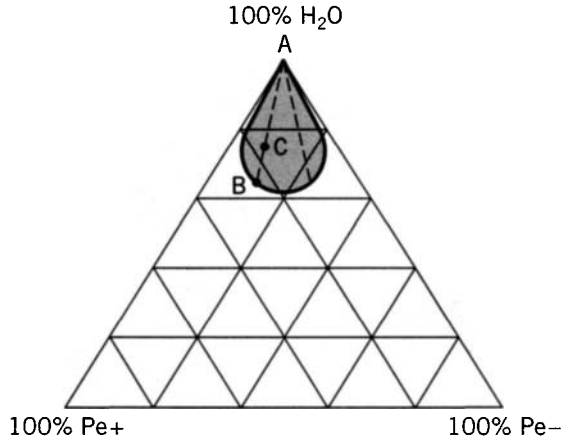

Figure 6. Phase separation diagram for a polyelectrolyte system.

feature of complex coacervation is that the supernatant or equilibrium liquid formed is a dilute polymer solution, whereas the coacervate is a polymer-rich phase (11–15% solids) containing both polymers.

Two factors which affect complex coacervation are pH and neutral salt ions. Because the ionic charge on gelatin and gum arabic varies with pH, coacervation of these species is sensitive to pH. Bungenberg de Jong (67) found that coacervation of alkali-precursor gelatin (pI = 4.8) and gum arabic occurred only between pH 2.0 and 4.8. At pHs outside this range no coacervate formed due to an imbalance in electrostatic charges. Neutral salt ions decrease the coacervation tendency of two polymers. This is attributed to the ability of such ions to screen the charged sites on the polyions involved and thereby reduce their mutual attraction. For example, Bungenberg de Jong (67) reported that 0.02M $CaCl_2$ or 0.035M KCl completely reverses coacervation of gelatin and gum arabic at 40°C. Suppression by salts is stronger the higher the valence of the added ion. Coacervation tendencies of gelatin and gum arabic also decrease with increasing initial concentrations of these polyions. Such self-suppression of coacervation has been attributed to an increase in ionic strength of the system due to increased diffusible microion concentration. Veis (98) reports that the volume of coacervate and fraction of gelatin in the coacervate decreases uniformly with increasing concentration of gelatin for coacervate systems consisting of two isoionic gelatins. The process of coacervation was first treated theoretically by Overbeek and Voorn (99) and later by Veis (98).

Interfacial Phenomenon

Adsorption of polymers on the core phase is a key step in encapsulation processes based on polymer phase separation phenomena. Thus we discuss were the surface free energy (γ, dynes/cm or ergs/cm^2) effects that occur in such processes.

Consider a case in which a droplet of liquid core material (representing the active drug) is engulfed by a liquid phase rich in polymer (i.e., the coacervate phase). Figure 7 is a schematic diagram of the process. Phase 1 is the drop of core material being engulfed, Phase 3 is the coacervate phase that is engulfing the core material, and Phase 2 is the continuous (or supernatant) phase in which Phases 1 and 3 are dispersed. If Phase 1 is designated such that $\gamma_{12} > \gamma_{23}$, the free energy change (ΔG_3) that occurs when Phase 3 spreads over Phase 1 is:

$$\begin{aligned} \Delta G_3 &= G_{\text{after}} - G_{\text{before}} \\ \Delta G3 &= \gamma_{13} + \gamma_{32} - \gamma_{12} \end{aligned} \tag{11}$$

Because the spreading coefficient S_3 is defined as $-\Delta G_3$:

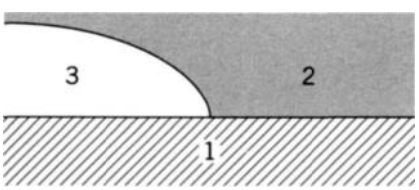

Figure 7. Schematic presentation of a three-phase system.

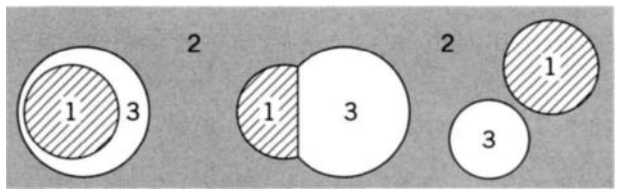
$$S_3 = -\Delta G_3 = \gamma_{12} - (\gamma_{12} + \gamma_{32}) \tag{12}$$

Because the core material, coacervate, and supernatant form a three-phase system, the spreading of Phase 1 over Phase 2 and the spreading of Phase 2 over Phase 1 must also be considered. The surface free energy change that occurs on spreading of Phase 1 over Phase 2 is given by:

$$\begin{aligned} \Delta G_1 &= G_{\text{after}} - G_{\text{before}} = \gamma_{12} + \gamma_{13} - \gamma_{23} \\ S_1 &= -\Delta_1 = \gamma_{23} - (\gamma_{12} + \gamma_{13}) \end{aligned} \tag{13}$$

The surface free energy change that occurs on spreading, of Phase 2 over Phase 1 is given by:

$$\begin{aligned} \Delta G_2 &= G_{\text{after}} - G_{\text{before}} = \gamma_{12} + \gamma_{23} - \gamma_{13} \\ S_2 &= -\Delta G_2 = \gamma_{13} - (\gamma_{12} + \gamma_{23}) \end{aligned} \tag{14}$$



Therefore, three spreading coefficients (S_1, S_2, and S_3) describe the equilibrium state of a three-phase system. The three S values can have three sets of values (100):

$$\begin{aligned} S_1 < 0,\ S_2 < 0,\ S_3 > 0;\ S_1 < 0,\ S_2 < 0,\ S_3 \\ < 0;\ S_1 < 0,\ S_2 > 0,\ S_3 < 0 \end{aligned} \tag{15}$$

Figure 8 shows the equilibrium configurations that results for each of the above three sets of S values. Of greatest significance to capsule-makers is that complete engulfing of core material by the coacervate occurs only when $S_1 < 0$, $S_2 < 0$, $S_3 > 0$, that is, one must have:

$$\begin{aligned} S_1 < 0 &= \gamma_{23} - (\gamma_{12} - \gamma_{13}) \\ S_2 < 0 &= \gamma_{13} - (\gamma_{12} + \gamma_{23}) \\ S_3 > 0 &= \gamma_{12} - (\gamma_{13} + \gamma_{32}) \end{aligned} \tag{16}$$

In encapsulation systems involving polymer phase separation (coacervation), γ_{23} usually is >0.2 dyne/cm. Because γ_{23} is so small, it is reasonable to assume that $\gamma_{23} \approx 0$. If this is done, and $\gamma_{12} > \gamma_{13}$, S_3 is > 0, S_1 is <0, and S_2 is <0. Thus, microcapsules form spontaneously. This is an assumption, and this may be part of the reason why methods such as coacervation may fail to produce microspheres.

(a) Complete engulfing	(b) Partial engulfing	(c) No engulfing
$S_1 < 0$	$S_1 < 0$	$S_1 < 0$
$S_2 < 0$	$S_2 < 0$	$S_2 > 0$
$S_3 > 0$	$S_3 < 0$	$S_3 < 0$

But the new method to make double-walled microspheres are more useful.

SOLVENT EVAPORATION

One of the oldest and most widely used methods of microsphere preparation is the solvent evaporation technique (18,36,75–80,101). This method yields drug-loaded polymer particles that could be called microspheres when drug loading is low or microcapsules when the drug loading is high.

The solvent evaporation encapsulation process, depicted in Figure 9, is a way of precipitating small polymer particles from an oil-in-water emulsion. The polymer is dissolved in a volatile organic solvent that is immiscible with water. Methylene chloride is a preferred solvent because of its high volatility (boiling point [bp] 41°C) and its capacity for dissolving a broad range of polymers. Table 5 lists a number of solvents that can be used and, it should be noted that, many solvents suitable for this process have a finite degree of water solubility, even though they are normally classified as water-insoluble solvents. Mixed solvents can also be used. The mixtures used so far tend to contain a water-immiscible solvent (e.g., CH_2CI_2) and a water-miscible solvent (e.g., acetone). The water-immiscible solvent is the predominant component of the mixture.

Once the desired coating polymer is dissolved in the organic solvent, the drug to be encapsulated is added to this solution. The drug agent may be a solid (crystalline or amorphous) or a nonvolatile liquid. The added drug may completely dissolve in the polymer solution or it may be completely insoluble and simply form a dispersion, suspension, or suspension-emulsion. In the latter case, the solid particles must be micronized so that their mean diameter is much less than the desired mean microsphere size. This is true for any encapsulation technique, and generally, a particle size/microsphere size ratio of 1:10 or less is preferred. The solubility of the drug in the organic solvent is also a major factor in determining the morphology of microspheres produced by the solvent evaporation process and the final state of the polymer itself (crystalline or amorphous).

The drug/polymer/solvent mixture (i.e., the oil phase) is emulsified in water to form an oil-in-water emulsion. The size of the oil phase droplets obtained is determined by how rapidly the system is agitated when the oil phase is added to the aqueous phase, and determines the size of the microspheres produced. Emulsification is carried out in a blender if small microspheres are desired (<20 μm) or with a suspended agitator for larger microspheres. In order to aid emulsification, a surfactant is normally dissolved in the water phase before the oil-in-water emulsion is formed. A good example is partially hydrolyzed (88%) poly(vinyl alcohol) (PVA).

Once the desired oil phase droplet size and emulsion stability have been obtained the system is stirred at a constant rate and the solvent evaporates. This is the basis of the name, because most of the solvent disappears by evaporation. Evaporation can occur in an open system at reduced pressure and range of evaporation temperatures can be used. Once solvent evaporation appears to be complete, the capsules are separated from the suspending medium by filtration, washed, and dried. The maximum drying temperature must remain below the glass-transition temperature of the polymer encapsulant or the microspheres fuse together. Although most of the process depends on evaporation, some of the solvent may diffuse into the aqueous solution and then evaporate. The amount that diffuses into the aqueous solution directly depends on the solubility of the organic solvent in water.

The solvent evaporation process is conceptually simple, but a large number of process variables exist which can profoundly affect the nature of the product obtained. Table 6 lists a number of such variables. How each of these variables influences a given system must be determined experimentally, although some general trends are known. For example, semicrystalline polymers often give porous structures with spherulites on the surface of the microspheres. Uniform, pore-free spheres are most readily obtained with amorphous polymers. If a polymer is not soluble in a single solvent, mixed solvents can be used (e.g., CH_2Cl_2/ethanol or CH_2Cl_2/acetone mixtures).

One requirement of the solvent evaporation process is that the active agent (i.e., drug) partition favorably into the oil phase. This partitioning is favored by using active

But the new method to make double-walled microspheres are more useful.

SOLVENT EVAPORATION

One of the oldest and most widely used methods of microsphere preparation is the solvent evaporation technique (18,36,75–80,101). This method yields drug-loaded polymer particles that could be called microspheres when drug loading is low or microcapsules when the drug loading is high.

The solvent evaporation encapsulation process, depicted in Figure 9, is a way of precipitating small polymer particles from an oil-in-water emulsion. The polymer is dissolved in a volatile organic solvent that is immiscible with water. Methylene chloride is a preferred solvent because of its high volatility (boiling point [bp] 41°C) and its capacity for dissolving a broad range of polymers. Table 5 lists a number of solvents that can be used and, it should be noted that, many solvents suitable for this process have a finite degree of water solubility, even though they are normally classified as water-insoluble solvents. Mixed solvents can also be used. The mixtures used so far tend to contain a water-immiscible solvent (e.g., CH_2CI_2) and a water-miscible solvent (e.g., acetone). The water-immiscible solvent is the predominant component of the mixture.

Once the desired coating polymer is dissolved in the organic solvent, the drug to be encapsulated is added to this solution. The drug agent may be a solid (crystalline or amorphous) or a nonvolatile liquid. The added drug may completely dissolve in the polymer solution or it may be completely insoluble and simply form a dispersion, suspension, or suspension-emulsion. In the latter case, the solid particles must be micronized so that their mean diameter is much less than the desired mean microsphere size. This is true for any encapsulation technique, and generally, a particle size/microsphere size ratio of 1:10 or less is preferred. The solubility of the drug in the organic solvent is also a major factor in determining the morphology of microspheres produced by the solvent evaporation process and the final state of the polymer itself (crystalline or amorphous).

The drug/polymer/solvent mixture (i.e., the oil phase) is emulsified in water to form an oil-in-water emulsion. The size of the oil phase droplets obtained is determined by how rapidly the system is agitated when the oil phase is added to the aqueous phase, and determines the size of the microspheres produced. Emulsification is carried out in a blender if small microspheres are desired (<20 μm) or with a suspended agitator for larger microspheres. In order to aid emulsification, a surfactant is normally dissolved in the water phase before the oil-in-water emulsion is formed. A good example is partially hydrolyzed (88%) poly(vinyl alcohol) (PVA).

Once the desired oil phase droplet size and emulsion stability have been obtained the system is stirred at a constant rate and the solvent evaporates. This is the basis of the name, because most of the solvent disappears by evaporation. Evaporation can occur in an open system at reduced pressure and range of evaporation temperatures can be used. Once solvent evaporation appears to be complete, the capsules are separated from the suspending medium by filtration, washed, and dried. The maximum drying temperature must remain below the glass-transition temperature of the polymer encapsulant or the microspheres fuse together. Although most of the process depends on evaporation, some of the solvent may diffuse into the aqueous solution and then evaporate. The amount that diffuses into the aqueous solution directly depends on the solubility of the organic solvent in water.

The solvent evaporation process is conceptually simple, but a large number of process variables exist which can profoundly affect the nature of the product obtained. Table 6 lists a number of such variables. How each of these variables influences a given system must be determined experimentally, although some general trends are known. For example, semicrystalline polymers often give porous structures with spherulites on the surface of the microspheres. Uniform, pore-free spheres are most readily obtained with amorphous polymers. If a polymer is not soluble in a single solvent, mixed solvents can be used (e.g., CH_2Cl_2/ethanol or CH_2Cl_2/acetone mixtures).

One requirement of the solvent evaporation process is that the active agent (i.e., drug) partition favorably into the oil phase. This partitioning is favored by using active

agents that are insoluble or sparsely soluble in water. Such agents may be insoluble in the organic solvent. In the latter case, the microspheres contain a dispersion of crystals embedded in a polymer matrix. The crystals should be the same ones dispersed initially in the polymer–solvent solution, assuming that there is no partial solubilization and/or recrystallization. If the active agent dissolves completely in the organic solvent phase, it may or may not form crystalline domains in the polymer matrix that makes up the microsphere. For example, microspheres with low active agent payloads (e.g., <20 wt %) have no crystalline domains as determined by differential thermal analysis. At higher payloads, crystallinity appears.

Preventing migration of active agent into the aqueous phase from the solvent phase is often a problem. Crystalline active agents completely soluble in the solvent phase tend to form free crystals in the aqueous phase or on the surface of the microspheres. This effect can be minimized by removing from the system the emulsifier located in the aqueous phase before solvent evaporation is complete. When the emulsifier is left in the system until evaporation is complete, it favors free crystal formation. Thus, by stopping agitation midway through the evaporation process, one can remove the emulsifier by a series of washing and decantation steps. Agitation (and evaporation) is then continued in the presence of emulsifier-free water until solvent loss is complete. This either eliminates or drastically reduces the amount of free crystals formed.

Mathiowitz et al. (55) used this method, with the following modifications, to prepare polyanhydride microspheres. (Please note that this is not a preferred method for polyanhydrides.) Poly(carboxyphenoxypropane-*co*-sebacic-acid) (poly(CPP-SA) 50:50) was dissolved in methylene chloride. Two different polymer concentrations were used (0.05 and 0.20 g/mL). The solution was loaded with drug and suspended in 200 mL of vigorously stirred distilled water containing 1% (w/v) PVA. After 4 hours of mixing, the microspheres were washed with water and dried overnight in a lyophilizer.

Figure 10a is a scanning electron micrograph (SEM) of the external surface of a poly(CPP-SA) 50:50 polymer microsphere containing 5% (W/W) insulin. For this particular formulation the initial polymer concentration was 0.05 g/mL of methylene chloride. The microspheres are spherical in shape and contain some pores on the surface; a cross-sectional view of the microsphere reveals a very porous internal structure (Fig. 10b), which is typical of this particular process. Porosity can be varied by changing the rate of solvent evaporation (via the temperature or stirring rate) as well as the concentration of the initial polymer solution. When the previously described fabrication was repeated with an initial polymer concentration of 0.20 g/mL, polymer in methylene chloride, the resulting microspheres showed a marked drop in porosity (Fig. 10c).

Besides resulting in high microsphere porosity, solvent evaporation also accelerates polymer degradation during the first stages of preparation due to the presence of the water phase. For these reasons, polyanhydride solvent evaporation is not recommended. Other fabrication methods were developed to make slower releasing and longer acting polyanhydride microspheres (see "Hot Melt Microencapsulation" and "Solvent Removal").

The biological activity of insulin released from microspheres was determined in vivo by monitoring daily blood and urine glucose levels in polymer-implanted diabetic female Sprague-Dawley rats. Diabetes was previously induced with a tail vein injection of 65 mg/kg of streptozotocin in pH 4.5, 0.1 M citrate buffer, the optimal dose for inducing diabetes in these rats. When serum glucose levels reached a minimum of 400 mg/dL the rats were considered diabetic and were treated with the insulin-loaded polyanhydride microspheres. Daily urine glucose outputs were estimated with Chemstrips UG. Blood was drawn daily from the tail vein and serum glucose levels were read on a Glucose Analyzer.

Dry microspheres were implanted subcutaneously through a small (1 cm) surgical incision in the skin of the dorsum of the rat and the skin was closed with monofilament nylon sutures. Where indicated, certain microspheres were injected in an aqueous suspension in 0.1 M pH 7.4 phosphate buffer through a 22-gauge needle. Three groups were studied; healthy rats, diabetic control rats, and diabetic rats that were implanted with the drug-loaded spheres. When insulin-loaded (10%), solvent evaporation microspheres were implanted in diabetic rats, the blood glucose level was lowered precipitously for one day, with the majority of the rats dying due to insulin overdose. The porous structure of the spheres presumably allowed water to enter the sphere quickly and led to complete insulin release in a short period of time, which may explain the extremely fast and generally fatal hypoglycemia that was observed. Figure 10d depicts insulin-loaded microspheres that were found in the rat tissue after one day of implantation (note the porous structure of the microsphere). Better results were obtained with microspheres made by hot-melt and solvent removal (see "Hot Melt Microencapsulation" and "Solvent Removal").

Polyester microspheres made by solvent evaporation were reported on extensively in the last 10 years, and the most successful microsphere product that is being used in

humans today is the Lupron Depo™. To understand the development of the Lupron Depo™ it may be interesting to follow some of the procedures described by Okada (102). In the double emulsion technique used, first the drug is dissolved in an aqueous solution. The patent describes how the pH can be adjusted by adding materials such as carbonic acid, acetic acid, oxalic acid, citric acid, tartaric acid, succinic acid, phosphoric acid, sodium or potassium salts, hydrochloric acid, or sodium hydroxide. In addition, agents such as albumin, gelatin, citric acid, ethylenediamine sodium tetraacetate, dextrin, and sodium hydrosulfite could be added as a stabilizer for the water soluble drug. The inner aqueous layer may also contain a preservative such as *p*-oxybenzoic acid esters (e.g., methylparaben, propylparaben, etc.), benzyl alcohol, chlorobutanol, or thimerosal (102).

Once the inner aqueous layer is prepared it is poured into a polymer solution (oil layer) and the mixture is emulsified to give a water-in-oil emulsion (102). The emulsification can be effected by the conventional dispersion techniques, e.g., intermittent shaking, mixing via an impeller, turbine mixer or the like, colloid mill operation, mechanical homogenization, ultrasonication, etc. (102).

When the viscosity of the inner aqueous layer in such a water-in-oil emulsion is greater than about 5,000 centipoises, or preferably greater than 10,000 centipoises from the beginning, the emulsion is immediately subjected to conditions that change the viscosity (102). Increasing the viscosity can be achieved by either heating or cooling. If gum acacia is used, adding metal ions such as iron or copper ion for carboxymethylcellulose, or calcium or magnesium ion for sodium pectinate, are useful (102).

If heating is used, then the procedure must be carried out in a closed vessel to avoid evaporation of the solvent contained in the oil layer. When proteins are used, the temperature used can be from 40 to 120°C for as little as 5 minutes to about 8 hours. This treatment thickens or solidifies the inner aqueous layer (102).

Cooling the emulsion to a low temperature is accomplished at temperatures of −5 to 35°C which are maintained with stirring for 1 minute to 6 hours. In the case of agar whose gelation point is about 40°C, the emulsification is conducted under heating, at about 50 to 80°C, and then caused to gel at the aforementioned temperature. For all types of inner aqueous layers, freezing may be effected by cooling to about −60 to 0°C, but the temperature should not be below the solidification point of the oil layer (102).

This step seems to reduce the amount of drug lost to the aqueous solution. Using gelatin as an example of a drug-retaining substance: a water-in-oil emulsion of predetermined particle size is first prepared and then cooled to about 0–10°C for 5 to 30 minutes with constant stirring, whereby the inner aqueous layer is caused to gel into a semisolid consistency. When agar is used as the drug-retaining substance, the desired semisolid consistency can be obtained by using a lower concentration than in the case of gelatin and the same procedure as that for gelatin. When albumin is employed, solidification is effected with a condensing agent such as glutaraldehyde (102). For large proteins this step is not recommended.

An attempt at developing leuprolide acetate-loaded, injectable microcapsules capable of one-month, zero-order rate delivery was reported by Ogawa et al. (103). A large amount of leuprolide acetate, a hydrophilic drug, was entrapped in poly(lactic acid) (PLA) and poly(lactide-*co*-glycolide) (PLGA) microcapsules prepared by an in-water drying method using a (W/O/W) emulsion. Under the conditions used, it was possible for the drug to be completely entrapped by the microcapsules at a loading of 10 to 20% (W/W). However, the release profiles of the drug in vitro fell short of controlled release for one month.

Leuprolide acetate is a highly potent analog of luteinizing hormone-releasing hormone (LHRH). Okada et al. (105) succeeded in preparing one-month release, injectable microcapsules of leuprolide acetate using poly(DL-lactide-*co*-glycolide) to treat an endocrine-dependent prostate cancer. A single injection of the microcapsules (100 μg/kg/day as leuprolide acetate) suppressed luteinizing hormone (LH), follicle-stimulating hormone (FSH), and estradiol for more than 4 weeks and caused a dramatic regression of growth in the Jones experimental endometriosis model in female rats. These results encouraged scientists to develop a one-month release, parenteral preparation of leuprolide acetate, subsequently used in the therapy of endometriosis in human beings (104).

The drug release profiles of the microcapsules after subcutaneous (s.c.) and intramuscular (i.m.) injection into rats was determined by following the amount of the analog remaining at the incised injection site. The release profiles after s.c. and i.m. injection were almost identical; they provided a pseudo zero-order release for 4 weeks, after a small initial burst. The regression line of the amount remaining, calculated by a least-squares regression analysis, revealed that the rate of release of leuprolide acetate was 2.8% of the dose/day, the initial burst was 17.8%. The correlation coefficient was 0.99. The serum levels of leuprolide acetate in rats after the PLGA microcapsules were injected s.c. showed that the initial burst of the analog was followed by a plateau level for 4 weeks. Administration of the microcapsules to normal female rats resulted in a transient rise and subsequent drastic decrease of serum LH and FSH levels. The decreased serum levels reached minima 2 to 3 weeks after the injection, and were maintained for another 1 to 2 weeks. The estradiol levels reached a minimum 3 weeks after the injection and remained there for another week. Thereafter, the levels of FSH and estradiol recovered gradually and rebounded slightly by 6 or 8 weeks of treatment. In contrast, the suppressed serum levels of LH persisted for 6 weeks. Daily cytological examination of vaginal smears indicated that the estrous cycle had stopped at diestrus in all rats 3 days after the microcapsules were injected, and remained at this stage for 6 weeks. The normal estrous cycle was recovered 8 weeks after the treatment began.

Expected depression in LH, FSH, and estradiol serum levels occurred at doses of more than 100 μg/kg/day. Serum LH levels were decreased already by a dose of 1 to 10 μg/kg/day; the levels were equivalent to those in diestrus rats. At a dose of 100 mg/kg/day, the serum FSH levels were also depressed, and significantly reduced serum levels of estradiol were produced by all doses between 1 to 250 μg/kg/day; the levels at a dose of over 100 μg/kg/day were close to that produced by ovarioectomy.

The infinite area under serum level-time curve in female rats after leuprolide acetate was injected s.c. as a saline solution (100 μg/kg) was 118.8 ng · h/mL, as described previously. The total body clearance (Cl_{tot}) is calculated by:

$$Cl_{tot} = \text{Dose/AUC} = 100 \times 10^3/118.8 = 841.8 \text{ mL/h/kg} \quad (17)$$

The release rate (k) of leuprolide from the microcapsules (TAP-6M), calculated in a similar manner in TAP-3M, was 3.1% of the dose/day, which is equal to:

$$k = 900 \times 10^3\ 0.031/0.305 \times 24 = 3811 \text{ ng/h/kg} \quad (18)$$

where the average body weight during 4 weeks of treatment was 305 g. If the analog is infused at a constant rate (k), the serum drug levels at a steady state (C_{ss}) is given by equation 19.

$$C_{ss} = k/Cl_{tot} = 4.53 \text{ ng/mL} \quad (19)$$

The serum levels estimated using body weight during 4 weeks of treatment as described before are 5.55 ng/mL (body weight, 249 g) to 3.98 ng/mL (body weight, 347 g). The experimental values agreed well with these calculated serum levels at a steady state. The microcapsules eliminated the time lag of the initial drug release and produced a more constant and lasting serum level of the analog throughout the 4 weeks of treatment than did an implantable depot formulation of D-Ser(tBu)-AzaGly LHRH and microcapsules of nafarelin or decapeptyl (104).

Okada et al. (105) worked on developing a more interesting system of Leuprorelin for 3-month delivery. The pharmacological effects of Leuprorelin 3-month depot microspheres were investigated in rats and dogs. After s.c. and i.m. injection, the microspheres provided similar linear drug release and sustained serum drug levels for 3 months. Persistent suppression of serum LH, FSH (in rats) and testosterone (in rats and dogs) for over 16 weeks was achieved when the microspheres were given at a dose of 100 (rat) and 25.6 (dog) μg/kg/day. These hormone release responses, upon periodic challenge tests, revealed that for a single injection of the microspheres over 3 months the strongest suppression was achieved at a dose of 100 μg/kg/

day. This 3-month depot formulation is expected to be more convenient than the 1-month depot with improved patient compliance and therapeutic effects. To obtain a 3-month release injection of leuprolide acetate, microspheres, were prepared with poly(DL-lactide-*co*-/glycolide) (DL-PLGA) or PLA using an in-water drying method, after which drug release was evaluated. The content of water-soluble oligomers in the polymers was found to strongly affect the initial burst, and reducing the content to less than 0.1% was necessary to keep the first-day release below 10%. Drug loading of more than 15% also increased the initial drug release; the acceptable maximum loading was 12%. Elevation of the glass-transition temperature of the microspheres was observed with an increase in drug loading. This suggests formation of a rigid structure, possibly with arrangement of the polymer around the drug cores such as in a micelle. This structure provides a hydrophobic barrier against diffusion of the hydrophilic peptide, resulting in high trapping efficiency and long-term sustained release dependent on polymer erosion. The microspheres prepared with PLA of 12,000 to 18,000 M_w provided linear sustained release and persistent serum levels of the drug in rats for over 3 months (106).

In order to prepare the long-release systems, the microspheres of Leuprorelin were made without the gelatin in the inner drug solution. Briefly, in the case of 12% drug-loaded PLA microspheres, 550 mg of drug dissolved in 1 mL of distilled water (W_1) and 4 g of PLA dissolved in 7.5 mL of CH_2Cl_2 were combined and agitated vigorously with a homogenizer to form a W/O emulsion. This emulsion was poured into 1 L of a 0.25% PVA solution (w_2) under stirring. This $W_1/O/W_2$ emulsion was stirred gently for 3 hours to evaporate the organic solvent, producing microspheres. The microspheres were sieved with a 74-μm screen to remove large particles and then centrifuged at 1,000 rpm for 5 minutes. The resulting microspheres were washed with water and lyophilized. PLGA 75:25 (M_w 9,000–23,000), PLGA 90:10 (M_w 9,200–22,900) and PLA (M_w 4,700–162,100) were used. To determine the effects of drug loading on drug release, microspheres containing 9, 12, 15, and 18% drug were prepared using PLA (M_w 18,200). The volume of the inner water phase and organic solvent and temperature of the W/O emulsion and outer water layer were varied with the kind of polymer and percent drug loading to maintain appropriate viscosity and obtain spherical and similar size microspheres (107).

The results of screening biodegradable polymers, PLA and PLGA, for the 3-month depot formulation indicated that microspheres prepared using PLA with a molecular weight of 12,000 to 18,000 gave linear sustained drug release for over 13 weeks. A similar sustained release pattern was confirmed by serum drug level assays following s.c. injection of these microspheres. The microspheres prepared using PLA (M_w 15,000), containing less than 0.1% water-soluble oligomers and loaded with 12% drug, may be the most desirable formulation for the 3-month depot injection (106).

Analyses of microparticle size and morphology during degradation by Brannon-Peppas et al. (107,108) have shown that the method of incorporating β-estradiol into PLGA microparticles has an effect on drug delivery that may be followed by changes of the microstructure of the particles over time. Nondestructive observation of microparticles during their full degradation has verified the coupling of drug release during early periods of degradation where small changes in the particle structure may be observed. However, it has also been shown that these particles retain their structural integrity and shape for many months in vitro after all drug delivery has been completed.

Schugens et al. (109) studied two semicrystalline poly(L-lactides) with different molecular weights as coating polymers in microencapsulation by the W/O/W double emulsion-evaporation technique. The scientists have shown that crystallizable chains have clearly a deleterious effect on the encapsulation efficiency of indigocarmine and on the internal morphology of microparticles. Moreover, a substantial increase in the molecular weight of poly(L-lactide) (from 60 to 840 kDa) requires dilution of the polymer solution to prevent exceedingly high viscosity and leads to less stable primary emulsions and more porous solid microspheres. Microparticles of semicrystalline poly(L-lactide) have proved unsuitable for the sustained drug release. When poly(DL-lactide) (M_n 50 kDa), was used, more efficient microencapsulation was obtained. This was true particularly when the primary emulsion was stabilized with gelation.

Using a predictive mathematical model from Li et al. (110) several important extrinsic process variables were developed to simulate process dynamics of microsphere formation. These included the composition profile in the dispersed phase, the solvent concentration profile in the continuous phase, and the solvent removal profile in the dispersed phase. This was one of the attempts to move closer to understanding microencapsulation in detail. By superimposing the composition profile in the dispersed phase with the phase transition boundary, the progression of phase transition in microsphere formation was evaluated. The authors found that a low dispersed phase/continuous phase ratio, high continuous phase-addition rate, high temperature, high heating rate, and high initial polymer concentration in the dispersed phase contributed to enhanced solvent removal. The higher solvent removal led to a heterogeneous composition distribution in the dispersed phase and the early crossover of the gelation point (viscous boundary) of the peripheral region which initiates the onset of solidification in this region. These phenomena resulted in an increasing pore size, lower surface area, denser periphery, higher residual solvent, and slower drug release. In addition, the progress toward the glassy boundary may also play a major role in the ultimate solvent residual. Slow solvent removal gave rise to a homogenous distribution of the components in the dispersed phase due to the delay of hardening. The extrinsic manageable parameters could be varied during microsphere formation to obtain the desired rate of solvent removal as well as the desired microsphere properties. The mathematical model was used to simulate such conditions to facilitate the experimental design for the desired microsphere properties.

Poly(L-lactic acid-*co*-L-lysine(Z)) (PLLA) with different Lys(Z) contents was synthesized by Sn(II) salt-catalyzed ring-opening copolymerization of 3(*s*)-benzyloxycarbonylaminobutyl-6(*S*)-methylmorpholine-2,5-dione with lac-

tide. Microcapsules of the copolymers were prepared by solvent evaporation from W/O/W emulsion, and fluorescein isothiocyanate (FITC) dextran release from the microcapsules was investigated. The FITC-dextran release was dependent on the composition and molecular weight of the copolymers. The release from the microcapsules containing Lys(Z) of 6.5 mol% was slowest among the present microcapsules, which is due to smooth surface and very small microcapsules included in a large microcapsule. On the other hand, the release from microcapsules containing Lys(Z) of 31 or 50 mol% became faster after several days of incubation. Gel permeation chromatography measurement of the microcapsules revealed that the copolymers were degraded during the incubation. Cracks and pores were formed on the microcapsule wall. PLLA microcapsules having comparable molecular weight to the copolymers showed neither release acceleration nor degradation in short-time incubation. Therefore, the introduction of Lys(Z) units made PLLA susceptible to degradation to result in delayed acceleration of release (111).

PLA microspheres containing soluble dyes as water-soluble model compounds were prepared using the W/O/W solvent evaporation method. The authors reported that addition of electrolytes such as NaCl or $CaCl_2$ into the external aqueous phase significantly improved brilliant blue (BB) entrapment efficiency compared to the case of no additives (75). NaCl was the most effective for obtaining high entrapment efficiency (80–90% of theoretical BB content). The average diameter of the obtained microspheres was in the region of 10–20 μm in all cases. PLA microspheres containing 5 and 10% (W/W) BB exhibited the so-called burst release. The release rate decreased with decrease in the internal aqueous droplet volume in the preparation process. In particular, with PLA microspheres containing 5% (W/W) BB, those prepared with the smallest internal droplet volume (63 μL), the initial burst release was reduced significantly and 50% (W/W) of the loaded BB remained in the microspheres for 7 days.

Reza and Whateley (112) developed sustained local release systems for iodinated iodo-2′-deoxyuridine (IudR) from biodegradable polymeric microspheres to facilitate the controlled delivery of IudR to brain tumors. The selective uptake of IUdR into the cell nucleus results in cell disruption over the short range of the low energy Auger electrons. The biodegradable microspheres can be precisely implanted in the brain by stereotactic techniques and the IUdR within the microspheres is protected from degradation and thus a sustained source of radiolabeled IUdR is available in the vicinity of the residual tumor cells. PLGA 85:15 microspheres containing cold IUdR and the Auger-electron emitter ^{125}I, as ^{125}IudR were prepared using the O/W, O/O, and W/O/W emulsion-solvent evaporation methods. The W/O/W emulsion method was most effective in achieving good drug loading with the use of bovine plasma in the internal water phase. The use of 20% acetone in the methylene chloride and the presence of Span® 40 in the organic phase improved the drug encapsulation efficiency. Electrolytes (NaCl and IudR) in the external aqueous phase also improved drug loading.

Okumo et al. examined the effects of size, charge, and conformation on the release of peptides from microspheres of DL-PLGA 50:50. These microspheres were prepared using a double emulsion technique and were characterized for size, morphology, and peptide release kinetics. The volume of water used as the internal phase has a significant effect on the release of the linear hexapeptide Ac-Trp-Ala-Gly-Gly-Asp-Ala-NH_2. For example, when no water was added, the release appears to be erosion-controlled. In contrast, when 150, 500, or 1000 μL of water are added, the release shifts to a diffusion-controlled mechanism. Changing the size, charge, and conformational flexibility of the model peptides had no significant effect on their release kinetics. The authors suggest that release kinetics that were observed for the neutral capped amino acid and the positively charged cyclic hexapeptide are due to unique specific interactions between these compounds and DL-PLGA (113).

A new preparation method for multireservoir-type microspheres was investigated on the basis of the phase separation of PLA and PLGA. Matsumoto et al. (114) have found that distinctive phase separation occurred when the total polymer concentration exceeded a critical level. The critical polymer concentration inducing this phase separation was independent of the PLA/PLGA ratio but highly dependent on the lactide/glycolide ratio, solvent, and molecular weight of PLGA. When various amino acid powders were added to the resultant two-phase polymeric solution, each powder seemed to be distributed either to the PLGA-rich phase or to the PLA-rich phase depending on its solubility parameter. When used, cisplatin powder also was completely distributed in the PLGA-rich phase. Using these findings, the preparation of the multireservoir-type microspheres of cisplatin was tried. The PLGA-PLA biphasic polymeric solution dispersing the drug powder was emulsified, and then solidified by the solvent evaporation method. Microscopic observation proved that the obtained microspheres have the unique "polymer alloys" structure, and the drug was distributed in the internal phase (PLGA-rich phase). The encapsulation efficiency was almost 100% at 10% loading. The in vitro dissolution study revealed that the release of cisplatin lasted 45 days without initial burst.

The distribution of a drug substance between two phases is represented as follows:

$$\frac{[X_a]}{[X_b]} = V_s \frac{(\delta_s - \delta_b)^2 - (\delta_a - \delta_s)^2}{2.3RT} \qquad (20)$$

where $[X_a]$ and $[X_b]$ are concentrations of drug substance s in a phase and b phase, respectively; δ_a, δ_b, and δ_s are solubility parameters of a phase, b phase, and substance s, respectively; V_s is the molecular volume of substance s; R is the gas constant; and T is absolute temperature. This equation means that the distribution of substance s varies depending on the solubility parameters of a phase and b phase. In the present situation, however, because substance s always exists as a solid state, V_s is considerably large so that the distribution of substance s favors one side (114).

To examine the applicability of equation 20 to predict the distribution of drug substance in the PLA-PLGA biphasic polymeric solution, 5 amino acids with different solubility parameters were selected as model compounds. If

PLGA and PLA separated completely, solubility parameters of the PLGA phase ($\delta_{PLGA/p}$) and PLA phase ($\delta_{PLA/p}$) were calculated by the following equations:

$$\delta_{PLGA/p} = \delta_{PLGA} + (1 - a)\delta_{solv}$$
$$\delta_{PLA/p} = b\delta_{PLA} + (1 - b)\delta_{solv} \quad (21)$$

where a and b are volume fractions of PLGA and PLA, respectively, δ_{PLGA}, δ_{PLA}, δ_{solv} are solubility parameters of PLGA (11.00), PLA (10.69), and solvent (114).

The authors showed that the distribution of drugs was dependent on the solubility parameter difference; that is, in the case of a positive value, drugs had a tendency to be distributed on the PLGA phase; in the case of a negative value, drugs had a tendency to be distributed on the PLA phase; and when the value was close to zero, drugs had a tendency to be distributed on the interface between PLGA and PLA phase.

An additional drug that was evaluated by Matsumoto et al. was cisplatin, known to be one of the most effective anticancer drugs in chemotherapy. However, due to various side effects (e.g., renal disturbances, nausea, vomiting), a lot of care has been taken in its clinical use. To minimize the side effects and to increase the therapeutic effects, it must be possible to restrict the blood level of the drug to the therapeutic level for a long period of time (114).

Cisplatin was predicted to be distributed in the PLGA phase from its solubility parameter (~12.2). This was proven by the fact that the drug was incorporated in the PLGA-rich phase when cisplatin powder was added to the PLGA-PLA biphasic polymeric solution. The distribution of the drug was highly dependent on the mixing ratio of polymers. When the PLGA/PLA ratio was given as 20:80 or 33:67, cisplatin was partitioned to the inner phase (PLGA-rich phase). On the other hand, when the PLGA ratio increased up to 67 or 80%, due to accompanying the phase inversion, the drug powder was distributed in the continuous phase (114).

Cleland et al. described how the administration of a subunit vaccine (e.g., gp120) for acquired immunodeficiency syndrome (AIDS) can be facilitated by a single shot vaccine that mimics repeated immunizations. To achieve this type of vaccine, they developed PLGA microspheres that provide a pulsatile release of gp120. Studies of a water-in-oil-in-water microencapsulation process with either methylene chloride or ethyl acetate as the polymer solvent revealed that the encapsulation efficiency was greatly enhanced by increasing the kinematic viscosity of the polymer phase via a reduction in temperature (~0°C) and an increase in polymer concentration. Excess methylene chloride (1.5% v/v) in the second emulsion reduced the encapsulation efficiency, whereas excess ethyl acetate (9% v/v) in the second emulsion was necessary for microsphere formation. The optimization of process variables allowed for complete encapsulation of the gp120 (100% efficiency). Drying of the microspheres had a significant impact on the initial emulsion, the density of the inner emulsion water droplets in the microspheres was reduced requiring significant polymer erosion to occur prior to protein release. The protein was released under physiological conditions in two discrete phases: an initial burst released over the first day and after several weeks or months a second burst of protein was released. The second burst of protein was dependent upon the PLGA inherent viscosity and lactide:glycolide ratio (bulk erosion). The initial gp120 released under physiological conditions as well as the gp120 extracted from the microspheres maintained their native conformation, as measured by a variety of physicochemical methods. Thus, PLGA or PLA microsphere formulations were developed to provide a second burst of gp120 to mimic immunizations at 1, 2, 3, or 6 months. A single administration vaccine for gp120 may then include two or more microsphere formulations resuspended with soluble gp120 (primary immunization) to provide three immunizations or more over the course of one year (115).

Sah (117) developed a process in which ethyl acetate was used to prepare DL-PLGA microspheres. They first emulsified a polymer/ethyl acetate solution with a 1% aqueous PVA solution (W_1) to make an oil-in-water (O/W_1) emulsion. The $O:W_1$ phase ratio was carefully chosen so as to saturate the W_1 by a small proportion of the dispersed solvent and to form successfully embryonic microspheres without generating polymer precipitates. The effects of the $O:W_1$ phase ratio on the morphology and size of microspheres were interpreted in terms of the solvent miscibility with water, as well as the influence of the W_1 volume on breakup of the dispersed phase. The extraction rate of ethyl acetate from the nascent microspheres was then adjusted by making use of both its miscibility with water and its volatility at atmospheric pressure. Variation of these parameters made it possible to fabricate hollow or matrix-type microspheres with different size distributions. It was also found that the tendency of microspheres to aggregate on drying was related to the extent of microsphere hydration and the residual ethyl acetate in wet microspheres, which probably decreased the glass transition of the polymer.

The use of methylene chloride may impose a problem in obtaining product approval by regulatory agencies. As evidenced by Lupron Depot, a small amount of methylene chloride remaining in a microsphere product is acceptable by the U.S. FDA, but only if the product's therapeutic benefits clearly outweigh a safety concern over the residual solvent. However, when faced with a microsphere product to be marketed as preventive medicament, such as a vaccine, the regulatory agency may raise a concern over the possible risk that the residual solvent triggers: methylene chloride is a suspected carcinogen and mutagen. In recognition of this issue, a number of investigations have sought safer solvents (Table 7). Among those found, ethyl acetate is considered one of the most preferable solvents (116).

Thompson et al. (117) developed biodegradable controlled release microspheres containing rismorelin porcine, a potent analog of growth hormone-releasing hormone (GHRH), using DL-PLGA in a modified solvent evaporation technique. Rismorelin porcine microspheres were prepared with a modified solvent evaporation technique to reduce water leeching of the peptide. A typical batch of microspheres is 2 g, consisting of polymer and drug. Ten percent weight/weight rismorelin porcine-containing microspheres were fabricated by dissolving 1.8 g of PLGA in 50 mL of methylene chloride. To this polymer

Table 7. News Solvent for Solvent Evaporation Process

Solvent	Preparation method
Acetone	A salting-out procedure using an electrolyte-saturated continuous phase
Ethyl acetate	Rapid freezing of a polymeric phase in a liquefied gas, followed by solvent extraction
Ethyl formate	In situ solidification of polymeric materials due
N-methyl-2-pyrrolidone dimethyl sulfoxide	To dissipation of solvents to external aqueous media
Methylethyl ketone	A solvent extraction technique making use of partial water-miscibility of the solvent
Phthalic acid diethyl ether	Freeze-drying of the polymeric solution by ball milling to produce randomly shaped particles

solution, 200 mg of micronized rismorelin porcine was added, forming a suspension of drug in the polymer solution. The viscosity of this polymer solution/drug suspension was intentionally kept low to aid in the formation of small, spherical microspheres. The suspension was sonicated at room temperature for approximately 1 minute to disperse the micronized rismorelin porcine particles. The polymer solution/drug suspension was emulsified with stirring into 250 mL phosphate-buffered saline (PBS) containing 0.4 w/v % AIRVOL™ PVA as an emulsifier to form an oil-in-water emulsion. Rismorelin porcine is insoluble in PBS and other salt-containing solutions. The partitioning of drug into the aqueous phase did not occur under these conditions. Stirring at 300 rev/min was continued at room temperature for approximately 16 hours to allow complete solubilization and evaporation of methylene chloride. The resulting rismorelin porcine microspheres were recovered using vacuum filtration, washed with PBS, dried under vacuum in a desiccator, and sieved to size using 60 mesh and 120 mesh U.S. Standard sieves (250 μm and 125 μm, respectively). Rismorelin porcine PLA/PGA microspheres with different loading values (5%, 10%, and 25%) were prepared by varying the ratio of drug to polymer in the suspension solution (117). Release rates of rismorelin porcine were characterized in vitro by use of a cell perfusion system and evaluated in vivo in pigs. Rismorelin porcine is 4-methylhippuroyl (1) porcine GHRH (2-76)-OH, which is a potent analog of a natural porcine GHRH. The biological efficacy of the rismorelin porcine microspheres was determined in swine by urinary urea nitrogen depression as well as by serum blood urea nitrogen. The physical site of injection of microspheres did not influence release profile in swine. In vivo release of rismorelin porcine from microspheres ceased after 9 to 12 days in all studies.

Diaz et al. (118) studied DL-PLGA microspheres of ^{125}I-bovine calcitonin prepared by the double emulsion technique (including Tween® 80 in the water phase and Span® 60 in the oil phase of the first emulsion) in vitro and in vivo. The release of ^{125}I-bovine calcitonin was determined in vitro at 37°C in isotonic phosphate buffer (pH 7.4). ^{125}I-bovine calcitonin microspheres (5 mg) were administered under the skin on the back of Wistar rats and the radioactivity at the injection site was subsequently measured over a 6-week period. The in vivo and in vitro ^{125}I-bovine calcitonin profiles were affected by the surfactant agents, but in vivo release was much faster than in vitro. Following injection in rats, microspheres made with Tween® 80 and Span® 60 to give a HLB value of 6 and 8 in the first emulsion, released 20 and 14% of the radioactivity within the first 24 hours, but only 1.3 and 1.2%/day at later times (up to 6 weeks), respectively. Under these conditions, they take 8 and 10 weeks, respectively, to release the total amount of calcitonin.

FITC-labeled bovine serum albumin has been entrapped in sub-5 μm particles of DL-PLGA using a W/O/W solvent evaporation technique. The concentration of PVA stabilizer in the external continuous phase was found to affect not only the particle size, size distribution, and protein content, but also the release characteristic and internal structure of the microparticles. The importance of primary emulsification was underlined by the finding that the protein content of microparticles with a mean size of 1 mm could be increased from about 1% W/W to around 12% W/W by increasing the amount of protein added to the primary emulsion and the homogenization time in this stage. Under conditions of low stabilizer concentration, multinucleate particles were formed by polymer precipitation and envelopment of the droplets of the primary W/O emulsion. In this case surface protein loading was on the order of 30% W/W. Under conditions of high PVA stabilizer concentration, disruption of the primary emulsion occurred, resulting in submicrometer particles which were characterized by a high surface protein loading on the order of 70% W/W. A mechanism for protein microencapsulation was presented which is heavily influenced by the shear stresses induced during the process of secondary emulsification (119).

Effects of additives on the drug release kinetics from biodegradable matrices is an important determinant in designing a drug delivery system. Song et al. (120) studied the influence of an array of additives on the drug release from double-layered PLGA matrices. Various additives such as L-tartaric acid dimethyl ester, Pluronic® F127 (F127); 2-hydroxypropyl derivative of β-cyclodextrin (HPB), methyl derivative of β-cyclodextrin and Beeswax (Wax), differing in molecular size, hydrophilicity, and steric configuration were selected for this study. An antiproliferative 2-aminochrome, U-86983 (U-86, Pharmacia and Upjohn), was used as a model agent for local delivery for the inhibition of restenosis. The in vitro release of U-86 from PLGA matrices without additive showed typical biphasic release kinetics, i.e., a slow diffusion release (Phase I) followed by a fast erosion-mediated release (Phase II). Water-soluble additives in the PLGA matrices changed the biphasic release pattern to a near monophasic profile by increasing the release rate of the Phase I. Increasing the ratio of additives to PLGA in matrices causes a significant increase in the U-86 release rates. The high molecular weight, water-soluble additive, F127, resulted in a matrix showing perfect zero-order release kinetics. The water-soluble cyclodextrin derivative, HPB, gave the highest release rate among all the matrices formulated. A hydropho-

bic additive, Beeswax, however showed biphasic release kinetics comparable to PLGA control matrices, but delayed the onset of the Phase II by 4 days. The morphological evaluation of matrices by SEM suggests that the water-soluble additives are leachable and thus generate a highly porous structure in the matrices. The matrix pore configuration (e.g., interconnected or closed) created with different additives determined the mechanism of drug release kinetics from the various matrix formulations.

Jager-Lezer et al. (121) examined the release kinetics of a water-soluble drug from two different W/O/W multiple emulsions prepared with two lipophilic surfactants at different concentrations. The study of the kinetics under both iso-osmotic and hypo-osmotic conditions allowed the author to distinguish between two possible release mechanisms, swelling-breakdown or facilitated diffusion. The results obtained indicate that water-soluble drug release occurs by a mechanism of swelling followed by a breakdown of the oil globules, in which the lipophilic surfactant is a decisive factor. It appears that the globule's swelling capacity is considerably increased when the lipophilic surfactant concentration increases, and the more the oil globule swells, the less the water-soluble drug releases. It seems that the stability could be improved by increasing the lipophilic surfactant concentration which could strengthen the interfacial film. In contrast, an excess of hydrophilic surfactant destabilized the emulsion.

Laugel et al. (122) studied the efficiency of suitable tracer incorporation in the aqueous inner phase for multiple emulsion studies. The use of dihydralazine as tracer allowed the evaluation of both the yield of preparation and the stability of eight multiple emulsions. In these, concentrations of several components were optimized, e.g., oil, lipophilic and hydrophilic emulsifiers, coemulsion and viscosity increasing agents. From entrapment data and droplet breakdown curves calculated from the dihydralazine chromatographic data, one emulsion was selected to study the release of some encapsulated moisturizing solutes such as urea, chitosan, and poly(ethylene glyco). Dihydralazine proved of value to discriminate between the two mechanisms responsible for the solute release, i.e., the breakdown of the multiple droplets and the diffusion of the solute through the oil layer. Diffusion curves were obtained from the levels of moisturizing substance in the outer aqueous phase, corrected by the amounts liberated by the droplet breakdown, calculated through dihydralazine levels. The lipophilicity of the solutes measured under conditions similar to those partitioning in the emulsions correlated with the diffusional route of solute transfer. Thus, the partition coefficient was an efficient parameter to predict the importance and the rate of the diffusion.

A mathematical model was developed by Li et al. (123) for the formation of PLGA microspheres loaded with a peptide using solvent extraction/evaporation methods. Intrinsic variables, such as solvent–polymer interaction parameters, and extrinsic variables, such as dispersed phase/continuous phase ratio, temperature and dispersed phase composition, were evaluated. A mathematical model based on mass transfer was developed by incorporating these variables and, by superimposing with the state of phase transition, the model was used to predict the microsphere properties. The mass transfer in the dispersed phase was based on diffusion theory and was a function of the driving force of chemical potential gradient and transport parameters. The solvent removal process involved solvent diffusion out of the dispersed phase followed by evaporation at the continuous phase–air interface, a process which can be facilitated by forced convective flow. Mathematically, the process can be expressed by coupling the equations for mass transfer in the dispersed phase and first order evaporation from the continuous phase. Two phase transitions, the viscous and glassy boundaries, were used to represent the phase transitions in the polymer solution. The phase transition can be superimposed on the composition profile in the dispersed phase; the solidification of microsphere can be evaluated from such a treatment (123).

Izumikawa et al. (124) studied the physiochemical properties of progesterone-loaded poly(L-lactide) microspheres prepared by the solvent evaporation method. The solvent evaporation process was found to govern the physical characteristics of microspheres. Solvent removal at atmospheric pressure yielded microspheres of crystalline polymer matrices, whereas faster solvent removal under a reduced pressure gave microspheres of amorphous polymer matrices. The crystallinity of the polymer matrices was closely correlated with the morphology and physical properties of microspheres, and affected the drug release rate. The microspheres of crystalline polymer matrices had rough surfaces with large surface areas, and exhibited a rapid drug release, whereas the amorphous microspheres provided a slower drug release. The results of X-ray powder diffraction, differential scanning calorimetry (DSC), and Fourier-transform infrared (FTIR) spectroscopy suggested that progesterone formed a molecular dispersion in the amorphous polymer matrices.

COMPLEX COACERVATION: GELATIN AND GUM ARABIC

When oppositely charges polyelectrolytes with a relatively low charge density are mixed at an appropriate temperature, pH, and concentration, a liquid polyelectrolyte complex called a complex coacervate is formed (11,22,32,80) The first commercial microencapsulation process used complex coacervates formed by acid precursor gelatin and gum arabic. Figure 11 is a schematic diagram of this encapsulation process.

The first step is to form a solution of gelatin (≈11 wt %) in 45–55°C water and gum arabic (11 wt %) in 45–55°C water. Distilled or deionized water must be used to avoid problems with solution. In most cases, high bloom strength (250–300 bloom) acid precursor gelatins were used, although lower bloom strength gelatins (150–225 bloom) can also be used. Bloom strength is a measure of how strong a gelatin sample forms and is indirectly related to gelatin molecular weight. High bloom strength gelatins tend to produce high molecular weight gelations and low bloom strength gelations tend to produce low molecular weight gelations, though there is not a direct correlation between bloom strength and molecular weight.

Once the gelatin and gum arabic solutions are prepared, the drug being encapsulated is emulsified or dispersed in

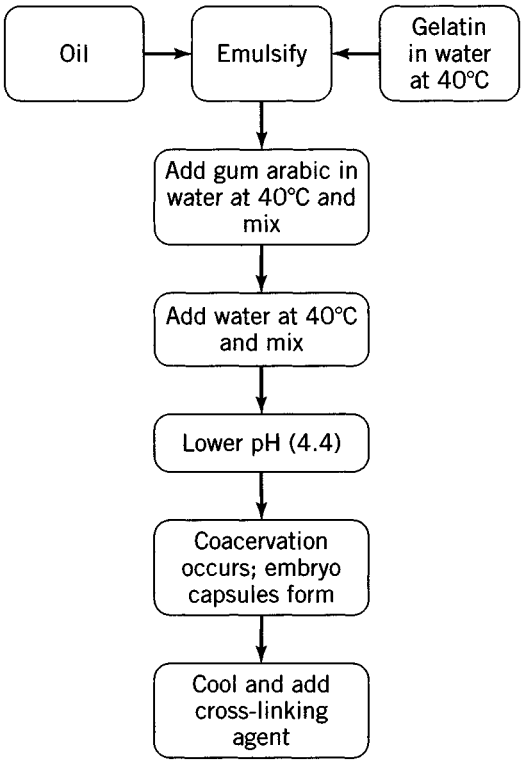

Figure 11. Microencapsulation by complex coacervation.

the 45–55°C gelatin solution. The drug is kept at the same temperature as the gelatin solution when the emulsion is made. The emulsion when formed should be above 45°C. Once the drug/gelatin emulsion or dispersion is formed, it is diluted by addition of a known volume of 45–55°C distilled (or deionized) water and 11 wt % gum arabic solution (45–55°C). The pH of the resulting mixture is adjusted to 3.8–4.4 by addition of acetic acid. The concentration of the acetic acid used can range from 10% (v/v) to glacial.

After the pH is adjusted, the system is allowed to cool slowly to room temperature. The system is stirred gently throughout this cooling period. Once room temperature is reached, the encapsulation mixture is cooled below 10°C and at this point, glutaraldehyde is added to cross-link the polymers. The pH of the system can then be raised to 9–10 with aqueous sodium hydroxide. The system is finally allowed to increase slowly to room temperature and the glutaraldehyde reaction proceeds for at least several hours (an overnight reaction is usually most convenient).

Slow cooling from 45 to 55°C to room temperature is essential to the success of the GGA encapsulation process. During this cooling process, the liquid coacervate slowly deposits around the core agent thereby forming embryo microcapsules. If the system is cooled too quickly, much of the GGA coacervate does not deposit around the active agent, but remains as discrete coacervate drops. (Such drops are called free coacervate and contain no active agent). Free coacervate is very undesirable, because coating material located in free coacervate drops is coating material not deposited around the active agent being encapsulated.

Rabiskova and Valaskova (32) encapsulated drugs that are often applied as solutions in plant oils. The encapsulation of the oils in the complex coacervate microcapsules can be improved by the addition of surfactants. Rabiskova used soybean, olive, and peanut oils as the representatives of plant oils. Using complex coacervation of gelatin and acacia they have found that when the surfactants with HLB values from 1.8 to 6.7 were used, the amount of encapsulated oil was high (65–85%). A significant decrease of the oil content in the microcapsules was found when Tween® 61 (HLB = 9.6) had been added to the mixture. No oil was found inside the microcapsules from the coacervate emulsion mixture containing Tween® 81 (HLB = 10) and Tween® 80 (HLB = 15), respectively.

ORGANIC PHASE SEPARATION: COACERVATION

Two chemically different polymers dissolved in a common solvent are usually incompatible. Thus, such a mixture separates into two phases. One phase is rich in one polymer, whereas the second phase is rich in the second polymer. As long as the phase containing the desired coating polymer preferentially wets or adsorbs on the surface of the core phase or drug, then embryo microcapsules spontaneously form which can be isolated and dried.

Figure 12 is a schematic diagram of a typical encapsulation process based on polymer–polymer incompatibility (58,125). The polymer that is to serve as the capsule wall

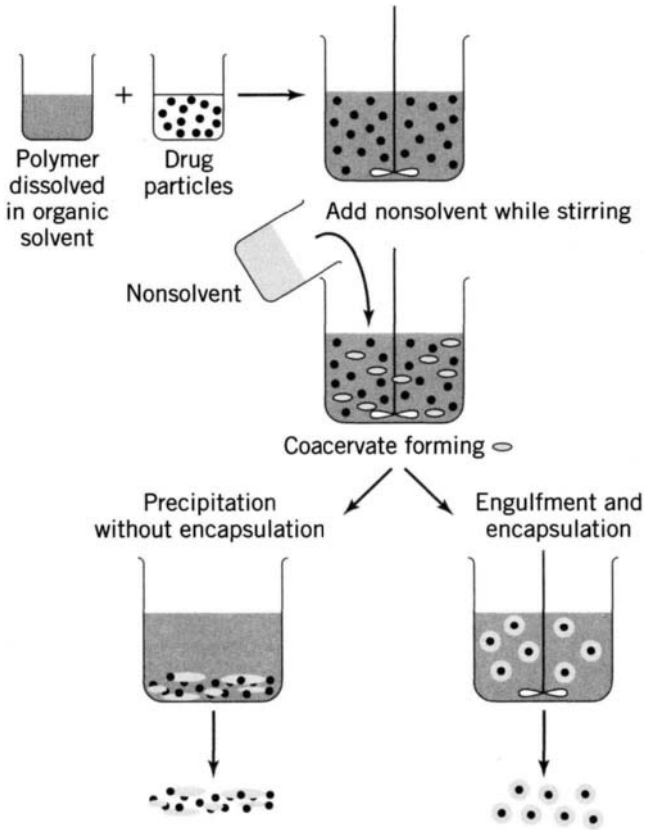

Figure 12. Microencapsulation by coacervation.

material is dissolved in an organic solvent. The material to be encapsulated is then added to this solution and an emulsion or dispersion is formed. To this emulsion a second polymer, or nonsolvent, that is incompatible with the capsule wall material is added. In Figure 12 it is nonsolvent but it could be cottonseed oil, silicone oil, low molecular weight polybutadiene, or any of a number of other materials. This second polymeric material is called the phase inducer and causes the coating material to phase separate. As long as the coating phase adsorbs on the core material, embryo capsules are formed. The system is then cooled and the embryo capsule walls are chemically cross-linked. Chemical cross-linking makes it possible to isolate the capsules as a free-flowing powder.

One of the polymers used to form the capsule wall could be Elvax® 40, a Dupont ethylene vinyl acetate copolymer that contains 40 wt % vinyl acetate. Fifty percent of the vinyl acetate units are hydrolyzed to form vinyl alcohol units. The latter are the units which react and could form a cross-linked or network polymer.

Many researchers have used triangular phase diagrams to describe microencapsulation by coacervation (60,126–129). Madan used phase diagrams to illustrate the coacervate region for several gelatin coacervation processes. He showed that the coacervation inducer could alter the area of coacervate formation on the phase diagram. Benita and Donbrow (60) used a phase diagram to describe the effect of polyisobutylene concentration on the coacervation of ethylcellulose microcapsules. They indicated that a minimum concentration was necessary for the formation of coacervate droplets while a relatively high polyisobutylene concentration prevented phase separation. Phase diagrams have also been used to describe the effect of polyisobutylene on the formation of Eudragit RS microcapsules. Namely, the two liquid phase regions which occurred prior to wall formation may be described, as well as changes in the phase diagrams that were related to occurrences in the microencapsulation process. Phase diagrams have been used to show how various surfactants affected the microencapsulation regions of cellulose acetate phthalate and of cellulose acetate trimellitate (129). Phase diagrams also have been used to describe coacervation as affected by coating polymer concentration, solvent amount, nonsolvent amount, and additives; however, they have not been used to identify potential solvent systems for microcapsule formation or to predict release rates from the microcapsules.

Membrane technology has shown that solubility parameters can be used to select solvents for membrane preparation. Klein and Smith (130) used Hansen's parameters for polarity and hydrogen bonding to form two-dimensional plots for ethylcellulose and cellulose acetate. These plots were then used to predict solvent systems for the formation of asymmetric membranes. Using Hansen's polarity parameters and hydrogen bonding parameters, Chawla and Chang (131) plotted the solubility of cellulose acetate. Several membranes were formed and shown to behave in a predictable fashion based on the solubility parameter of the solvent system. Shen and Cabasso (132) used Hansen's parameters to investigate their solvent systems and a phase diagram to describe how their ethylcellulose membranes were formed. This discussion suggests that potentially useful solvent systems for microcapsule membrane formation could also be chosen using solubility parameters.

Robinson (133) has suggested the use of the solubility parameter, the polymer–solvent interaction parameter and the polymer–solvent interaction parameter for the identification of potentially useful solvents for microcapsule preparation. He determined the solubility of ethylcellulose and plotted the solvent fractional polarity on a two-dimensional map versus the solubility parameter of the system that should be near the limit of the ethylcellulose solubility region for coacervation to occur. Robinson, however, did not report the preparation of microcapsules based on his findings.

Solubility parameters may provide a predictive method by which solvent systems can be chosen for the formation of microcapsules. As shown by the work in membrane technology, it may be possible to predict general structural characteristics of the microcapsule coat, thereby allowing the microcapsules to be formed with desired release rates.

Moldenhauer and Nairn (25) employed a coacervation method using an ethylcellulose and ion-exchange resin–drug complex to show that solubility parameters of the microencapsulation system can be correlated with morphological characteristics and release rates. Microcapsules prepared using solvent mixtures, which had a solubility parameter in the area of a two-dimensional solubility parameter map, usually exhibited similar release rates and morphological characteristics. The ability of polyisobutylene to promote mononucleated microcapsules decreased as the dispersive solubility parameter decreased. Three of the microencapsulation solvent systems were also analyzed using phase diagrams. It was found that the solubility parameter map provided predictive methods of solvents selection for microencapsulation, whereas the phase diagram provided information about the solvent and nonsolvent, with which the phase diagram are formed.

The phase separation of PLGA solutions in methylene chloride induced by the addition of a silicone oil in order to promote protein microencapsulation was studied by Nihant et al. (29). Because the process is very fast, the system was out of equilibrium at all times studied. The effect of the main processing parameters on the microencapsulation process has been analyzed and has highlighted that the kinetics of the main encapsulation steps have a great effect on the characteristics of the final microspheres. These results have been discussed on the basis of a physicochemical study of coacervation.

Ethylcellulose microcapsules containing theophylline were prepared by Sa et al. (134) by the phase separation coacervation process. To induce phase separation a nonsolvent and a variable amount of polyisobutylene were used. Results indicated that the overall release was governed by a diffusion controlled process. No statistical difference was evident between the different sized microcapsules with respect to their drug content, wall thickness, and in vitro drug dissolution profiles. Polyisobutylene was, however, found to influence the release profiles of drug to a great extent. An increase in polyisobutylene concentration retarded the release of theophylline from the micro-

Next Page

capsules due to the formation of small and spheroidal coacervate droplets in larger volumes, which resulted in the formation of more evenly coated microcapsules. Although the release of theophylline from the microcapsules was found to fit both the first-order and diffusion-controlled release processes, differential rate treatment indicated that the overall release was governed by diffusion controlled process (134).

In a different study Bachtsi and Kiparissides (59) developed oil-containing PVA microcapsules that were prepared by the simple coacervation method followed by the chemical cross-linking of the coacervated PVA membrane with glutaraldehyde. The effect of various parameters such as the microcapsule size, the degree of cross-linking of the coacervated polymer membrane, the amount of the desolvating agent, the surfactant concentration, and the ionic strength of the aqueous release medium on the release rate of the oil from the microcapsules into a model surfactant solution was experimentally investigated. It was shown that the oil release rate exhibited first-order kinetics. The permeability coefficient of the santosol oil the PVA coacervated/cross-linked membrane was found to vary from 10^{-4} to 10^{-6} cm/s and was strongly dependent on both the environmental conditions of the release medium and the physical and morphological characteristics of the microcapsules (59).

INTERFACIAL POLYMERIZATION

When two reactive monomers are dissolved in immiscible solvents (e.g., water and an alkane), the monomers diffuse to the oil–water interface where they react to form a polymeric membrane. This phenomenon has been used to form a range of microcapsules. Figure 13 is a schematic diagram of microencapsulation using an interfacial polymerization reaction. The interfacial reaction occurs rapidly and is

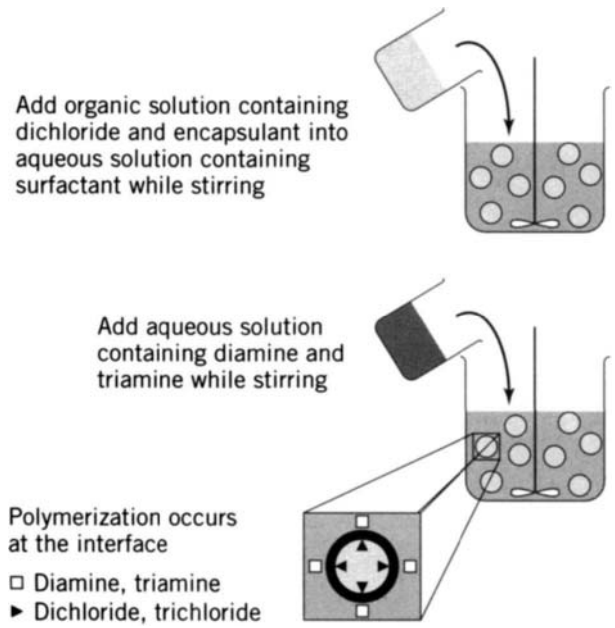

Figure 13. Microencapsulation by interfacial polymerization.

therefore considered a rapid means of preparing microcapsules. It was, however, found to be incorrect for some systems and long reaction times were needed to get strong microcapsules. The preferred acid chloride has relatively long carbon chains between the acid chloride groups, because such acid chloride hydrolyzes slowly at an oil–water interface. The acid chlorides are always added to the oil phase, whereas the amines are always added to the water phase. Isocyanates can be used rather than (or as a partial substitute for) acid chlorides (135). A base could be added to the aqueous phase to neutralize the HCl byproduct formed by reaction of an acid chloride with an amine.

The yield and quality of the membrane of the microcapsules obtained by interfacial polymerization may be controlled by a number of factors, some of which have been listed by Morgan (136). Specifically, in microencapsulation systems the chemical natures of the chloride and amine components and of the solvent, and the conditions under which the polycondensation reaction is performed, determines the nature and molecular weight of the polymer as well as its degree of cross-linking and crystallinity, and whether or not the membrane is porous. Experimental parameters likely to be of importance are the concentrations of the monomers, the temperature, the rate of mixing, and the reaction time. Cohen and Mathiowitz (44) determined the effect of the chemical nature of the monomer components; all reaction parameters were kept constant except for the monomer concentrations and reaction time. During these studies it became clear that the properties of the membrane vary after the initial formation of the microcapsules. There was much evidence that after the formation of the "premembrane" the polymerization proceeds via diffusion of the amine through the membrane where it reacts with the chloride at the inner face of the microcapsule wall. The effective amine concentration at the reaction site is then very much less than in the bulk aqueous solution (44).

Microcapsules were fabricated by preparing an aqueous solution of water and PVA as a surfactant (Fig. 13), and in some cases silane was added as a coupling agent (137). To this solution an organic solution containing the dichloride was added while stirring. After the correct emulsion size was obtained an aqueous solution of diamine was added. The polycondensation reaction which ensued was allowed to continue for different lengths of time. In several cases the silane was added to the chloride suspension prior to the addition of the amine solution. In this way there was an initial formation of a premembrane, resulting from the reaction between the chloride and the amine groups of the silane. After this step the amine was added, in solution, which underwent polycondensation with the chloride. The length of time for the reaction varied with the type of monomer. (For each system the disappearance of the dichloride monomer was followed by thin-layer chromatography.) The time required for the concentration of acid chloride to decrease by 0.5% is called the maturation time. After maturation the microcapsules were separated by decantation, repeatedly washed with distilled water, and dried by rapid washing with acetone (44,137).

Table 8 lists the amine and chloride components used, and Table 9 summarizes the compositions of the monomer mixtures employed. In different attempts the amine/

capsules due to the formation of small and spheroidal coacervate droplets in larger volumes, which resulted in the formation of more evenly coated microcapsules. Although the release of theophylline from the microcapsules was found to fit both the first-order and diffusion-controlled release processes, differential rate treatment indicated that the overall release was governed by diffusion controlled process (134).

In a different study Bachtsi and Kiparissides (59) developed oil-containing PVA microcapsules that were prepared by the simple coacervation method followed by the chemical cross-linking of the coacervated PVA membrane with glutaraldehyde. The effect of various parameters such as the microcapsule size, the degree of cross-linking of the coacervated polymer membrane, the amount of the desolvating agent, the surfactant concentration, and the ionic strength of the aqueous release medium on the release rate of the oil from the microcapsules into a model surfactant solution was experimentally investigated. It was shown that the oil release rate exhibited first-order kinetics. The permeability coefficient of the santosol oil the PVA coacervated/cross-linked membrane was found to vary from 10^{-4} to 10^{-6} cm/s and was strongly dependent on both the environmental conditions of the release medium and the physical and morphological characteristics of the microcapsules (59).

INTERFACIAL POLYMERIZATION

When two reactive monomers are dissolved in immiscible solvents (e.g., water and an alkane), the monomers diffuse to the oil–water interface where they react to form a polymeric membrane. This phenomenon has been used to form a range of microcapsules. Figure 13 is a schematic diagram of microencapsulation using an interfacial polymerization reaction. The interfacial reaction occurs rapidly and is

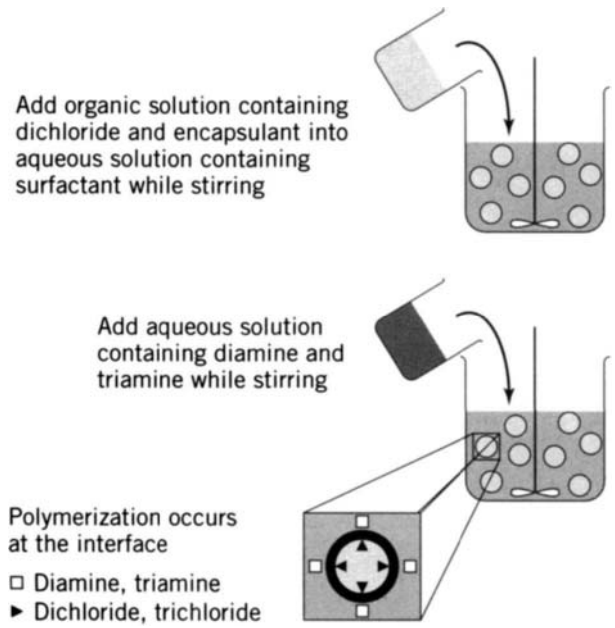

Figure 13. Microencapsulation by interfacial polymerization.

therefore considered a rapid means of preparing microcapsules. It was, however, found to be incorrect for some systems and long reaction times were needed to get strong microcapsules. The preferred acid chloride has relatively long carbon chains between the acid chloride groups, because such acid chloride hydrolyzes slowly at an oil–water interface. The acid chlorides are always added to the oil phase, whereas the amines are always added to the water phase. Isocyanates can be used rather than (or as a partial substitute for) acid chlorides (135). A base could be added to the aqueous phase to neutralize the HCl byproduct formed by reaction of an acid chloride with an amine.

The yield and quality of the membrane of the microcapsules obtained by interfacial polymerization may be controlled by a number of factors, some of which have been listed by Morgan (136). Specifically, in microencapsulation systems the chemical natures of the chloride and amine components and of the solvent, and the conditions under which the polycondensation reaction is performed, determines the nature and molecular weight of the polymer as well as its degree of cross-linking and crystallinity, and whether or not the membrane is porous. Experimental parameters likely to be of importance are the concentrations of the monomers, the temperature, the rate of mixing, and the reaction time. Cohen and Mathiowitz (44) determined the effect of the chemical nature of the monomer components; all reaction parameters were kept constant except for the monomer concentrations and reaction time. During these studies it became clear that the properties of the membrane vary after the initial formation of the microcapsules. There was much evidence that after the formation of the "premembrane" the polymerization proceeds via diffusion of the amine through the membrane where it reacts with the chloride at the inner face of the microcapsule wall. The effective amine concentration at the reaction site is then very much less than in the bulk aqueous solution (44).

Microcapsules were fabricated by preparing an aqueous solution of water and PVA as a surfactant (Fig. 13), and in some cases silane was added as a coupling agent (137). To this solution an organic solution containing the dichloride was added while stirring. After the correct emulsion size was obtained an aqueous solution of diamine was added. The polycondensation reaction which ensued was allowed to continue for different lengths of time. In several cases the silane was added to the chloride suspension prior to the addition of the amine solution. In this way there was an initial formation of a premembrane, resulting from the reaction between the chloride and the amine groups of the silane. After this step the amine was added, in solution, which underwent polycondensation with the chloride. The length of time for the reaction varied with the type of monomer. (For each system the disappearance of the dichloride monomer was followed by thin-layer chromatography.) The time required for the concentration of acid chloride to decrease by 0.5% is called the maturation time. After maturation the microcapsules were separated by decantation, repeatedly washed with distilled water, and dried by rapid washing with acetone (44,137).

(HMDA, Tm)	30	—

chloride ratio was kept constant (30:1 or 15:1, in equivalent units) in order to avoid effects due to the diminishing monomer concentrations. For cases where the amine:chloride ratio was 30:1, the concentrations were 5.62 and 0.197 mole eq/L, respectively. Because these concentrations were constant, the main variable parameter was the character of the monomer. Note that from the list in Table 8 one could select monomers which are bifunctional or monomers which are of functionality three or higher. The polymer from two bifunctional monomers was linear and when one or both monomers had a functionality of three or higher, the resulting polymer was cross-linked (44).

It can be seen from Table 9 that Cohen and Mathiowitz (44) used an amine:chloride ratio of 15 or 30:1. This is near the upper limit of, or greater than, the ratio used by Morgan. These authors suggested that for amines with partition coefficients of between 14 and 180, amine:chloride ratios of 3 to 17:1 are optimal for obtaining high molecular weight polymers. They measured the partition coefficients for some amines and found values of 22 for HMDA and 27 for DETA, whereas that of EDA must be very high because of its low solubility in the organic phase. Thus the ratios are much higher than those required by Morgan's rule (44).

Reaction time in microcapsule preparation is extremely important in determining the time at which that capsules have attained their maximum impermeability. Consider microcapsules from (EDA,Tr), for, example; these are observed to form very rapidly (44). However, microcapsules separated from the reaction vessel after very short periods proved to be extremely fragile and collapsed even during the drying process. Further, analysis of the Tr content (of the core material; microcapsules were removed from the reaction vessel after various times) showed that an appreciable period is required for complete consumption of this monomer. When EDA was replaced by an amine monomer of higher molecular weight and functionality, it was found that the time required for full maturation was appreciably longer. For example, the approximate maturation times determined were (EDA,Tr) 5 min, (HMDA,Tr) 10 min, (DETA,Tr) 180 min, and (TEPTA,Tr) 240 min (44).

Thermal gravimetric analysis (TGA) is a often-used technique for characterizing polymer thermal stability, but Mathiowitz and Cohen have introduced this technique to determine the mechanical strength of microcapsules and also to study the maturation of the microcapsules immediately after preparation. This method is particularly useful because it enables examination of the individual microencapsulation and thus provides information about the reproducibility of the rate of release amongst a population of microcapsules. This in turn helped us to develop a mathematical model for photochemical rupture (47).

The effect of the reaction time on the thermal behavior of microcapsules from DETA is illustrated in Figure 14. The "immature" capsules released their contents at low temperatures, whereas the mature ones are stable until they reach a sharp rupture temperature. This may be due to more rapid diffusion of the core contents through thinner walls of immature capsules.

The time required for maturation was determined by the diffusion of the amine from the bulk aqueous solution through the membrane to the organic phase. The rate of this diffusion, which is low when compared with the reaction rate of the monomers in solution, is determined by the permeability of the membrane. The permeability, in turn, depends on factors such as the molecular weight of the polymer and the extent of its cross-linking. The growth of the membrane, which accompanies maturation, can be

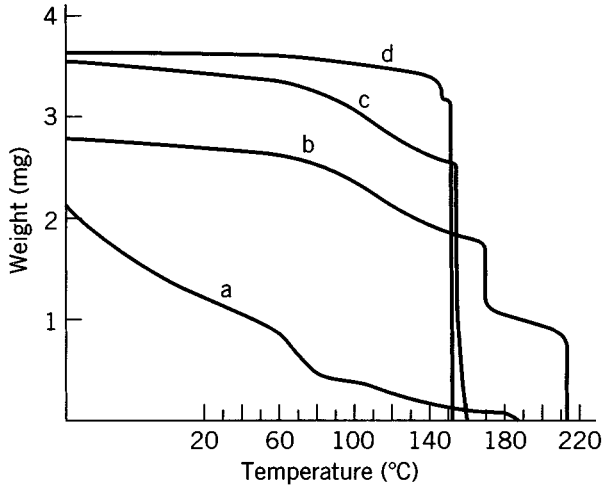

Figure 14. Effect of reaction time on thermal behavior of (DETA,Tr)S microcapsules as measured by TGA: (a) 1, (b) 4, (c) 10, (d) 100 minutes after starting the polymerization reaction. *Source:* With permission from Ref. 45.

seen clearly in electron micrographs (data not shown). After 1 minute the internal side had a smooth internal surface. After 4 minutes, small spheres of polymer were found to be formed on this surface and subsequently grow and cover the whole inner face of the membrane. The results suggest that, throughout the formation of the membranes of linear polymers, the diffusion rate of amine is constant. For the cross-linked polymers, however, there appear to be channels though which diffusion is more rapid. These channels could be voids or could contain a high proportion of polymer which is not cross-linked (44).

An indication of the stability of the membranes to heat can be obtained from TGA measurements. The membranes were prepared either by direct interfacial polymerization or by rupturing microcapsules and were carefully dried before use. In this way it was found that (EDA,Tr), (DETA + EDA,Tr) and (DETA,Tr) all begin to lose weight at 220–230°C, whereas (HDMA,Tr) does so only above 300°C.

Dry membranes were investigated also by DSC. The DSC curve for (DETA,Tr) shows no structure; at about 230°C, where weight loss starts, there was a slight change of slope and as the temperature rises, there was a continuously increasing heat loss. There is no sign of melting up to 450°C. This type of behavior is typical of cross-linked polymers. Visually, one observed that the material chars on heating. By contrast, the DSC curve for (EDA,Tr) shows a melting temperature at 450°C and the glass temperature at 225°C. (EDA + DETA,Tr) membranes also show an endotherm at 70°C, but no melting was observed. Repeated measurements suggest that $T_g \cong 260$°C. Above this temperature the polymer starts to decompose.

FTIR spectra can be very helpful in providing information on the bonding state of polyamides. What prominent features may we expect in these spectra? If there are any residual NH_2 groups present which have not reacted during the polymerization, one expects to see the absorptions corresponding to the stretching modes of NH_2. In both primary amines and primary amides these modes are known to give an intense doublet around 3,450 and 3,225 cm^{-1}. The N-H stretch of secondary amines and amides gives a single strong absorption band near 3,335 cm^{-1}. Amide vibrational spectra are characterized by two intense bands, called amide I and amide II. The first of these is largely due to C = O stretching and is found at 1,665–1,640 cm^{-1}. The amide II band, at about 1,540 cm^{-1}, is due to a coupling of vibrations of C-N and of N-H, when the H is *trans* to the C =.

The FTIR results indicate that during the polycondensation reaction the doublet structure associated with the $-NH_2$ of the amine monomer (Figs. 15a,b,c) disappears and is replaced by an intense singlet (compare Figure 15a with 15d,f, and 15b with 15e,f). In many cases this latter band has a shoulder on the high frequency side. This structured band is undoubtedly the N-H stretch of the secondary amines and amides. It has been found also in other polyamides, and the main peak and shoulder have been assigned to a superposition of "free" and hydrogen-bonded N-H.

On this basis it was concluded that little or no unreacted NH_2 was present in the polymer. However, because of the breadth of the N-H adsorption, it was not possible to conclude that there was none present.

The X-ray powder diffraction patterns of a number of dried membrane materials were recorded for membranes of the (EDA + DETA,Tr) series. There were differences in crystallinity, with (EDA,Tr) > (EDA + DETA,Tr) > (DETA,Tr), and with the last membrane being essentially amorphous. Also, membranes of (HMDA + DETA,Tr) are of higher crystallinity than (DETA,Tr) ones (44). Thus, addition of one of the bifunctional amines EDA of HMDA to the trifunctional DETA in the preparation of the microcapsules leads to membranes of higher crystallinity than those membranes we have shown to be appreciably cross-linked. Morphological studies of microcapsules by SEM and transmission electron microscopy (TEM) were done on each sample. The external and internal faces and a cross section of the membrane wall was evaluated. Preparation for TEM required embedding the samples and cutting by microtome, the latter being difficult because of the fragility of the materials. Most membranes were stained with uranyl acetate which attaches to free amino groups and increases the resolution. Figure 16 capsules of (DETA,Tr) are seen from the external side (some capsules full, some ruptured). The structure is homogeneous and "closed." In fact, most of the membranes we studied looked similar at the external face, but there were differences in the internal faces. The internal faces and membrane cross-sectioning (Fig. 16) of (DETA,Tr) also show quite closed structures. The internal face is hilly, suggesting that the interfacial polymerization takes place in the organic phase. TEM studies (Fig. 16f) of the cross section provide a similar picture, with the polymer density apparently lower in the hills than in the other regions of the membranes. The thickness of the membrane of the (DETA,Tr) microcapsules was 2 μm, as measured by SEM.

Microcapsules of (EDA,Tr) appear nonporous under the optical and scanning electron microscopes. However, SEM

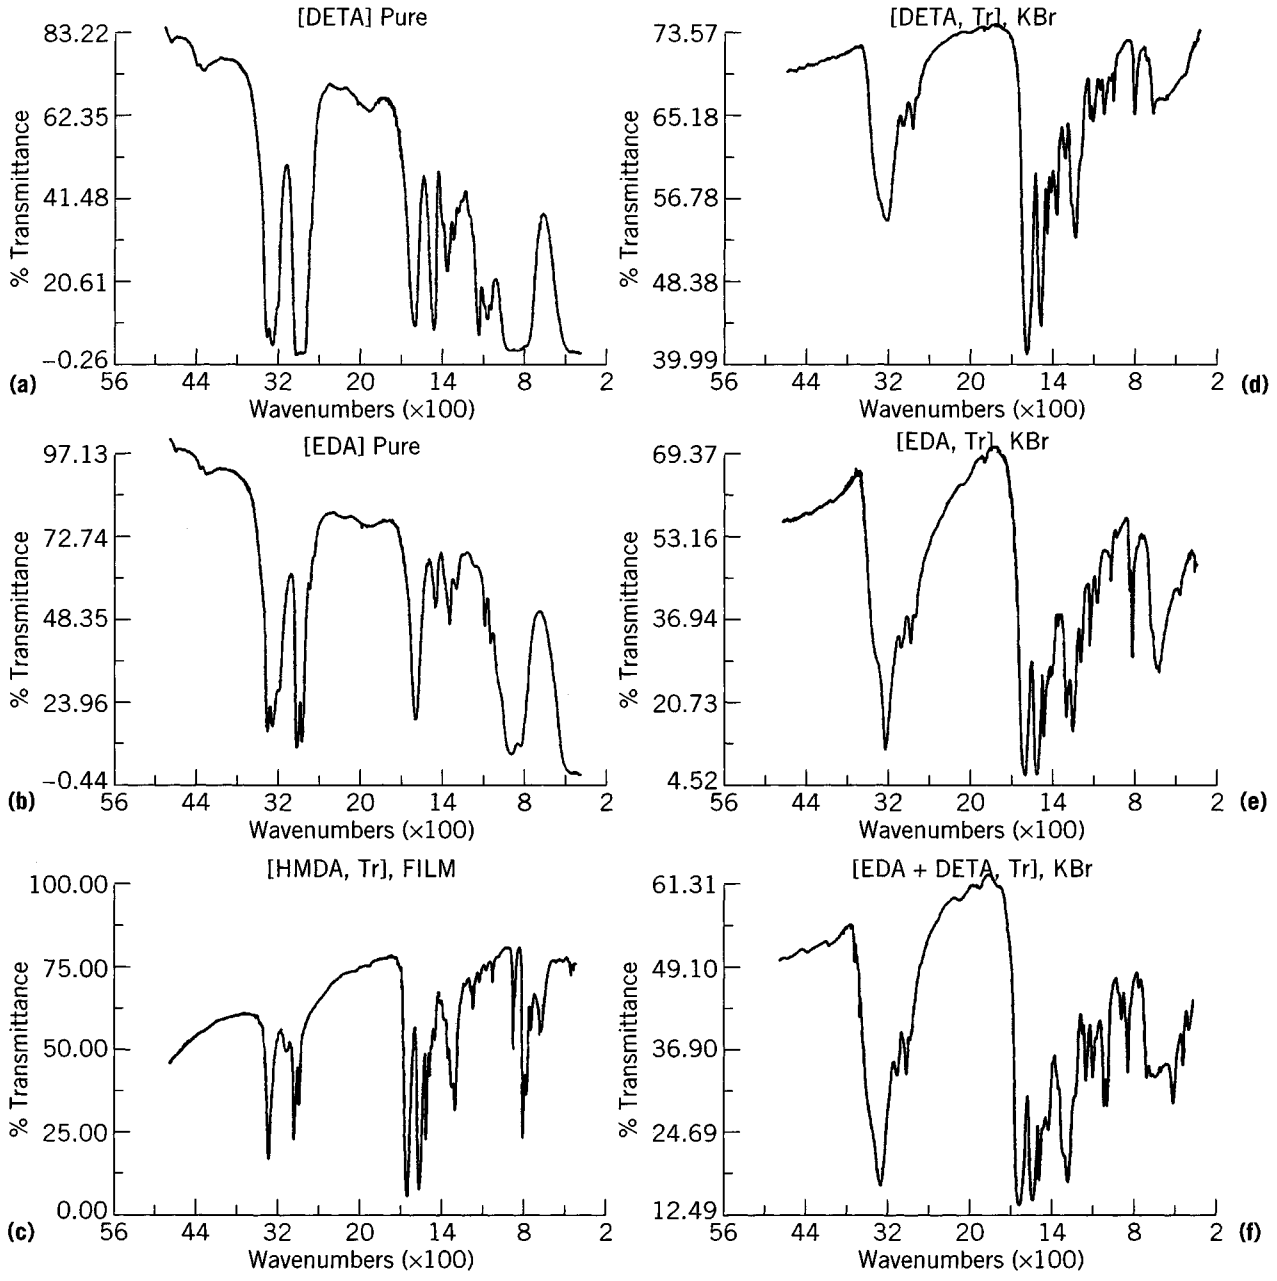

Figure 15. FTIR spectra of some amines and Tr membranes.

examination of the internal face and cross section of the membranes reveal a very porous structure (Fig. 17a,b). This membrane is clearly of the "skinned" type: one side has a closed structure, but the membrane is full of voids. This is shown also in the TEM pictures of the cross section (Fig. 17e). Note that the long axes of the pores lie parallel to the faces of the membrane. These pores are less than 1 μm in diameter, which classifies the membrane as microporous.

Figures 17c and 17d, show the internal face and cross section of such membranes with a double relative concentration of Tr. Here the number of pores is fewer and the internal face more homogeneous, but the structure is still porous.

In Figure 18a we see the internal face of capsule from (EDA + DETA(1:1.5),Tr). The structure is less porous than is (EDA,Tr), as was confirmed by the cross section (not shown). This membrane after silanation is shown in Figure 18b and its cross section in Figure 18e. Such treatment appears to decrease the porosity. An increase of the proportion of triamine further decreases the porosity, as shown for the internal face and cross section of a membrane from (EDA + DETA(1:4),Tr) in Figures 18a,b. In this case the wall thickness was 2.5 μm. In additional papers the use of those microspheres as swelling-controlled, diffusion-controlled, and photochemically controlled delivery systems were studied separately (46–48).

Interfacial Coacervation

The first example of a phase separation process is an extreme case of polymer adsorption used to prepare small capsules (49). In this process Chang dissolved a polymer in the organic phase, and this polymer migrated to the water–organic liquid interface where it precipitated spontaneously from solution to form a membrane. This process is called interfacial coacervation (135). Phase separation in this case is not induced by addition of a nonsolvent, change in temperature, or the presence of incompatible polymers, instead occurring spontaneously at the interface. A good example of this process is the emulsification of an aqueous protein solution in diethyl ether using a nonionic surfactant that is soluble in oil. Sorbitan trioleate (Span® 85) is a good surfactant. The emulsification process gives microcapsules that can easily be separated from the

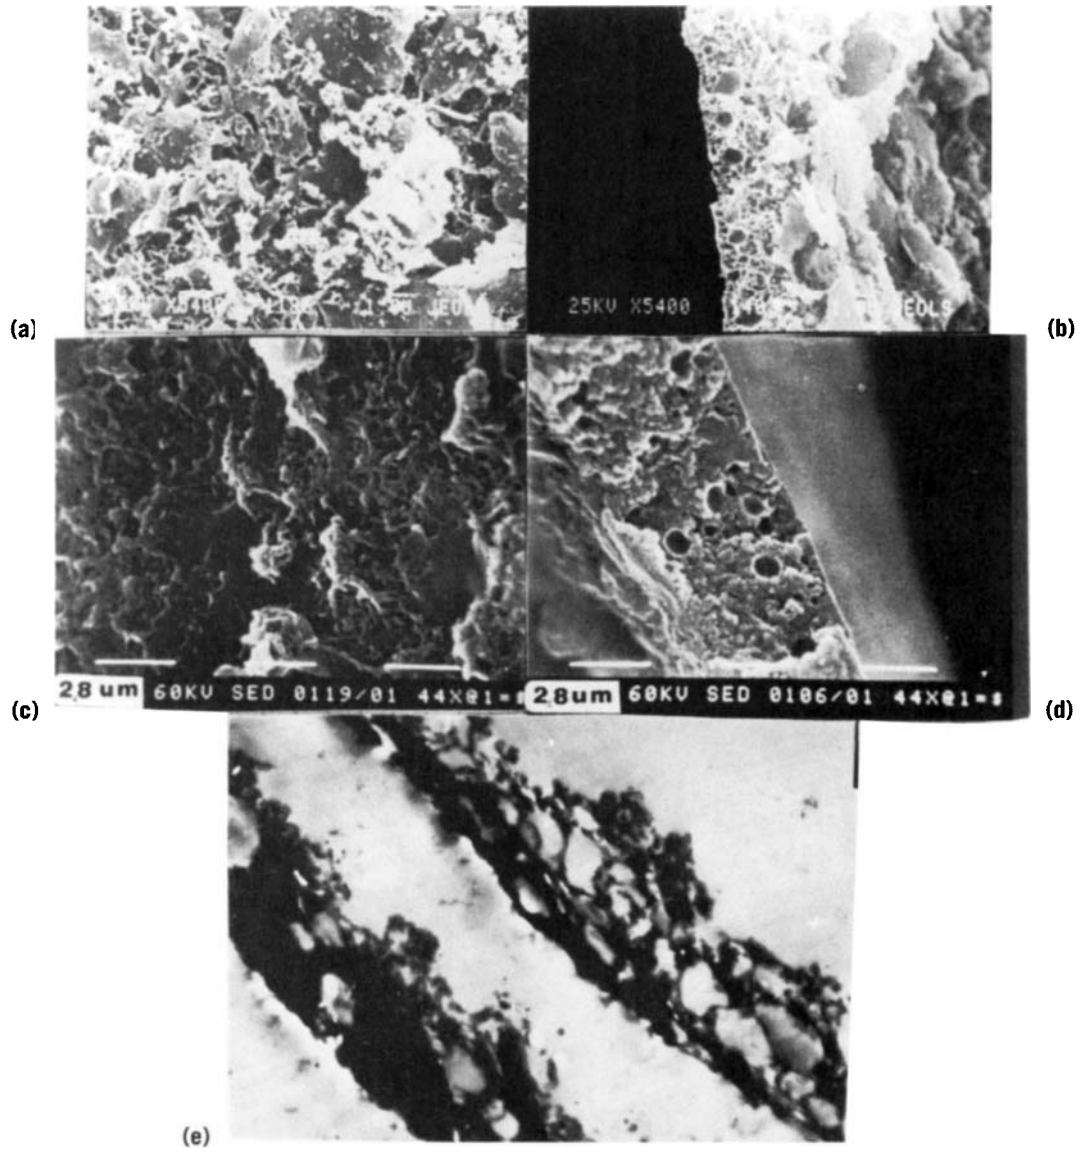

Figure 17. (EDA,Tr) MC: (**a**) SEM of internal face; (**b**) SEM of cross section of same membrane; (**c**) SEM of internal face of (EDA,Tr)x MC; (**d**) SEM of cross section of same membrane; (**e**) TEM of (EDA,Tr) MC shown in (**b**), ×10,000. *Source:* With permission from Ref. 44.

ether suspending medium and resuspended in *n*-butyl benzoate. Chang often used collodian (nitrocellulose) as a wall material, but emphasized that microcapsules can also be formed by interfacial coacervation or precipitation of other polymers using other solvents.

THERMAL DENATURATION

A number of water-soluble proteins are sensitive to heat and can denature when heated. The denaturation process causes the protein chain to unfold and become chemically cross-linked. This insolubilizes the protein and creates a convenient method of forming protein microspheres. Figure 19 is a schematic flow diagram of a process for forming protein microspheres. A relatively concentrated aqueous protein solution (e.g., 20 wt %) is emulsified in an aliquot of oil at room temperature. This emulsion is then poured into an excess of agitated hot oil (120–200°C), which denatures the protein while simultaneously driving off the water. The product is a solid protein microsphere which can be isolated from the oil by a series of settling and decantation steps. The higher the temperature of the hot oil bath, the more thoroughly the microspheres are cross-linked. Proteins suitable for this process include serum albumin and egg albumin.

Jameela et al. (138) produced chitosan microspheres in the following manner. A 4% solution of chitosan in 5% acetic acid containing 2% sodium chloride was prepared. Six grams of this viscous solution was weighed, mixed with progesterone (20% by weight of chitosan) and dispersed in a mixture of 35 mL of liquid paraffin and 25 mL of petro-

leum ether containing 0.85 g of sorbitan sesquioleate, in a 100-mL round-bottomed flask at room temperature (27°C). The dispersion was stirred at 2,000 rpm for 5 min, and then 10 mL of glutaraldehyde-saturated toluene was introduced into the flask and the stirring continued. Microspheres were prepared using different amounts of glutaraldehyde saturated toluene for cross-linking. Highly cross-linked microspheres were prepared by adding 1 mL aqueous glutaraldehyde at the end of 30 min, in addition to 10 mL of glutaraldehyde-saturated toluene which was introduced initially. The cross-linking reaction was allowed to proceed for a total of 1.5 hours. The hardened microspheres were then separated by centrifugation, washed four times with petroleum ether, once with acetone, once with a 5% solution of sodium metabisulphite, three times with water, centrifuged, vacuum-dried at room temperature and stored in a desiccator. Progesterone content in the microspheres was measured by extracting 5 mg of powdered microspheres with three 5 mL portions of ethanol, filtering the solution through a 0.45 μm filter and assaying spectrophotometrically at 247 nm. Particle size analysis of the microspheres was done using standard test sieves. Particles that passed through one sieve, but retained on the other were collected and weighed in an analytical balance, and the percent weight distribution was plotted against size (138).

The extent of drug release had a remarkable dependence on the cross-linking density of the microspheres, the highly cross-linked spheres releasing only around 35% of the incorporated steroid in 40 days compared to 70% from

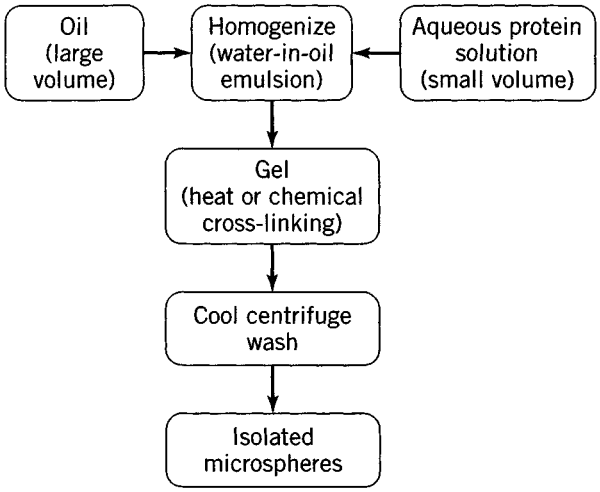

Figure 19. Thermal denaturation process.

spheres lightly cross-linked. Determination of the in vivo bioavailability of the steroid from microsphere formulation by intramuscular injection in rabbits showed that a plasma concentration of 1 to 2 ng/mL was maintained up to 5 months without a high "burst effect." Data obtained suggest that the cross-linked chitosan microspheres would be an interesting system for long term delivery of steroids (139).

Modena et al. (139) investigated hyaluronidase injectable microparticles. The goal of these researchers was to obtain a sustained release preparation of hyaluronidase or to use the enzyme as drug carrier. Microspheres were prepared by emulsification of the protein and were cross-linked either by thermal or chemical means. Results show that hyaluronidase microspheres with good morphological characteristics can be obtained by this preparation method.

Heelan and Corrigan (140) used whey protein (WPI) microspheres containing hydrochlorothiazide, eosin, blue violet, and sodium salicylate. The release of these compounds from WPI microspheres occurred rapidly, with at least 70% of the incorporated material released for all systems within the first 20 minutes. Release of microsphere contents was essentially complete within one hour. The degree of glutaraldehyde cross-linking was found to have no effect on the release profile, for durations of cross-linking up to 24 hours. Out of a range of release equations examined, the experimental release data was best described by a biexponential equation, and this agrees with the work of others for the release of drugs from albumin microspheres. Swelling of the microsphere systems was examined as this may contribute to the rapid release of drug from these systems.

Akbuga and Bergisadi prepared cross-linked chitosan microspheres containing 5-fluorouracil (5-FU). Variables included drug and chitosan concentrations, the cross-linking process, the type of oil, stirring rate, and additives. Initial 5-FU concentration, the type and concentration of chitosan, the viscosity of oil phase and glutaraldehyde concentration affected drug release for chitosan microspheres. 5-FU release from cross-linked chitosan microspheres is characterized by an initial rapid release of drug. Addition of substances such as alginic acid, chitin, agar, sodium caprylate, and stearic acid changed the release properties of 5-FU microspheres.

Monodisperse albumin micropheres were prepared by Muramatsu and Nakauchi (142) Uniform-sized emulsion droplets were successfully obtained by passing an albumin solution through the membrane and into kerosene at appropriate, applied pressures. After heating the emulsion monodisperse albumin microspheres were prepared. The heat-denaturing process itself did not affect the monodispersity once uniform emulsion droplets had been prepared. The shape and size of the albumin microspheres were strongly dependent on the concentration of the albumin solution and the heat denaturing temperature. Lower albumin concentrations produced nonspherical particles and higher denaturing temperatures made the particles smaller. Incorporated riboflavin released quite rapidly from the albumin microspheres, and increases in both albumin concentration and denaturing temperature caused the drug release to be sustained, presumably because a rigid and dense matrix was formed within the albumin microspheres.

Chitosan microspheres containing phenobarbitone were successfully prepared by glutaraldehyde cross-linking of an aqueous acetic acid dispersion of chitosan in light liquid paraffin containing sorbitan mono-oleate as a stabilizing agent. Uniform and spherical microspheres, with a loading efficiency up to 57.2%, could be fabricated, depending on the conditions. The main parameters which affected the preparation and performance of the microspheres were the molecular weight and concentration of chitosan as well as the concentration of the stabilizing agent. The incorporation of citric acid into the microspheres was found to increase the formation of a water-soluble gel when the microspheres come in contact with the dissolution medium, increasing the rate of drug release. The particle size was shifted toward smaller diameters with increased concentration of chitosan (1% w/v) and chitosan with low molecular weight. Rapid initial release (20–30% of the incorporated drug) was exhibited in all the prepared microspheres followed by slow release of the remaining drug. The release rate of the drug from the microspheres of high molecular weight chitosan was slow in comparison with that prepared from medium and low molecular weight chitosan. High concentrations of sorbitan mono-oleate increased the rate of the drug release (143). Lim and Wan (63) prepared chitosan microspheres by preparing a W/O emulsion comprising a mixture of light and heavy liquid paraffins containing sodium dioctyl sulphosuccinate as the oil phase and a chitosan solution as the aqueous phase. Pentasodium trypolyphosphate was included as a counterion. The chitosan microspheres obtained showed a high degree of aggregation. This was markedly reduced by the incorporation of magnesium stearate in the dispersed phase. The resultant microspheres were discrete and spherical with smooth surfaces. Additionally, with an increasing magnesium stearate content, larger-sized microspheres were produced. The DSC analysis data suggested that the magnesium stearate was converted to stearic acid during the

preparation process. Chitosan microspheres containing propranolol hydrochloride were similarly prepared, but their surface was convoluted and their shape was not well defined. Unlike the microspheres without drug, the size of the drug-loaded microspheres decreased with increasing magnesium stearate content. The release of propranolol hydrochloride from the microspheres was fast, irrespective of the content of magnesium stearate. Drug encapsulation efficiency was enhanced when a greater amount of magnesium stearate was used (63).

GELATION: ALGINATE

One of the most important and useful properties of alginates is the ability to form gels by reaction with calcium salts (Fig. 20). These gels, which resemble a solid in retaining their shape and resisting stress, consist of almost 100% water (normally 99.0–99.5% water and 0.5–1.0% alginate). A gel, in classical colloid terminology, is defined as a system which owes its characteristic properties to a cross-linked network of polymer chains which form at the gel point. A considerable amount of research has been carried out in recent years to elucidate the nature of the cross-links and determine the structure of alginate gels.

It had been suggested that the cross-links were caused either by simple ionic bridging of two carboxyl groups on adjacent polymer chains via calcium ions or by chelation of single calcium ions by hydroxyl and carboxyl groups on each of a pair of polymer chains. Although these bonds may play a role in the gelation mechanism, they are not sufficiently energetically favorable to account for the gelation of alginate. It has been shown on the basis of fiber diffraction data and model-building calculations that the shape of both polymannuronic acid segments and the polyguluronic acid segments of alginic acid is ribbon-like and extended, and that these extended ribbons can stack together in sheets. On the basis of these data and the properties of gels, it has been suggested that the cooperative association of either polymannuronic acid segments or polyguluronic acid segments is involved in the formation of the cross-linked network of polymer chains.

Lim et al. developed a method of enclosing viable cells, tissues, and other labile biological substances within a semipermeable membrane. Preliminary in vitro studies of several types of microencapsulated cells and tissues (red blood cells, sperm cells, hepatoma cells, hepatocytes, pancreatic endocrine tissues, and islets) were described by Lim (19). Essentially, the process involves suspending the living cells or tissues in sodium alginate solution.

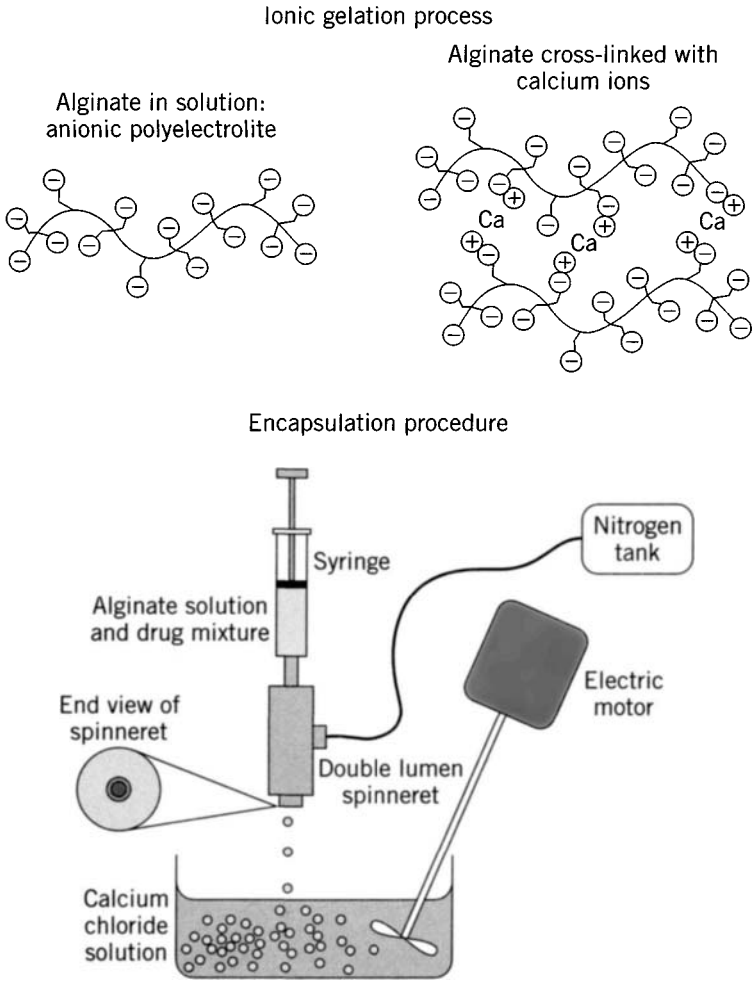

Figure 20. Sodium alginate gelation process.

The cell or tissue suspension is extruded through a microdroplet-forming device producing microdroplets which fall into a $CaCl_2$ solution and form gelled microbeads with the cells or tissues entrapped (Fig. 20). These cell-containing, gel microbeads are next treated with a solution of polylysine which displaces the surface layer of calcium ions and forms a permanent polysalt shell or membrane. Finally, the interior calcium alginate gel is "liquefied," either to stay in or to come out (depending on molecular weight and size of the starting alginate) of the capsule with a calcium sequestrant such as buffered citrate solution (19).

Diclofenac sodium is an ideal candidate for incorporation in a controlled release device to diminish its adverse effects after oral administration. Gohel et al. prepared microspheres by using sodium alginate as a polymer and $CaCl_2$ as a cross-linking agent. In this investigation, 3 full factorial design was used to investigate the joint influence of three variables: the stirring speed (X_1), concentration of $CaCl_2$ (X_2), and percent of heavy liquid paraffin in a blend of heavy and light liquid paraffin in the dispersion medium (X_3) on the time required for 80% drug dissolution (t_{80}). Potential variables such as concentration of sodium alginate and drug:sodium alginate ratio were kept constant. A statistical model with significant interaction terms is derived to predict t_{80}. The results of multiple linear regression analysis and F-statistics revealed that, for obtaining controlled drug release, the microspheres should be prepared using relatively lower stirring speed, higher interactions were found to be statistically significant in nature. A response plot was presented to show the effects of X_1, X_2, and X_3 on t_{80}. The drug was released by diffusion of anomalous type. A model was validated for accurate prediction of drug release profile (70,71).

Stable membranes were formed around alginate beads using a transacylation reaction between polysaccharidic esters, namely propylene glycol alginate (PGA) or pectin, and various proteins (human serum albumin [HSA], ovalbumin, bovine hemoglobin, lactoserum proteins). In a standard procedure, two reagents formed by dropwise addition into a calcium solution. Then the transacylation reaction was started by alkalization of the bead suspension. A membrane was formed around the beads made of a protein directly bound to a polysaccharide through amide linkages. The thickness of the membranes and the lysis time in trypsin were increased by raising the amount of NaOH used in the transacylation step. In a modified procedure, coated beads were obtained, incorporating PGA in the initial Na-alginate solution, and HSA in the transacylation bath. Activated charcoal was encapsulated in HSA-PGA beads, giving particles with adsorption properties toward creatinine. Assays were performed using PGA associated with alkaline phosphate as the membrane-forming protein. Stable beads were obtained having a relative activity of 39.3% as compared with free enzyme (73).

Lee et al. (72) developed a sustained release formulation which delivers melatonin (MT). MT is a pineal hormone of clinical value because of its short half-life, for those who have disordered circadian rhythm. The purpose of the study was to prepare MT-loaded microspheres by the emulsion melting/cooling method using stearyl alcohol (SA) and also dual-walled chitosan and sodium alginate beads, and to evaluate the release characteristics in simulated gastric and intestinal fluid. The MT-loaded microspheres were spherical, ranging in diameter from about 250 to 750 μm. When poly(ethylene glycol) 4000 (PEG) as a water-soluble additive, or aluminum tristearate (AT) as a water-insoluble additive, was incorporated, the surface roughness was further reduced resulting in a smooth matrix structure. The dual-walled chitosan and sodium alginate beads entrapping small MT-loaded microspheres were not spherical in structure. As the additive incorporated into SA microspheres increased, the drug content decreased. The release profiles of the MT-loaded microspheres were independent of pH. When the melted SA solution was cooled rapidly (in 10 minutes) to 25°C, the drug content increased but the release rate of MT-loaded microspheres decreased. The release rate of drug decreased as the amount of SA increased but an increase of agitation speed and amount of AT and PEG resulted in increased release rates. The release rate of drug from dual-walled chitosan beads increased slightly, but was retarded in the case of dual-walled alginate beads, when compared with MT-loaded microspheres. The emulsion melting/cooling method used to prepared MT-loaded microspheres using SA is simple and inexpensive, and may provide an alternative for the preparation of an oral sustained release dosage form of MT without using harmful organic solvents. The dual-walled chitosan and sodium alginate beads may also provide a convenient way to control the release of drugs (72).

Calcium alginate microspheres were prepared by an emulsification process (68). The effects of two copolymers, namely poly(vinylpyrrolidone) (PVP) and ethylcellulose, on the properties of the microspheres were studied. Microspheres prepared with and without PVP exhibited a better flow property but the drug content was lower and the drug release rate higher. The method of incorporating PVP was found to significantly affect the size distribution and drug content of the microspheres. Ethylcellulose produced marked aggregation of the microspheres which also showed a lower drug content, but a slower drug release. The retardation in drug release was attributed to the formation of aggregated microspheres with a less permeable matrix. The addition of triethylcitrate, which is a water-soluble plasticizer, was found to increase the rate of drug release, whereas the use of a higher viscosity grade of ethylcellulose produced the opposite effect. Ethylcellulose improved the flowability of the microspheres to a greater extent than PVP (68).

Porous microspheres were formed by the gelation of two polysaccharides, a polyanionic sodium alginate and a polycationic chitosan, followed by lyophilization which creates the porous structure (74). Porous microspheres were also formed by gelation of sodium alginate with $CaCl_2$ and gelation of sodium alginate with polylysine. FITC-BSA was incorporated into the microspheres by mixing the protein with the polysaccharide solution prior to gelation. Interleukin-2 (IL-2) was incorporated into the preformed microspheres by diffusion from an external aqueous solution of IL-2. Sustained release of the proteins from porous

alginate/chitosan microspheres is of longer duration than from alginate/$CaCl_2$, or from alginate/polylysine microspheres. Activity of the released IL-2 was investigated by determining the induction of cytotoxic T lymphocytes (CTL) when incubated with tumor cells and lymphocytes. It was found that the IL-2 remained active in the alginate/chitosan microspheres because the released IL-2 triggered induction of CTL more efficiently than free IL-2. Tumor-killing specific activity of CTL was the same whether induced by the sustained released IL-2 or by the addition of free IL-2 (74).

Microspheres of theophylline were prepared by ionotropic gelation method. The objective of this study was to investigate the influence of variables such as stirring speed, concentration of $CaCl_2$, and composition of the dispersion medium on the characteristics of the microspheres. A 3^3 randomized full factorial design was used to study the effect of the selected variables on the time for 90% drug dissolution (t_{90}). A linear model with interactive terms was generated using the multiple linear regression approach. F-statistics were carried out to evolve the reduced model. Significant interactions were not detected between the selected variables and good agreement was observed between the predicted and experimental checkpoint. The microspheres were evaluated during in vivo studies in dogs and the pharmacokinetic parameters were estimated by performing nonlinear regression analysis. The Wagner-Nelson method was adopted to compute the percentage drug absorbed. A good correlation was observed between the in vitro and in vivo results (70).

Chitosan microspheres were prepared by Berthold et al. (144) by a novel precipitation process using sodium sulfate as a precipitant. Low, medium, and high molecular weight chitosan was chosen for the formulation of microspheres. The extent of precipitation was controlled by the concentration of sodium sulfate and monitored by turbidity measurement. The amount of sodium sulfate required for the preparation of the microspheres depended on the molecular weight of chitosan. The particle size was determined by photon correlation spectroscopy and centrifugal sedimentation. The morphological characteristics were examined using SEM. The surface charge was measured by microelectrophoresis. After preparation the loading property with various antiinflammatory drugs was investigated using spectrophotometry. The influence of surface adsorption on the drug modification was controlled by DSC. Drug liberation was tested in vitro using side-by-side diffusion cells with dialysis membrane made of cellulose acetate. The highest loading (up to 30.5% relative to the polymer mass) was achieved with prednisolone sodium phosphate. The adsorbed drug was present in an amorphous form. The drug release from the microspheres was dependent on the drug/polymer ratio (144).

GELATION AGAROSE

Agarose is a water-soluble, nonionic polysaccharide that self-associates in water to form a gel (145). Thus, it can be used to fabricate spherical gel particles in which an active agent is entrapped. Figure 21 contains a flow diagram of

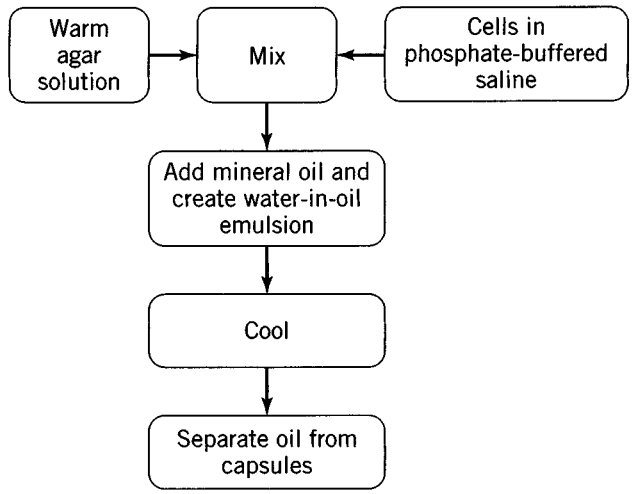

Figure 21. Microencapsulation by gelation using agarose.

recently developed fabrication procedure. The first step in the process consists of forming a molecularly dispersed solution of agarose in water. This requires heating an agarose-water mixture above 70°C, which is the melting point of agarose gels. The resulting solution is cooled to 40°C at which point the core material solidifies, thereby setting up the agarose gel structure and converting the aqueous droplets to spherical gel particles. The mineral oil is separated away from the gel particles by decantation and washing.

This procedure uses the large difference in gelation and melting temperatures of agarose. Agarose samples that gel at low temperatures (15–20°C) exist, but these gels, once formed, do not melt until 70°C. Thus, agarose can be completely dissolved in water at an elevated temperature, and then the solution obtained can be cooled to a reasonable temperature (i.e., above 25°C) without gelation occurring. At temperatures of 25–40°C, heat-sensitive core materials (e.g., live cells) can be added to the agarose solution. The agarose gel structure is then formed by cooling the mixture to 5–10°C. Significantly, the obtained gel particle has a matrix structure and is not a microcapsule with a continuous membrane surrounding a continuous core.

HOT MELT MICROENCAPSULATION

Hot melt is a process developed in the 1970s for photographic applications. In this process the melted polymer is mixed with drug, which can be encapsulated as solid or liquid particles. The mixture is then suspended in a immiscible solvent that is heated 5°C above the melting point of the polymer and stirred continuously using an overhead stirrer and a four blade impeller. Once the emulsion is stabilized (Fig. 22), it is cooled until the core material has solidified. The solvents used in this process could be silicon and olive oil. The low solubility of various drugs in these organic solvents makes them effective. It is recommended to sieve the drug, but in general, drug particle size is less than 50 μm. Using drugs with small particles sizes was

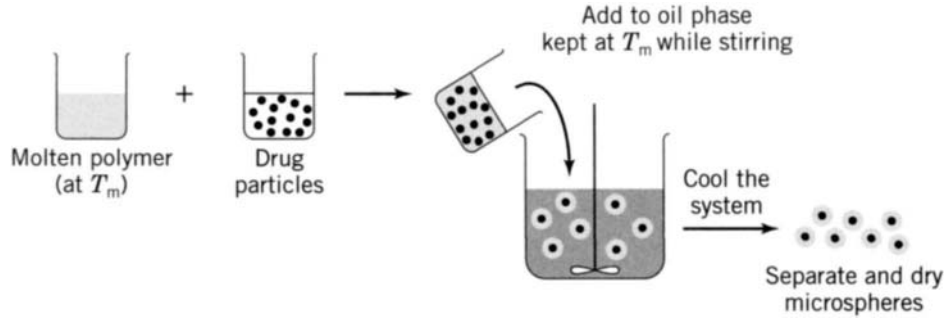

Figure 22. Microencapsulation by hot melt. Note that the dark dots represent drug particles; however, when the drug is water-soluble, an additional step may be required to prepare a water-in-oil emulsion, which is later encapsulated as shown here.

found to improve the drug distribution within microspheres. After cooling, the microspheres are washed by decantation with petroleum ether to give a free-flowing powder. Then they are sieved, dried, and stored in a freezer (when biodegradable polymers are used). Size distribution can be controlled by the stirring rate and the yield of encapsulation is 70–90%. This microencapsulation procedure is reproducible with respect to yield and size distribution, but the disadvantage of this approach is the moderate temperatures to which the drug must be exposed.

One way to overcome this problem is to synthesize polymers with lower melting points. This can be achieved by changes in the backbone of the polymer (i.e., in polyanhydrides), or using polymers that have a low melting point. When more stable drugs are involved the temperature, as well as the type of the polymer used, may be more versatile. Mathiowitz and Langer used this method to prepare polyanhydride microspheres (81). Surface morphology of the polyanhydride microspheres was studied via stereo microscopy and SEM and was performed immediately after preparation and after different periods of degradation. Both external and internal faces were examined. The microspheres were mounted on metal stubs, cut with a blade, and sputter-coated with gold-palladium. SEM of the poly(CPP-SA) are shown in Figure 23a. Microspheres are spherical, and the external surfaces appear smooth and crenellated. The crenellated surface is a typical result of this method. It is possible that the external surface is loaded with spherulites which formed during the slow cooling. No traces of drug or dye are found on the outer surfaces and cross sections reveal a dense internal structure, as seen in Figure 23b. Morphological studies made after 24 hours of in vitro degradation show that only the surface of the microsphere was attacked. The surface possessed small cracks and an irregular structure, whereas the internal face remains intact the same microspheres (Fig. 23c). A well-defined degrading zone, characterized by a spherical shape appeared and moved progressively from the surface towards the center of the microsphere. The erosion zone is composed of monomers (macromolecules). Figure 24d shows the same microspheres after 20 days of in vitro degradation. The microspheres show a weak structure (composed of monomers) which collapses easily (again these are insoluble monomers). The weight of this material is 5–10% of the initial weight; after 4 weeks the microspheres completely disintegrate. Figure 23e,f demonstrate a case where the drug loading of the microsphere was too high (70%) resulting in high amounts of drug on the surface of the microsphere.

A good correlation was achieved when comparing weight loss of degrading samples with the production of the degradation products (81,83). These observations suggest that these microspheres display surface erosion. Incorporating hydrophilic molecules such as acid orange (M_W 364) at high loadings (30%) changes the degradation rate of the polymer. Release experiments were conducted in 10–50 mL of 0.1M, pH 7.4 phosphate buffer at 37°C in small columns. The release of acid orange was almost complete in 200 min and the degradation of the polymer lags behind the dye (81). Actually the release kinetics are affected more by the water uptake of the dye than by the degradation process. The influence of loading on the release profile was more pronounced when the loading is about 2%. Here release was controlled by polymer erosion. Except for the small burst effect at the beginning, the dye and polymer were released simultaneously. At higher loadings, the dye was released much faster than the polymer eroded. At high loadings of hydrophilic drugs, the release rate is not controlled by polymer erosion. Instead the polymer degradation is faster than that of a pure microsphere, and the drug is released faster than polymer dissolves. The reason for this is that the polymer starts to degrade from inside as well. The hot melt fabrication technique produces spheres with density independent of size. The study was confined to low loadings, that is, 2–5%, and the particles of the drug were mostly of small size (less than 50 μm) and for acid orange the size was less than 50 μm. The results demonstrate that the smaller the microspheres, the faster the release rate. It should be noted, however, that as the size of the microspheres approaches that of the incorporated drug particles, dissolution- or diffusion-controlled release may also occur due to particles touching the surface of the microspheres. Such a phenomenon may be occurring in the smallest microspheres. Incorporating insulin in microspheres changes the (release) degradation profile (81,83). In this case, drug release corresponds closely to polymer degradation. One explanation is the fact that zinc insulin has a low solubility in water (0.22 mg/dL) so that diffusional escape and osmotic swelling are diminished, which helps to achieve erosion-controlled release. Alternatively, it is possible that the small size of the insulin particles entrapped in the microspheres enabled good dispersion inside the polymer. The release of insulin in bioactive form was evident from the in vivo experiments. A possible mech-

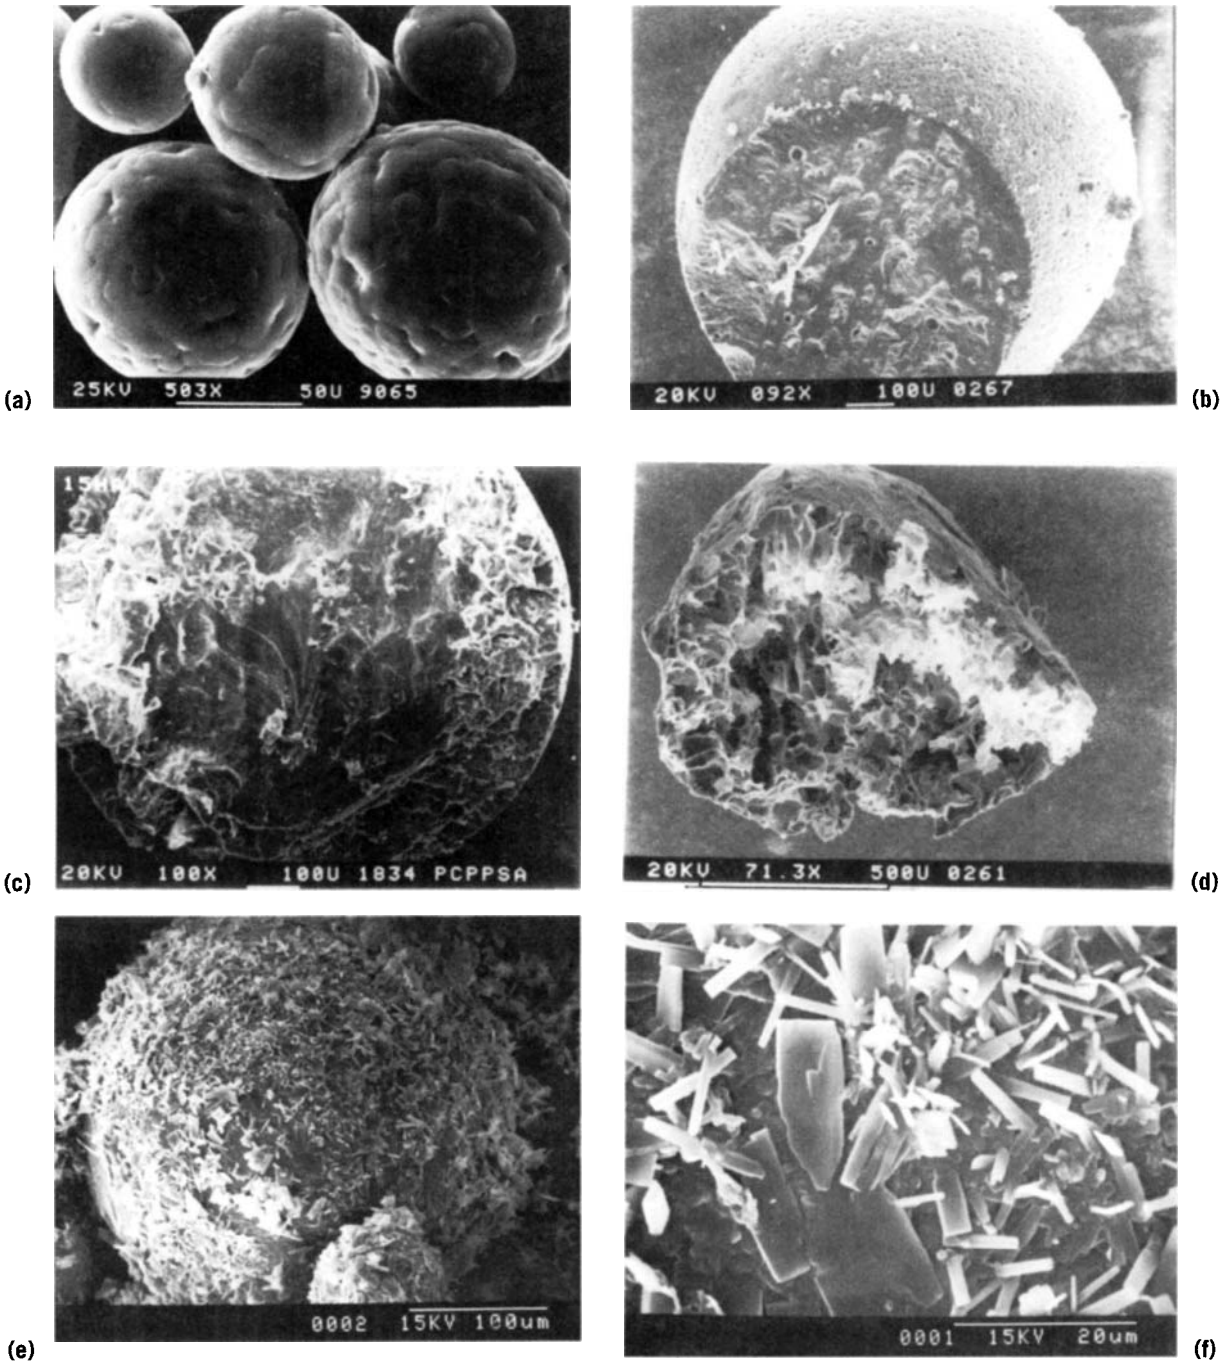

Figure 23. SEM of polyanhydride microspheres (**a**) external surface; (**b**) cross section; (**c**) cross section after 24 hours in buffer; (**d**) cross section after 20 days in buffer; (**e**) microsphere with 70% loading of salicilic acid; (**f**) higher magnification of same capsule.

anism describing these observations is that the release from polyanhydride microspheres loaded this low levels of drug involved two main steps. When microspheres are immersed in a buffer solution, the degradation process starts. A particle of drug, which is very close to the surface, dissolves and is released. As the degrading zone, which is composed of monomers, advances toward the center, all the hydrophilic drugs are released. Fewer hydrophilic drugs, however, may be entrapped in the polymer, until the polymer completely dissolves. The latter phenomenon was observed for insulin.

The effect of in vivo performance of Zn/insulin-loaded (15% W/W) poly(CPP-SA) 20:80 microcapsules prepared by hot melt microencapsulation and implanted in diabetic rats, was sustained normoglycemia for up to 4 days (81) with no deaths due to insulin overdose. This stands in

sharp contrast to the microspheres made by solvent evaporation which caused short-lived, often fatal hypoglycemia (see "Solvent Evaporation").

SOLVENT REMOVAL

This method is a modification of organic phase precipitation (15) which, in specific situations, offers significant advantages. The fabrication occurs at room temperature and totally in organic solvents, an important consideration because for hydrolytically labile polymers such as polyanhydrides the avoidance of aqueous solutions is particularly important. Mathiowitz et al. (82,146) used this method to develop an improved technique of encapsulating insulin. In this example the polymer was dissolved in methylene chloride, the desired amount of drug was added and then the mixture was suspended in silicone oil containing Span® 85 and methylene chloride. After pouring the polymer solution into the silicone oil, petroleum ether was added and the mixture was stirred until the methylene chloride was extracted into the oil solution and sufficient microcapsule hardening was achieved. The resulting microspheres were isolated by filtration, washed with petroleum ether and dried overnight under vacuum (Fig. 24). The size of microspheres was always smaller than 300 μm. The best correlation between the expected and achieved loadings (82,83) was obtained with the hydrophilic substances myoglobin, acid orange, and insulin. This is understandable because the microencapsulation occurred in an organic solvent, preventing the loss of drug by diffusion.

The difference between solvent removal and organic phase separation is evident when comparing Figure 24 and Figure 12. In solvent removal the polymeric solution is introduced into the continuous phase, an emulsion is formed first and then the organic solvent is extracted to the continuous phase. In organic phase separation the polymer is dissolved in the continuous phase, a phase inducer is introduced, a coacervate is formed and, finally, encapsulation of drug occurs.

SEM of microspheres made from polymer without drug are shown in Figure 25. The amorphous, poly(CPP-SA) 50:50 microspheres are spherical with smooth and dense surfaces (Fig. 25a and 25b), whereas the crystalline poly(SA) (poly[sebacic acid]) microspheres display a very rough morphology containing fractures extending throughout the entire structure (Fig. 25c). The microspheres of poly(CPP-SA) 20:80 (Fig. 25d) and poly(CPP-SA) 50:50 exhibited a less porous internal structure (82,83), but the external dense layer was always present. A cross section of the poly(carboxyphenoxyhexane-*co*-sebacic acid) 50:50 microspheres reveals a very porous structure surrounded by a dense layer near the surface (Fig. 25d). When microspheres containing drugs were prepared, no change was observed in the external surface, for drug loadings up to 16.5%. Above that level, some crystals appeared on the surface (83).

The dense external structure and the porous core are typical of most of the microspheres produced by this method, especially the less crystalline polymers. A closer inspection of the physical events occurring during microsphere formation may help in understanding their performance. A schematic representation of the process is described in Figure 24 and a description of the process taking place is proposed. The polymer solution is introduced into the oil phase followed by rapid diffusion of the methylene chloride into the oil phase. The concentration of the polymer near the wall is high, which explains why precipitation of the outer shell occurs first (82,83), leaving high concentrations of polymer dissolved in methylene chloride inside the core. This organic solvent can be later removed by addition of a nonsolvent or by applying high vacuum. The process of microencapsulation is presumably diffusion controlled—at least during the first stages where the difference in concentration of methylene chloride between the two phases (silicone and polymer solution) is significant. After precipitation begins, the process becomes more complicated. It involves diffusion of methylene chloride, both in the polymer solution and in the already precipitated polymer. The first precipitation occurs in the external area of the forming sphere, and this layer slows subsequent diffusion of methylene chloride into the oil phase. This dense external structure and porous internal core are presumably obtained because during precipitation of the microspheres the external surface precipitates first, thus making it difficult for the microsphere to shrink. The re-

sharp contrast to the microspheres made by solvent evaporation which caused short-lived, often fatal hypoglycemia (see "Solvent Evaporation").

SOLVENT REMOVAL

This method is a modification of organic phase precipitation (15) which, in specific situations, offers significant advantages. The fabrication occurs at room temperature and totally in organic solvents, an important consideration because for hydrolytically labile polymers such as polyanhydrides the avoidance of aqueous solutions is particularly important. Mathiowitz et al. (82,146) used this method to develop an improved technique of encapsulating insulin. In this example the polymer was dissolved in methylene chloride, the desired amount of drug was added and then the mixture was suspended in silicone oil containing Span® 85 and methylene chloride. After pouring the polymer solution into the silicone oil, petroleum ether was added and the mixture was stirred until the methylene chloride was extracted into the oil solution and sufficient microcapsule hardening was achieved. The resulting microspheres were isolated by filtration, washed with petroleum ether and dried overnight under vacuum (Fig. 24). The size of microspheres was always smaller than 300 μm. The best correlation between the expected and achieved loadings (82,83) was obtained with the hydrophilic substances myoglobin, acid orange, and insulin. This is understandable because the microencapsulation occurred in an organic solvent, preventing the loss of drug by diffusion.

The difference between solvent removal and organic phase separation is evident when comparing Figure 24 and Figure 12. In solvent removal the polymeric solution is introduced into the continuous phase, an emulsion is formed first and then the organic solvent is extracted to the continuous phase. In organic phase separation the polymer is dissolved in the continuous phase, a phase inducer is introduced, a coacervate is formed and, finally, encapsulation of drug occurs.

SEM of microspheres made from polymer without drug are shown in Figure 25. The amorphous, poly(CPP-SA) 50:50 microspheres are spherical with smooth and dense surfaces (Fig. 25a and 25b), whereas the crystalline poly(SA) (poly[sebacic acid]) microspheres display a very rough morphology containing fractures extending throughout the entire structure (Fig. 25c). The microspheres of poly(CPP-SA) 20:80 (Fig. 25d) and poly(CPP-SA) 50:50 exhibited a less porous internal structure (82,83), but the external dense layer was always present. A cross section of the poly(carboxyphenoxyhexane-*co*-sebacic acid) 50:50 microspheres reveals a very porous structure surrounded by a dense layer near the surface (Fig. 25d). When microspheres containing drugs were prepared, no change was observed in the external surface, for drug loadings up to 16.5%. Above that level, some crystals appeared on the surface (83).

The dense external structure and the porous core are typical of most of the microspheres produced by this method, especially the less crystalline polymers. A closer inspection of the physical events occurring during microsphere formation may help in understanding their performance. A schematic representation of the process is described in Figure 24 and a description of the process taking place is proposed. The polymer solution is introduced into the oil phase followed by rapid diffusion of the methylene chloride into the oil phase. The concentration of the polymer near the wall is high, which explains why precipitation of the outer shell occurs first (82,83), leaving high concentrations of polymer dissolved in methylene chloride inside the core. This organic solvent can be later removed by addition of a nonsolvent or by applying high vacuum. The process of microencapsulation is presumably diffusion controlled—at least during the first stages where the difference in concentration of methylene chloride between the two phases (silicone and polymer solution) is significant. After precipitation begins, the process becomes more complicated. It involves diffusion of methylene chloride, both in the polymer solution and in the already precipitated polymer. The first precipitation occurs in the external area of the forming sphere, and this layer slows subsequent diffusion of methylene chloride into the oil phase. This dense external structure and porous internal core are presumably obtained because during precipitation of the microspheres the external surface precipitates first, thus making it difficult for the microsphere to shrink. The re-

Figure 25. mainder of the solvent then diffuses out of the microsphere leaving a porous structure.

In the more crystalline poly(SA) microspheres, there was no formation of a dense external layer, but a quick precipitation of the entire polymer emulsion led to a very porous structure. In other cases in the literature (84,146). The rate of precipitation may also be a key to understanding the type of microspheres which were obtained. The rough surface of the poly(SA) microspheres may be due to the faster precipitation of poly(SA) compared with poly(CPP-SA) 50:50. Thus precipitation occurred in the poly(SA) microspheres before a stable emulsion could form. In contrast, in slower precipitating systems—poly(CPP-SA) 50:50, for example—there is first the formation of an emulsion and then precipitation. This "two-step" process during microencapsulation can be further controlled using different surface-active compounds to stabilize the emulsion. It should be noted that all experiments were done with the same organic solvents, because different solvents may lead to different external morphologies.

DSC and X-ray analysis of the polymers, dyes, and drug-loaded microspheres were performed in order to characterize the physical state of the polymers and dyes after microencapsulation (82,146). In cases where the drug formed a dispersion in the first stage of microencapsulation, we would expect that, at the end of the process, crystalline drug particles would be dispersed in the polymer matrix. In such a system DSC would display two endotherms, each relating to the melting point of either drug or polymer. In cases where the drug is dissolved in the organic polymeric solution, solvent removal causes the drug to either dissolve in the polymer or crystallize out and form a dispersion. In the latter case DSC would again display two endotherms. In the former case, where the drug forms a solution inside the polymer, no separate event relating to the melting of the drug would occur. However, some changes in the melting of the polymer might occur, provided the concentration of the drug in the polymer phase is high enough to cause changes exceeding the sensitivity of DSC. Mathiowitz thus monitored melting points of the dyes and polymer before and after encapsulation. A sharp endotherm was observed for free acid orange, *p*-nitroaniline and methyl red (119.4, 149.8, 181.2°C, respectively) corresponding to the melting phase transitions. The "blank" microspheres displayed a sharp endotherm at 78°C corresponding to the melting of the crystalline regions of the polymer (83).

In loaded microspheres (up to 16% loading), no melt corresponding to the acid orange appeared around 121°C (83). These facts may imply that the dye forms a solution inside the polymer (at loadings lower than 23%). However, the absence of the thermal event at low loadings does not always indicate that this is the case. In order to verify this point X-ray diffraction was used and indicates that acid orange was dispersed as crystals in the microspheres (data not shown) (82,146).

X-ray diffraction analysis of methyl red–loaded microspheres indicated no crystalline diffraction related to the dye, nor did the DSC show any endotherm related to the melting of the dye. However, the melting point of the polymer had slightly decrease compared to blank microspheres. X-ray diffraction displayed the typical diffraction pattern of pure poly(SA), but the crystallinity decreased from 55% to about 40% (82,146). However, the change in the melting point and the decrease in crystallinity suggested that the drug may be soluble in the polymer. It is quite possible that the dye, being soluble in the amorphous state, hindered the crystallization of the polymer and thus decreased the degree of crystallinity.

Similar experiments were performed with poly(CPP-SA) 50:50 microspheres loaded with the same substances. Both DSC and X-ray diffraction confirmed that acid orange was dispersed as crystals in the polymer, whereas the hydrophobic dyes formed solutions inside the polymer (82,146).

Blank poly(CPP-SA) 50:50 microspheres prepared by solvent removal were implanted subcutaneously in rats. The spheres were smaller than 300 μm and were injected as an aqueous suspension. After 10 days of implantation several spherical microsphere remnants were found among the remains of degraded microspheres in tissue samples taken from the implantation site. These remnants were composed of the same polymer degradation products as seen in the nonintact remnants (as judged by infrared spectroscopy) and eventually disappeared from the implantation area. Although the appearance of external remnants might, at first glance, appear to contradict other evidence supporting surface erosion, the SEM analysis of microspheres already presented suggests a possible explanation based on polymer density. Cross sections of microspheres during release show an outer zone in which degradation has already occurred but the degradation products have not yet disappeared. In addition, cross-sectional views of undegraded microspheres formed by both solvent removal and hot melt microencapsulation show a dense external surface and a less dense inner core (82,83,146). It is quite plausible that during degradation the external surface erodes completely, leaving behind a dense but permeable layer of degradation products that must dissolve and diffuse away. Meanwhile, erosion continues into the core, where the degraded material is less dense and is able to more easily dissolve and diffuse out. The fact that the remnants disappear after a longer time in vivo is further evidence that solubilization of the degradation products may be the controlling step in the disappearance of the microspheres, but not in the release of the drug.

Histological studies of both samples revealed a moderate acute inflammatory response that peaked at day 3. Histological examination of tissue removed at day 40 from the implantation site revealed a layer of amorphous fibril material within the subcutaneous tissue, a remnant of the implanted polymer. There was no evidence of tissue reaction to this material within the subepidermis.

An in vivo study with insulin-loaded microspheres prepared by solvent removal demonstrated more successful serum and urine glucose control than previously seen with microspheres made by solvent evaporation. Five diabetic rats were implanted with 200 mg of insulin-loaded (10%) microspheres. The results demonstrate near-zero urine glucose levels and serum glucose control. A similar experiment with 200 mg of 5% (W/W) loaded microspheres decreased urine glucose effectively for 3 days and resulted in only 1 day of normoglycemia, whereas 100 mg of 10% (W/W) loaded microspheres showed 3 days of lowered urine glucose and 2 days of serum glucose control. For comparison, urine and blood glucose levels for both diabetic control and healthy control rats (5 rats in each group) were measured. As expected, glucose was never found in the urine of healthy rats and the untreated diabetic rats showed no significant lowering of blood or urine glucose levels (82).

Atkins et al. (144) prepared spherical, monolithic, poly(DL-lactide-*co*-glycolide) (PLGA) 50:50 and PLGA 75:25 microspheres with a honeycomb-like internal architecture, composed of and containing a range of vancomycin loadings. Microspheres were prepared using W/O emulsification, except that Span® 40 was used as the continuous oil phase surfactant. In a typical fabrication the organic polymer phase was prepared by the ultrasonication (100 W bath) of 1 g of either 75:25 or 50:50 PLGA together with either 1, 0.333, or 0.1 g vancomycin in 30 mL acetonitrile

at 35°C for 15 minutes, providing theoretical percentage loadings of 50, 16.7, and 5% vancomycin, respectively. This organic phase was maintained at 55°C in a water bath. The continuous oil phase consisted of 125 g light mineral oil containing 2% (W/W) Span® 40 maintained at 55°C. The organic polymer phase was slowly added to the continuous phase and emulsified at 55°C using a high shear head at 3,000 rpm for 30 minutes. Droplet formation was monitored by light microscopy and the final emulsion was stirred at 440 rpm with a three-blade impeller in an off-center position for a further 60 minutes at 55°C to facilitate solvent evaporation. The emulsion was cooled to just above 35°C to prevent the precipitation of Span® 40, and left for 1 hour to allow the microspheres to harden. The microspheres were separated by vacuum filtration using solvent resistant polypropylene-backed PTFE filters (1 μm pore size) and washed with excess petroleum ether at 55°C to remove the Span® 40. The resultant microspheres were air-dried and weighed to determine percentage yield. The free-flowing preparation of grey/white microspheres were stored desiccated, under vacuum at room temperature (147). In a way, this method is a combination of solvent evaporation and solvent removal, because some of the solvent is removed by the organic phase and some is evaporated by the applied heat.

Porous salmon calcitonin-loaded PLGA microspheres (size range 35–140 mm) of varying matrix characteristics were prepared by an aqueous emulsification process using either a temperature gradient (Tmp) or dilution (Dil) of the continuous phase. The Tmp technique resulted in microspheres with a hollow internal core and a porous wall. The core size and thickness of the porous wall were dependent on the temperature gradient used. A rapid ramp in temperature from 15 to 40°C resulted in a large core and a thin wall, whereas a gradual temperature rise resulted in a smaller core. The Dil technique produced microspheres with a uniform, honeycomb-like pore structure without a core where pore size was dependent on the dilution volume used. The specific surface area was higher and bulk density lower for microspheres prepared by the Tmp technique, whereas there was no significant difference in the peptide load (3.2–4.5%) between both techniques. A rapid removal of CH_2Cl_2 was observed in the case of the Tmp technique while the Dil technique facilitated a slower and gradual CH_2Cl_2 removal. Residual CH_2Cl_2 was approximately <10–20 ppm for microspheres prepared by the Tmp technique, whereas the levels were 20–130 ppm for microspheres produced by the Dil technique. Higher retention of methanol (~15–20%) was observed in the droplet formation stage with the Tmp technique, subsequent removal of which affected the core size. In the Dil technique, very low levels of methanol (<2%) were retained in the droplets soon after dispersion resulting in a uniform porous structure without core. Slower removal of methanol from the microspheres was partly responsible for the core formation (148).

The use of supercritical solvents as an extraction method to prepare microspheres is an interesting approach. The aerosol solvent extraction system (ASES) uses a supercritical gas as nonsolvent for an organic solution of drug and polymer in order to form microparticles by a flocculation process. Due to the miscibility of organic solvent and supercritical gas phase, microparticles with residual organic solvents below 30 ppm are formed. This principle was tested to encapsulate model drugs such as hyoscine butylbromide, indomethacin, piroxicam and thymopentin. As a carrier, the polymer poly(L-lactide) was used. The resulting microparticles were investigated with regard to particle formation, morphology, particle size, size distribution, and drug loading. The lower the polarity of incorporated drug, the greater the extraction, which reduced the drug loading of the microparticles. The extraction capacity of the gas phase depends on temperature and pressure which determines density and polarity of the gas. The obtained results show that the production conditions have to be optimized for each drug/polymer combination. Totally nonpolar drugs are completely extracted together with the organic solvent; however, polar drugs (especially peptides and proteins) are easy to incorporate with the ASES process (149).

Poly(L-lactide) microspheres containing a low molecular weight pharmaceutical agent were prepared using the precipitation with a compressed antisolvent (PCA) process with supercritical carbon dioxide as the antisolvent. Gentamycin, naloxone, and naltrexone were solubilized in methylene chloride using hydrophobic ion pairing (HIP) to stoichiometrically replace polar counter ions with an anionic detergent, aerosol OT (AOT, sodium bis-2-ethylhexyl sulfosuccinate). Through HIP complexation, solubilities in excess of 1 mg/mL were attainable in methylene chloride, allowing levels of direct incorporation that are not possible with other PCA approaches. The drug/polymer particles were spherical in shape and between 0.2 and 1.0 μm in diameter, as determined by SEM. Drug incorporation efficiencies were determined and in vitro release profiles measured. At 37°C, the release of the ion-paired drugs into phosphate-buffered saline displays minimal burst effects and exhibits release kinetics that are approximately linear with the square root of time, indicating matrix diffusion control of drug release. For gentamycin, linear release from the poly(L-lactide) microspheres was observed for more than 7 weeks, even at a drug loading of near 25% (W/W). Naltrexone exhibits similar release characteristics, although more drug was found on the surface of the microspheres. Conversely, rifampin, which was not ion-paired, was poorly encapsulated (150).

SPRAY-DRYING

Spray-drying is a method for preparing microspheres that is reproducible, rapid, and easy to scale up. Mathiowitz et al. (151) used this fabrication technique to examine its influence on crystallinity (by X-ray and DSC), external morphology (by SEM) and release kinetics of polyanhydrides. Model drugs, including the dyes, acid orange 8 and methyl red, and the protein, bovine somatotropin (STH), were examined with a variety of polyanhydride homo- and copolymers.

The following polymers were studied poly(sebacic anhydride) (PSA), copolymers of 1,3 bis-(carboxyphenoxypropane) (CPP) and sebacic acid (SA) having molar ratios of 20:80 and 50:50, copolymers of 1,6 bis-(carboxyphenoxy

hexane) (CPH) and sebacic acid (SA) having a molar ratio of 50:50, copolymers of fumaric acid (FA) and sebacic acid (SA) having a molar ratio of 20:80, and poly(valeric anhydride) (PCPV).

In order to create a delivery system using spray-drying it is essential to dissolve the polymer in a volatile liquid. Polyanhydrides degrade in aqueous solutions, and therefore it is preferable to process them in organic solvents. With volatile solvents such as methylene chloride it possible to encapsulate various heat-sensitive drugs, including proteins, at low temperature. For this particular study only polymer that was soluble in methylene chloride was used. The polymer is first dissolved in methylene chloride, and the drug can be either dissolved (e.g., methyl red) or suspended as particles (e.g., acid orange 8 and STH). Because the spray-dryer nozzle was 0.5 mm in diameter, it was important to obtain very small particles of the insoluble drug. Particle size reduction, via spray-drying a dilute, aqueous, acid orange solution, resulted in raisin-shaped particles, 1 to 5 μm in size. These particles were subsequently suspended in the polymer solution and sprayed-dried as already described. STH (the pure drug) had a narrow size distribution (1 to 2 mm). Methyl red was soluble in the organic solvent and was sprayed dried as a solution. Throughout this work, the conditions of spraying were kept identical: the same organic solvent and the same polymer concentration were used. This fact allowed us to correlate the morphology of a series of polymers, spray-dried under the same conditions. In general, it was possible to spray dry the crystalline polymers PSA, P(CPP-SA) 20:80, P(FA-SA) 20:80, and P(FA-SA) 50:50. However, each polymer displayed a different morphology as judged by SEM. When using more hydrophobic polymers—P(CPP-SA) 50:50, P(CPH-SA) 50:50, and PCPV—some aggregation occurred during spraying. This could have been a result of the more viscous solutions of these polymers as well as their low glass transition.

SEM of black microspheres made of PSA are shown in Figure 26a. The microspheres are spherical in shape with few aggregates and display a rough external structure. Some of the polymer precipitated as long rods, which could be a result of fast precipitation that is typical of the PSA polymer. Microspheres made of P(CPP-SA) 20:80 polymers exhibited a crenellated external surface (Figure 26b) and sizes ranging from 1 to 5 μm. The same external surface appeared when acid orange-loaded (3%) P(CPP-SA) microspheres were examined. When methyl red was encapsulated, the external surfaces of the individual microspheres were spherical in shape with few pores on the surfaces. In this particular preparation some of the spheres accumulated in the spray-dryer trap.

The STH-loaded P(CPP-SA) 20:80 microspheres were spherical with smooth external surfaces, but with a few pores on the surface of some of the capsules. In this case, the drug was supplied as fine particles, 1 to 2 μm in size. It is possible that some of the spheres were single particles of drug encapsulated by a continuous polymer membrane. P(FA-SA) 20:80 was the next crystalline polymer that was studied. In this case, the microspheres were spherical and smaller than 10 μm (Figure 26c). High magnification reveals a highly porous structure. This porous structure was typical of all spray dried fumaric polymers—both blank and loaded microspheres.

The external surfaces of the amorphous P(CPP-SA) 50:50 and P(CPH-SA) 50:50 microspheres were smooth and dense. However, the microspheres tended to fuse before the final drying. The same phenomenon was observed with PCPV microspheres (Figure 26d). This aggregation can be prevented by lowering the concentration of the polymer solution. However, the glass transitions of these polymers are very low, and this may have been the main reason for the high degree of fusion during spray-drying (151).

DSC and X-ray analyses of the spray-dried polymers loaded with dyes and drugs were performed in order to characterize the physical state of the polymers after microencapsulation. By monitoring the melting points of the dyes and the polymer before and after encapsulation it was possible to determine when a solution or phase separated system was obtained. A sharp endotherm was observed for free acid orange and methyl red (119.4 and 181.2°C, respectively) corresponding to the melting phase transitions. The "blank" spray-dried PSA microspheres displayed a sharp endotherm at 81°C, corresponding to the melting of the crystalline regions of the polymer. The crystallinity of the PSA microspheres was lower than the crystallinity of the original polymer (decrease of 7.6 cal/g). However, the crystallinity was not completely destroyed, and the typical powder diffraction of the PSA units was still retained. After acid orange is incorporated, the crystallinity of the polymer remains almost unchanged. To further study the behavior of the spray-dried microspheres, the P(CPP-SA) 20:80 microspheres were analyzed by DSC. A dramatic decrease was seen in the melting point of the blank microspheres (58.5°C) compared with the pure polymer (72°C). The melting was broad, and the numbers reported represent the peak maxima. This was true for microspheres loaded with acid orange (56.6°C), methyl red (56.2°C), and STH (58°C). The decrease in melting point could be a result of residual solvent (up to 5% by weight) in the microspheres, which acts as a diluent. There was also a pronounced decrease in the heat of fusion, which directly reflects a decrease in crystallinity. X-ray diffractions of two different loadings of acid orange in P(CPP-SA) 20:80 microspheres are shown in Figure 27. The four well-defined diffraction patterns, which correspond to the P(CPP-SA) 20:80 (152) are hardly seen and are replaced by broad bands, indicating a profound decrease in the degree of crystallinity. The blank microspheres seemed to be less crystalline than the loaded spheres, as judged by X-ray diffraction (Fig. 28). A comparison of blank P(CPP-SA) 20:80 microspheres to microspheres loaded with acid orange, as well as methyl red, is shown in Figure 28. As mentioned previously, the polymer still retains some crystallinity, but the fine structures of the crystalline areas are gone. The lower degree of crystallinity is more pronounced in the methyl red sample and is also supported by the lower heat of fusion (83,151). Previous publications, describing different encapsulation systems, indicated that methyl red may form solutions with polyanhydrides, resulting in a lower degree of crystallinity (83).

P(FA-SA) 20:80 behaved differently. The melting point, as well as the heat of fusion, was lowered for both loaded

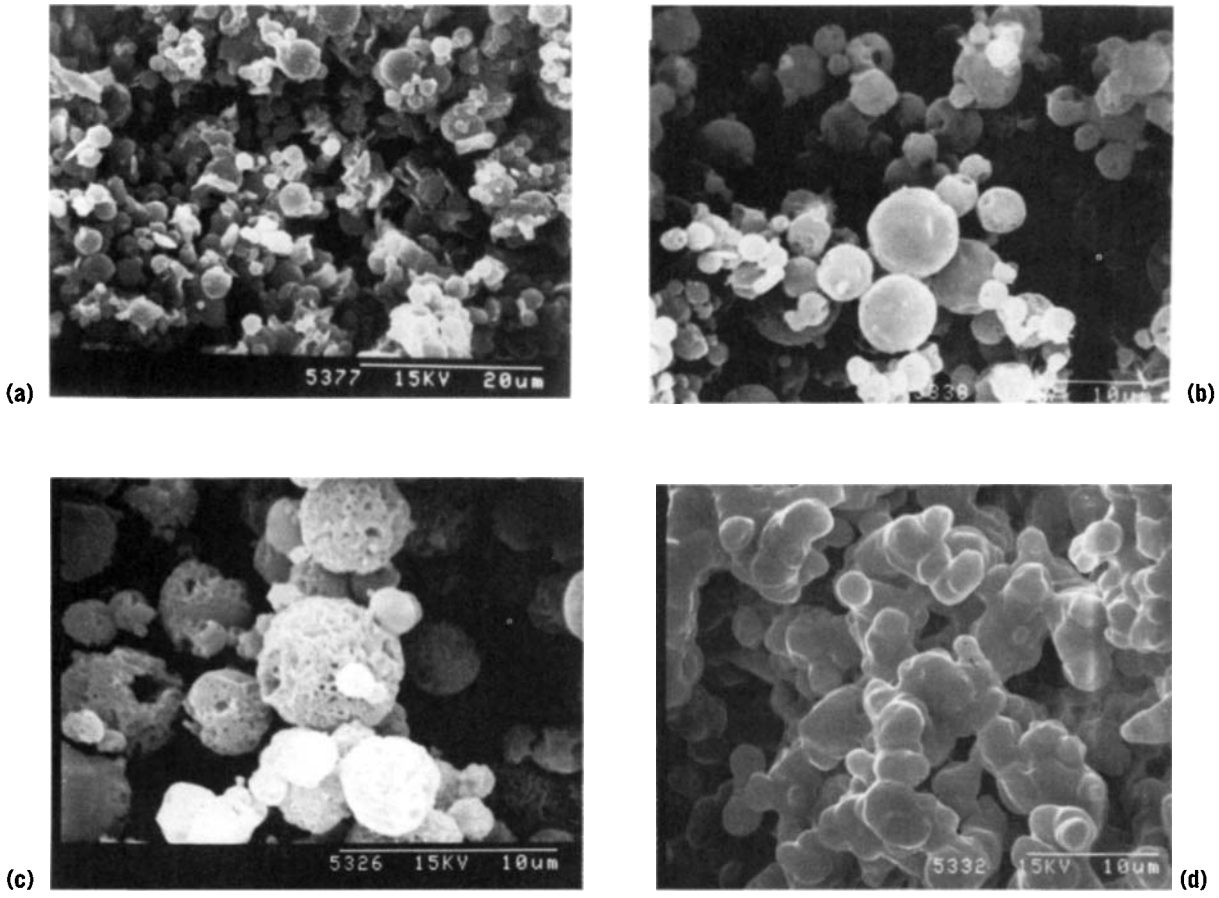

Figure 26. SEM of spray-dried microspheres: (**a**) blank poly(SA): (**b**) blank poly(CPP-SA) 20:80; (**c**) blank poly(FA-SA) 20:80; and (**d**) PCPV microspheres.

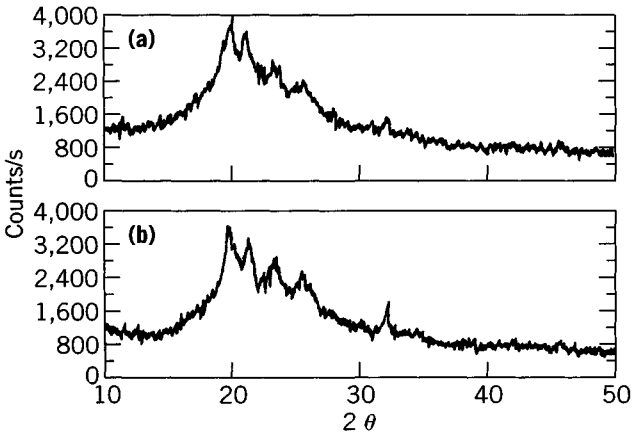

Figure 27. X-ray diffraction of P(CPP-SA) 20:80 spray-dried microspheres (**a**) loaded with 3% acid orange and (**b**) loaded with 10% acid orange. *Source:* With permission from Ref. 151.

and unloaded microspheres. However, the fine structure of the P(FA-SA) 20:80 polymer was retained (Fig. 29). This indicates that the polymers crystallized during the spray-drying process.

It was evident from the X-ray powder diffraction, as well as from thermal studies, that the polymers tend to lose their degree of crystallinity during spray-drying. This phenomenon is known in spray-drying of both polymers as well as small molecules (152,153). The fast drying process provides very short times for the polymer to precipitate, resulting in a more amorphous structure. Addition of drugs, especially those soluble in the organic solvents, further decreases the degree of crystallinity.

The release of acid orange from P(CPP-SA) 20:80 occurred over a period of 15 hours, and the polymer degraded completely over 24 hours. Similar release rates were observed in P(FA-SA) 20:80 microspheres, where polymer degradation was more closely correlated to release rates. In this case, both the porous structure and the good solubility of the degradation products resulted in a better correlation between the release and degradation products. Release of STH (Fig. 30) lasted over 24 hours and resulted in the release of about 90% of the drug. The short release rates (24 hours) that were obtained are expected. First, the degradation time of P(CPP-SA) 20:80 polymer is very fast (81). In addition, the size of the microspheres is very small (1–5 mm). This type of delivery system may find applications in cases where fast release is needed, for example, in oral delivery systems.

The release of the incorporated material can occur via two independent processes. The first is diffusion of the drug through fluid-filled pores formed by the dissolution of

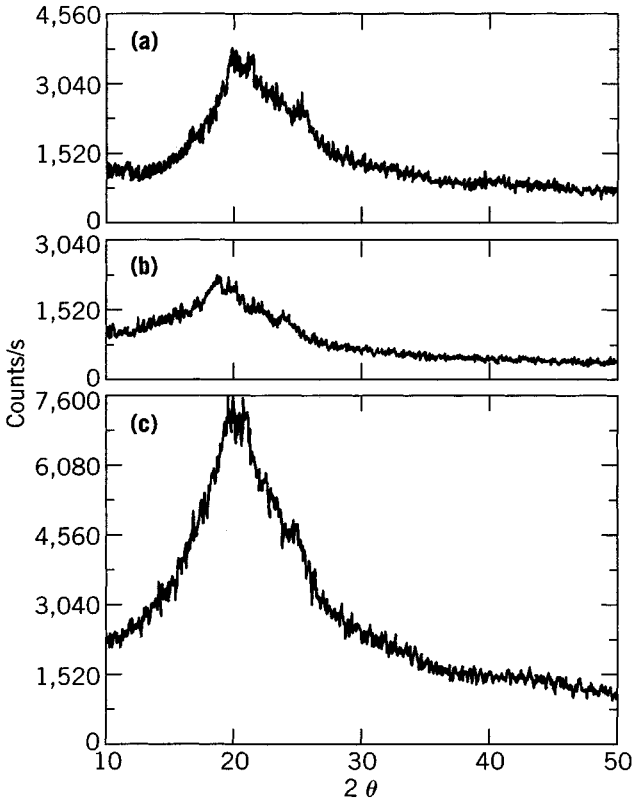

Figure 28. X-ray diffraction of P(CPP-SA) 20:80 spray-dried microspheres: (**a**) blank; (**b**) loaded with methyl red; and (**c**) loaded with acid orange. *Source:* With permission from Ref. 151.

the incorporated drug particles; the second is via erosion of the polymer matrix as the anhydride bonds are hydrolyzed. The total release of drug is the sum of these two release rates.

For most of the polymer types used, the erosion of the polymer is less than 15% over the first four hours. During this time period, cumulative drug release is in the range of 60–70%. Thus, to compare the effect of different polymers and drug loadings, the release over this early time period was modeled as a diffusion process, since the release due to erosion is low. The following mass balance applies for the drug within the microspheres:

$$\frac{\partial C}{\partial t} = D_e \nabla^2 C \tag{21}$$

where C is the concentration of the drug in the particle, t is the time, D_e is the effective diffusion of the drug in the polymer matrix, and ∇^2 is the Laplacian.

The first equation can be integrated, and the cumulative fraction of the drug released as a function of time can be computed as follows:

$$\frac{M_t}{M_\infty} = -\frac{6}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{n^2} \exp\left(-n^2 \pi^2 D_e \frac{t}{r_0^2}\right) \tag{22}$$

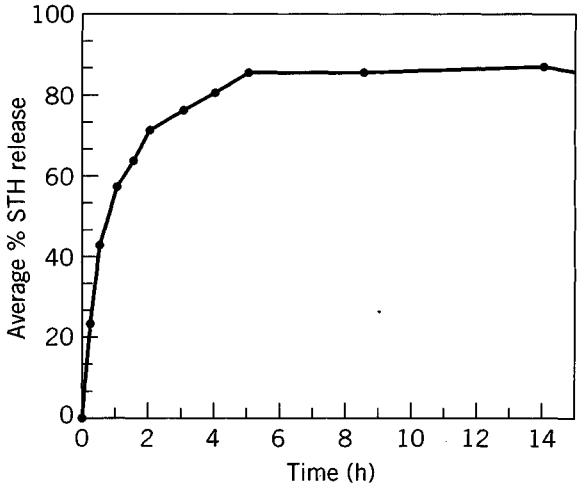

Figure 30. STH released from P(CPP-A) 20:80 microspheres. *Source:* With permission from Ref. 151.

where

$$\frac{M_t}{M_\infty} \tag{23}$$

is the cumulative fraction released, and r_0 is the sphere radius.

The effective diffusion coefficient is governed by the fabrication parameters, such as the quantity of drug loaded, the size of the drug particles loaded, the crystallinity of the polymer, and the porosity of the system. The release curves are fitted to the second equation using a least squares fitting method and an estimate of the effective diffusion coefficient (D_e) is obtained. Knowing the diffusion coefficient of the drug in saline D_s, a retardation factor can be calculated as follows: $R = D_s/D_e$.

The degree of retardation provides information as to whether the drug or dye was successfully encapsulated. Diffusion coefficients were calculated for the 20:80 polymer for both acid orange and STH. The diffusion coefficients in saline for acid orange and STH (D_s) were estimated as 1×10^{-5} cm2/s and 1×10^{-6} cm^2/s, respectively. The estimated effective diffusion coefficients and the net retardation factors are summarized in Table 10.

The microspheres produced have approximately the same diameter as the drug particles that were incorporated. Thus, it is likely that only a single drug particle is contained within each microsphere. The retardation factors for acid orange and STH are on the same order of magnitude, despite the large difference in molecular weight. This supports the notion that the individual drug particles are completely entrapped within the polymers as the initial release is not a function of the characteristic properties of the drug.

Kreitz (154) studied the degradation of spray-dried PLGA microspheres for a period of up to three months using FTIR and SEM. Briefly, 10 g of PLGA 50:50 (35,000 M_w) were dissolved in methylene chloride, producing a 5% (w/v) polymer solution. This solution was spray-dried at 40°C, and the resultant microspheres were lyophilized. Fifty milligrams of the microspheres and 1 mL of buffer were added to separate microcentrifuge tubes for each time point (1 and 3 days and 1, 2, 3, 4, 6, 8, 10, 12, 16, and 20 weeks), and were placed in a 37°C water bath. At the specified time points the buffer was removed from a tube, the polymer was washed with distilled water and then lyophilized. SEM and FTIR were performed on each of the degradation samples and on preliminary (nondegraded) samples.

In the SEMs (Fig. 31) the degradation of the microspheres over three weeks is shown. In Figure 31a (day zero), the spheres are seen as 0.5–5 μm-diameter distinct particles with porous, crenellated surfaces. After only 1 day in 37°C buffer (Fig. 31b) the microspheres have lost their original surface features. They now appear smooth and have started to coalesce, indicating a drop in the glass-transition temperature due to degradation. At 3 days (Fig. 31c) the coalescence has proceeded but the original morphology remains discernible. At 7 days (Fig. 31d) the continuing degradation induces agglomeration from individual spheres, and at 2 weeks (Fig. 31e) the polymer appears as an amorphous mass, the original morphology now gone. The samples at 3 weeks (Fig. 31f) and subsequent time points were viscous liquids, having undergone extensive degradation.

Table 10. Diffusion Coefficients D_s, (Salin), D_e (Polymer), and Retardation Factors for P(CPP SA) 20:80 Microspheres

Drug	D_s cm^2/s	D_e cm^2/h	R
Acid orange	1.0×10^{-5}	6.3×10^{-9}	5.7×10^{6}
STH	1.0×10^{-6}	8.0×10^{-10}	4.5×10^{6}

The FTIR spectra of the microspheres' degradation over 12 weeks are shown in Figure 32, from 2,000 cm^{-1} to 600 cm^{-1}. The most apparent changes in the progression are seen in the peak at 1,760 cm^{-1}, which represents the carbonyl bond of the polyester, and in the peak triplet around 1,400 cm^{-1}, which represents the bonds between the lactide-lactide (L-L, 1,456 cm^{-1}), glycolide-glycolide (G-G, 1,425 cm^{-1}), and lactide-glycolide (L-G, 1,398 cm^{-1}) mer units of the polymer. The spectra remain fairly constant over the first week of degradation. At 2 weeks the carbonyl peak is broader, possibly due to the transition of some crystalline regions to amorphous regions. The peak triplet at 2 weeks shows no distinct change. At 3 weeks the L-L (left) peak in the triplet appears to have receded slightly relative to the G-G and L-G peaks, suggesting greater degradation of this bond relative to the other two types of ester bonds present in this polymer. Also, the carbonyl peak is slightly broader than that of 2 weeks indicating further crystalline-to-amorphous transition. At 4 weeks the carbonyl peak appears sharper and all three peaks of the triplet have decreased relative to the peak of the carbonyl bond. The carbonyl peak's sharpness may be the result of the amorphous regions' partial degradation and dissolution, leaving behind the more crystalline regions. The reduction in the triplet peak at this stage indicates a general progression of the polymer degradation via hydrolysis of the ester bonds. At 6 weeks the carbonyl peak appears unchanged from that of 4 weeks while the triplet peaks have decreased extensively. The peaks of the G-G and L-G bonds have decreased to a greater extent than that of the L-L peak. At 8 weeks the carbonyl peak's sharpness indicates continued degradation and dissolution of oligomers from the polymer. The G-G peak is the only one of the triplet which remains, a finding that continues to the last measurement at 12 weeks. This may be due to the degradation resistance of oligomer blocks consisting mostly of glycolide mers.

In the present Luck et al. studies the influence of the polymer composition and the production method of microspheres on the in vitro plasma protein adsorption were investigated using two-dimensional electrophoresis. Microparticles were prepared from poly(L-lactide) (L-PLA), (PLGA), and ABA triblock copolymers containing hydrophilic poly(oxyethylene) (B-block) domains connected to hydrophobic polyesters (A-blocks). Two different microencapsulation methods were employed, namely the W/O/W emulsion solvent evaporation method and the spray-drying technique. It could be demonstrated that the polymer composition and, especially, the encapsulation technique, influenced the interactions with plasma proteins

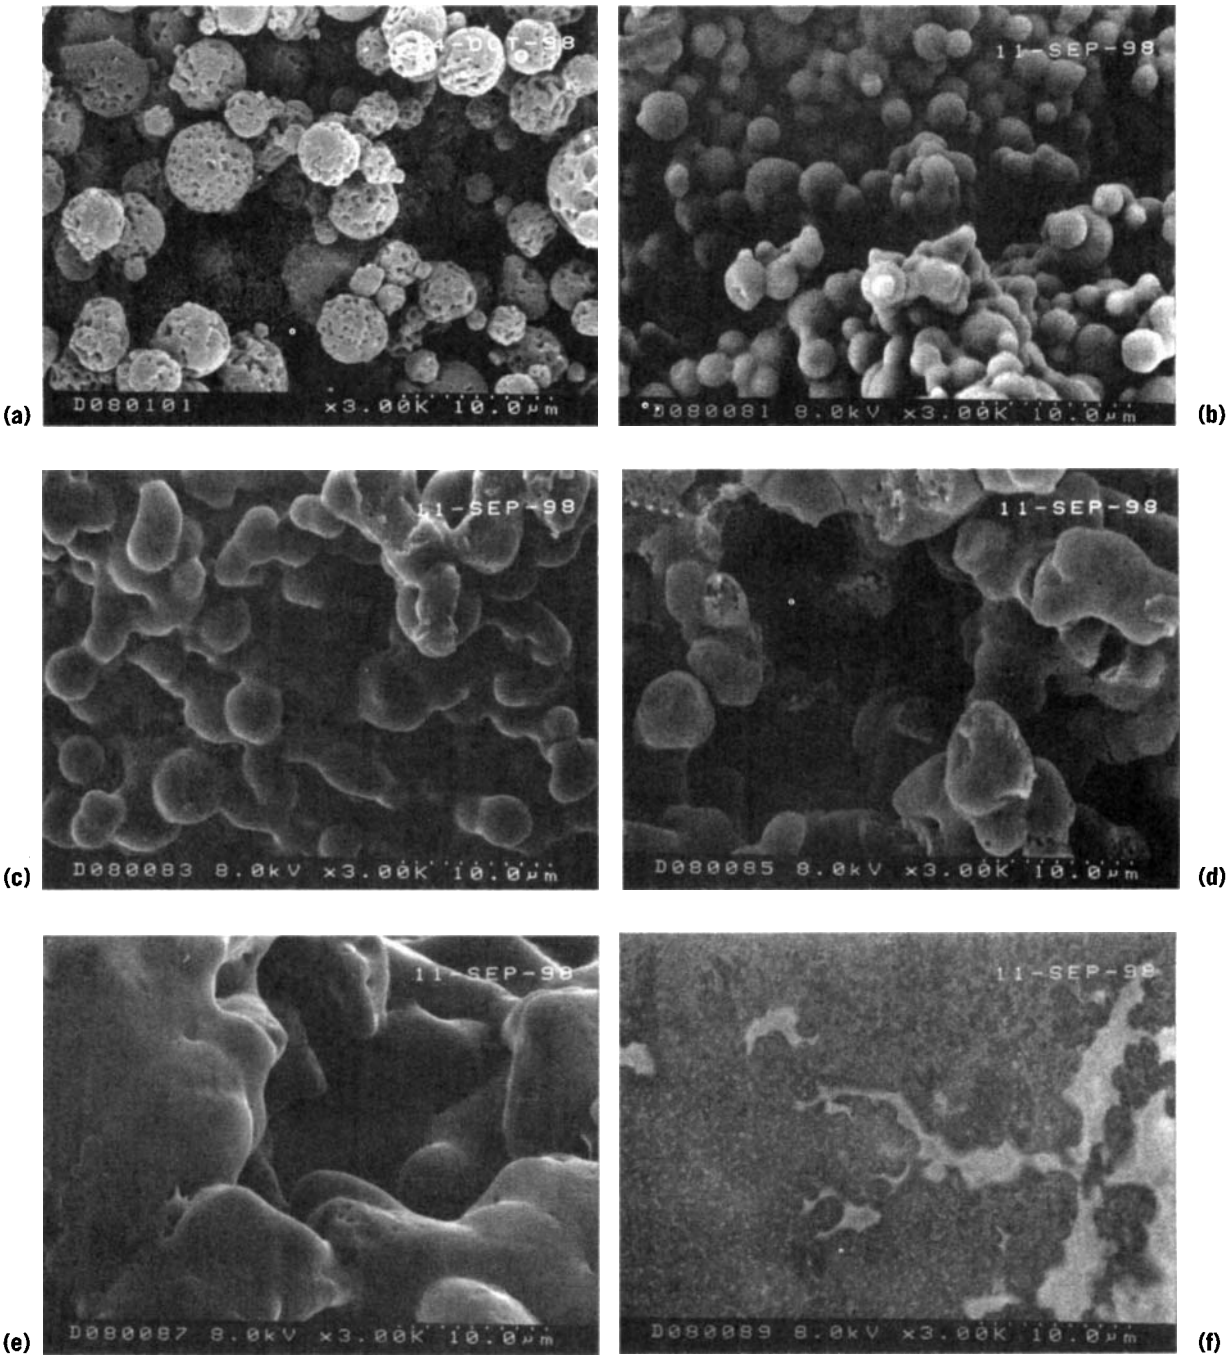

Figure 31. SEM series showing the procession of PLGA microsphere degradation at (**a**) time zero, (**b**) 1 day, (**c**) 3 days, (**d**) 2 weeks, and (**f**) 3 weeks.

significantly. For example, the percentages of several apolipoproteins in the plasma protein adsorption patterns of spray-dried PLGA and L-PLA particles were distinctly higher when compared with the adsorption patterns of the particles produced by the W/O/W technique. Some adsorbed proteins were found to be characteristic or even specific for particles produced by the same method or consisting of identical polymers. PVA used as stabilizer in the W/O/W technique may decisively influence the surface properties relevant for protein adsorption. The plasma protein adsorption on particles composed of ABA copolymers was drastically reduced when compared to microspheres made from pure polyesters. The adsorption patterns of ABA particles were dominated by albumin. The plasma protein adsorption patterns detected on the different microspheres are likely to affect their in vivo performance as parenteral drug delivery systems (155). It is known that the hydrophobicity of a surface can influence protein adsorption, i.e.,

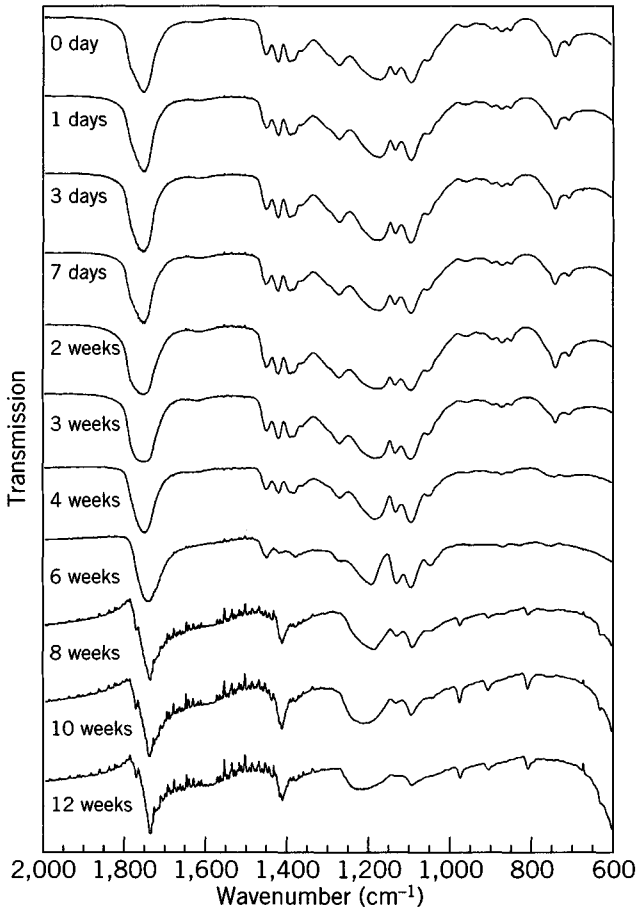

Figure 32. FTIR degradation studies on the same microspheres as shown in Figure 31.

hydrophobic surfaces favor protein adsorption. Therefore, the hydrophobicity of films made of the polymers used for the microparticle formation was characterized using contact angle measurements. The measurement of contact angles gave the following rank order of hydrophobicities as a function of contact angles: L-PLA>PLGA>ABAI>ABAII (155). The most striking difference between the two particle types was the strong adsorption of the apolipoproteins on the spray-dried particles (155).

Three methods were used, namely spray-drying, W/O/W solvent evaporation and ASES, for the preparation of microparticles having the same size range, to study the influence of the preparation method on polymer degradation in vitro (phosphate-buffered saline, 37°C, one month). The following five polymers of the biodegradable PLA and PLGA groups were selected to prepare blank and drug-loaded microparticles: L-PLA (M_w 81,200); DL-PLGA 75:25 (M_w 64,300); DL-PLGA 50:50 (M_w 52,600); DL-PLGA 50:50 (M_w 14,500); and DL-PLGA 50:50 (M_w 3,400). Tetracosactide was selected as the model peptide. When microparticles were prepared by solvent evaporation, the mean diameter and, more markedly, the drug encapsulation efficiency decreased with decreasing molecular weight and an increasing proportion of glycolic acid in the polymer. In contrast, no direct influence of the polymer nature on these parameters was observed in spray-dried microparticles. Polymer degradation was heterogeneous in L-PLA and DL-PLGA 75:25 microparticle and was not influenced by the presence of the drug at a nominal loading of 1% (W/W), when prepared by the three methods (note that with ASES, only L-PLA could be used for microencapsulation). In batches made of DL-PLGA 50:50 (M_w 52,600), the degradation rate decreased slightly with increased drug loading. Only for the case of DL-PLGA 50:50 (M_w 14,500) was the polymer degradation rate for spray-dried microparticles higher than that of microparticles prepared by the W/O/W solvent evaporation method. Generally, the degradation rates of the different microparticles followed the expected order: L-PLA < DL-PLGA 75:50 < DL-PLGA 50:50 (M_w 52,600) < DL-PLGA 50:50 (a mixture of M_w 52,600 and M_w 3,400). Polymer degradation was homogenous in DL-PLGA 50:50 microparticles. Decreasing the molecular weight of DL-PLGA 50:50 from 52,600 to 14,500 did not result in accelerate polymer degradation (156).

ONE-STEP FORMATION OF DOUBLE-WALLED MICROSPHERES

With the increasing complexity of therapeutic regimens, drug delivery systems may become more sophisticated. There are many approaches to achieving long-term release of pharmacologic agents using microspheres, but this technology is not without problems. One drawback to this sort of system is the initial "burst" effect caused by the rapid release of the drug particles trapped on the surface during manufacturing. One solution to this problem that was developed was to prepare multilayered microspheres consisting of concentric spheres of polymer. Traditional methods to form such delivery systems (e.g., pan- or dip-coating and air suspension coating) require multiple steps, which decreases process yield (157–159). First, the core would be formed, and then each of the coating layers was added in separate steps. More recently, Mathiowitz et al. have developed a method to manufacture multilayered microspheres in a single step (84,101,160–162). This process combines the natural tendency of polymers to phase separate as solution concentration increases with the microencapsulation process of solvent evaporation. Moreover, it is a one-step process for creating double-layered microspheres and has advantages over other methods for coating microspheres. In the dip-coating process, the coating is usually nonuniform in both coverage and thickness (Fig. 33). Also, each coating adds an additional step to the manufacturing process, increasing quality control problems at each stage, and further decreasing the yield. Coating processes involving fluidized beds have produced microspheres with a uniform coating, but fluidized beds are difficult to design for particle sizes of less than 100 μm.

The one-step process described here combines the phenomenon of phase separation with emulsion theory and can be used to produce spheres of diameters less than 20 μm and up to 1,000 μm. The basic difference between this process and organic phase separation or coacervation is that two polymers are used to cause the phase separation and that both are used in high concentration. Thus the

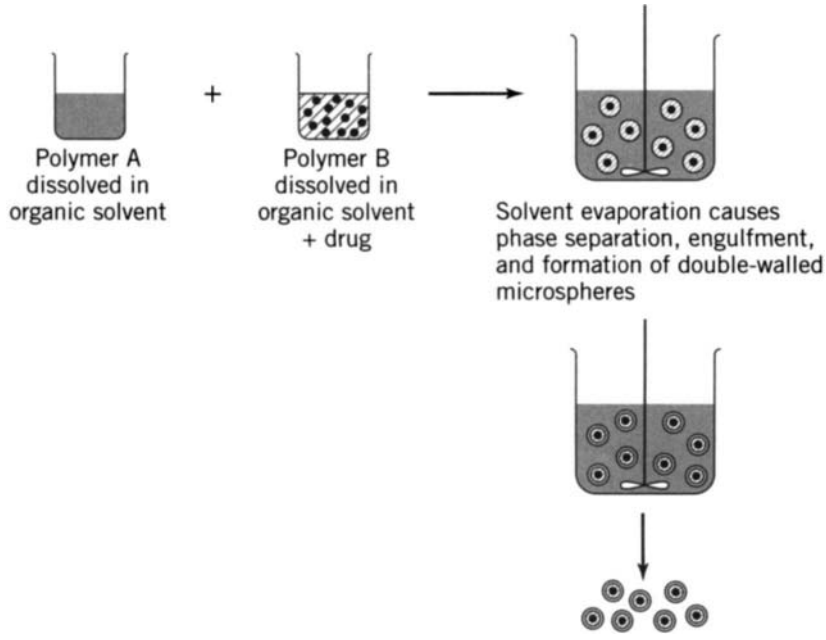

Figure 33. Formation of one-step double-walled microspheres.

final product, unlike coacervation, is the formation of two layers each containing two separate polymers.

The section entitled "Interfacial Phenomenon" and Figure 8 describe the tendency of a liquid to spontaneously spread across a solid or liquid surface in terms of the surface and interfacial tensions of the components. It can be modified to represent a system in which two dissimilar phases are dispersed within a third by substituting the appropriate interfacial tensions for the surface tensions in Harkin's equation (163):

$$\lambda_{AB} = \gamma_{BS} - \gamma_{AS} - \gamma_{AB} \qquad (24)$$

where γ_{AS} and γ_{BS} are the interfacial tensions of the solvent and polymer A or B, respectively, and γ_{AB} is the interfacial tension between polymers A and B. For positive values of λ_{AB}, polymer A spontaneously spreads on polymer B. The actual configuration of the two dissimilar phases (A and B) depends on the values of the three possible spreading coefficients and can be described as complete engulfing, partial engulfing, and nonengulfing (see Fig. 8).

Combination of the emulsion theory described here with the phenomenon of phase separation provides a novel approach for preparing double-walled polymer microspheres. By introducing a two-polymer solution into a continuous phase, a stable emulsion is created in which phase separation occurs within each drop. The phase separation can be engineered such that one polymer engulfs the others, forming double-walled microspheres in a single step. Each of the configurations shown in Figure 8 can be visualized using SEM (Fig. 33). Figure 34a shows a cross section of a double-walled sphere of polyanhydride and PLA exhibiting phase separation and complete engulfment. Figure 34b shows a nonengulfing, chaotic structure formed from PLA and polystyrene when precipitation occurred after phase separation but before engulfment. And Figure 34c shows a high-magnification SEM photo of the wall material in Figure 34a indicating that some of the core phase is entrapped in the wall.

The microspheres were formed by first preparing separate solutions (10–20% w/v) of the two polymers in a volatile organic solvent (see Fig. 33). The drug or protein was added to the appropriate polymer solution at this stage and dispersed evenly. Then the two polymer solutions were mixed and dripped into a stirred bath of 0.5% PVA in water. As the solvent evaporated, the polymer solution concentration increased to the point where they were no longer mutually soluble and began to separate. If allowed enough time before hardening, the two phases configured themselves according to the modified Harkin's equation. There was only one thermodynamic equilibrium configuration of polymer A spreading on polymer B, but the extent of spreading was determined by the rate of polymer precipitation, as controlled by the rate of solvent evaporation. Therefore, two scenarios to produce double-walled microspheres were possible and achieved by balancing the thermodynamic and kinetic factors. In the first, polymers for which Harkin's equation predicts complete engulfment were given sufficient time during the evaporation process for the polymers to reach thermodynamic equilibrium. In this case, complete engulfment was the most stable thermodynamically, and the kinetic factors were minimized by slowing the rate of polymer precipitation. In the second scenario, the completely engulfed configuration was a transient intermediate in the progression from a non–phase separated system toward equilibrium, and the precipitation rate was manipulated such that the polymers were trapped in this configuration, thus allowing the formation of double-walled microspheres when not predicted by the modified Harkin's equation. Once the microspheres had hardened, they were filtered, washed with water, and freeze-dried in preparation for storage and further characterization by optical microscopy with or without cross-polarized light, SEM, TEM, FTIR spectroscopy and DSC.

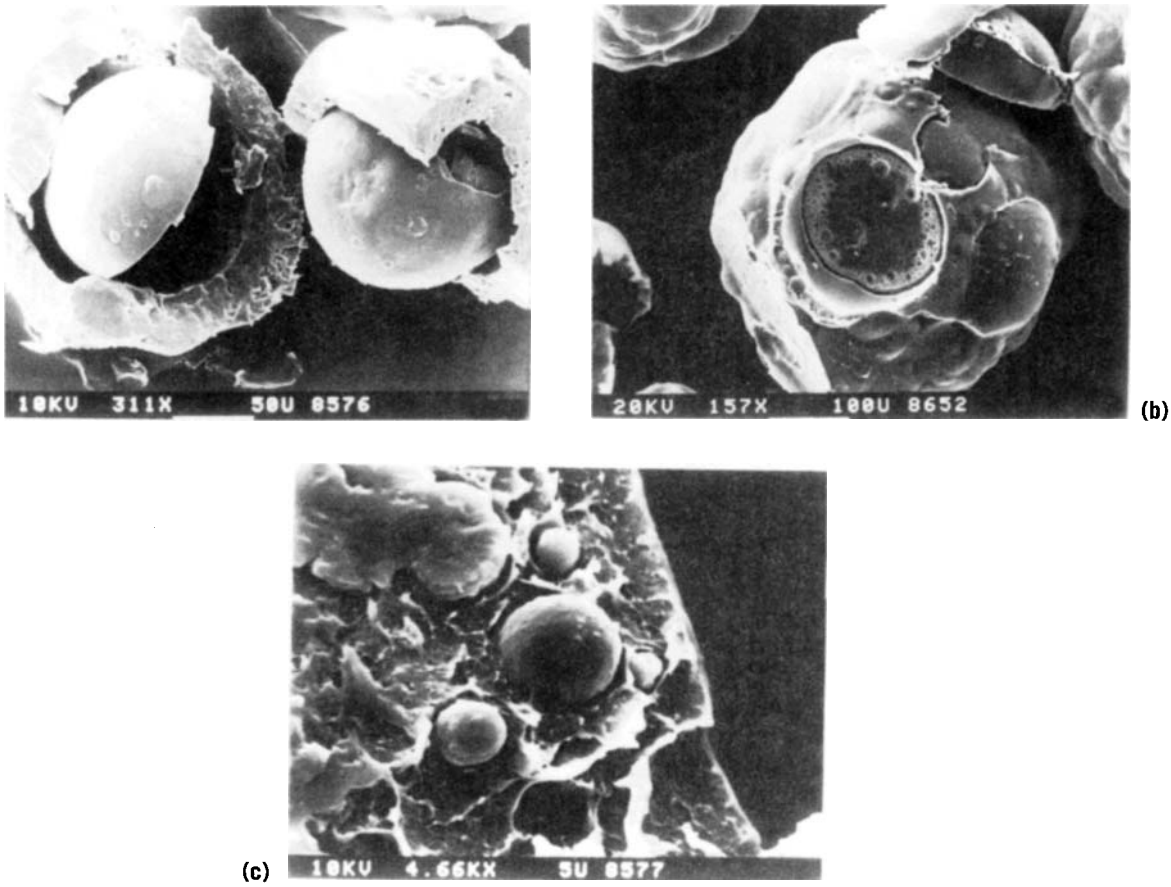

Figure 34. SEM of (**a**) double-walled microsphere; (**b**) multiphase microspheres; (**c**) higher magnification of the external layer in (**a**).

Optical microscopy proved to be a useful tool to study the microspheres as they were hardening. Cross-polarized light allowed the different polymers to be identified as they crystallized, and fluorescently labeled proteins aided in determining in which layer the protein has been trapped (84,101,162).

In a series of two papers (160,161) a more detailed description of the degradation of double-walled microspheres with a core of poly(CPP-SA) 20:80 and a coat of PLLA is given. The first paper presents the in vitro degradation, whereas the second paper discusses the in vivo degradation of these double-walled microspheres implanted subcutaneously and intramuscularly in rats. The second paper also correlates the degradation of the microspheres in the two environments, a critical step in the development of polymeric delivery systems for drugs or therapeutic proteins. Single polymer (SW) microspheres of PLLA, also made by solvent evaporation, were included in the study for comparison.

The general trends observed for double-walled microspheres of an inner core of poly(CPP-SA) 20:80 and outer layer of PLLA was that the inner core degraded first, becoming more granular in appearance as the polyanhydride broke down into short chain oligomers and then finally monomers. These monomers were insoluble in chloroform and were therefore not detectable by GPC or FTIR spectroscopy. DSC (Fig. 35) and SEM analyses of intact microspheres clearly showed their presence out to 6 months after being introduced to the buffer solution (161). The GPC data shows that the SW PLLA microspheres degraded significantly over the 6 months of in vitro degradation, despite the minimal morphologic changes seen by SEM. The PLLA of the double-walled microspheres degraded slightly faster than did the PLLA in the SW microspheres. At the early time points, the molecular weights of the two polymers could be calculated separately, showing that the poly(CPP-SA) 20:80 initially maintained a polymeric molecular weight, but after 2 weeks was no longer detectable.

FTIR also showed the disappearance of the anhydride bonds over the first two weeks of degradation (Fig. 36). DSC confirmed this, showing a decrease in size of the melting transition for the poly(CPP-SA) 20:80 polymer with the emergence of an intermediate peak due to the oligomers and monomers of the degraded polyanhydride. The SW PLLA microspheres remained dense and smooth in appearance throughout the study, and the FTIR spectra remained constant. The melting temperature of the PLLA decreased over the 6-month study due to the drop in molecular weight, which was confirmed by GPC.

Selected samples of the SW microspheres implanted subcutaneously were analyzed by SEM, and the micrographs are shown in Figure 37. After 1 week, the implant

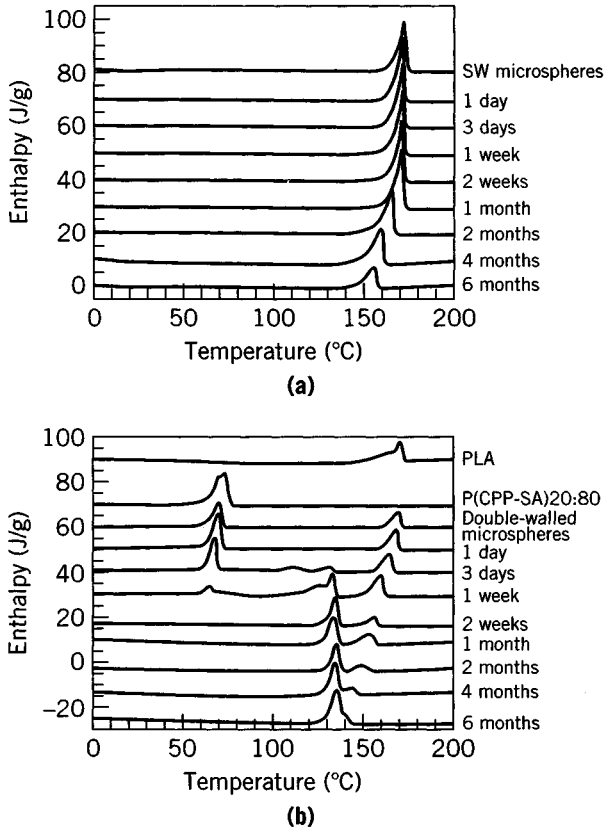

Figure 35. DSC thermogram of microspheres degraded in vitro. (**a**) SW PLLA and (**b**) Double-walled PLLA and poly(CPP-SA) 20:80. *Source:* With permission from Ref. 160.

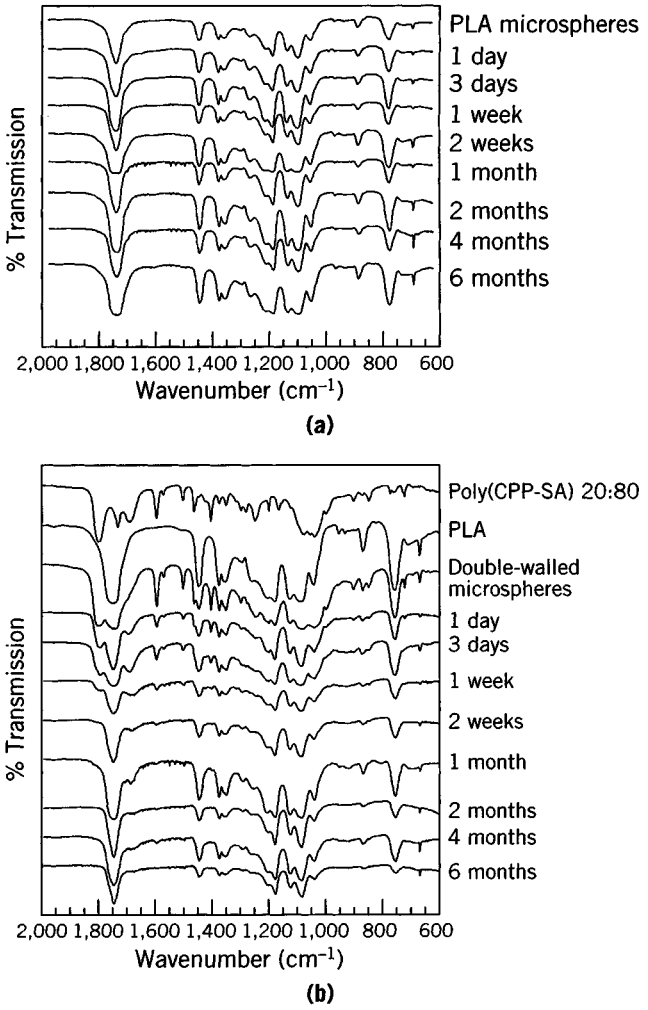

Figure 36. Transmission FTIR spectra of microspheres before and after in vitro degradation: (**a**) SW PLLA microspheres and (**b**) double-walled PLLA and poly(CPP-SA) 20:80. *Source:* With permission from Ref. 160.

site was slightly inflamed and the implant was filled with some excess fluid, resulting in a gap in the center of the implant seen after cross-sectioning (Fig. 37). This inflammation had cleared after 2 weeks. Even out to 6 months of degradation in vivo, the PLLA still appeared very dense. SW PLLA microspheres implanted intramuscularly degraded similarly to those implanted subcutaneously (data not shown).

Selected SEM micrographs of double-walled microspheres implanted subcutaneously are shown in Figure 38. Figure 38a shows the subcutaneous implant site after 1 week, revealing the empty center that was filled with fluid upon explantation. Higher magnification of the spheres after 1 week showed the degradation of the polyanhydride core (Fig. 38b). A higher magnification of the interface shows the differences in the rates of degradation of the two polymers (Fig. 38c). The PLLA coating was still relatively intact. After 1 and 6 months of degradation, the inner core continued to degrade and disappear, shrinking in size (Figures 38d, 38e, and 38f).

The degradation of the microspheres showed the same trends in vitro as in vivo. Microscopy showed no differences in the pattern or kinetics of the degradation. Physical characterization showed more differences between the degradation in vitro and in vivo, but the separate extraction step required for the in vivo sampling may have skewed these results. The M_w of the microspheres degraded in vitro decreased faster than did the M_w of those degraded in vivo. In both cases and at all time points, the M_w of the double-walled microspheres was lower than that of the SW microspheres. FTIR spectroscopy and DSC analyses of the double-walled microspheres degraded in vivo identified PLLA as the only polymer present in the extracted sample at all time points. No differences were seen by these two methods between the samples degraded in vitro and in vivo.

Degradable, multilayered microspheres such as those described in this article could serve as complex delivery vehicles for therapeutic agents. The applications for such microspheres within the field of drug delivery are numerous, and a well-characterized degradation profile, both in vitro and in vivo, will aid in the development of a clinically useful delivery system.

NOVEL ENCAPSULATION TECHNIQUES

One of the most interesting methods is being used for scale-up preparation of the injectable Prolease microsphere product, manufactured by Alkermes. The process is based on solvent extraction in nonaqueous solutions and, in addition, it is produced under cryogenic conditions. These two facts ensure high encapsulation efficiency of the drug while maintaining its integrity. A good review on the process, as well as approaches to scale it up, have been discussed by Tracy (164).

Mathiowitz et al. group has recently develop a new method to produce microspheres and nanospheres in the range of 0.2 to 30 μm, called the PIN (phase inversion microencapsulation) method (165). This process is based on the spontaneous formation of microspheres in an environment of a nonsolvent. Here the challenge is in developing oral delivery systems for proteins and genes, and the PIN system has been used to successfully deliver small molecules, insulin, and plasmid DNA by the oral route. The method is very gentle and thus the activities of very sensitive bioactive molecules and proteins such as IL-2 are not destroyed (166; N.K. Egilmez et al., unpublished data). Encapsulation of IL-2, PEG-modified IL-2 (PEG/IL-2), and interleukin-12 (IL-12) using the PIN technique resulted in release of bioactive cytokines for up to one month in vitro (Y.S. Jong et al., unpublished data). The in vivo bioactivity of IL-2 released from PIN microspheres was demonstrated in a human tumor xenograft/SCID mouse model (166). Subcutaneous coinjection of IL-2 microspheres and tumor cells resulted in complete suppression of tumor engraftment in 80% of the animals. More recently, IL-12 releasing PIN microspheres were shown to be similarly effective in a mouse head and neck tumor model (M.A. Kuriakose et al., unpublished data) indicating the versatility of the PIN technique for functional encapsulation and release of different proteins.

APPLICATIONS OF MICROENCAPSULATION

With the vast array of encapsulation techniques currently available, nearly any active agent can be successfully incorporated into a microparticulate formulation. The limiting factors in applying these processes are imagination and, ultimately, cost. Encapsulation is a fairly standard practice in both the food, consumer product, and cosmetics industries. Flavors have been encapsulated since the 1930s, vitamins since the 1940s, and ink for carbonless paper since 1956 (167). The main purpose behind encap-

sulating these materials was often for their protection and enhanced stability, as in foods and vitamins. The release of the active agent was triggered by drastic environmental changes in going from a dry to a wet environment or by physical trauma to the capsules in grinding or chewing. Encapsulated ink for carbonless paper is actually a triggered release device, where the trigger is the physical force that ruptures the capsule and releases the ink.

Encapsulation in the Food, Consumer Products, and Cosmetics Industries

For most products in the foods and consumer products industries, encapsulation must be accomplished on a very large scale and cannot add a significant cost to the product either in materials, processing, or labor. Even with these limiting factors, the majority of these products currently

on the market have at least one component encapsulated. The most common techniques for encapsulating materials are spray-drying, extrusion, molecular inclusion, and coacervation (167). Of these, spray-drying and coacervation are true microencapsulation processes which have been discussed earlier in this article.

Spray-drying is often used to convert an oil or other liquid into a solid for easier handling and increased shelf life. This stability is dependent upon the wall materials used as well as the microcapsule porosity and the presence of any trace prooxidants or antioxidants. In general, spray-drying may be accomplished at a low cost and appropriate equipment is readily available. The resulting particles can be small and a variety of edible, soluble, and degradable wall materials may be used. Coacervation will usually give larger particles (20 μm and larger) and can also be made at a fairly low cost. A high loading can be achieved if the material to be encapsulated and the wall material are immiscible. Both liquids and solids have been encapsulated using coacervation with wall materials such as wax, protein, fat, carbohydrate, and gelatin.

Many of the same polymers used for pharmaceutical and medical applications are also used for cosmetic formulations, including polysaccharides, polypeptides, acrylates, and methacrylates (168). Most encapsulated ingredients in cosmetics products are in the nanoparticle size range. These nanoparticles usually contain cosmetic hydrophilic components which are designed to modulate the release in and onto the skin (169). Nanocapsules for cosmetic applications usually contain a lipophilic active substance which should be protected from the environment by encapsulation and release the active agent slowly over time. One of the key components in Lacome's Primordial is nanoencapsulated vitamin E.

Applications of Encapsulation for Agricultural Products

Encapsulated products with controlled release behavior can have significant advantages in the use of pesticides (59). Along with the traditional advantage of more constant release over extended periods of time, encapsulated pesticides can also show reduced mammalian toxicity, reduction of evaporative losses, and reduction in flammability of liquids. Most encapsulated pesticide materials are produced by interfacial polymerization or phase separation. The most widely used shell materials for interfacial polymerization are polyamides polyurea and polyurethane. For a variety of formulations, including Penncap M (encapsulated diazinon by Pennwalt), Penncaptrin (encapsulated permethrin by Pennwalt), Antifly (encapsulated pyrethrins by Kedem Chemicals), and Empire (encapsulated chlorpyriphos by Dow), the toxicity of the encapsulated material is no more than one-tenth that of the unencapsulated material with a longer efficacy and without a reduction in activity. The greatest advantage of the phase separation technique of encapsulation is the tremendous range of natural polymers, synthetic elastomers, and other synthetic polymers which may be used as the particle wall material. Markus has compiled a table of 46 different polymers that have been used in phase separation encapsulation and also provides examples of processes to encapsulate biological pesticides (59).

Applications and Opportunities for Encapsulation to Enhance Human Health

Although most of the current applications that have been realized using encapsulation are undoubtedly useful, they do not directly address the field of human health insofar as life-threatening conditions are concerned. Encapsulation has been used for decades for vitamins and other drugs, but only one product is currently on the market which uses microencapsulation to deliver a life-saving drug over 4 weeks. This is the Lupron Depot®, from Tap Pharmaceuticals, which contains leuprolide acetate, a LHRH agonist, gelatin, PLGA, and D-mannitol (135). This therapy results in inhibition of the growth of certain hormone dependent tumors.

Many of the formulations mentioned earlier in this article are being studied to treat the wide range of diseases and conditions which would respond well to controlled drug delivery. Other possible medical uses of encapsulation include artificial red blood cells, treatment of acute poisoning and kidney failure using encapsulated adsorbents and immunoadsorbents, encapsulation of living cells as well as encapsulation of enzymes for treatment of phenylketonuria, histidenemia, and other conditions (170). It is the hope of all working in this field that the Lupron Depot® is only a beginning and that medical science can embrace the opportunities that encapsulation can provide with the same enthusiasm that the consumer products and cosmetics fields have already shown.

INTRODUCTION

Since Watson and Crick's determination of DNA structure, advances in molecular biology and recombinant DNA technologies have had an enormous impact on biological sciences. DNA-based diagnostics and recombinant pharmaceuticals have emerged as important additions to medical research and treatment methods. Gene therapy, however, has yet to provide similar tangible benefits. Nonetheless, it is often heralded as a panacea, the ultimate application of recombinant DNA research.

Gene therapy is based on the premise that a disease is the failed expression of a gene or expression of a defective one, which can be treated by the transfer of genes into specific cells of patients rather than through conventional pharmaceutical means. Gene transfer can be used to restore and/or supplement defective functions or interfere with the expression of aberrant genes. Currently, there are three categories of gene therapy (1). INTRODUCTION

Since Watson and Crick's determination of DNA structure, advances in molecular biology and recombinant DNA technologies have had an enormous impact on biological sciences. DNA-based diagnostics and recombinant pharmaceuticals have emerged as important additions to medical research and treatment methods. Gene therapy, however, has yet to provide similar tangible benefits. Nonetheless, it is often heralded as a panacea, the ultimate application of recombinant DNA research.

Gene therapy is based on the premise that a disease is the failed expression of a gene or expression of a defective one, which can be treated by the transfer of genes into specific cells of patients rather than through conventional pharmaceutical means. Gene transfer can be used to restore and/or supplement defective functions or interfere with the expression of aberrant genes. Currently, there are three categories of gene therapy (1). The ex vivo approach involves the removal of patient cells from the body, the transduction of these cells using an appropriate vector, and the subsequent return of the genetically altered cells to the

patient. The in situ approach involves injecting the vector directly into the affected tissues. Finally, the in vivo approach uses the bloodstream to transport the vector to the affected tissues and/or cells.

Clinical success has been limited to genetic diseases caused by a single gene defect such as adenosine deaminase deficiency (2). However, advances in molecular biology are rapidly leading to the identification of defective genes and an increased understanding of the regulation of gene expression. Gene transfer constitutes the sine qua non of gene therapy. In fact, the application of human gene therapy is limited more by the lack of effective delivery methods for gene transfer. The December 1995 Report and Recommendations issued by NIH states that "Given the central role of vectors for delivering genes to somatic cells for therapeutic purposes, the Panel endorses *vigorous* and *expanded* research aimed at developing improved vectors" [our emphasis]. Thus, the development of both viral and nonviral gene transfer methods has come to the forefront of gene therapy research.

Viral-vector-mediated gene transfer makes use of the evolutionary advances by viruses to deliver genetic information into the cells they infect (3). Viral vectors are commonly recombinant animal viruses that contain exogenous information in their genome. They are usually replication-defective to prevent the occurrence of a pathological condition. There are four main types of viral vectors currently used in clinical trials: retrovirus, adenovirus, adeno-associated virus, and herpes-simplex virus (4). The advantages and disadvantages of each are described in Table 1. Generally viral vectors are more efficient than nonviral vectors, but do not have much in the way of capacity to deliver large expression cassettes (5). There is also the possibility of recombination into a replication-competent virus. However, viruses remain the most resourceful in entering cells and will probably be included in the next generation of hybrid vectors containing viral components expressly for this purpose. The basic scheme for viral transduction is as follows. An expression cassette is inserted into a replication-defective viral vector. This virus is inserted into a packaging cell, which produces all the necessary viral proteins necessary to package the virus. Target cells are then infected with these vectors (either in vitro or in vivo), thus allowing the viruses to transmit the genetic information. What happens to the information then depends on the type of virus as well as the type of target cell.

Nonviral vectors rely on chemical or physical means to facilitate cellular uptake and intracellular transport of plasmid DNA without viral packaging (6). These vectors including liposomes, gene gun, ligand-mediated polylysine complexes, direct injection, and others. Table 2 summarizes the main nonviral vector approaches employed for gene therapy. These vectors contain plasmid DNA; circular double stranded DNA which exists extrachromosomally in bacteria. Nonviral vectors are considered to be more safe than viral vectors (no risk of infection or tumor formation), have no limit to the expression cassette size carried, and are easier to manufacture and purify (1). Their main drawbacks are low transfer efficiency and transient gene expression (7). With the exception of the gene gun, where adsorbed DNA can be shot directly into nucleus, nonviral vectors have generally been designed to enhance endosomal escape, cytoplasmic transport, and/or nuclear uptake of plasmid DNA. Strategies include inclusion of ligands for specific targeting, adenoviral attachment for endosomal escape, and other numerous modifications (8,9). However, it should be noted that some tissues have the intrinsic ability to internalize and express exogenous plasmid DNA. For example, in muscle tissue, the use of viral or chemical nonviral vectors to enhance gene transfer has been shown to be less efficient than injecting purified, plasmid DNA alone (10).

The goal of this article is not to present a review of all available viral and nonviral vectors. An excellent review by Nakanishi provides a comprehensive discussion of the various vector systems, both viral and nonviral, as well as their applications in human gene therapy (11). This article focuses on one specific emerging technology, vectors based on thermoplastic microencapsulation of plasmid DNA. A variety of polymers have been used for DNA delivery, including liposomes (DOTMA/DOPE), hydrogels (chitosan, alginate, poly[vinylpyrrolidone]), dendrimers (polyamidoamine), and water-soluble polymers (polylysine), which provides for either DNA condensation, charge neutralization, or binding/complexation (6,12–14). Some of these sys-

Table 1. Viral Vectors Used for Gene Therapy

Viral vector system	Advantages	Disadvantages
Retrovirus	Stable, long-term expression	Requires mitogenic cells for infection
	Can infect wide range of cell types	Small expression cassette (~9 kb)
		Possibility of insertional mutagenesis
		Difficult to concentrate/purify
Adenovirus	Can infect nondividing cells	Strongly immunogenic
	Capable of high expression levels	Small expression cassette (~7.5 kb)
	Easy to concentrate/purify	Significant risk of recombination into replication-competent
Adeno-associated virus	Can infect nondividing cells	Very small expression cassette (~5 kb)
	Does not cause any known human pathologies	Requires coinfection with helper virus
	Site-specific integration	System still not well characterized
Herpes-simplex virus	Ability to establish lifelong latent infections	Wild type virus is cytotoxic
	High titre stocks	Reactivation of wild-type virus is possible
	Large expression cassette capacity	High prevalence of seropositivity in general population

Table 2. Nonviral Vectors Used for Gene Therapy

Nonviral vector system	Advantages	Disadvantages
Cationic lipids and liposomes	Simple procedure Large expression cassette capacity Low immunogenicity/toxicity	Low transfection efficiency Transient expression Unstable complex formation Nonspecific targeting
Ligand-mediated polylysine complex	Specific targeting possible Low toxicity	Weak gene expression Low transfection efficiency May be immunogenic
Direct injection of DNA	No carrier molecules needed Minimum contaminants Low immunogenicity	Cannot be applied to cultured cells Low efficiency Transient expression Mechanism of entry not well-understood

tems are described in other articles. The particular vectors described in this article focus on the use of water-insoluble, thermoplastic, biodegradable polymers to encapsulate plasmid DNA. These polymers differ in that they do not interact with DNA (chemically or electrostatically) and serve simply to physically entrap DNA uniformly within a matrix structure. Once hydrated, plasmid DNA is released from the matrices in its "naked" form, via diffusion (through preexisting pores), which is enhanced by the actual hydrolytic degradation of the matrix itself (Fig. 1). The use of these types of systems has not been limited to plasmid DNA; whole viruses and oligonucleotides have also been successfully encapsulated within these polymer matrices for a number of different applications (15,16). However, the focus of this review is the use of these encapsulation systems specifically for applications in DNA vaccination.

BACKGROUND

DNA Vaccination

DNA vaccination can be defined as the induction of an immune response to antigen expression by cells in situ, following direct gene transfer of the antigen encoding DNA. Mechanistically, DNA vaccination is somewhat analogous to the use of live attenuated viral vaccines, as both result in intracellular production of antigenic proteins. However, it is inherently a subunit vaccine and the immune response is directed toward specific components instead of the whole virus. First, the antigen expressing plasmid DNA is administered into the host animal, most commonly via direct injection of the plasmid DNA in a buffer. Second, transfected cells begin expression of the antigen, which in some cases is actively secreted. Third, the host animal develops a specific immune response against the expressed antigen. Interest in DNA vaccination stems primarily from its ability to induce both cytotoxic T cell and antibody responses, with low DNA doses, for long periods of time (17,18). Antigens are produced de novo in its native form and thus compared to administration purified recombinant antigens, result in efficient presentation of both Class I and Class II major histocompatibility complex (MHC) (19). Moreover, DNA vaccination protocols require significantly less (up to 1,000-fold less) protein compared to the protein doses required for the more classical subunit vaccine approaches (20). Although there are some potential risks (tolerance, autoimmunity, integration), experimental studies to date indicate they are unlikely and the primary disadvantage appears to be the fact that DNA vaccination is limited to protein antigens.

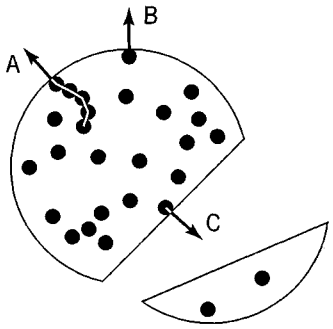

Figure 1. Macromolecule release from degrading matrix-type controlled release microsphere. (A) Diffusion of molecules from within the polymer matrix following the formation of interconnecting pores. (B) Diffusion of surface localized molecules. (C) Diffusion of molecules from within the polymer matrix following degradation of encapsulating polymer material.

Much of the work with DNA vaccination has focused on the use of direct injection of plasmid DNA. Direct injection of plasmid DNA was first demonstrated as a viable gene transfer technique in 1990 (21). This form of gene transfer uses purified bacterial DNA constructs without any additional chemical or biological agents, often referred to as naked DNA. Although transfection efficiencies are generally low, this technique has been used successfully in a number of different animal models. Subsequently, it was shown that direct gene transfer with plasmid DNA could provoke an immune response against the encoded protein antigen (19,22) heralding this revolutionary new approach to vaccine development. A number of excellent reviews have been written regarding DNA vaccination. Interested readers should access "The DNA Vaccine Web" by Robert Whalen (http://www.genweb.com/Dnavax/dnavax.html), which provides a comprehensive overview of DNA vaccination, including an extensive bibliography of related research and review articles.

Researchers have devised a number of strategies to improve the efficacy of DNA vaccination. The first involves

the selection of the plasmid construct. In addition to the promoter, enhancer, and intron sequences, inclusion of palindromic single-stranded immunostimulatory sequences, specifically the unmethylated cytosine motif adjacent to a guanine residue (CpG) can dramatically upregulate the immune response (23). The same study demonstrated that the location of these sequences within the plasmid construct is important as well. It appears that these sequences increase the immune response through increased proliferation and cytokine release of B and T lymphocytes. The second is the selection of the inoculation site. Direct injection of plasmid DNA is most effective in muscle tissue both in terms of transfection efficiency and transgene expression. However, it has been demonstrated that other tissue such as the epidermis, which is much less permissive to direct injection vectors, can provide for more efficient vaccination (24,25). This apparent dichotomy has been attributed to the fact that the epidermis contains a rich population of specialized "professional" antigen presenting cells (APCs), that are absent in normal muscle tissue. In fact, it is thought that immune responses generated following intramuscular injection of DNA may be due primarily to APCs migrating into the injection site (26,27). It is important to note that the increased vaccine efficacy does not necessarily imply transfection of APCs themselves as it has been shown that transfected muscle cells can transfer antigens to APCs to trigger an immune response (28). The third strategy lies in the selection of the vector system. A number of vectors have been developed to increase transfection efficiency and provide alternative innoculation sites where naked plasmid DNA is ineffective (e.g., the oral route). The inoculation site is especially important as the type of immune response generated is modulated in part by the site of antigen exposure and lymphoid tissue targeted (29). Specialized vectors have been developed for intradermal, intranasal, intraperitoneal, and oral plasmid DNA delivery through the use of liposomes, gene guns, microbes, and cochleates (30) to increase the versatility of DNA vaccination protocols.

Microencapsulation for DNA Vaccination

The primary rationale for thermoplastic microencapsulation of plasmid DNA for DNA vaccination is based on the exploitation of two biological phenomenon, gastrointestinal (GI) tissue uptake and microsphere phagocytosis.

Although the extent of uptake remains somewhat controversial, particle uptake along the GI tract is an established biological phenomenon (31,32). It is thought that the uptake phenomenon is primarily due to a size effect; particles smaller than 10 μm in diameter can cross the GI barrier (33). The study of GI uptake of particles has focused on the possibility of targeting gut-associated lymphoid tissue or Peyer's patches known to be important in mounting the mucosal immune response (34,35). As delivery of purified unencapsulated antigens alone to this mucosal site is difficult, a major focus of GI uptake has been the development of effective oral vaccines. Thus, delivery systems have been designed to protect labile antigens from degradation within the harsh environment of the GI tract and to transport them across the "M" cell barrier for presentation to cells of the immune system (B cell follicular regions, interfollicular T cell zones, and APCs). Antigens derived from the simian immunodeficiency virus, influenza, staphylococcal enterotoxin, and others have been delivered orally via microsphere systems to generate both systemic and localized mucosal immunity (36).

Uptake can occur via paracellular as well as transcellular routes (37) and thus does not necessarily imply cellular internalization. In contrast, phagocytosis is defined as direct cellular internalization, a process primarily exhibited by antigen processing cells of the immune system such as macrophages and neutrophils. A form of endocytosis, phagocytosis refers specifically to internalization of soluble and insoluble macromolecules greater than 250 nm in size. The phagocytic capabilities of APCs are astounding, as it has been estimated that macrophages phagocytose 10^{11} senescent red blood cells on a daily basis. The intrinsic ability of APCs for phagocytosis of microspheres combined with their immunoregulatory function provides a potential passive targeting mechanism for efficient delivery therapeutic molecules to the immune system (38–40).

Advanced controlled release systems provides an alternative approach to the standard oral, intravenous, or intramuscular delivery of pharmaceutical agents. Controlled release systems have traditionally been designed to deliver drugs in a localized, prolonged manner through a sustained depot effect (41,42). These systems can be designed to locally administer drugs to any site in the body. Furthermore, in the case of labile drugs, they can provide protection from rapid in vivo degradation and more efficient dosing. Microencapsulation constitutes one approach for fabrication of matrix-based polymer controlled release systems in microsphere geometry. Microencapsulation of drugs within polymer materials can allow for control of the release rate and duration of delivery to enhance the pharmacokinetics of drugs compared with traditional dosage forms. A detailed review of microencapsulation and drug delivery is reviewed elsewhere in this encyclopedia.

Given that plasmid DNA degrades rapidly in vivo, on the order of minutes (43,44), controlled release systems designed for DNA delivery and gene transfer offer similar advantages. Most importantly for DNA vaccine applications, fabrication of these systems into small microsphere form offers the added possibility of targeting specific tissue; in the case of oral administration, the Peyer's patch, and for parental injections, the APCs. Conceptually, DNA would be released extracellulary within the Peyer's patch or the parental injection site upon administration. Internalization of DNA released from microspheres by adjacent cells is not thought to be facilitated and is assumed to follow the same pathway as direct injection of naked plasmid DNA. In the case where cells have successfully phagocytosed microspheres, DNA would be released intracellularly and serve to facilitate translocation of encapsulated DNA across the cellular membrane, the first barrier for naked plasmid DNA. It should be noted that although there are numerous reports of cytoplasmic internalization, there are no reports regarding nuclear internalization of microspheres. The two pathways are not mutually exclusive, as plasmid DNA release in these systems occurs immediately

following hydration and is not specifically triggered to occur upon cytoplasmic entry.

FABRICATION TECHNIQUES

Physiochemical Properties of Plasmid DNA

Plasmid DNA exhibits a number of distinct physiochemical characteristics which present a number of challenges distinct from peptide or protein encapsulation (45). Plasmid DNA is an extremely large, negatively charged macromolecule with molecular weights in the millions of daltons; at least an order of magnitude higher than proteins. Moreover, plasmid DNA can exist in three different conformations (supercoiled, open circular, and linear), each with different hydrodynamic characteristics. Gene transfer is most effective with the supercoiled form (46,47) and thus delivery systems must optimize the encapsulation and release of this particular fraction. Although plasmids appear stable in organic solvents and are thermally stable (on the order of years), they are extremely sensitive to physical manipulation such as sonication, a processing step crucial for most microencapsulation techniques (48). In addition, aqueous DNA solutions are extremely viscous at relatively low concentrations, providing challenges for both loading and dispersion during the fabrication stage.

Manipulation of Plasmid DNA

Generally, fabrication steps involve (*1*) dispersion of plasmid DNA within the polymer solution, (*2*) formation of desired geometry, and (*3*) removal of solvent. The primary difficulty in encapsulation of DNA through traditional microencapsulation techniques is dispersion of DNA within the polymer matrix. Lyophilized solutions of DNA form macroaggregates, resembling a ball of cotton, which cannot be milled or otherwise physically micronized without shearing DNA strands. Although DNA can be spray-dried into particles (49), most techniques disperse DNA in solution to form an emulsion of DNA droplets dispersed in a continuous polymer–solvent phase. Once dispersed, techniques generally follow traditional "double emulsion" microencapsulation protocols designed for peptides and proteins. Formation of the initial emulsion has been achieved via vigorous vortex, homogenization, or sonication. A homogenous emulsion is critical for minimizing microsphere size distribution as well as reducing variability in drug loading (50). However, the principal limitation of this process stems from the physical sensitivity of DNA, which requires that both the duration and magnitude of agitation must be minimized (51). Thus an optimal emulsion, in terms of decreasing droplet size, is difficult to achieve. Although Adami et al. have reported that condensation of plasmid DNA with a peptide allowed for sonication at 100 W for up to 60 seconds, uncondensed, naked plasmid DNA was fragmented in less than 15 seconds (52).

Encapsulation Techniques for Plasmid DNA

A number of fabrication techniques have been used for encapsulation of plasmid DNA for various therapeutic applications (Table 3). However, only two techniques, solvent evaporation and phase inversion nanoencapsulation, have been used to fabricate microsphere formulations for DNA vaccination.

Table 3. Fabrication Techniques for Plasmid DNA Encapsulation

Technique	Reference	Polymer
Solvent evaporation	53,54	PLGA
	40	PLGA
	55	PLGA
	56	PLGA
Phase inversion nanoencapsulation	37	P(FA:SA)
Heat extrusion	57	EVAc
Solvent cast coating	58	Proprietary
	59	PLGA

Solvent evaporation is one of the most common techniques used to produce matrix-type delivery systems in microsphere geometry (53,60). Briefly, the polymer is dissolved in an organic solvent is emulsified with the drug of choice in an aqueous solution to produce a dispersed phase of drug/water within a continuous phase of polymer/solvent. The emulsion is subsequently dripped into a stirred aqueous bath for removal of solvent. Due to the limited miscibility between the organic solvents used and the aqueous bath, solvent is gradually removed from the polymer matrix via evaporation over a period of hours.

Jones et al. first reported encapsulation of plasmid DNA in poly(lactide-*co*-glycolide) (PLGA) microspheres using solvent evaporation (53,54). Microspheres were reported as 1~2 μm in diameter with an encapsulation efficiency of 25%. The in vitro bioactivity of released plasmid DNA was determined to be 25% compared to unencapsulated plasmid controls using bacterial transformation assays and luciferase expression in tissue culture transfection assays. A second group reported using solvent evaporation for encapsulation of plasmid DNA in PLGA-based microspheres (40,51). The volume percent analysis of microsphere size indicated 85% of the microspheres were between 1.1 μm and 10 μm in diameter with a theoretical loading of 0.45% (w/w). In vitro coincubation of microspheres containing a luciferase reporter plasmid DNA with a macrophage cell (P388D1) resulted in engulfment and luciferase expression at 24 hours postengulfment, confirming release and bioactivity of the encapsulated plasmid DNA. The conformation of plasmids released from microspheres, as reported by both groups, showed that there was a partial conversion from supercoiled DNA to open circular DNA, which Hedley et al. attributed to the fabrications conditions during solvent evaporation.

Phase inversion nanoencapsulation (PIN) is a recently developed microencapsulation technique which has been used to encapsulated small drugs, proteins, and genes (37). In this method, nanosized microspheres are fabricated by the spontaneous phase inversion of dilute polymer solutions, which are then quickly dispersed into an excess of nonsolvent for the polymer. This method differs from existing methods of encapsulation in that no stirring or agitation of the nonsolvent bath is required. Most traditional microencapsulation techniques required the formation of

a polymeric emulsion using stirrers, sonicators, air-jet, etc., and the final size of the particles is determined by the rate of stirring. In the PIN technique, as solvent leaves the polymer solution and enters the bulk nonsolvent phase, polymer instantaneously precipitates into the form of microspheres in what appears to be a self-assembling system.

A reporter plasmid DNA encapsulated into poly(fumaric acid-*co*-sebacic acid) (P(FA:SA), 20:80, Mw 2k) microspheres (0.1 ~ 5.0 μm) via the PIN technique was reported by Mathiowitz et al. (37). Extraction analysis of microspheres following encapsulation showed a DNA loading of 0.1% (w/w) which retained a large fraction of the supercoiled form following fabrication (Fig. 2). Furthermore, in vitro release studies indicated that plasmid DNA was released from PIN microspheres in supercoiled and open circular conformation up to a period of 4 days.

IN VIVO APPLICATIONS

Microsphere Uptake and Gene Delivery

The feasibility of using microsphere uptake to deliver genes into the Peyer's patch for functional gene transfer was first demonstrated by Mathiowitz et al. (37). Using PIN, a reporter plasmid was encapsulated in microspheres composed of P(FA:SA). P(FA:SA) is an extremely bioadhesive polyanhydride that degrades rapidly via hydrolytic degradation (61). The authors selected P(FA:SA) upon the theory that increased bioadhesion can promote particle uptake in the gastrointestinal tract. In vivo light and transmission electron microscopy studies of GI tissue sections, following oral feeding of P(FA:SA) microspheres, indicated traversal of microspheres across both the mucosal epithelium and the follicle-associated epithelium covering the lymphatic elements of Peyer's patches (37).

Analysis of small intestinal tissue, five days after a single dose (50 mg microspheres encapsulating 50 μg pCMV/βgal) to rats, revealed functional expression of the encapsulated reporter gene product β-galactosidase. Whole tissue X-gal histological staining of the Peyer's patch areas revealed transfection of cells primarily in the serosal surface of Peyer's patch area. Control animals receiving a much higher dose (500 μg) of unencapsulated plasmid DNA did not show any expression in the Peyer's patch. Analysis of frozen cross sections showed that the majority of transfected cells were located in the muscularis mucosae and the adventitia below the Peyer's patches. The general localization of transfected cells was consistent with previous observations using fluorescently tagged microspheres, which suggests that the serosal tissue layer acts as a sieve to trap appropriately sized microspheres that have passed through the mucosal barrier (62).

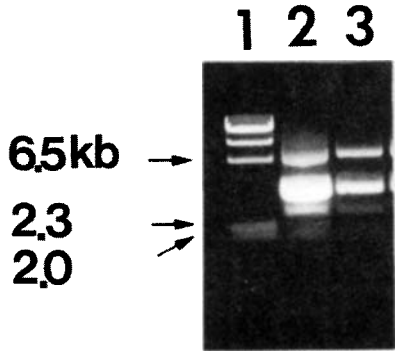

Figure 2. Agarose gel electrophoresis analysis of encapsulated pCMV/βgal plasmid DNA. (1) λ *Hind* III; (2) unencapsulated stock pCMV/βgal; (3) pCMV/βgal extracted from microspheres.

Microsphere-Based Oral DNA Vaccination

The efficacy of inducing an immune response, following oral administration of microspheres containing the antigen encoding plasmid DNA, was demonstrated by Jones et al. (53,54). Solvent evaporation was used to encapsulate luciferase reporter plasmid DNA in PLGA microspheres (~2 μm) and a 50 μg DNA dose fed to mice. Although neither luciferase expression nor PLGA uptake was evaluated, induction of luciferase specific serum IgA, IgG, and IgM responses were evident from 3 to 9 weeks following a single dose indicating successful gene transfer. A dose response study of 1, 5, 20, and 50 μg doses suggested increased titres with increasing dose. Interestingly, even the 1 μg dose was sufficient to induce the humoral response. Moreover, analysis of fecal extracts showed significant levels of IgA antibodies, which was detectable up to 16 weeks, illustrating that the oral route is effective in inducing mucosal as well as systemic immune responses.

In addition to oral administration (O), these same studies reported comparative data regarding delivery of encapsulated plasmid DNA via intramuscular (IM) and intraperitoneal (IP) injections. Analysis of serum IgG titres following a single dose (IP, IM, O) of 50 μg of encapsulated plasmid DNA indicated that the IP route provoked the strongest IgG response at both 3 and 6 weeks following administration. IP injections of unencapsulated small hepatitis B surface antigen plasmid DNA alone does not induce a cellular and humoral immune response (63) indicating improved transfection with microencapsulation at this site. In contrast, animals given the encapsulated plasmid DNA via O administration showed the highest levels of fecal IgA levels, reflecting the importance of the delivery site in modulating the immune response. In both IP and O administration, animals receiving the encapsulated plasmid DNA showed enhanced serum IgG levels compared to the unencapsulated naked DNA controls. Somewhat surprisingly, animals receiving naked unencapsulated plasmid DNA orally also developed specific IgG titres, albeit at lower levels. Although other reports indicated that direct oral administration of plasmid DNA was ineffective (64), this observation suggests the intriguing possibility that plasmid DNA may have some ability to bypass the enzymatic and mucosal barrier of the GI tract.

Microsphere-Based Parental DNA Vaccination

A parental DNA vaccine application based on microsphere phagocytosis has been reported by Hedley et al. (40). In an effort to target APCs in a parental inoculation site, a microsphere system was evaluated to enhance vaccination efficacy. The authors hypothesized that successful delivery

of a single antigen expressing DNA construct could be more efficient than direct delivery of the synthetic antigen, as it has been shown previously that an APC expressing a peptide gene construct results in over 10,000 Class I MHC associated peptide molecules (65).

Using solvent evaporation, plasmid DNA was encapsulated in PLGA microspheres. Subsequently, plasmid DNA (VSV N_{52-59}) encoding for a peptide derived from the vesicular stomatitis virus (VSV), was encapsulated in PLGA microspheres (1.1~10 μm). Both intraperitoneal and subcutaneous immunization of mice with encapsulated VSV N_{52-59} plasmid DNA produced significant cytotoxic T lymphocyte (CTL) responses, which were more pronounced when compared with a subcutaneous injection of purified VSV N_{52-59} peptide alone. Moreover, comparison of intraperitoneal or subcutaneous injections of 2~5 μg VSV N_{52-59} plasmid DNA generated stronger CTL responses compared with an intramuscular injection of a much larger 200 μg of unencapsulated VSV N_{52-59} plasmid DNA. The increased immune response was attributed to decreased degradation of the administered plasmid DNA dose as well as increased uptake of plasmid DNA, via microsphere phagocytosis, by APCs.

CONCLUSION

At the time of this review, there are over 270 approved human gene transfer protocols approved by the Office of Recombinant DNA Activities (see website at http://www.nih.gov/od/orda/protocol.htm). Currently, the three major targets are infectious disease, monogenic disease, and cancer. Due to the diverse nature of these categories, there is most likely no "perfect" vector. The most effective vectors will need to be tailored to the disease. Application of gene therapy to target vaccine development has recently provided an alternative approach to vaccination. DNA vaccination is an entirely new area of research which will require specialized vector systems for optimal therapeutic efficacy. While still in the very early stages, with further development, microencapsulation techniques may find a niche for specific applications in DNA vaccination.

Bibliography

Although often thought of under the umbrella term of buccal delivery, drug delivery via the membranes of the oral cavity is traditionally divided into three categories: (*1*) buccal delivery, which infers drug administration through the lining of the cheek to the systemic circulation; (*2*) sublingual, the administration of drug via membranes of the floor of the mouth or the underside of the tongue to the systemic circulation; and (*3*) local delivery to the mouth, which involves treatment of conditions within the oral cavity by administration to the affected mucosal tissues. These sites for delivery differ in both structure and composition, as well as in degree of permeability and, therefore, also vary in their ability to retain a delivery device for a desired length of time. The following article provides a chronologically oriented overview of the various methods and technologies that exist or have been attempted in the utilization of the oral mucosae for applications in buccal delivery, sublingual delivery and local drug delivery to the mouth. Table 1 summarizes some of the specific drugs delivered to the oral mucosa.

THE STRUCTURE OF THE ORAL MUCOSAE

In general terms, the oral mucosae is made up of an outermost layer of stratified squamous epithelium, which is covered with mucus and consists of a stratum distendum, stratum filamentosum, stratum suprabasale, and a stratum basale. Below this lies a basal lamina, the lamina propria, and the submucosa (Fig. 1). The epithelium serves as the mechanical barrier that protects underlying tissues, whereas the lamina propria acts as a mechanical support and also carries the blood vessels and nerves. Some regions of the oral mucosa are keratinized, whereas others are not (Fig. 2). The nonkeratinized regions, such as buccal mucosa, are more permeable than the keratinized regions. This is due, to some extent, to the composition of intercellular lipids comprising the particular region. Whereas keratinized regions contain predominantly neutral lipids (ceramides), nonkeratinized areas are composed of a glycosyl ceramide that appears to be derived from membrane-coating granules that differ morphologically from the lamellate membrane-coating granules of keratinized tissue.

In general, it appears that the patterns of epithelial differentiation observed in the oral mucosa vary to produce a surface layer that sufficiently meets the demands placed upon that particular tissue (54,55). Furthermore, in dealing with drug delivery, the amount of a certain drug absorbed through the buccal mucosa are determined by many factors, including the pKa of the base, the rate of partition of the unionized form of the drug, the lipid–water partition coefficient of that particular drug, and lastly, on the pH of the solution (56).

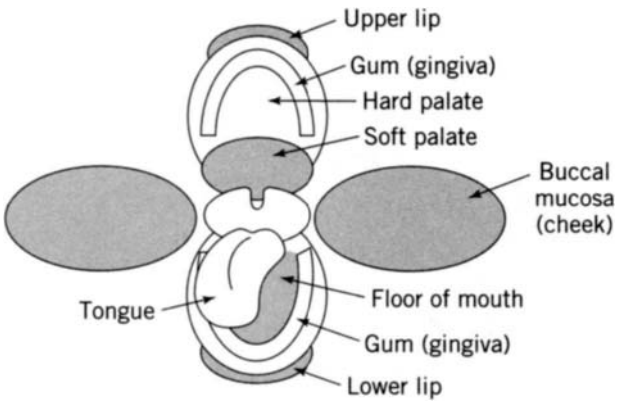

Figure 2. Schematic representation of the "open" oral cavity, showing keratinized (white) and nonkeratinized (shaded) regions of the mouth. *Source:* From Ref. 53.

DELIVERY TO THE SYSTEMIC CIRCULATION

Via Buccal Mucosa

Administration of a drug via the buccal mucosa (the lining of the cheek) to the systemic circulation is defined as buccal delivery. Though the buccal mucosa is significantly less permeable than the sublingual mucosa and usually not able to provide rapid drug absorption or good bioavailabilities, it is more permeable than skin and also boasts other advantages over alternative delivery routes. The fact that the buccal mucosa is less permeable than the sublingual makes it a more desirable site for sustained release delivery. The oral mucosa itself provides a protective covering for the underlying tissues, acting as a physical barrier against toxins and microorganisms. Patient compliance is high with buccal delivery due to the accessibility of the cheek lining and lack of invasive measures. In the case of an adverse reaction, administration of drug can be stopped at any time by device removal. Most importantly, however, drugs administered via the buccal mucosa directly enter the systemic circulation, thereby avoiding enzymatic degradation in the gastrointestinal tract as well as first-pass metabolism in the liver. Furthermore, peptides and proteins are not only susceptible to the acidic environment of the stomach, but they are generally high in molecular weight and are hydrophilic in nature, and therefore cannot permeate the intestinal mucosa as easily as they can the buccal tissues. For these reasons, buccal delivery is being researched with increasing intensity as a route of administration for the increasing number of peptide drugs currently on the market.

Applications in Buccal Delivery

Due to the buccal mucosae being more permeable than the skin, as well as the other advantages already mentioned, the buccal mucosae have been increasingly used as a route of drug delivery. Evidence of a biexponential absorption curve suggests that the buccal membrane can also act as a storage area for certain drugs before they are passed into the bloodstream. In studies by Davis and Johnston in 1979, in which occurrence of the antianginal agent verapamil in biological fluids and tissues was assayed fluorometrically, the buccal absorption of verapamil was found to occur in a biphasic manner (1). Despite this fact, interest in the buccal mucosa as a route for delivery led Ishida et al. in 1981 (2) to attempt to develop an oral dosage form that would solve the problem of insulin administration via injection. The system was a core of cacao butter, insulin, and additive surrounded by a layer of hydroxypropyl cellulose-H and Carbopol-934 (a polyacrylic acid) that adhered to the oral mucosa of beagle dogs for up to 6 hours. Furthermore, a decrease of blood sugar levels was maintained at over 70% for 3 hours. The amount of insulin absorbed in this manner, however, was found to be only 0.5% of the amount absorbed when given as an intramuscular insulin injection (2).

Release of glyceryl trinitrate from modified hydroxypropylmethylcellulose (Synchron) matrix tablets via the buccal route was accomplished in 1983 by Davis and his colleagues. The matrix tablets look like conventional tablets, but contain a drug that is entrapped in a slowly eroding, nondisintegrating Synchron and lactose base. The Synchron formulation showed sustained release of a model drug in excess of 3 hours, whereas normally dissolving tablets had completed release within 20 minutes (4).

Nagai et al. published a good deal of research in the 1980s, a portion of which was concerning oral mucosal adhesive tablets for the administration of insulin. They used a combination of hydroxypropylcellulose and Carbopol to prepare tablets that would turn into a gel-like substance in the swollen state. This gel would adhere firmly to the oral mucosa for extended periods of time, releasing the insulin in a controlled manner (26). The bioavailability was about 0.5% of that observed in intramuscular administration in dogs, but has recently been improved to 0.75% by

using Witepsol® as the core base in place of cocoa butter (57). The adhesive tablets were then developed into a system releasing triamcinolone acetonide ointment to treat aphthous stomatitis. The product, Aftach®, is a small, thin, double-layered tablet and is now commercially available (3). The upper layer consists of lactose and serves as a supporting layer; the triamcinolone acetonide is dispersed in the lower lydroxypropylcellulose and Carbopol 934 adhesive layer (57).

Ketobemidone is a powerful narcotic analgesic that is traditionally administered perorally or rectally and, therefore, has a low and variable bioavailability. In 1991, Hansen et al. began studies in which they synthesized various carboxylic acid and carbonate esters of ketobemidone. The goal was to improve the bioavailability of the drug by using the buccal approach. However, due to the limited lipophilicity of the compound, the drug did not permeate the oral mucosa. To improve penetration of the drug across the oral mucosa, Hansen and her colleagues developed more lipophilic prodrugs of ketobemidone, which are converted back to the active parent drug during or after absorption across the mucosa (5). The esters synthesized were, in fact, found to have increased lipophilicity over the parent drug and are potentially more capable of crossing the buccal mucosal barrier.

Buccal delivery of the nonsteroidal antiinflammatory drug diclofenac sodium (Voltaren) from a hydrogel disk was studied in humans by Cassidy et al. (6). The 1-cm^2 hydrogel disks were formulated with 80 wt% hydroxyethyl methacrylate and 20 wt% hydrophobic difunctional macromolecular cross-linker. A 50 wt % solution of diclofenac sodium in 85.5% (v/v) methanol:water was loaded into the dry disks over a period of 48 hours. Patients had the hydrogel device affixed to their buccal mucosa for 4 hours, and blood samples were taken at regular intervals for diclofenac sodium quantification. Results were compared with intravenous infusion of the drug into the same patients for 4 hours at 3 mg/hour. The study demonstrated that diclofenac was readily transported across the buccal mucosa, with a steady-state flux of 2.1 mg/cm^2-hr. (6).

Carbopol 934, polyisobutylene (PIB), and polyisoprene (PIP) formed by a two-roll milling process and loaded with buprenorphine was formulated for controlled drug delivery by researchers at 3M Pharmaceuticals. Guo noted that the surface properties of the buccal patches were dependent upon the Carbopol 934 content as well as the existing polymeric ratio. Polymer patches with higher Carbopol content, or higher PIB:PIP ratios, had higher water uptake capacity, which led to increased swelling and more buprenorphine release (7). The analgesic buprenorphine was delivered safely and effectively over a 12-hour period to the upper gum or lip from these thin, noneroding, ethylcellulose-backed, mucoadhesive polymeric disks. However, this period only accounted for release of 15% of the drug load, which indicates that an extended application time could result in prolonged buprenorphine release. Evaluation of the 3M Transmucosal Drug Delivery System was discussed by Benes et al. in the June 1995 3M Delivery newsletter. Results demonstrated that the 3M system, named CYDOT™, is also comfortable and acceptable to the wearer of the device (58). Pharmacologically relevant serum concentrations of buprenorphine were attained using these devices and sustained for 12–24 hours in humans in 1995 (8). Greater drug delivery was achieved from patches applied to the gum rather than the lip, most likely because of the superior mucoadhesion present at this site.

In 1995, it was reported by Ahuja et al. that diltiazem, a calcium channel blocker commonly used in the treatment of cardiovascular disorders, could be formulated into polymeric buccal tablets that achieved up to an 86% in vitro release of the diltiazem obtained from a dissolution study after 4 hours. The multilayered tablets were comprised of a cap layer of Carbopol 934 combined with either hydroxypropyl cellulose, hydroxypropylmethyl cellulose, or poly(vinyl pyrrolidone) compressed using a die punch set around an already compressed core of drug. In vitro release data was compiled using bovine cheek pouch membrane in a Franz diffusion cell (9).

Lee and Chien developed a method of controlling transmucosal delivery of luteinizing hormone-releasing hormone (LHRH) from a bilayer system composed of a fast-releasing layer containing a polypyrrolidone (PVP (K-30)) and a sustained-release layer formulated from Carbopol 934 and PVP (K-90). The delivery device also contains an enhancer, sodium cholate, which promotes the transmucosal permeation of LHRH and a stabilizer, cetylpyridinium chloride, which stabilizes LHRH from degradation by the oral microflora. Simulation of the system in vivo involves adhering the film to the alveolar mucosa, with the other side facing the buccal mucosa in a specially designed device holder. Results demonstrated a burst release of LHRH from the fast-release layer, thereby providing a rapid delivery of the hormone, and a prolonged release of LHRH from the sustained-release layer. Therefore, varying the formulation of the device can result in modulation in the rate of LHRH transmucosal permeation (10).

Buccal delivery of testosterone was achieved in 1995 by Kim et al. The buccal matrix was comprised primarily of a blend of water-soluble polymers that melt near body temperature. Testosterone (T) was dispersed in the polymer matrix. When introduced into the buccal cavity, the polymer matrix melts and disperses within 5 minutes, exposing mucosal tissues to the testosterone. A single 10-mg transbuccal dose of the testosterone was found to induce a prompt rise in testosterone levels in the serum as well as dihydrotestosterone (DHT) concentrations. Furthermore, the method of administration was associated with a more normal DHT:T ratio than other preparations. The serum testosterone levels remained elevated above baseline for 24 hours. Therefore, transbuccal delivery of testosterone seems promising due to its simplicity, acceptability, reversibility, lack of toxicity, and protection from hepatic first-pass metabolism (11).

Two types of sustained release buccal dosage forms were prepared by Iga and Ogawa for nitroglycerin and isosorbide dinitrate (12). One device is a slowly disintegrating plain tablet, whereas the other is a slowly disintegrating polyethylene film-covered tablet, which has a single hole on the top surface through which disintegration and drug release can occur. The plain tablets disintegrated in 3–6 hours, whereas the film-covered tablets resulted in an almost constant plasma drug level for both drugs for over 10

hours until the tablet was removed. The tablets achieved almost complete bioavailabilities for both nitroglycerin and isosorbide dinitrate, which is in contrast to the near negligible bioavailabilities achieved when delivering these drugs orally, indicating that this type of sustained release buccal dosage form could be of importance in increasing the bioavailabilities of rapidly eliminating drugs and prolonging their absorption times (12).

The buccal delivery possibilities of progesterone were investigated in 1997 by Voorspoels et al. using a slow release degradable bioadhesive tablet in dogs. The bioadhesive tablet consisted of micronized progesterone, drum-dried waxy maize starch, Carbopol 974P, and sodium stearylfumarate compressed into a tablet. The tablet was placed above the right upper canine in the oral cavity. Delivery of progesterone involves release of the drug from the bioadhesive tablet, which is erosion controlled, followed by dissolution of the progesterone into the saliva, and finally, absorption of the drug into the buccal mucosa. The mean residence time of the drug was measured as well as the absolute bioavailability. Results indicated that buccal delivery may be useful, as mean residence time was dramatically improved by the administration of a bioadhesive tablet compared with intravenous formulations (13).

Applications in Peptides. Due to the emergence of peptides as a major class of future drugs, the buccal epithelium is being closely scrutinized as a possible route of peptide delivery. Initial studies of peptide absorption and permeability through the buccal mucosa were performed by Veillard et al., and preliminary results showed that although a higher drug dosage was administered via the buccal route than intravenously, corresponding plasma levels were much lower from buccal delivery than by direct intravenous injection (14). Therefore, penetration enhancers may be needed to achieve the desired activity when using the buccal route for peptide delivery.

Further studies on peptide delivery by Merkle and his colleagues in 1986 closely followed those by Veillard. Hydroxyethylcellulose patches containing the tripeptide protirelin and backed with an impermeable laminate were designed as buccal patches (15). Protirelin has a molecular weight of 362 and was readily absorbed across the buccal mucosa, as shown by increases in pituitary thyrotropin and prolactin levels, whereas calcitonin with a molecular weight of 3,500 could not permeate the buccal mucosa at all. However, after 30 minutes of contact with the mucosa between 48% and 72% of the protirelin was still found in the patches, indicating that a large portion of the drug was unable to be absorbed within this short contact time. This was most likely due to the high viscosity of the polymer, as much more drug was released when a lower viscosity polymer was used.

Via Sublingual Mucosa

Sublingual delivery traditionally involves systemic administration of drug via membranes of the floor of the mouth or the ventral surfaces of the tongue. The sublingual mucosa is relatively permeable due to the thin membrane and large veins, allows rapid absorption and acceptable bioavailabilities of many drugs, and is a convenient and easily accessible location. Furthermore, the sublingual mucosa is a smooth surface, not furred like the top of the tongue, and is free of mucus and undigested food, unlike the stomach.

Applications in Sublingual Delivery

The history of sublingual delivery dates back to 1858 when A. G. Field first realized that nitroglycerin dropped on the tongue was readily absorbed through the membranes (17). But it was not until a century later that Riseman et al. noted that many nitrates are highly effective in treating patients with angina pectoris when administered from either hypodermic injection, inunction, buccally or sublingually. Of the six nitrates tested to treat angina pectoris, including nitroglycerin, erythrol tetranitrate, pentaerythritol tetranitrate, mannitol hexanitrate, triethenolamine trinitrate, and sodium nitrate, the erythrol tetranitrate administered buccally or sublingually had the greatest prophylactic impact (18). However, it appears that the prolonged duration of action of the tablets may be due to their prolonged duration of tablet dissolution, directly leading to a prolonged period of absorption into the bloodstream. Therefore, another study by the group was undertaken to determine if, in fact, the prolonged dissolution time was essential for the prolonged therapeutic effect, as well as to assess the effect of varying the dosage of the erythrol tetranitrate. Results showed that the erythrol tetranitrate is absorbed more rapidly and uniformly from the sublingual route than from the buccal pouch. However, the prolonged beneficial effects of erythrol tetranitrate are not dependent upon prolonged absorption. The effects are long lasting even following sublingual administration of erythrol tetranitrate with rapid dissolution time (59).

Research in 1985 by Pimlott and Addy measured the absorption of isosorbide dinitrate (ISDN) into the systemic circulation after application of tablets to the buccal, palatal, and sublingual mucosal sites. For the buccal and sublingual sites, maximum plasma levels of ISDN were achieved at 5 minutes, after which levels fall gradually. Concentrations of ISDN were about 1.2 ng/mL after 30 minutes from either the sublingual or buccal route. On the other hand, plasma levels of ISDN were undetectable at all times from the palatal mucosa (19).

Another study involving oral nitrate treatment for patients with angina pectoris was completed by Thadani and Lipicky in 1994. It is currently accepted that intermittent use of short-acting oral nitrates used to terminate an attack of angina as well as provide prophylaxis for anticipated activity, and intermittent use of long-acting oral nitrates to provide prophylaxis for anticipated activity are both valid and successful therapies. However, tolerance presents a problem in limiting multiple dosing regimens of most oral long-acting nitrates and continual prophylaxis has not yet been achieved by any long-acting oral nitrate. Here, nitroglycerin spray and sublingual tablets of isosorbide dinitrate were used to successfully relieve an established attack of angina, and infrequent use of such substances is not associated with the development of tolerance (20).

Studies evaluating the use of sublingual buprenorphine in patients following surgery and comparing its effects

with intramuscularly administered morphine were done by Edge et al. in 1979. Each patient received either a tablet of 0.4 mg buprenorphine and an injection of 5% dextrose in 1 mL, or a dummy tablet and an injection of 10 mg morphine in 1 mL. A pain "score" was obtained from the patients by means of a visual linear analog. Results indicated a slower onset of action by the buprenorphine, but a much longer duration than the morphine (23).

Temazepam is one of the shorter acting membranes of the 1,4 benzodiazepine group of drugs that is commonly prescribed for short-term therapy for adult insomnia. The pharmacokinetics of a new 10 mg sublingual temazepam tablet were compared with the currently marketed 10 mg oral gelatin capsule by Russell et al. in 1988 (25). Evidence shows the sublingual formulation to have a 98.4% bioavailability relative to the oral capsule, and the mean maximum plasma concentrations were similar. Therefore, it seems that the sublingual tablet is an acceptable alternative to the currently used oral capsule.

Although most sublingual delivery is accomplished via mouthwashes, oral sprays, or topical gels, controlled release tablets are currently being investigated as the most promising future technology for delivery drug sublingually.

LOCAL DELIVERY TO THE MOUTH

The classification of local delivery to the mouth includes any system that is applied to the oral mucous membranes in order to treat conditions of the mouth such as periodontal disease, gingivitis, oral candidiasis, and other chronic lesions or topical fungal infections. Traditional methods of delivery to the diseased site have involved chewing gums, mouthwashes, ointments, and gels. However, these methods share a common disadvantage in that they all have relatively short residence times and, therefore, fail to maintain therapeutic concentrations long enough to affect the bacterial population. Furthermore, drug is lost in the saliva (i.e., with swallowing), and patients on these treatments often have low patient compliance due to the need for frequent drug application. Current technology, however, is attempting to prolong residence time and increase patient compliance by using sustained release drug delivery systems.

Applications in Local Delivery

One of the earlier controlled release products to go through clinical trials was the Orabase system by Kutscher et al. composed of a finely ground pectin, gelatin, and carboxymethyl cellulose in a polyethylene–mineral oil gel base. This vehicle, in which therapeutics could be incorporated, has the ability to adhere to the site of application without causing any deleterious effects on the underlying tissue. Results varied with duration of maintenance ranging anywhere between 15 and 152 minutes, depending on the site in the oral cavity to which the device was adhered (60).

A device by Nagai et al. similar to that described earlier to deliver insulin systematically was also fabricated of hydroxypropyl cellulose and Carbopol, yet loaded with lidocaine for the local treatment of toothache. Unfortunately, lidocaine was not absorbed and remained in the dosage form for up to 6 hours. Nagai and Konishi, known for their work in the buccal delivery field, also formulated an adhesive gingival plaster that is loaded with prostaglandin $F_{2\text{-}\alpha}$ for the facilitation of tooth movement in the orthodontic process (26). A minimum of 70% of the drug load was released within the first 6 hours. In vivo studies in monkeys showed that application of the plaster to the gingiva did, in fact, accelerate tooth movement and, therefore, decrease movement time.

Bottenberg and his colleagues researched the possibility of using various bioadhesive polymers as fluoride-containing, slow-release tablets for oral use, specifically in the war against dental caries. Modified starch, poly(acrylic acid) (PAA), poly(ethylene glycol) (PEG) and sodium carboxymethylcellulose were the bioadhesive polymers investigated. A modified maize starch tablet containing 5% (w/w) PAA and PEG with a 300,000-dalton molecular weight proved to be the most successful formulation. Two formulations were then tested in vivo, including a drum-dried waxy maize and a PEG. Tablets were placed on the attached gingiva in the upper canine region, held for 30 seconds, and then moistened with the tongue. After insertion of the tablets, saliva samples were taken at regular intervals. In vivo, fluoride levels between 150 and 1,000 μg/mL were maintained for up to 8 hours, which is significantly longer than levels obtained with the administration of 4 times the amount of fluoride in a fluoride toothpaste. A patent for the application of modified starch as a bioadhesive slow-release drug carrier was applied for in 1991 (27).

A miconazole-loaded oral gel was tested in a study by Reading et al. for its efficacy against erythema, plaques, and perlèche in children with oral candidiasis. After one week, the gel boasted a 100% clinical cure rate for both plaques and perlèche. It showed a 97% cure rate for erythema (28). Buccal gels loaded with miconazole nitrate are also used for the treatment of topical fungal infections such as oral candidiasis. These gels are traditionally applied several times a day. Immediately following each application, the salivary miconazole nitrate concentration is at its maximum and then is rapidly cleared from the oral cavity. In an effort to prolong residence time of the drug, Bouckaert et al. formulated a bioadhesive tablet of modified starch and 5% PAA. Although a drug amount sixfold lower than that existing in the gel was released from the tablet, the salivary miconazole nitrate concentrations produced by the tablet were higher than by the gel and remained at a therapeutic level for over 10 hours. In vivo, a mean adhesion time of the tablet to the mucosa was in excess of 9.5 hours. The polymer tablets eventually eroded completely, and none had to be removed due to irritation to the mucosa. Furthermore, erosion seems to play an important role in the drug release rate from these systems. Although further investigation is required, variability in drug level appears to be due to tablet erosion by soft tissue movements and the individual movement patterns occurring within the mouth (29).

Mucosal Oral Therapeutic System (MOTS) is a controlled nystatin-releasing osmotic system based on an osmotic technique for delivering highly water-soluble or insoluble drugs that was developed by Encarnacion and Chin

at the Alza Corporation in California (31). Nystatin is an antibiotic that exerts both a fungistatic and fungicidal effect for the treatment of oral candidiasis. Salivary concentrations of nystatin produced by the MOTS exceeded those produced by a nystatin pastille for all time points beyond 30 minutes. Release continued for at least 2 hours. The higher sustained concentration produced by the MOTS would hopefully decrease the duration of therapy and thereby increase patient compliance.

Buccoadhesive matrix tablets have also been used for delivery of hydrocortisone hemisuccinate in the treatment of aphthous stomatitis and other gingival ulcers. The polymers used included hydroxypropylcellulose, hydroxypropylmethycellulose, polycarbophil, and modified maize starch. The maize starch formulation, which proved to have the optimal gingival tolerance, was found to deliver hydrocortisone in vitro for up to 24 hours, dissolve, and eventually result in the complete erosion of the tablet (31).

Local Delivery to Treat Dental Disease. Much of the local delivery research is geared toward the treatment of periodontal disease and gingivitis. Periodontal disease is a disease of the supporting structures of the teeth, namely the periodontal ligament, cementum, alveolar bone, and the tissue components of the gingiva (see Fig. 1). Abundant evidence implicates the microorganisms in the dental plaque as the primary causative agent of various forms of periodontal disease. In fact, there exists a strong correlation between the presence and amount of plaque and calculus on the teeth and the severity of disease. When microflora are allowed to build up in the moist, warm, anaerobic, ecologically ideal environment of the sulcus, the bacteria proliferate and produce an excess of enzymes and toxins that diffuse through the gum epithelium and cause inflammation. This condition, known as gingivitis, leads to an increase in polymorphonuclear neutrophil (PMN) migration into the sulcus. The PMNs destroy bacteria but also release enzymes, such as collagenase, that cause the breakdown of collagen. The sulcus deepens, forming a periodontal pocket into which plaque can migrate. Plaque then colonize the cementum, causing it to break down. Macrophages invade to fight the infection, releasing interleukin I, a substance inducing osteoclast stimulation, which in turn leads to bone resorption. Alveolar bone resorption hallmarks the breakdown of the structural support system and leads to eventual tooth loss (61).

A healthy periodontal situation appears to be associated with a primarily facultative gram-positive organism located almost entirely supragingivally on the tooth's surface. Normally, the host's defense mechanisms, including saliva, crevicular fluid, and PMNs, provide the necessary protection to the dentogingival area. The constant contact between saliva and the oral mucosa serves as a flushing action, ridding the mouth of excess bacteria. Saliva also contains substances that not only interfere with bacterial adhesion and growth, but actually phagocytose the bacteria. The crevicular fluid is formed in the gingival connective tissue as a result of extraction from the microcirculation, then unidirectionally flushes through the tissues and junctional epithelium into the gingival crevice. The flushing action serves to minimize bacterial colonization of the crevice and increases in relation to the level of inflammation in the gingival tissues. The crevicular fluid also contains protective components such as complement proteins, antibodies, and nonspecific opsonins. Many bacteria harbored in the gingival crevice turn on the host's immune response, activating the complement cascade (61). PMNs are also thought to play an integral role in the protection of the gingival tissues from bacteria. When plaque builds up in the gingival sulcus, the PMNs provide a barrier by preventing direct contact between the bacteria and the epithelial cells. PMNs in the gingival sulcus proceed to phagocytose the bacteria, in an effort to save the tissues from bacterial attack (62). Therefore, the onset of gingivitis and periodontal disease occurs when the bacterial composition of the mouth is imbalanced and plaque growth is allowed to flourish. Due to the fact that the primary cause of these dental diseases is bacterial overgrowth, antibiotics are frequently used in their treatment. Common local microbial therapies evaluated include chlorhexidine, tetracycline, and metronidazole.

A study in 1982 by Soh et al. investigated the effect of direct application of chlorhexidine to periodontal pockets (32). After 28 days it was found that chlorhexidine treatment had significantly reduced periodontal inflammation, whereas further deterioration had occurred in the placebo cases.

In an effort to prolong residence time of chlorhexidine in the periodontal pocket, Coventry and Newman in 1982 attempted the slow release of 20% chlorhexidine gluconate from Cuprophan (cellulose-based) hollow fiber dialysis tubing inserted in the periodontal pocket. The tubing had been loaded with the drug solution via capillary action, heat sealed, and then cut to a length suitable for the periodontal pocket. The devices were retrieved after only one week, at which time significant reduction in disease manifestations were noted (33).

In 1983, Soskolne et al. examined release kinetics of chlorhexidine from two formulations of sustained release devices, including a faster-releasing ethyl cellulose system or a slower-releasing ethyl cellulose–PEG system. Data confirmed the kinetics of chlorhexidine release in vivo to be diffusion controlled, as expressed by the Higuchi model. The effects of the drug on the bacterial flora within the periodontal pockets was also noted. Data shows release of up to 80% of the chlorhexidine within 3 days from the fast release devices, whereas the slow release devices had a release of about 50% of the drug after 6 days. The microbial floral content was examined in 16 pockets from 6 patients. All chlorhexidine-treated pockets had a decreased relative amount of motile rods and spirochetes, as well as a corresponding increase in nonmotile organisms in comparison with the placebo-treated pockets and to the flora present prior to chlorhexidine treatment (34).

A partially cross-linked soluble Byco protein, obtained from Croda Colloids in England, was used for the sustained release of chlorhexidine in 1990. Steinberg et al. found that the release kinetics of the degradable films were affected by the chlorhexidine loading, the cross-link density of the polymer, and the particular chlorhexidine salt

used (36). Highly cross-linked films exhibited antibacterial activity for over 24 days, whereas low cross-linked films maintained therapeutic levels for only 10 days. This was an improvement over earlier versions, such as the degradable films made of hydroxypropylcellulose in 1988. All of the drug from these films was released within 24 hours (63).

In 1990, Larsen prepared some acrylic strips as described by Addy et al. (35) to examine release of doxycycline in vitro from three other bioabsorbable materials to compare with release from the acrylic strips. The bioabsorbable materials used were a hemostatic gauze made of oxidized regenerated cellulose, a collagen wound dressing, and a fibrin sealant. Results indicated that only the hemostatic gauze and the fibrin sealant may be capable of prolonged doxycycline release in vivo due to the rapid dissolution of the other devices or low levels of concentration and residual activity remaining in these devices after only a few days (48).

Controlled release of another antibiotic, tetracycline, was attempted by Goodson et al. in 1983 from monolithic fibers of various polymeric compositions for use in periodontal therapy. Fibers made of polyethylene, polypropylene, polycaprolactone, polyurethane, and cellulose acetate released 100% of their drug load within the first 24 hours. Ethylene vinyl acetate fibers, however, achieved sustained release of tetracycline for up to 9 days (37). The monolithic fibers were prepared by the melt extrusion process, in which 25% tetracycline and 75% ethylene vinyl acetate was heated to 214°C and extruded as a 0.5 mm fiber. Goodson and his colleagues continued the research to find, in 1985, that these monolithic fibers released 57% of the drug into the periodontal pocket within the first 9 days. Furthermore, immediately following treatment, the total bacterial counts (spirochetes, motile rods, and nonmotile rods) were significantly reduced in the periodontal pockets (64). This research went one step further when the team declared the release of drug into the periodontal pocket from these fibers to be zero-order. This can be explained by the structure of the device. The fiber delivery system is composed of a polymeric matrix loaded with tetracycline hydrochloride powder. After extrusion, some of the tetracycline crystallites end up on the fiber surface. Upon device insertion into the periodontal pocket, the crystallites dissolve, forming pores on the surface. In turn, these pores allow solvation of deeper particles, resulting in zero-order drug delivery (38). This contrasts with the nonlinear release pattern of the fiber observed previously in vitro by Goodson et al. (37). In addition, fiber therapy alone was determined to be more effective than scaling alone, based on the degree of elimination of causative bacteria, amount of reduction in total viable counts, degree of elimination of bleeding on probing, and the amount of reduction in gingival index. It was, however, shown that combining scaling and fiber therapy is the most effective treatment (39).

In vitro studies by Baker et al. in 1988 used tetracycline-loaded biodegradable microparticles prepared by solvent evaporation with between 5 and 30 wt% of drug and suspended in a carrier gel to accomplish release of up to 3 days. The prepared formulation was injected into the periodontal pocket via syringe and needle. Such in vitro results typically correspond to about 10 or more days of release in vivo considering the low rate of crevicular fluid exchange within the periodontal pocket (40). Although nonbiodegradable polymers tried in this microparticle formulation included polysulfone, polystyrene, and polycarbonate, the biodegradable polymer of choice was a lactic acid–glycolic acid copolymer that tends to degrade in 4–12 weeks in an aqueous environment. Patents were obtained by Baker in both 1988 and 1990 (patent numbers 4,780,320 and 4,919,939, respectively) for these formulations of drug-containing microparticles suspended in a fluid carrier medium for the treatment of periodontal disease. The poly(lactide-*co*-glycolide) (PLGA) system was found to deliver tetracycline for a period of 25 hours, although the authors estimate this to be the equivalent of up to 10 to 20 days of release in vivo (65,66).

Investigators Minabe et al. in 1989 administered cross-linked processed collagenic film preparations loaded with tetracycline to the periodontal pocket to halt excessive growth of periodontopathogenic bacteria. They found that they could control the amount of drug release somewhat by adjusting the original drug loading and the time of the cross-link process. It was also found that an amount of drug exceeding the therapeutic dose was present in the gingival crevicular fluid of the periodontal pocket for up to 10 days postinsertion (41).

An intracrevicular application of 40% tetracycline HCl in a white petrolatum carrier gel was compared to scaling and root planing by Eckles et al. (44) in the treatment of periodontitis. Results indicated that biologically effective tetracycline was released from the gel into the gingival crevicular fluid for at least 3 days. Posttreatment analysis indicated that reduced probing pocket depths and bleeding on probing relative to baseline measurements remained for 8–12 weeks. Reduced percentages of spirochetes and motile rods, as well as the increase in cocci that accompanies this phenomenon, lasted for 2–8 weeks (44). However, similar effects seen in scaled and root-planed sites lasted longer and, therefore, led to the conclusion that the subgingival application of tetracycline cannot replace conventional treatment methods, but only supplement them.

A new type of poly(ortho ester) was prepared by Heller et al. in 1989 by the condensation of a triol and an alkyl ortho ester. This reaction produces a viscous paste at room temperature, despite molecular weights in excess of 50,000 daltons. This is beneficial for mixing in therapeutic agents without using solvents, as well as for application into the periodontal pocket. Furthermore, such materials may be useful in drug delivery because rates of release can be altered by adding small amounts of basic or acidic excipients to the polymer (42). For example, the system was loaded with tetracycline and injected into periodontal pockets using a blunt needle. Complete release occurred within 24 hours. However, when 0.5 wt% of the basic excipient $Mg(OH)_2$ was incorporated into the polymer, release was extended to about 10 days (45). This was based on the knowledge that poly(ortho esters) contain a pH-sensitive linkage in their backbone. Therefore, hydrolysis of the polymer chain can be sped up by the addition of acidic excipients to the environment, or retarded by the incorporation of basic excipients.

Deasy et al. delivered tetracycline hydrochloride or metronidazole from degradable polyhydroxybutyric acid strips for the treatment of periodontal disease. The system components were physically mixed using a mortar and pestle, then aliquots of the mixture were compressed under 106 kg cm^{-2} of force into strips 0.5 mm in thickness. In vitro studies were performed in simulated gingival fluid and revealed that increasing the loading of tetracycline resulted in increased drug release, whereas at a constant drug loading of 25%, metronidazole was released much faster. In vivo, the strips loaded with tetracycline produced the greatest results. The strips were inserted into periodontal pockets at 4-day intervals for 16 days, reducing the plaque index, gingival index, and pocket depths significantly when compared with untreated controls. The microflora of the treated pockets was altered favorably, increasing the proportion of cocci and decreasing the numbers of gram-negative rods, fusiforms, and spirochetes. Unfortunately, the clinical improvements resulting from the treatment were not maintained upon the conclusion of the treatment (43).

In 1995, Maze et al. achieved 10-day controlled release of tetracycline hydrochloride from biodegradable PLGA film strips in periodontitis patients. Films were prepared by film casting a dispersion of the antibiotic in a 85:15 solution of the polymer dissolved in methylene chloride. All films were γ-irradiated and secured in the periodontal pockets via a suture/cement technique. Results indicated that film-treated pockets caused significant probe depth reduction for 26 weeks, a clinical attachment level gain for 12 weeks, lower percentages of spirochetes for 4 weeks, decreased levels of motile rods for 8 weeks, and a corresponding increase in cocci levels for 4 weeks. Furthermore, when compared with scaling and root planing, the films appear to have an enhanced antibacterial effect (46).

Webber et al., in 1997, successfully modulated the release of tetracycline from degradable PLGA films to achieve release over a 30-day period. The incorporation of soluble salt excipients in the polymer films changed the release kinetics of the system dramatically. The classical triphasic PLGA release curve involving the initial release due to diffusion of the drug, a lag phase, and then the second release due to degradation of the polymer is no longer apparent. Instead, the salt-loaded systems achieve continuous release of drug for 30 days. Figure 3 depicts the release curves for the five experimental systems. All of the films were fabricated via the solvent casting technique using 1 g of PLGA polymer (Boehringer Ingelheim, Resomer RG503, lot #223808, M_r = 34,000) dissolved in 1 mL of methylene chloride (Fisher Scientific) per film. The films contained either 0% (control films), 1%, 5%, or 25% loadings (w/w) of sodium chloride that was predissolved in 200 μL of distilled water and sonicated into the polymer solution. One system contained a blend of 75% PLGA (Boehringer Ingelheim, Resomer RG503, lot #223808, M_r = 34,000) and 25% PLGA (Polysciences, lot #85761, M_r = 5,000) as well as 25% NaCl. All systems also contained a 5% loading (w/w) of tetracycline HCl also predissolved in 100 μL of distilled water and sonicated into the polymer solution.

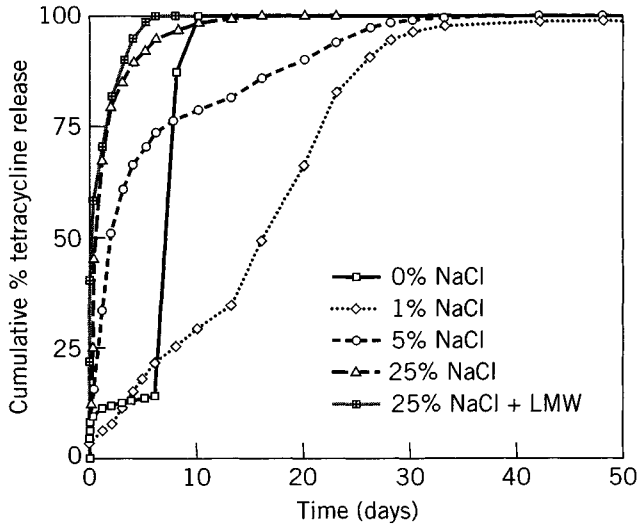

Figure 3. Comparison of tetracycline release from PLGA solvent cast films loaded with different amount of NaCl. *Source:* W. Webber, unpublished data.

This approach to modulating release of therapeutics from the PLGA matrix was unique in that the degradation of the polymer was not altered during the process of modulation. Figures 4 and 5 show degradation trends as monitored by gel permeation chromatography readings of molecular weight and differential scanning calorimetry measurements of glass-transition temperatures, respectively. In both cases, the salt-loaded films degrade at the same rate as the control (or 0% NaCl) film. Therefore, mod-

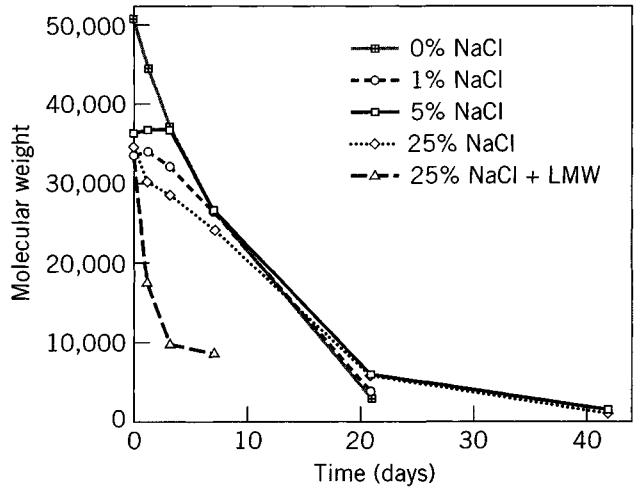

Figure 4. A measure of molecular weight of the various PLGA systems over time as measured by gel permeation chromatography. The similar decreasing trend in the control and salt-loaded systems shows that the salt is not speeding up the degradation process. The last system containing some low molecular weight polymer, however, does decrease in molecular weight faster than the other systems. In this case, the low molecular weight excipient is acting as a plasticizer and speeding up the polymer degradation. *Source:* W. Webber, unpublished data.

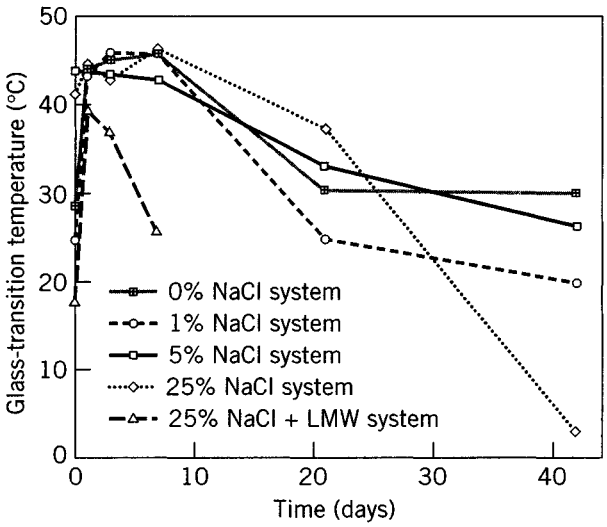

Figure 5. A measure of glass-transition temperature of the various PLGA systems over time as measured by differential scanning calorimetry. Again, the similar decreasing trend in the control and salt-loaded systems shows that the salt is not speeding up the degradation process. The last system containing some low molecular weight polymer, however, does decrease in molecular weight faster than the other systems. These results correlate well with the molecular weight data seen in Figure 4. *Source:* W. Webber et al., unpublished data.

ulation of tetracycline release is most likely caused by pore formation occurring where the salt particles are located. Further experimentation has shown that the systems are swelling and the water is being trapped within the polymer matrix, causing the tetracycline to be released at a constant rate for an extended period of time (W. Webber et al., unpublished data).

Studies by Loesche et al. in 1987 evaluated ethylcellulose films containing 20% metronidazole for their ability to reduce the proportionate levels of spirochetes in periodontal pockets. Though the films were brittle and unable to remain fixed within the pocket, they did succeed in reducing levels of plaque and spirochetes. It was also found that the use of films over a one-week period in conjunction with scaling and root planing had more of an impact clinically than the use of scaling and root planing alone (47).

Release of three antimicrobials, including chlorhexidine, tetracycline, and metronidazole, occurred from acrylic resin vehicles in which the drugs were polymerized into the acrylic strips and placed into periodontal pockets. Strips were changed on a weekly basis over a period of 14 weeks (35). All drug treatments produced immediate improvements based on reduced bleeding, reduced crevicular fluid flow, increased percentage of cocci, and decreased total motiles in comparison with the control groups. The study showed that sole use of antimicrobial drugs could achieve results similar to those reached by conventional mechanical debridement techniques, but the combination of root planing followed by metronidazole strip treatment appeared to be the most effective.

Polypeptide growth factors are an important class of potent biologic mediators which have recently been found to significantly enhance regeneration of both hard and soft tissue components of the periodontium. Studies by Lynch et al. demonstrate the effectiveness of short-term application of a combination of platelet-derived growth factor B (PDGF-B) and insulin-like growth factor one (IGF-1) on periodontal attachment apparatus formation during the early phases of postsurgical wound healing (67). Following conventional periodontal surgery in 13 beagle dogs, a methylcellulose gel containing a combination of 3 μg of recombinant PDGF-B and IGF-1 was applied. More than 96% of the protein was cleared by 96 hours, and none of it could be detected at 2 weeks postapplication. However, histological analyses at 2 and 5 weeks revealed 5 to 10-fold increases in new bone and cementum in the treated sites compared with the control sites (49).

Bone morphogenetic proteins (BMPs) represent a unique family of proteins that induce new bone formation at the site of implantation without affecting the growth rate of preexisting bone. Studies show that recombinant human BMP-2 (rhBMP-2) induces ectopic bone formation in vivo and can cause mesenchymal precursor cells to differentiate into cartilage- and bone-forming cells in vitro (50). RhBMP-2 has been tried and proven to repair bony defects in animal models of bone loss due to periodontal disease. Sigurdsson et al. suggest that implantation of a rhBMP-2 containing device not only regenerates original alveolar bone height, but also additional periodontal attachment apparatus. In Sigurdsson's research, defects were treated with polypropylene-reinforced expanded poly(tetrafluoro ethylene) membranes. The membranes are supposed to maintain the necessary space required for successful reconstruction of periodontal architecture. Histologically, the membrane-treated defects showed significant alveolar bone and cementum regeneration as well as some periodontal ligament fibers forming between the new bone and cementum. Supraalveolar defects treated with rhBMP-2 revealed bone and cementum regeneration to average 95% and 40% of the defect height, respectively, whereas control defects achieved only 20% and 10%, respectively. Therefore, the space provision membranes offer a significant, natural potential for bone and cementum regeneration, whereas the rhBMP-2 filler offers an unlimited regeneration potential for alveolar bone and a noteworthy regeneration potential for cementum (51).

Due to its high permeability, natural protective barrier against toxins and microorganisms, and high patient treatment compliance, the oral mucosal tissues have been the site of delivery for a variety of drugs in numerous therapies. Controlled release from polymeric systems allows for increased device residence time and therefore achieves longer delivery of drug. Although more immediate delivery of substances is possible through the sublingual mucosa, buccal mucosa is permeable to larger molecular weight species such as peptides and proteins and has the potential for achieving sustained delivery for up to many weeks.

INTRODUCTION

Drug delivery to the posterior segment is a major challenge in ophthalmology. Treatment of vitreoretinal diseases has so far been limited to conventional forms of drug administration, that is, topical instillation, subconjunctival injection, or systemic (oral and parenteral) administration. Unfortunately, owing to the anatomical and physiological barriers that exist, in most cases these routes have not proved to be efficient for treating vitreoretinal disorders because the intravitreal or retinal levels of drugs achieved were too low.

The topical route of drug delivery severely limits the access of most drugs to the vitreoretinal tissues. In general, approximately 1% or less of an applied dose is absorbed across the cornea and reaches the anterior segment tissues, and only a tiny fraction of this absorbed dose will then move to the posterior segment of the eye (1). This is due to the existence of protective mechanisms in the eye that are essential for its normal visual function; those include solution drainage, lacrimation, diversion of exogenous substances into the systemic circulation via the conjunctiva, and the structure of the cornea itself, which is relatively impermeable to most drugs (1).

Subconjunctival injections represent an attempt to increase intraocular drug levels while minimizing the frequency of dosing. However, with this technique, higher drug concentrations are generally achieved in the anterior chamber rather than in the posterior segment tissues. Drug delivery to the eye after systemic administration depends on the ocular vascular circulation for transport to the targeted area. The inner two-thirds of the retina are perfused by the central retinal artery. The capillary walls are quite permeable to many substances (1). However, for most drugs, the concentrations achieved in the vitreous humor are much lower than the corresponding serum concentrations unless the eye is inflamed. In this latter case, drug concentrations in the posterior segment can reach as high as 10% of the serum drug levels. The blood–retinal barrier (BRB) plays a major role in restricting drug coming from the choriocapillaries and entering the vitreoretinal compartment as well as restricting drug elimination from this space. This barrier is characterized by the *zonulae occludentes* between the contiguous cells of the retinal vessels and the retinal pigmented epithelium, which prevent the flow of substances by the paracellular pathway, thereby diverting them to a highly selective transcellular route. The ability of a drug to penetrate the BRB is related to its lipid solubility. Furthermore, some substances are transported out of the vitreous body by an active transport system that is inhibited by probenecid, a situation similar to that in the kidney tubular epithelial cells (2). Circumstances that may alter the BRB, inducing its breakdown, include posttraumatic inflammation; viral, bacterial, or fungal infection; and iatrogenic causes such as vitrectomy (3).

Because of these constraints in delivering drugs to their site of action in the vitreoretinal tissues in such a way as to achieve therapeutic levels, it appears then that the only way to attain therapeutic concentrations is by intravitreal injection (4). The vitreous humor is a hydrophilic gel containing 99% water and 1% organic substances such as collagen and hyaluronic acid through which drugs diffuse freely as they would in water (5). After injection into the vitreous body, drugs may be eliminated by diffusion into the aqueous humor of the posterior chamber with subsequent removal by the normal egress of fluid from the anterior chamber. This pathway is limited by the small surface available for diffusion. Drugs eliminated by this route generally have half-lives in the range of 20 to 30 h (6). The other possible elimination pathway from the vitreous is through the retina via penetration of the BRB: this is the so-called posterior route. Drugs eliminated by this way typically exhibit half-lives in the range of 5 to 10 h (6).

INTRODUCTION

Drug delivery to the posterior segment is a major challenge in ophthalmology. Treatment of vitreoretinal diseases has so far been limited to conventional forms of drug administration, that is, topical instillation, subconjunctival injection, or systemic (oral and parenteral) administration. Unfortunately, owing to the anatomical and physiological barriers that exist, in most cases these routes have not proved to be efficient for treating vitreoretinal disorders because the intravitreal or retinal levels of drugs achieved were too low.

The topical route of drug delivery severely limits the access of most drugs to the vitreoretinal tissues. In general, approximately 1% or less of an applied dose is absorbed across the cornea and reaches the anterior segment tissues, and only a tiny fraction of this absorbed dose will then move to the posterior segment of the eye (1). This is due to the existence of protective mechanisms in the eye that are essential for its normal visual function; those include solution drainage, lacrimation, diversion of exogenous substances into the systemic circulation via the conjunctiva, and the structure of the cornea itself, which is relatively impermeable to most drugs (1).

Subconjunctival injections represent an attempt to increase intraocular drug levels while minimizing the frequency of dosing. However, with this technique, higher drug concentrations are generally achieved in the anterior chamber rather than in the posterior segment tissues. Drug delivery to the eye after systemic administration depends on the ocular vascular circulation for transport to the targeted area. The inner two-thirds of the retina are perfused by the central retinal artery. The capillary walls are quite permeable to many substances (1). However, for most drugs, the concentrations achieved in the vitreous humor are much lower than the corresponding serum concentrations unless the eye is inflamed. In this latter case, drug concentrations in the posterior segment can reach as high as 10% of the serum drug levels. The blood–retinal barrier (BRB) plays a major role in restricting drug coming from the choriocapillaries and entering the vitreoretinal compartment as well as restricting drug elimination from this space. This barrier is characterized by the *zonulae occludentes* between the contiguous cells of the retinal vessels and the retinal pigmented epithelium, which prevent the flow of substances by the paracellular pathway, thereby diverting them to a highly selective transcellular route. The ability of a drug to penetrate the BRB is related to its lipid solubility. Furthermore, some substances are transported out of the vitreous body by an active transport system that is inhibited by probenecid, a situation similar to that in the kidney tubular epithelial cells (2). Circumstances that may alter the BRB, inducing its breakdown, include posttraumatic inflammation; viral, bacterial, or fungal infection; and iatrogenic causes such as vitrectomy (3).

Because of these constraints in delivering drugs to their site of action in the vitreoretinal tissues in such a way as to achieve therapeutic levels, it appears then that the only way to attain therapeutic concentrations is by intravitreal injection (4). The vitreous humor is a hydrophilic gel containing 99% water and 1% organic substances such as collagen and hyaluronic acid through which drugs diffuse freely as they would in water (5). After injection into the vitreous body, drugs may be eliminated by diffusion into the aqueous humor of the posterior chamber with subsequent removal by the normal egress of fluid from the anterior chamber. This pathway is limited by the small surface available for diffusion. Drugs eliminated by this route generally have half-lives in the range of 20 to 30 h (6). The other possible elimination pathway from the vitreous is through the retina via penetration of the BRB: this is the so-called posterior route. Drugs eliminated by this way typically exhibit half-lives in the range of 5 to 10 h (6).

Lipophilic drugs are eliminated more rapidly for the same reason: They pass into the vitreoretinal compartment more readily after systemic administration. The elimination of an intravitreally administered drug is influenced by infection and inflammation. Infection tends to accelerate the rate of clearance, whereas the effect of inflammation on vitreous pharmacokinetics is drug dependent. In general, the half-life of nontransported drugs, such as aminoglycosides, is reduced in the presence of ocular inflammation, whereas the half-life of carbenicillin, an actively transported drug, is slightly increased. Intravitreal dosage route was initially reserved primarily for the treatment of endophthalmitis; nowadays this route is also occasionally used for the treatment of diseases such as proliferative vitreoretinopathy (PVR), viral retinitis, and uveitis. Intravitreal injection allows high intraocular drug levels to be reached rapidly, thus resolving the problems of conventional application. Unfortunately, successful treatment of most vitreoretinal diseases requires multiple injections to maintain therapeutically effective drug concentrations in the vitreous for a desired period of time. Additionally, even if repeated drug injections into an already compromised eye improve the ocular condition, this strategy can cause several complications, such as increased risk of ocular infection, intraocular hemorrhage, retinal detachment, and cataract. Moreover, the initial peak level of drug achieved immediately after a bolus intravitreal injection may result in toxicity to the retina and other ocular tissues.

Because of the rapid clearance of drugs from the eye and the variable toxicity encountered in previous studies, researchers have thus been encouraged to develop new systems of drug delivery to the posterior segment that would sustain a therapeutic level of the drug over an extended period of time. Thus, the "peak and valley" effects could be minimized, and drug concentrations could be maintained at an effective therapeutic level for a prolonged period of time. Several delivery systems with a slow-release feature have been developed, including polymeric matrices (biodegradable or not), colloidal systems (liposomes and microspheres), and other delivery systems such as iontophoresis or the prodrug approach.

This article first provides an overview of the vitreoretinal disorders amenable to intraocular drug therapy such as PVR, viral retinitis, endophthalmitis, and uveitis and then discusses the various systems of sustained drug delivery for treatment of these diseases.

VITREORETINAL DISEASES

Proliferative Vitreoretinopathy

Among the severe and blinding diseases of the posterior segment of the eye, many are pathophysiologically characterized by a proliferation of one or more cell types and are therefore referred to as proliferative disorders.

PVR is a pathologic condition occurring as a complication of retinal detachment in 5–10% of the cases (7) in which benign cells proliferate in the vitreous cavity, resulting in the formation of membranes on both surfaces of the detached retina. It is the most common cause of failure following retinal reattachment surgery (8). There are some risk factors that increase susceptibility to the development of PVR: repeated procedures (such as failure of previous surgery), damaged retinal surface (retinal folds or holes), treatment modality (vitrectomy, cryotherapy), and preoperative vitreous hemorrhage (9).

First described in 1939, PVR was formerly known as "massive vitreous retraction," "massive preretinal retraction," and "massive periretinal proliferation." In 1983, the Retina Society introduced the new terminology to reflect the pathologic changes in the vitreous and the retina (7). They also established a standardized classification to determine the different stages of the disease so as to compare and evaluate methods of treatment and clinical results. This classification has since been revised many times (10).

The pathogenesis (11) of PVR is related to the loss of integrity of the vitreoretinal structures. The first important step of the disease process is the disruption of the BRB, allowing serum components to penetrate into the vitreous cavity (12). Serum, a stimulus to migration, exerts chemotaxis to retinal pigmented epithelial (RPE) cells, glial cells, and Müller cells, which migrate into the vitreous cavity through retinal holes. Fibronectin and platelet-derived growth factors promote cellular adhesion to the vitreous collagen and fibroblast proliferation, leading to membrane formation. The presence of contractile elements in these epiretinal membranes, mainly composed of myofibroblasts, provokes cell contraction, which can distort or redetach the retina. The epiretinal membranes formed are stabilized by the collagen of the extracellular matrix. An inflammatory response is often provoked, as evidenced by the presence of various white blood cells such as macrophages and lymphocytes (13). Even though the mechanism that triggers certain cells or cell types to proliferate is still obscure, many attempts have been made to find a pharmacological cure for the disease.

The development of suitable treatments for PVR has been assisted by experimental animal models, produced by intravitreal injection of autologous (14) or heterologous fibroblasts (15) or by the injection of macrophages, which mimics the development of PVR from its initial stage onwards (16).

The pharmacological treatment of PVR consists in the inhibiting progression of the disease at various stages (Table 1). PVR parallels the wound-healing process and follows a course that can be divided into three phases: inflammation, cellular proliferation, and regeneration (Fig. 1) (26). The time course of PVR development is important in the selection of particular drugs. In the initial stage, that is, the inflammatory phase, long-effect steroids are more suitable. In the proliferative phase, antiproliferative drugs can be used. Because inflammatory factors may still continue to act in this stage, better control may be achieved if the antiproliferative drugs are combined with steroids.

Drugs such as corticosteroids and nonsteroidal antiinflammatory agents (NSAIs) prevent the breakdown of the blood–retinal barrier (17). As they act early in the disease process, they are particularly effective in reducing the incidence of PVR in experimental models (26). Corticosteroids were the first drugs investigated to treat PVR (27). Their major mechanism of action is the reduction of the inflammatory response in the eye, thereby moderating the

Table 1. The Mechanism of Action of Drugs for the Treatment of PVR

Pathogenesis	Pharmacologic therapy
Breakdown of the blood–retinal barrier	Steroids and nonsteroidal antiinflammatory agents (17)
Cell migration	Colchicine (18), taxol (19)
Cell attachment	Synthetic tetrapeptide (20), heparin (21)
Cell proliferation	Fluoropyrimidines, daunorubicin, taxol, colchicine, and other antineoplastic drugs (19)
Cell contraction	Fluorouridine (22), colchicine, taxol, cytochalasin B (19)
Synthesis of extracellular matrix	D-penicillamine (23), *cis*-hydroxyproline (24), β-aminopropionitrile (25), 5-fluorouracil (26)

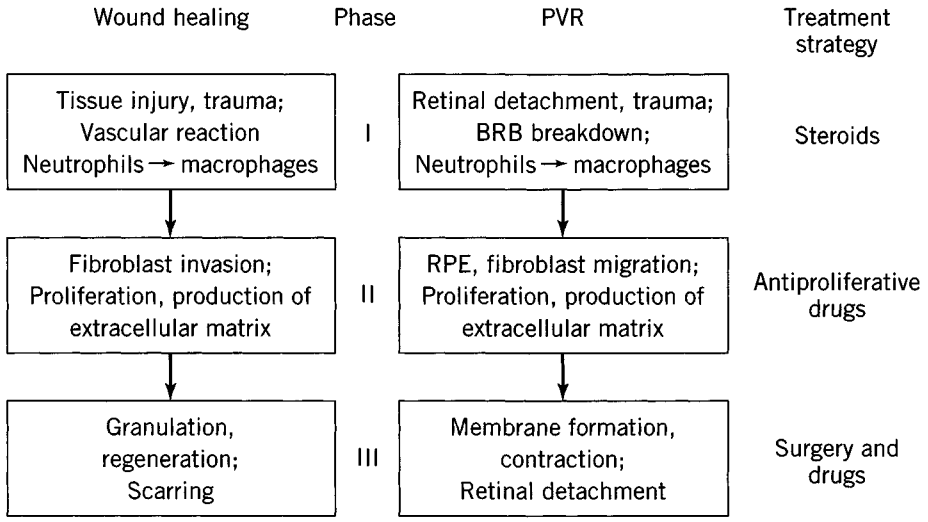

Figure 1. Parallels in the evolution of PVR and wound healing: treatment strategy. I, inflammatory phase; II, proliferative phase; III, regeneration (contraction and consequence); BRB, blood–retinal barrier; RPE, retinal pigment epithelium. *Source:* Adapted from Ref. 16.

breakdown of the BRB; however, it is known that at low doses corticosteroids stimulate cell proliferation, whereas at supraphysiologic doses they have an inhibiting effect. This bimodal behavior has been demonstrated in vitro (28). Intravitreal dexamethasone (27) and triamcinolone acetonide (29) have been investigated in experimental models of PVR in rabbits and found efficient in reducing the frequency of retinal detachment. Chandler (30) administered triamcinolone acetonide 24 h preceding the injection of fibroblasts in rabbit eyes and found better results when the eyes were pretreated, which suggests that the inhibition of the inflammatory process is a main part of the management of PVR.

A wide variety of intravitreal antiproliferative drugs have been used experimentally for the treatment of intraocular proliferative conditions. They have all been shown to be effective, particularly against RPE cells and fibroblasts, both in vitro (28) and in animal studies. Antiproliferative drugs act on the various stages of cell growth, that is, the growth phase (G1), the synthesis of DNA (S), the postsynthetic phase (G2), and the mitosis (M) (31). Among the antimetabolites, fluoropyrimidines have been the first and the most extensively studied. 5-Fluorouracil (5-FU), a synthetic pyrimidine analog, affects the S phase of the cell cycle. It is a substrate for the thymidilate synthetase enzyme and inhibits thymidine formation for DNA synthesis. It may also incorporate into RNA and inhibit replication, transcription, and cell division (32); it also inhibits ribosomal synthesis of intracellular procollagen (26). 5-FU has been found effective in reducing the incidence of PVR in experimental models (33,34). A single 1-mg intravitreal injection of 5-FU in rabbit eye can reduce the rate of tractional retinal detachment in experimental PVR without causing any noticeable retinal toxicity (35). Unfortunately, 5-FU has limited clinical application owing to its short intravitreal half-life: Therapeutic levels are maintained in the vitreous for only 12–24 h (36), yet the PVR process is active for a longer time. Multiple intravitreal injections are necessary to obtain a significant effect, as demonstrated by Stern et al. (37). 5-Fluorouridine, another member of the fluoropyrimidines family, is more potent than 5-FU in inhibiting fibroblast proliferation in vitro (38). This is due to its additional anticontractile effect.

Daunomycin (also called daunorubicin) (39), aclacinomycin A (40), and adriamycin (41) are anthracycline antibiotics with complex biological effects on DNA binding, free radical formation, membrane binding, and metal ion chelation (42). Their mechanism of action is independent of the cell cycle. Daunomycin has been shown to be one of the most effective intraocular antiproliferative agent for the treatment of experimental PVR (43,44). It is very potent but also more toxic than 5-fluorouracil; its safety margin is very small (45).

Taxol is a substance isolated from the plant *Taxus brevifolia* and has antitumor activity in several experimental systems. In contrast to other plant products such as colchicine, taxol acts as a promoter rather than an inhibitor of microtubule assembly. It prevents fibroblast migration and replication by stabilizing microtubules and blocking the cell in the G2 and M phases. In an experimentally in-

duced PVR, taxol effectively controlled the development of retinal detachment after an intravitreal injection as little as 0.5 μg (46).

Colchicine, an alkaloid from the *Colchicum autumnale* plant, interferes with microtubule metabolism and blocks the cell in the mitotic phase of its growth cycle. It inhibits in vitro fibroblast migration and proliferation at very low concentrations (18). Oral colchicine has been studied in rabbits and found effective in the prevention of PVR (47); on the other hand, intravitreal colchicine seems to be quite toxic to the retina (48).

Retinoids are products derived from vitamin A that have an antiproliferative effect on RPE cells and inhibit their migration (49). Several studies have been made with retinoic acid, a very lipophilic substance that is the most potent member of this family of compounds. At concentrations up to 10 μg/mL in silicone oil (50,51), retinoic acid did not cause any retinal toxicity and prevented PVR in experimental models.

The general problem with antiproliferative drugs is their narrow therapeutic interval: Retinal toxicity is all too common when these compounds are administered intravitreally (52,53).

Cytomegalovirus Retinitis

Cytomegalovirus (CMV) retinitis is an opportunistic infection frequently seen in patients with AIDS and other forms of immune suppression. CMV retinitis is the most common opportunistic ocular infection in patients with AIDS, occurring in 15–40% of patients (54). Often bilateral, it is part of a systemic CMV infection. It may be the first manifestation of AIDS in 1.8% of cases (55). If untreated, this disease can progressively lead to blindness.

Ganciclovir (formerly known as DHPG and BW-759U) was the first antiviral agent that showed activity against CMV in patients with AIDS. It is a nucleoside analog of acyclovir, with 10 to 100 times greater activity against CMV (56,57). Ganciclovir has been determined to act as a virustatic agent, rather than completely eliminating the virus and its recurrence from the retina. This is the reason why CMV retinitis is so hard to eradicate. Intravenous treatment with ganciclovir has been widely studied and determined useful in the management of CMV retinitis by delaying or reducing vision loss in AIDS patients (58,59), and the current recommended treatment strategy is an induction therapy with high doses of intravenous ganciclovir followed by a maintenance regimen with lower doses (60). This produces clinical regression of the retinitis in nearly all patients, but recurrence frequently occurs when patients are on maintenance therapy (61). On the other hand, it may prevent development of the virus in the other eye if it is not already infected (62). However, ganciclovir has a small margin of safety, and severe complications such as neutropenia, fever, anorexia, thrombocytopenia, progressive neuropathy, diarrhea, psychosis, and phlebitis occur following parenteral administration (58,63). The treatment must then be stopped after a certain period of time for these intolerant patients. The limited systemic use of these drugs in intolerant patients owing to severe side effects has lead to the evaluation of intravitreal injection. In a study by Pulido et al., 400 μg of intravitreally injected ganciclovir was determined to be nontoxic (64), so this dosage has been used clinically to treat CMV retinitis (65). Unfortunately, maintenance of sufficient intravitreal levels of ganciclovir requires repeated injections, at least twice weekly until healing occurs and then once per week until relapse (66).

Another drug used in the treatment of CMV retinitis is foscarnet. It acts by inhibiting viral DNA and RNA polymerases. One of its major side effects is reversible nephrotoxicity and anemia, but it has no harmful effect on the bone marrow (67). Therefore, synergistic or additive effects have been proved in vitro when a combination of ganciclovir and foscarnet was used; one could thus use lower doses of both drugs and then reduce their side effects (68). On the other hand, foscarnet is an alternative to ganciclovir if resistant strains of CMV develop (69). Intravitreal foscarnet has also been investigated (70) and was found to be active against CMV without retinal toxicity. The combined intravitreal injection of ganciclovir and foscarnet can also be particularly useful when the infection is clinically resistant to either intravitreal drug alone (71).

Zidovudine, formerly known as azidothymidine or AZT, a drug effective against HIV but not CMV, showed some beneficial effects in some cases (72). It is believed to act by diminishing HIV enhancement of CMV infection or by improving the general immune status. Unfortunately, both AZT and ganciclovir are toxic to the bone marrow.

A new drug, cidofovir, also known as HPMPC, has been recently evaluated in treating CMV retinitis. It is a nucleotide analog with a higher potency and a longer duration of action than ganciclovir or foscarnet (73,74). Intravitreal cidofovir is an effective treatment at concentrations as low as 20 μg, but it is associated with side effects such as uveitis and iritis (75).

Other viral retinitis types include acute retinal necrosis syndrome (ARN), which is a necrotizing retinitis with retinal vasculitis and vitritis that occurs in both healthy and immunocompromised individuals; it frequently renders the affected eye legally blind. Several lines of evidence suggest that this is a viral infection, probably mediated by varicella–zoster virus (VZV) (76) or herpes simplex virus (HSV) (77). The current recommended treatment involves intravenous acyclovir or vidarabine (78) and topical and oral steroids.

Endophthalmitis

Endophthalmitis is an inflammatory response to the invasion of the internal structures of the eye by replicating microorganisms: bacteria (in 90% of cases) (79), fungi, or parasites (79). This disease is most often a complication of ocular surgical procedures such as cataract extraction, corneal transplantation, glaucoma filtering surgery, or retinal detachment surgery. Another cause is a penetrating ocular trauma, which can occur in up to 20–30% of cases. The vitreous body and the retina are generally involved, and depending on the virulence of the infectious agent, this disease can lead to retinal necrosis and blindness within a very short period of time. The different species of microorganisms identified in bacterial endophthalmitis are

Staphylococcus aureus, Pseudomonas aeruginosa, Proteus, and coliform species, with increasing incidence of *Staphylococcus epidermidis* (80). An anaerobic species, *Bacillus*, is associated with penetrating ocular trauma, most often in rural areas (81). All these microorganisms cause exogenous endophthalmitis; the agents invade the eye from outside, for example, during ophthalmic surgery or penetrating injury. Sometimes, however, endophthalmitis can be endogenous, or blood borne. Endogenous endophthalmitis is most often mycotic, caused by *Candida albicans*. The frequency of endogenous infections, though three times less frequent than exogenous infections, is now increasing in both immunocompromised patients and patients under prolonged treatment with antibiotics, corticosteroids, or antimetabolites (82).

The symptoms of acute endophthalmitis are ocular pain and decreased visual acuity, with edematous lids, conjunctival hyperemia and chemosis, and corneal edema. On the other hand, patients with chronic endophthalmitis (caused by organisms of low virulence) do not present many clinical signs other than photophobia.

An early diagnosis and the beginning of an optimal therapy are both important to increase the chance of getting rid of the microorganisms and enhancing the visual prognosis. At this stage, the intravitreal injection of an antibiotic and eventually vitrectomy plays a very important role, not only in removing the infectious microorganisms, their associated toxins, and the inflammatory components, but also in capturing the infecting organism(s) for a microbiological identification (83) and proper antibiotic selection.

Before the use of intravitreal injections of antibiotics, the treatment of endophthalmitis had poor results (84). Indeed, the eye is an organ extremely susceptible to inflammation; it has poor defense mechanisms, and most antibiotics penetrate very poorly into the ocular cavity. There are actually two crucial parameters to note when treating such a disease: the drug must achieve sufficient levels in the vitreous, above the ID_{50}, and it must do so over a prolonged period of time. That is why topical, systemic, and subconjunctival administration of antibiotics failed to adequately treat endophthalmitis. In a series of experiments over the past 20 years, Peyman and coworkers as well as D'Amico et al. attempted to determine the toxic levels of various antibiotics by clinical, histological, and electroretinographic examination; to measure the clearance of nontoxic doses from the intraocular fluids after intravitreal injection; and to compare the effectiveness of intravitreal injection with systemic or subconjunctival administration in treating experimentally induced endophthalmitis (Table 2).

Experimental endophthalmitis was produced by injecting various organisms into the animal eye, with or without vitrectomy. Those studies in rabbits or monkeys showed that intravitreal administration of antibiotics is the most effective way of achieving high and immediate intravitreal drug levels without retinal toxicity (108,109).

Current therapeutic strategy for presumed endophthalmitis includes the intravitreal injection of a single or, more frequently, a combination of broad-spectrum antibiotics (110). These antibiotics are used at the highest possible nontoxic dose. Besides antibiotics, intravitreal corticosteroids such as dexamethasone play an important role in the management of bacterial endophthalmitis because of their beneficial effect in reducing the inflammation that accompanies the infection. Adjunctive treatment of endophthalmitis is the systemic administration of another antibiotic, especially in the case of endogenous endophthalmitis, to provide extraocular coverage and to maintain some intravitreal levels, with steroids used to reduce the inflammatory response.

Therapy for fungal endophthalmitis is similar to that for bacterial endophthalmitis except that antifungals, rather than antibacterials, are administered. The recommended therapeutic strategy is the direct intravitreal administration of amphotericin B. If the treatment fails, miconazole may be used (1). Systemic antifungal treatment is also employed.

Posterior Uveitis

Posterior uveitis, whether it is endogenous and chronic or associated with systemic diseases such as Behçet's disease, is a pathology characterized by vitreal inflammation and retinal vasculitis. In the majority of patients, the etiologic agent is not known. It has been postulated that in many cases uveitis may be autoimmune in origin. Uveitis usually has a low response to treatments with steroids or cytotoxic drugs, and it may require long-term chronic treatment. If untreated, the outcome is generally severe, eventually leading to progressive blindness.

The immunomodulating drug cyclosporin was investigated and found effective in treating experimental autoimmune uveitis (111) and acute inflammation unresponsive to usual treatment (112). Cyclosporin A is a cyclic polypeptide composed of 11 amino acids that effectively inhibits the development of experimentally induced uveitis (113). It acts by inhibiting the synthesis of interleukin 2 by the T helper lymphocytes (114). Cyclosporin A has been shown in several human clinical trials to be effective in treating chronic uveitis, especially that associated with Behçet's disease (115). Unfortunately, its systemic administration causes severe complications, such as renal toxicity, hypertension, and immunosuppression, which limit its use. Topical administration, on the other hand, resulted in nondetectable levels of the drug in all the intraocular structures because of its poor ocular bioavailability (116). To avoid these toxic effects and to achieve sufficient levels in the vitreous, cyclosporin was injected intravitreally and prevented experimental autoimmune uveitis (117). Grisolano and Peyman found no toxic effects in rabbits treated with 100 μg of intravitreal cyclosporin (118).

An adjunct to immunosuppressive treatment for noninfectious inflammation of the posterior segment is the use of corticosteroids. They are frequently employed to reduce intraocular inflammation and are currently the mainstay in the treatment of uveitis. Local steroid injections are preferred so as to avoid the side effects associated with systemic steroid administration. It is possible that a combination of drugs, attacking different targets in the immune response system, might work synergistically and thus would allow effective treatment with lower doses and presumably fewer side effects.

DRUG DELIVERY SYSTEMS

Biodegradable Polymers

Systems that control and prolong the action of therapeutic agents have grown in importance during the recent years with the development of biodegradable polymers. They are particularly important in the case of implants, because their use eliminates the step of removing the implant after the drug has been released, which, in some applications, can represent a significant advantage over other systems.

Biodegradable polymers gradually dissolve by hydrolytic or enzymatic cleavage of the polymeric structure or by simple dissolution. Heller (119) defined three mechanisms of polymer erosion (Fig. 2). Mechanism I concerns polymers that are made water insoluble by their hydrolytically unstable cross-links. These polymers, such as cross-linked gelatin, collagen, or poly(vinyl alcohol), provide highly hydrophilic matrices. Thus, substances with low molecular weight and high water solubility diffuse rapidly through the polymeric network independently of the rate of erosion of the matrix. These polymers are mainly used for the release of sparingly water-soluble drugs and for macromolecules such as enzymes and antigens (120).

Mechanism II includes polymers that are initially water insoluble and are solubilized by hydrolysis, ionization, or protonation of a pendent group yet lack backbone cleavage. This mechanism has the feature of not causing any significant change in the molecular weight of the polymer. These polymers, such as poly(vinyl methyl ether/maleic anhydride), cannot therefore be used for implants because of the difficulty of their elimination.

Mechanism III refers to hydrophobic polymers that are converted to small soluble molecules by backbone cleavage. As long as these breakdown products are not toxic, these polymers, for example, polyanhydrides, polycaprolactones, poly(ortho ester)s, poly(lactic acid)s (PLA), poly(glycolic acid)s (PGA), and their copolymers, are suitable as implantable carriers for the administration of drugs to any organ. They offer a wide range of applications in the ophthalmic field, whether applied on the surface of the eye or as intraocular implants.

The breakdown of polymers does not necessarily proceed through one mechanism only, and erosion occurs by a combination of these mechanisms (Table 3).

Poly(vinyl alcohol). Poly(vinyl alcohol) (PVA) is used in ophthalmology as a viscosifier for collyria and also as an intravitreal drug delivery carrier. PVA is synthesized by the polymerization of vinyl acetate to poly(vinyl acetate), which is then hydrolyzed to PVA. Its solubility in water will depend on the extent of hydrolysis and the degree of polymerization (122).

In a recent study, Hainsworth et al. evaluated various methods of sustained delivery to achieve therapeutic levels of ciprofloxacin (123). He compared in vitro two devices made either of PVA or of the bioerodible PLA. He found that the release of ciprofloxacin from the PVA matrix was very fast; over 90% of the drug was released within the

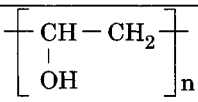
DRUG DELIVERY SYSTEMS

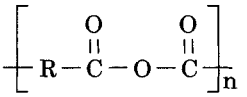
Biodegradable Polymers

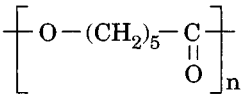
Systems that control and prolong the action of therapeutic agents have grown in importance during the recent years with the development of biodegradable polymers. They are particularly important in the case of implants, because their use eliminates the step of removing the implant after the drug has been released, which, in some applications, can represent a significant advantage over other systems.

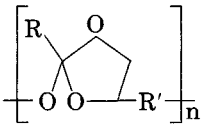
Biodegradable polymers gradually dissolve by hydrolytic or enzymatic cleavage of the polymeric structure or by simple dissolution. Heller (119) defined three mechanisms of polymer erosion (Fig. 2). Mechanism I concerns polymers that are made water insoluble by their hydrolytically unstable cross-links. These polymers, such as cross-linked gelatin, collagen, or poly(vinyl alcohol), provide highly hydrophilic matrices. Thus, substances with low molecular weight and high water solubility diffuse rapidly through the polymeric network independently of the rate of erosion of the matrix. These polymers are mainly used for the release of sparingly water-soluble drugs and for macromolecules such as enzymes and antigens (120).

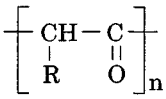
Mechanism II includes polymers that are initially water insoluble and are solubilized by hydrolysis, ionization, or protonation of a pendent group yet lack backbone cleavage. This mechanism has the feature of not causing any significant change in the molecular weight of the polymer. These polymers, such as poly(vinyl methyl ether/maleic anhydride), cannot therefore be used for implants because of the difficulty of their elimination.











Mechanism III refers to hydrophobic polymers that are converted to small soluble molecules by backbone cleavage. As long as these breakdown products are not toxic, these polymers, for example, polyanhydrides, polycaprolactones, poly(ortho ester)s, poly(lactic acid)s (PLA), poly(glycolic acid)s (PGA), and their copolymers, are suitable as implantable carriers for the administration of drugs to any organ. They offer a wide range of applications in the ophthalmic field, whether applied on the surface of the eye or as intraocular implants.

The breakdown of polymers does not necessarily proceed through one mechanism only, and erosion occurs by a combination of these mechanisms (Table 3).

Poly(vinyl alcohol). Poly(vinyl alcohol) (PVA) is used in ophthalmology as a viscosifier for collyria and also as an intravitreal drug delivery carrier. PVA is synthesized by the polymerization of vinyl acetate to poly(vinyl acetate), which is then hydrolyzed to PVA. Its solubility in water will depend on the extent of hydrolysis and the degree of polymerization (122).

In a recent study, Hainsworth et al. evaluated various methods of sustained delivery to achieve therapeutic levels of ciprofloxacin (123). He compared in vitro two devices made either of PVA or of the bioerodible PLA. He found that the release of ciprofloxacin from the PVA matrix was very fast; over 90% of the drug was released within the

first 24 h, and this release showed a square-root dependence of time, whereas release from PLA matrices followed a similar but slightly slower pattern.

On the other hand, as an intravitreal administration, PVA is most frequently coupled with ethylene vinyl acetate (EVA) in nonbiodegradable implants. These devices will be discussed later in this article.

PLA, Poly(glycolic acid), and Their Copolymers. Initially, poly(α-hydroxy acid)s were developed as synthetic, bioresorbable sutures in the 1960s. As a result of their good histocompatibility (124), this family of polyesters now includes the most-investigated biodegradable polymeric carriers for drug delivery systems. The principal polymers of this class are homo- and copolymers derived from lactic and glycolic acids: PLA, PGA, and its copolymers (PLGA).

Poly(α-hydroxy acids) are generally synthesized by a condensation reaction at high temperatures. The ring-opening polymerization of cyclic glycolic and lactic acid diesters is an efficient method to produce high-molecular-weight polymers. The simple step-growth polymerization method leads only to low-molecular-weight polymers with poor mechanical properties (125). The presence of an asymmetric carbon in lactic acid makes it possible to obtain levorotatory (L), dextrorotatory (D), or racemic (D,L) forms of the corresponding polymer, which can have different physicochemical properties.

The mechanism of degradation of these polyesters is a homogeneous erosion of the core. The polymeric chains are first cleaved by hydrolysis and then by an enzymatic chain scission process, thereby releasing acidic monomers that are rapidly eliminated by a physiological pathway. PGA is far too sensitive to hydrolysis to be considered useful as a carrier for sustained drug delivery (126). PLA degrades more slowly than PLGA; it also shows less initial burst of the drug than PLGA.

Drug delivery from PLGA matrices appears to follow biphasic kinetics (127). A mechanism to explain this profile would include a delayed increase in the permeability of PLGA arising from different factors, such as a reduction of the glass-transition temperature (T_g), an increase in the degree of hydration of the polymer, or a delayed onset of polymer weight loss by a bulk process (127). Kunou et al. studied the in vitro release pattern of plugs made with different types of PLA and PLGA and containing various percentages of ganciclovir as a model drug (128). The in vitro release of ganciclovir was shown to follow a triphasic process: (*1*) initial burst, (*2*) diffusional stage, and (*3*) final burst due to swelling and disintegration of the polymeric matrix (Fig. 3). The initial burst is certainly due to the rapid release of the drug located on the surface and in the water channels of the polymeric matrix. During the second phase, the drug is slowly released, controlled by the degradation rate of the polymer. In general, the release rate decreases with increasing molecular weight of PLA and PLGA and lactide content of PLGA. On the other hand, an increase in ganciclovir loading results in a higher release rate (128). During this second phase, a significant weight loss is observed. However, drug release from the implant is more rapid than the polymer weight loss. This observation suggests that the drug can diffuse through channels in the polymeric matrix during biodegradation but that the weight of the polymer does not change until a moment in hydrolysis when oligomers are produced by a random chain-scission mechanism, small enough to be soluble in

water. The third phase of release occurs when the polymeric bulk swells and disintegrates.

The degradation rate can be varied by many factors in addition to the composition and configuration of the polymer or copolymer used, its porosity, and also the physicochemical properties of the incorporated drug.

The in vivo applications of poly(α-hydroxy acids) in the field of ophthalmology are mainly as topical and intraocular drug delivery systems, and as implants as well as microspheres. Besides microspheres, which will be discussed later in this article, implantable biodegradable polymeric matrices have been developed as new drug delivery systems in the vitreous. These implants are generally in the form of small cylinders that can be implanted in the eye by means of a syringe with a conventional needle (19- or 20-gauge) (129). Table 4 summarizes the different studies using these polyesters.

Rubsamen et al. (129) investigated PLGA-based rods containing 5-FU to treat experimental PVR in rabbit eyes. The devices can deliver therapeutic levels of 5-FU for almost 3 weeks and reduce the incidence of tractional retinal detachment. No adverse mechanical or toxic effects were apparent during the time of the study. However, because these devices were not fixed in the vitreous cavity, they might move and come into contact with the retina. Consequently, a stable localization of the device in the vitreous base through a suture fixation or an alternative mode of fixation at the site of implantation might be desirable.

In 1994, Hashizoe and coworkers designed a new device that is implanted at the *pars plana* and releases drugs directly into the vitreous (134). These scleral plugs, made of PLGA (40 kDa), were charged with 1% doxorubicin. The scleral plug gradually released doxorubicin in a concentration maintained within the therapeutic level for 1 month without any notable toxicity to the retina. In another study, Hashizoe et al. (131) demonstrated that the implantation of a scleral plug composed of PLA (20 kDa) and 1% doxorubicin effectively inhibited intravitreal proliferation of fibroblasts and could be a very effective way to treat PVR. Compared to the release of doxorubicin from the PLGA scleral plug (134), the authors observed that the PLA plugs have a longer period of drug release and showed less initial burst. Kunou and coworkers (128) investigated the use of scleral plugs to release ganciclovir for the treatment of CMV retinitis. The concentration of ganciclovir was maintained within the therapeutic range for over 3 months in the vitreous and for over 5 months in the retina and the choroid. A modulated release could be obtained with the scleral implant by varying the ratio and composition of the polymers, the molecular weight, and the drug concentration. Hashizoe et al. (137) further investigated the retinal toxicity of these plugs containing ganciclovir. At 3 months after implantation, only slight inflammatory changes occurred around the plug; the authors concluded that the biocompatibility of the device might be clinically acceptable. One of the advantages of scleral plugs is that the device becomes swollen during hydrolysis and seals the sclerotomy from inside. Fixation on the sclera is easy and requires no sutures. The same observations were made when other drugs were incorporated into the scleral plug, such as fluconazole (136), adriamycin (133), or betamethasone (135).

Table 4. Use of PLA–PLGA Implants for Intravitreal Administration

Polymer	Drug	Implant form	Animal model	Duration (weeks)	Year	Author (et al.)	Ref.

PLGA	Ganciclovir	Scleral plug	Rabbit	12	1997	Hashizoe	137

On the other hand, it would be interesting to develop an injectable liquid-polymer drug delivery system that would solidify in the vitreous cavity and might overcome some disadvantages of the current solid implants. Indeed, the problem with polyesters is their very high melting point, above 170°C (138). Davis et al. reasoned that a family of injectable poly(α-hydroxy acid)s would provide an important therapeutic alternative to implants that require surgical procedures (139). They formulated a polymer system called Meltamer composed of block copolymers that are solid at 37°C but melt at various temperatures above 42°C and resolidify at body temperature. In vivo screening in rabbit eyes demonstrated that the heated polymer can be easily and safely injected into various ocular sites. The biocompatibility was excellent for more than 5 weeks, and the polymer completely degraded after that period of time (140).

Polycaprolactones. Other polymers from the polyesters family have been evaluated as long-term drug delivery systems. Poly-ϵ-caprolactone (PCL) was used in 1973 as a subdermal delivery system for contraceptive steroids under the trademark Capronor (141).

PCL is synthesized by a ring-opening polymerization of the monomer ϵ-caprolactone. It is semicrystalline, rather hydrophobic compared to poly(α-hydroxy acid)s, and has a high molecular weight. However, because of the great interest for low-molecular-weight polymers due to their controllable degradation profile and their low melting point, low-molecular-weight (LMW) polycaprolactones were prepared by means of hydrolytic degradation of high-molecular-weight (HMW) commercial PCL (142). Polymers of molecular weight from 4,000 to 10,000 were obtained without any structural changes. Comparison of the in vitro release rate of 5-FU as a model drug showed that the LMW PCL matrices exhibited more uniform drug release than the HMW devices. In a further study (143), Chin et al. mixed HMW and LMW PCL in different proportions, incorporated ganciclovir inside, and observed that the in vitro release rate of ganciclovir increased with the proportion of LMW. In general, these experiments demonstrated first-order kinetic release from matrices of PCL.

As with PLA and PLGA, PCL hydrolyzes by random chain scission through hydrolytic cleavage of ester groups to ϵ-hydroxycaproic acid, leading to a continual decrease of the molecular weight without any significant loss of weight. Enzyme catalysis is excluded in this first phase, because the diffusion of such HMW substances is impossible in the polymer bulk. When the molecular weight reaches about 5,000, the cleavage of the chain is catalyzed by enzymes and accompanied by a loss of weight resulting from the diffusion of small polymeric fragments from the matrix, which subsequently fragments and undergoes phagocytosis (141).

Concerning the application of PCL in the ophthalmologic field, many investigations have been made concerning the use of topical instillation of colloidal PCL-nanoparticles for the administration of β-blocking agents or indomethacin.

Intraocular application of polycaprolactone-based delivery systems has been investigated by Borhani et al. (144,145). They mixed HMW and LMW polycaprolactones in different proportions with 5-FU, and the pellets obtained showed, as expected, a faster release rate when the proportion of LMW polycaprolactone increased (144). In an in vivo study in rabbits (145) with 5-FU (10% or 20%) and HMW PCL, Borhani et al. demonstrated that these devices permit a slow release of 5-FU and thus increase the efficacy by providing a constant concentration of drug during the active period of PVR. An inflammatory cell reaction was found in the sclera near the implant site; however, in a study of biocompatibility and toxicity of PCL, no implant-related inflammation was observed (145).

Peyman and associates (146) have developed a PCL-based biodegradable porous implant for sustained and constant drug delivery. Nontoxic water-soluble inorganic salts such as NaCl or KCl were used as pore-forming agents and incorporated into PCL by a melting process. Biodegradable porous reservoir devices were prepared and loaded with different substances, for example, 5-FU, ganciclovir, foscarnet, and the dye carboxyfluorescein. During the in vitro release of the drug, the inorganic salts dissolved in water, leaving pores in the PCL devices. As the percentage of inorganic salt increases, a higher density of pores was observed in the devices. The porous reservoir devices provided a constant release of the drugs, depending on the pore size of the polymer. A concentration gradient across the wall of the polymer was created that forced the flow of the drug from the inner reservoir system to the surrounding aqueous medium. The release pattern followed zero-order kinetics without any initial burst, and the release lasted more than 6 months (Fig. 4) (146). This PCL reservoir device can be produced with various ratios of HMW polymer, allowing the device to degrade very slowly and therefore dissolving only after all the drug is released.

Polyanhydrides. Polyanhydrides were first investigated in the 1930s as substitutes for polyesters in textile applications, but because of their hydrolytic instability, the idea was soon abandoned, and attention turned to their use as

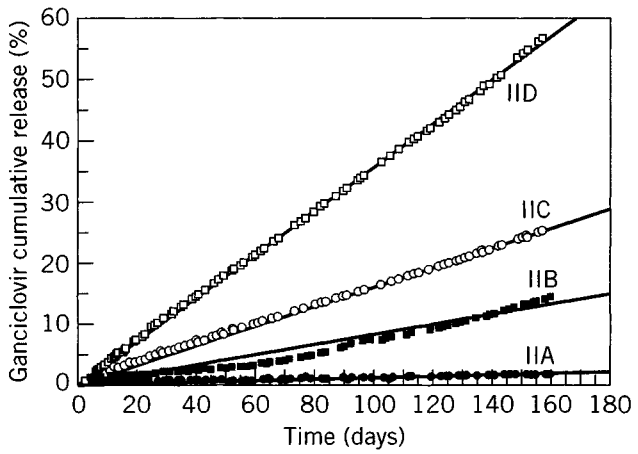

Figure 4. Cumulative release of ganciclovir over time from porous reservoir. IIA, 0% of porogen; IIB, 20% of porogen; IIC, 30% of porogen; IID, 40% of porogen. *Source:* Reproduced from Ref. 146 with permission.

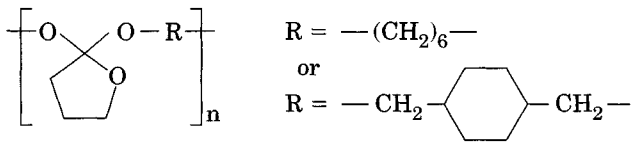
biomaterials. Their very rapid hydrolysis is due to the lability of the anhydride links. The rate of hydrolysis of the polymeric chains on their surface is much faster than the penetration of water into the core of the matrix; this so-called heterogeneous surface erosion enables a zero-order kinetic profile and a good control over the rate and the duration of the release (147).

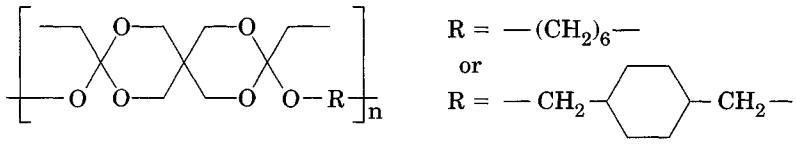
The most frequently investigated ocular matrix carrier consists of 1,3-bis(carboxyphenoxy) propane (PCPP) and its copolymers with sebacic acid (SA), a more hydrophilic monomer. Previous studies also described carriers with other 1,3-bis(carboxyphenoxy) alkanes with SA (148). Pure PCPP has an extremely long life (over 3 years) (147,149), whereas after copolymerization with 80% of SA, this is reduced to a few days. The ratio of the two monomers plays an important role in the rate of hydrolysis of the resulting polymer: When the proportion of SA increases, the hydrophobicity of the polymer decreases, resulting in a faster rate of hydrolysis of the polymeric chains at the surface. It should also be noted that polyanhydrides are pH-sensitive; they undergo faster breakdown at high pH and are more stable in acidic media.

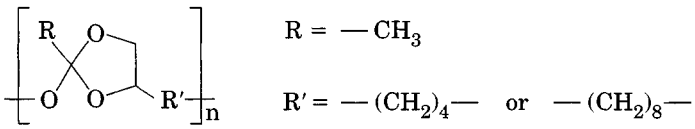
Because of their surface erosion and excellent biocompatibility (149), polyanhydrides have been particularly useful for the controlled delivery of antimetabolites for the postsurgical treatment of glaucoma (121).

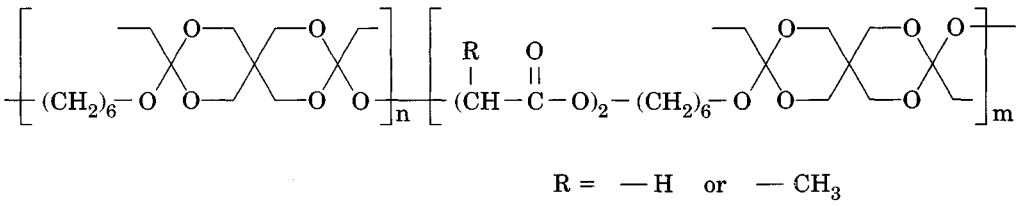
In a recent study (150), Lewis et al. reported the use of polyanhydride as an intravitreal bioerodible vehicle for 5-FU in the treatment of proliferative vitreoretinopathy. PCPP-SA loaded with 20% of 5-FU was compressed into a T-shaped device and sutured to a sclerotomy. Sustained release of 5-FU decreased the short- and long-term rate of retinal detachment in experimental PVR in rabbits. Alonso and coworkers described (151) the use of 1,3-bis(carboxyphenoxy) butane and SA to study the intraocular biocompatibility and in vitro kinetics of gentamicin. The implants were well tolerated in the vitreous body of rabbit eyes, and continuous levels of gentamicin were released in vitro.

Poly(ortho ester)s. The predominant mode of drug release from the previously mentioned hydrophilic systems such as PLA and PLGA is diffusion, with poor correlation between the rate of polymer erosion and the rate of drug release. For this reason, the development of new polymers that contain pH-labile linkages in their backbone has been proposed. Under certain conditions, the hydrolysis of such hydrophobic polymers can be confined predominantly to the outer surface. The resultant heterogeneous surface erosion allows excellent control of the release kinetics. Poly(ortho ester)s (POEs), as well as the previously described polyanhydrides, are polymers whose main characteristic is a release of the drug by surface erosion, following zero-order kinetics.









Since the late 1970s, four generations of POEs have been synthesized to produce bioerodible carriers for drug delivery (Table 5). The first was synthesized at ALZA Corp. in California; it was a hydrophobic solid polymer whose hydrolysis was catalyzed in acidic media (actually by the acidic coproducts released by the breakdown of the polymer). Various potential applications were described by Choi and Heller in their patents, but none concerned ophthalmic use (152).

The second generation of POEs was also a solid. The backbones of these polymers contain acid-labile linkages that are stable in alkaline media, hydrolyze slowly in pH 7.4 phosphate buffer, and degrade at increasing rates as the acidity of the medium increases. To produce drug delivery devices with lifetimes ranging from hours to months, studies were carried out by different investigators who incorporated acidic or basic excipients into hot-molded samples to modify erosion rates (152).

Recently, a new polymer has been described (153) and characterized by Merkli and coworkers (152). This viscous ointmentlike material allows the incorporation of drugs by simple mixing into the polymer at room temperature without the use of a solvent. This characteristic is of considerable interest with respect to peptide and protein delivery as well as for other thermolabile drugs. This third generation of POEs can be injected using a syringe with an appropriate hypodermic needle without any other surgical intervention, which is a significant advantage when compared with solid bioerodible devices that must be placed either with a trocar or through a surgical procedure. It is the only POE up to now that has been used in ophthalmic formulations. It has been investigated as an injectable bioerodible polymeric implant for controlled subconjunctival release of antimetabolites such as 5-FU and mitomycin C after glaucoma filtration surgery (154). The release of drugs from this semisolid POE occurs via a combined erosion and diffusion mechanism. For a LMW POE, the degradation rate is relatively fast, and the diffusion component is almost absent. On the other hand, for an HMW POE, the degradation rate of the polymer is slower, so the effect of drug diffusion through the flexible polymeric chains is more noticeable. The semisolid POE exhibits Newtonian behavior (152), and its viscosity is related to polymeric chain rigidity. In semisolid POE with low viscosity, high-chain flexibility facilitates hydrolysis. The first step of the reaction is the rapid hydrolysis of the labile orthoester bonds. This initial reaction is followed by a slower hydrolysis that produces a carboxylic acid and a triol. For more viscous polymers, where the chains are less flexible, water penetration is severely hindered, and the rate of initial hydrolysis is slowed. Consequently, to obtain drug release over an extended period of time, it is necessary to synthesize HMW polymers, but the major concern with these POEs is their very high viscosity, which makes their injection through a hypodermic needle very difficult.

A number of parameters have been shown to be important in controlling the release rate of drugs incorporated in POEs (155). Among these are the hydrophilicity of the drug, the particle size, and the amount incorporated. The influence of acidic excipients added to the system is directly proportional to their concentration, solubility, and pK_a. The use of highly water-soluble acids characterized by a low pK_a value leads to a fast polymer degradation where the drug is released principally by polymer erosion. For POEs stabilized with a basic excipient such as magnesium hydroxide, the release of the therapeutic agent is principally determined by diffusion and can be controlled by the amount of base incorporated into the polymer. The

concomitant release of 5-FU and dexamethasone has been investigated by Zignani and coworkers (unpublished data). The addition of dexamethasone phosphate, a hydrophobic steroidal antiinflammatory agent, to the highly hydrophilic and basic POE prolongs the release of the hydrophilic antimetabolite 5-FU while minimizing inflammation due to the polymer (Fig. 5). This system is promising for a subconjunctival application following glaucoma filtration surgery or intravitreally for the management of PVR.

The biotolerance of the semisolid biodegradable POE was investigated subcutaneously and with the cage-implant system (156); the biocompatibility appeared to be acceptable. The subconjunctival biocompatibility was studied by Bernatchez et al. (157). The acute inflammation resolved rapidly, and no chronic inflammation developed. After further purification of the polymer and using an aseptic preparation method, Zignani (158–160) further improved the biocompatibility of the polymer. After extensive testing, the same authors reported that the initial monomers and intermediate degradation products induced only a slight to moderate inflammatory reaction and no chronic response. As a matter of fact, aseptic preparation is up to now the only way to obtain sterile preparations because it has been shown that irradiation procedures produce degradation of the polymer and induce free radical formation (161–163).

A new family of POE, a self-catalyzed polymer, has been developed by Ng et al. (164). These POEs are similar to the second generation in that they contain short dimer segments of α-hydroxy acids in their backbone. Because POEs are susceptible to acid-catalyzed degradation, polymer hydrolysis can be controlled by the amount of incorporated α-hydroxy acids, and no acidic excipient has to be added (165). Concerning the in vitro drug release (166), it was found that the acidic 5-FU was released much faster than the weakly basic mitomycin C. These polymers appear to be very promising candidates for ophthalmic applications.

Nonbiodegradable Polymers

Ethylene Vinyl Acetate. The EVA copolymers are a family of materials with a number of promising advantages.

EVA, a thermoplastic lipophilic polymer, is mainly used as a membrane in reservoir systems and is quite permeable to certain lipophilic substances such as pilocarpine but is sufficiently hydrophobic to be relatively impermeable to hydrophilic drugs as well as water. The intrauterine progesterone contraceptive system Progestasert® (167) and the pilocarpine ocular insert Ocusert® produced by ALZA Corporation in Palo Alto, California (168), are examples of commercially introduced sustained-release systems based on EVA. In both cases, EVA is the constituent of a membrane that controls the rate of release of the drug, keeping it almost constant over several days.

In 1992, Ashton and coworkers developed an implantable sustained-release device to treat chronic disorders of the eye (169). This device consists of a central core of drug entirely coated in PVA, a permeable polymer. The surface area available for release, and consequently the release rate, is, then controlled by additional layers of EVA, which is impermeable to the drugs used, and PVA (Fig. 6). Water diffuses into the device and dissolves part of the pellet, forming a saturated drug solution. The drug then diffuses from the device, and as long as the solution inside the device is saturated, the release rate is constant. This is a so-called reservoir system (170). This device has been implanted intravitreally in animal and human eyes (Fig. 7) for the treatment of various vitreoretinal disorders (Table 6). As it is nondegradable, this system is almost devoid of any intraocular inflammatory response. However, it has to

be removed or replaced to prevent any risk of fibrous encapsulation.

The first device was developed by Smith et al. in 1992 to treat CMV retinitis with ganciclovir (170). We have seen before that the treatment of CMV retinitis requires repeated intravitreal injections of ganciclovir to maintain therapeutic levels in the eye and to prevent relapse. Because of the severe complications associated with these frequent injections and the short intravitreal half-time of ganciclovir, this drug is a good candidate for a local sustained-release delivery system. Pellets of ganciclovir were thus prepared as described earlier and implanted intravitreally into rabbit eyes. Sustained levels of ganciclovir could be maintained in the vitreous of rabbits for more than 80 days after implantation of the polymeric device, and both the device and the resulting chronic low concentrations of ganciclovir appeared to be well tolerated (170). Ashton et al. compared the pharmacokinetics data of a ganciclovir implant in healthy rabbit eyes and in diseased human eyes. The rabbit eye was found to be a good model for studying the intravitreal pharmacokinetics of ganciclovir, suggesting a common elimination mechanism (178). Sanborn et al. (171) implanted devices releasing ganciclovir at a steady rate over approximately 4–5 months in patients with AIDS-associated CMV retinitis and found that the progression of the disease was first halted out and subsequently reversed, with all patients eventually being free of retinitis.

In 1993, Anand and associates reported the cumulative experience with this device: 30 eyes from 22 patients received the intraocular device and were followed up for a median of 125 days (172). Conventional intravenous therapy had failed in these patients; however, 5 patients had no history of intravenous therapy. The authors reported initial stabilization of the disease in 90% of eyes, with a mean time to disease progression of 133 days. In 1994, a new implant was developed, characterized by a slower release rate and a longer life span (8 months). In a randomized controlled clinical trial conduced by Martin et al. (173), this implant was found to be effective with a median time to progression of retinitis of 226 days, compared with 15 days for untreated patients. The devices were well tolerated intraocularly and did not experience significant biodegradation. Furthermore, Anand et al. (179) as well as Charles and Steiner (180) reported the histopathologic and electron microscopic features of some of the human eyes treated with the device and were encouraged by the relative lack of toxicity of the ganciclovir-containing intraocular devices and the fact that they are effective in sustaining clinical nonprogression of CMV retinitis. This ganciclovir device was approved by the U.S. Food and Drug Administration (FDA) in 1996 and is commercially available under the name Vitrasert™ (Chiron Vision Corporation), each implant containing a minimum of 4.5 mg of ganciclovir and being designed to release the drug over a 5- to 8-month period of time.

The life span of the device is an important factor influencing the therapeutic outcome and the potential costs and risks of repeated implantation procedures. In many reported cases, progression of disease in patients with intraocular devices has been attributed to depletion of drug

Table 6. Use of the EVA–PVA Devices for Intravitreal Administration

from the device. When the device becomes depleted, it then has to be replaced. Morley and associates (181) described their initial surgical experience in replacing ganciclovir implants in patients with AIDS-associated CMV retinitis. Most patients retained good vision after ganciclovir implant replacement; however, the implants were occasionally difficult to extract because they were fibrosed into the scleral wound. Furthermore, in four of nine eyes that received a second implant, a retinal detachment developed. The purpose of a very recent study by Chen and Ashton (182) was to investigate various factors affecting in vitro release rate and to develop an implantable intraocular device providing sustained release of ganciclovir over 2 years. Pellets of ganciclovir were coated in a solution of PVA and then partially coated in films of the impermeable EVA, leaving a diffusion pore to allow release. The assembly was coated in PVA and heat treated. A slower release rate was obtained by decreasing the size of these pores and by increasing the heating temperature during the manufacturing process. On the other hand, increasing the percentage amount of PVA added to the pellet enhanced the release, while coating the device one more time, even in 5% PVA solution, significantly slowed down the release. Finally, a release rate of approximately 1.5 μg/h was achieved. Thus, these devices have a theoretical life span of over 600 days (183).

Treatment of posterior chronic uveitis with these EVA–PVA devices was also investigated. Cyclosporin devices were prepared by Pearson et al. (174). No significant decrease of cyclosporin level in the core of the device could be measured after intravitreal implantation in rabbit eyes during the 6 months of the study. Data suggest that owing to the high potency of cyclosporin and the very slow release rate of the device, these implants would provide sustained intravitreal levels of the drug for about 10 years (174). A second series of devices was prepared containing cyclosporin and dexamethasone (175). These two drugs might be beneficial in diseases such as uveitis and also proliferative vitreoretinopathy. Based on the fact that cyclosporin and corticosteroids reduce inflammation by different mechanisms, a device containing both drugs in combination would be more effective than a device containing either agent alone. These devices maintained therapeutic levels of both cyclosporin and dexamethasone in the vitreous over 10 weeks, and the presence of dexamethasone did not seem to change the release characteristics for cyclosporin (175). In an experimental model of PVR, the device containing both drugs lessened the severity of the disease and delayed the onset of neovascularization, but addition of cyclosporin to a device containing dexamethasone did not enhance efficacy (184). Devices were also prepared, containing dexamethasone alone for the treatment of PVR (177) and uveitis (176). Dexamethasone was released continuously for 3–4 months at an effective concentration in both cases. Furthermore, the devices were well tolerated, with no indication of toxicity or inflammation.

Polysulfone. Polysulfone is a water-impermeable polymer. A polysulfone capillary fiber (PCF) has been investigated as a slow-release delivery system. It is an anisotropic ultrafiltration fiber mainly developed for cell culture purposes by Amicon Corporation. PCF has the following important features: (*1*) it has deep macrovoids in its outer membrane, which increases the surface area for drug diffusion and release; (*2*) it seems to be permeable to lipophilic as well as hydrophilic compounds; (*3*) the PCF–drug device can be readily sterilized; (*4*) the device prevents dispersion of drug formulations, such as liposomes or microspheres, in the vitreous, and (*5*) most importantly, the bioactivity of the drug is unchanged by utilizing the PCF device because the fabrication process does not require chemical reaction, heat, or solvent exposure. The obvious disadvantage of this device is the need for surgical removal of the drug-depleted device because it is not a biodegradable system.

Rahimy and coworkers found that the PCF system is capable of maintaining a relatively constant intravitreal level of the hydrophilic dye carboxyfluorescein (CF) for up to 45 days (185). The in vitro CF release profile appears to be biphasic: The device releases about 50% of its CF content during the first 10 days; from day 10 to day 30, it exhibits slower release with approximately zero-order kinetics. From this standpoint, the PCF device can be classified as a reservoir diffusion-controlled system. Dye diffusion through the PCF membrane is mainly driven by the concentration gradient between the PCF core and the incubation medium. The transport of dye molecules across the PCF membrane remains constant if the core is main-

tained in a saturated state, such as a solid or suspension form. However, such a state is difficult to maintain in this case because the drug used is highly water soluble. As a result, it can be expected that during the second phase of the release, the rate would decrease as the concentration in the core drops below the saturation value. Intravitreal implantation of this device into rabbit eyes showed sustained-release kinetics. The in vivo time-course study showed CF levels for up to 45 days in the vitreous cavity. Furthermore, both clinical and histopathological data demonstrated that the PCF device is well tolerated by rabbit eyes (185).

Promising results have been obtained with daunomycin-charged PCF, as studied by Rahimy and coworkers, for the treatment of PVR (186). This device was implanted intravitreally in rabbit eyes, and the results demonstrated that the device could prolong the release of daunomycin at a therapeutic concentration in the vitreous for at least 21 days. At the doses of daunomycin used, the device prevented tractional retinal detachment in an experimental model of PVR and was well tolerated without causing toxicity to ocular tissues.

Silicone. Silicone oil is a highly hydrophobic polymer of dimethylsiloxane showing transparency, good tolerance, and properties similar to the vitreous humor concerning the refractive index and the viscoelasticity. These characteristics have led to its use in vitreoretinal surgery; silicone oil is most frequently used as an intraocular tamponade after vitrectomy (187). It can serve as a long-term tamponade, preventing recurrent retinal detachment. However, owing to many complications such as emulsification, keratopathy, increased intraocular pressure, and cataract formation, its use is restricted to specific applications like repair of retinal detachment with proliferative vitreoretinopathy (188).

Most of the antiproliferative drugs are water soluble and thus cannot be used with silicone oil. However, lipophilic drugs, such as carmustine (also known as BCNU), can be dissolved in silicone oil, which in turn acts as a depot material and releases the drug gradually into the vitreous cavity, thus prolonging its activity (189). High doses of BCNU can be loaded in the oil without increasing its toxicity, because the effective dose gradually released to the tissues is much smaller. However, silicone oil does not dissolve and does not have sustained-release properties itself.

Another antiproliferative lipophilic drug used in association with silicone oil is retinoic acid. Araiz (50) concluded that retinoic acid given in a single intravitreal administration in solution with silicone oil produces a significant and lasting reduction in cellular proliferation in an experimental model of PVR.

Nanoparticles, Microspheres and Liposomes

Nanoparticles and Microspheres. Microparticles and nanoparticles are colloidal drug carriers in the micron and submicron size range. These systems were first developed to resolve solubility problems of poorly soluble drugs as well as for long acting injectable formulations and improved drug targeting. These carriers have been evaluated as ophthalmic drug delivery vehicles over the past 15 years. An important potential use for these systems was to improve the classical aqueous eye drop formulations, which have several disadvantages such as a rapid elimination of the drugs from the precorneal site. Consequently, colloidal suspensions were designed to combine ophthalmic sustained action with the ease of application of eye-drop solutions (190).

Nanospheres have a diameter between 10 and 1,000 nm and are monolithic particles made of a porous or solid polymeric matrix, whereas nanocapsules consist of a solid or liquid drug reservoir surrounded by a polymeric membrane. Nanoparticles are usually prepared by the emulsion polymerization method, with synthetic polymers such as polyalkylcyanoacrylates (PACA), polyacrylamides, and polymethylmethacrylates. PACA has certain advantages over the two others polymers; it is biodegradable and has no adverse toxic profile (191).

Concerning the ophthalmic potential applications of nanoparticles, they are mainly used as a topical treatment for glaucoma, inflammation, or external infections of the eye because they are administered as drops and provide sustained action. However, only a few studies have been conducted concerning the intravitreal application of nanoparticles. El-Samaligy and coworkers (192) described the intravitreal injection of acyclovir and ganciclovir nanoparticles made of biodegradable polymers, such as bovine serum albumin (BSA), polyethylcyanoacrylate (PECA), and chitosan. All of these polymers exhibited interesting characteristics during in vitro evaluation (drug-loading capacity, particle size, homogeneity of nanosphere formation, and drug release). PECA was chosen for in vivo studies in rabbits because it demonstrated the best drug loading and the smallest particle size. Therapeutic levels of ganciclovir were detected in the vitreous for up to 10 days following injection of the nanospheres. Lens opacification and vitreous turbidity appeared after the PECA–nanospheres injection, most certainly due to the drug formulation, a colloidal opaque dispersion.

Microparticles have a particle size above 1 μm and comprise microspheres and microcapsules. Microspheres are polymeric drug combinations in which the drug is homogeneously dispersed in the polymer matrix. The polymers used for the preparation of microspheres are mainly based on PLA and PLGA. These bioerodible systems present the advantage that the microspheres degrade after delivering the drug; they do not have to be removed. Following administration of the suspension in the eye, the particles remain at the delivery site and the drug is released from the polymeric matrix through diffusion, polymer degradation, erosion, or a combination of these processes.

So far, it seems difficult for biodegradable polymer microspheres to encapsulate hydrophilic drugs and obtain satisfactory release profiles without burst effects (193,194). When using the conventional method of preparation of the microspheres, microcrystals of the hydrophilic substance may form in the matrix with a nonhomogeneous distribution. These microcrystals create pores in the microspheres, which in return increase the surface area of

the matrix and by this means induce a faster degradation and release of the drug by diffusion. The near-linear release of drugs has been correlated with a corresponding linear decrease of molecular weight of the polymer and to the fast progression in pore formation. Diffusion of the drug from the deeper layers of the microspheres to the surface might partially explain the faster release from the lower-molecular-weight polymers. For hydrophobic drugs, the most important mechanism of release seems to be the degradation of the polymer matrix.

The factors affecting biodegradation are therefore the following: (*1*) LMW polymers and copolymers with a medium to high content of glycolide have faster degradation time (with 50:50 PLGA having the shortest half-life), (*2*) smaller-size microspheres show faster degradation, (*3*) the presence of drug may affect degradation time, and (*4*) vitrectomized eyes show faster clearance times compared to normal eyes (195).

Besides topical ophthalmic applications, which have been widely studied (191), some authors have investigated microspheres for subconjunctival (194,196,197) as well as intravitreal injections to provide sustained release of drugs (Table 7). In 1991, Khoobehi et al. (193) investigated the intravitreal injection of microspheres as a sustained-delivery system. Microspheres were made of different combinations of PLA and PLGA and contained fluorescein as a drug model. After intravitreal injection in the rabbit eye, high concentrations of the dye were detected within 24 h; they gradually decreased after 5 days, and lower concentrations were still measurable for 16 days. The in vitro and in vivo release rates from PLGA microspheres were faster than from PLA (193).

Moritera and associates (198) entrapped 5-FU in PLA and PLGA microspheres and injected it intravitreally in rabbits. The drug was released over a period up to 7 days, and the release profile was accelerated by using lower-molecular-weight polymers or copolymers. The microspheres were observed as a white mass in the vitreous cavity and were completely cleared out, on average after 48 days. Administration of microspheres had no adverse effects on the ocular tissues, even though the degradation products of PLA and PLGA are acidic. Moritera also injected PLA microspheres with adriamycin in rabbits (199). This drug, 50 times more potent than 5-FU, was released at a continuous rate for over 14 days, was effective in preventing the rate of retinal detachment after 4 weeks in an experimental model of PVR, and showed no toxicity to the retina even at a relatively high dose. Peyman and associates (200) demonstrated the efficacy of microspheres in increasing the half-life of encapsulated antimetabolites when injected intravitreally in primate eyes. Both cytosine arabinoside (ara-C) and 5-FU were entrapped in PLGA microspheres. ara-C and 5-FU released from microspheres were still detectable in the eye 11 days after injection, and the clearance kinetics were similar for both drugs. The release patterns for all these hydrophilic drugs showed an initial burst. On the other hand, Giordano et al. (201) entrapped retinoic acid, a highly hydrophobic drug, in PLGA microspheres and obtained a constant release of the drug. This system could provide therapeutic levels of retinoic acid for 40 days (Fig. 8) and avoids the use of silicone oil as a reservoir; neither does it require surgery to implant or remove the drug delivery system. Veloso and coworkers (202) recently reported the use of PLGA microspheres loaded with ganciclovir for the treatment of experimental CMV retinitis in rabbits. Using a new preparation technique, the authors obtained a very high loading of the drug, and the microspheres released ganciclovir within the therapeutic range for at least 42 days. The progression of the retinitis decreased after 3 days. Neither retinal toxicity nor adverse tissue reaction were observed after 8 weeks. Acyclovir was also investigated as a candidate for microsphere incorporation for chronic treatment of herpes simplex infections or acute retinal necrosis syndrome (140). In vitro release of acyclovir was slower when higher-molecular-weight PLA, higher-lactide-content PLGA, and larger microspheres were used. After intravitreal injection in rabbit eyes, acyclovir levels were sustained for 14 days after microsphere injection, whereas no more acyclovir was detected 3 days after administration of raw drug (140).

A biocompatibility study was conducted by Giordano and coworkers (195); following intravitreal injection of empty microspheres of relatively low molecular weight PLGA, a mild, localized, nonprogressive foreign-body reaction was observed. The choroid and retina were normal, and no clinical inflammatory signs were observed 4 days postoperatively and thereafter.

Liposomes. Liposomes were first investigated in the 1960s as a membrane model. They have been studied for many years since as a potential drug delivery system. Liposomes are microscopic vesicles composed of membrane-like lipid bilayers surrounding aqueous compartments. These lipid layers are composed of natural phospholipids such as egg lecithin or synthetic phospholipids, for example, dipalmitoylphosphatidylcholine. Cholesterol is usually

included in the formulation to stabilize the liposomal membrane and to minimize leaching out of the encapsulated water soluble drug. Substances such as α-tocopherol are added to decrease liposome permeability (204).

Liposomes may be classified as multi- or unilamellar depending on the number of concentric, alternating layers of phospholipids and aqueous spaces. Small unilamellar vesicles (SUV) have a diameter less than 100 nm. LUV refers to large unilamellar vesicles; and MLV, to multilamellar vesicles.

The rate of drug release from liposomes will depend upon the quality of the liposomes as well as the property of the drugs and the state of the eye. The drugs escape either by leakage through the membranes of intact liposomes or by diffusion from degraded or destabilized liposomes. Barza et al. (204) examined the effect of the size and composition of liposomes on their pharmacokinetic disposition following intravitreal injection. LUV liposomes have a longer retention time in the eye than SUVs. Concerning the components of liposomes, cholesterol stabilizes liposomal membranes, so in this case the rate of drug release is determined by the clearance of the liposome itself, whereas for non-cholesterol-containing vesicles, it is determined by the rate of leakage of the drug from the liposome. The physicochemical properties of the encapsulated drug determine its rate of release. Hydrophilic drugs are captured in the aqueous phase of liposomes, whereas lipophilic drugs, such as amphotericin B, are usually bound to the lipid bilayer or dissolved in the lipid phase. Such drugs will thus not leach out as readily as hydrophilic compounds to the external water phase. The state of the eye is also a major factor; liposomes showed a higher clearance rate in infected eyes, maybe due to an enhanced rate of diffusion of the liposome, an increased rate of flow from the vitreous to the anterior chamber, an augmented uptake by fixed or mobile phagocytes, or a breakdown of the blood–retinal barriers.

The pharmacokinetics of liposomally encapsulated drugs is not yet fully understood. Following intravitreal injection of liposomes, several processes begin simultaneously; intact as well as degraded liposomes clear from the vitreous body, the vesicles leak their contents in the vitreous humor, and these contents are eliminated. The mode of elimination of liposomes themselves from the vitreous remains unclear. The liposomes may egress by diffusion via the anterior route, or they may be removed by phagocytosis, for example, by pigmented epithelial cells or by degradation in situ as well as by other mechanisms or a combination of these processes (204). The state of the blood–retinal barrier and the structural integrity of the vitreous body may markedly affect the pharmacokinetic behavior of intravitreal liposomes. The liposomes are more rapidly cleared in vitrectomized eyes (205), and the breakdown of the blood–retinal barrier induced by inflammation allows the liposomes to egress and the drug to leak more easily from the vitreous.

Liposomes have been administered by practically every conceivable route. Some degree of success has been achieved for the topical and parenteral routes; a prolongation of plasma half-lives with liposome-encapsulated drugs has been reported. The development of liposomes for ocular drug delivery has been studied for various approaches of administration. Topical instillation is the most convenient and frequently used means of administration for ophthalmic therapy (206). Liposome encapsulation enhances the corneal penetration of topically applied drugs. It provides a convenient way to retard their release from a relatively inert depot without changing the intrinsic characteristics of the agents and to increase the duration of therapeutic levels. Some investigators have also experimented with the subconjunctival and intravitreal injection of liposomally entrapped drugs. Others have attempted to target ocular tissues by a systemic route of administration (207) (Table 8).

Antibiotics for the treatment of endophthalmitis were the first drugs to be encapsulated into liposomes and injected intravitreally in rabbit eyes. As early as 1986, Fishman and associates (208) incorporated gentamicin in MLV. The authors observed a lower peak value of gentamicin in the vitreous, which would presumably result in a decrease of toxic effects on the intraocular structures. However, enhanced toxicity from liposome-entrapped drugs arising from longer exposure may still be possible. Nevertheless, the release profile was significantly improved, and liposome encapsulation was thought very promising for sustained intravitreal drug administration. Another antibiotic, clindamycin, was studied by Fiscella (209) and Rao (210). The clearance of encapsulated clindamycin was 10 hours, compared to 3 hours for nonencapsulated clindamycin. Furthermore, this treatment was successful and efficacious in treating an experimental model of *S. aureus* endophthalmitis. Tobramycin, an antibiotic with marked inhibitory action against many gentamicin-resistant strains of bacteria, such as *P. aeruginosa*, was encapsulated in liposomes by Kim and Kim (211) and allowed to reduce the initial burst of the drug so as to prolong its action in the vitreous (Fig. 9) and to prevent any retinal toxicity. Zeng and associates (212) prepared liposomes with amikacin, a more effective antibiotic than gentamicin. The duration of therapeutic concentrations was generally prolonged. They observed that liposomes were more rapidly

cleared in vitrectomized eyes and in severely infected eyes. This is probably due to damage of the blood–retinal barrier and therefore an enhanced elimination of the drug. They concluded, however, that in severe endophthalmitis the intravitreal injection of liposomes alone could not suppress the inflammation.

Amphotericin B is a hydrophobic drug that showed different behavior from the other antibiotics described above. In a study in 1986 by Tremblay and coworkers (213), it was shown that liposome encapsulation of amphotericin B noticeably reduced its toxicity in rabbit eyes (Fig. 10) but without enhancing the therapeutic levels compared to nonencapsulated amphotericin B. The toxicity of this drug was also reduced in primate eyes (214). Indeed, unlike water-soluble molecules, which are trapped in the aqueous phase of the liposomes, amphotericin B is presumably intercalated in the liposomal bilayers. Because amphotericin B binds to sterols, this protective effect of the liposomes may result from competition for drug binding between cholesterol in the liposome and in the host's cellular membranes, reducing the acute interaction between amphotericin B and the sterol receptors. Liu and coworkers (215) further investigated the efficacy of liposomally bound amphotericin B for the treatment of experimental fungal en-

Extent of vitreal band formation and retinal damage observed ophthalmoscopically 5 weeks after injection of commercial amphotericin B (AMB) or liposomal amphotericin B (lip–AMP) in the indicated dosage in pigmented rabbits. Each bar is the result in one eye using the following score system:

Grade	Vitreal bands	Retinal damage
0	None	None
1+	Minimal	Silvery sheen or atrophy of the retina occupying 0.5–1 whole field visible at one time
2+	Moderate	Retinal sheen or atrophy of the retina occupying >1 field visible at one time
3+	Severe	More extensive than above (no such lesions actually found)

Control eyes receive phosphate-buffer saline (PBS) or empty (drug-free) liposomes.

dophthalmitis in rabbit eyes. Liposomal amphotericin B eradicated the infection in only 40% of the eyes treated, whereas the same dosage of free drug eradicated 100% of the infection. This reduction of efficacy might be due to the membrane-stabilizing effect of cholesterol and, consequently, the reduced availability of the drug against infective organisms or to competition between liposomal membrane cholesterol and fungal ergosterol. As a result, it appears that intravitreal liposomal preparations are not ideal for treating acute clinical conditions, such as endophthalmitis, that require initially high doses of antibiotics. Liposomes may, however, be advantageous for chronic dis-

orders for which a persistent low concentration of drug is necessary. In this latter case, liposomal preparations not only avoid the initial toxicity of the drug but also reduce the need for repeated intravitreal injections.

A disease such as CMV retinitis requires frequent intravitreal injections and long-term treatment. In 1987, the first antiviral compound, trifluorothymidine, was tested for liposomal encapsulation. Liu et al. (216) found that a substantial amount of drug remained in the vitreous 28 days after intravitreal injection, an effective concentration against most HSV types and CMV. Ganciclovir, the highly efficacious antiviral drug, has been extensively studied. Peyman et al. were the first to encapsulate it into LUV (217). The injection of liposome-entrapped ganciclovir appeared as a whitish suspension located in the inferior part of the vitreous body. This haze disappeared after 4 weeks, a period of time during which the total concentration of ganciclovir was within the therapeutic range to treat different viral strains. Díaz-Llopis et al. (218) further compared liposomal ganciclovir to a free ganciclovir solution. Liposomally encapsulated ganciclovir increased the time period required for reinjection in the treatment of CMV retinitis. The results reported are comparable to those of Peyman (217), but Díaz-Llopis used a simplified production procedure. The first clinical study performed in human eyes was undertaken by Akula et al. (219) in 1994. Intravitreal injection of liposomal ganciclovir formed a whitish suspension located in the inferior part of the vitreous cavity that gradually disappeared over 2 weeks and allowed the retention of ganciclovir for up to 24 days. Finally, Le Bourlais and coworkers (220) managed to obtain sustained release from liposomal ganciclovir for up to 60 days without toxic effects on the retina. A cyclic phosphate derivative of ganciclovir, 2′-nor-cyclic GMP, anionic in nature at neutral pH, proved an ideal candidate for encapsulation into MLV (221). This drug is as potent as ganciclovir and has a long-lasting antiviral effect, thus requiring less frequent dosing. The liposomal incorporation of 2′-nor-cyclic GMP allowed the half-life to be prolonged up to 1,000 h, more than 75 times that of ganciclovir, without any toxic signs. Finally, cidofovir was recently investigated by Besen (223) and Kuppermann (224). This compound has a different mechanism of action from ganciclovir and foscarnet; it might be beneficial for viral strains resistant to usual therapy. Cidofovir is 10 times more potent and more selective than ganciclovir and requires only short exposure time for antiviral action. Being polar and water soluble, it is highly suitable for liposomal encapsulation. Liposomal cidofovir was present in the vitreous 90 days after injection at a concentration 10 times above the ID_{50} of CMV. The efficacy of a single injection of this liposomal formulation of cidofovir may thus prevent reactivation of retinitis for more than 8 months. Kuppermann and coworkers used a lower, more appropriate dose of cidofovir (224). This system possessed a potent antiviral effect lasting up to 4 months.

PVR is a clinical condition that requires a sustained delivery of antiproliferative drugs, thus prolonging the duration of the therapeutic effect while minimizing the toxic side effects of a high initial dose. Liposome-encapsulated 5-FU was investigated by Joondeph et al. (226). This formulation allowed higher intraocular levels of 5-FU over a prolonged period after injection of a dose that, when given in the free form, is indeed toxic to the retina. Antimetabolites such as ara-C and 5-fluorouridine-5′-monophosphate (FUMP) were encapsulated by Assil and coworkers (227) and investigated for the treatment of experimental PVR in rabbits. The half-lives of both drugs were significantly prolonged. ara-C was found to be less effective than FUMP in reducing tractional retinal detachment, probably because of its lower potency (227). Liposomal FUMP was found very efficacious by increasing exposure time of fibroblasts to the drug from 1 to 72 hours, resulting in a 20-fold increase in efficacy. FUMP was further investigated by Gariano and coworkers (228) to evaluate its retinal toxicity when entrapped in MLV. It was found nontoxic at doses sufficient to inhibit PVR. García-Arumí and coworkers (229) encapsulated 5-fluorouridine in collagen-coated liposomes, knowing that this protein is the most important constituent of the extracellular matrix of epiretinal membranes in PVR and that cells involved in this process have specific receptors for collagen. This coating may increase the affinity of the target cells for the surface of liposomes. In an electron microscopy study, these authors confirmed that intravitreally injected liposomes bind extensively to the internal limiting lamina of the retina without entering the retina, thus potentially decreasing retinal toxicity. Liposomal ara-C has also been shown to be nontoxic to the retina when encapsulated into liposomes (230). Heath et al. selected a so-called liposome-dependent drug, fluoroorotate, a compound that seems not to enter cells unless bound to liposomes (231). Heath demonstrated the in vitro antiproliferative and anticontractile effects of fluoroorotate, properties that are essential for the treatment of PVR. The liposome drug complex was delivered to epiretinal membranes within the rabbit eye while minimizing toxicity to underlying tissues such as the retina. A single injection of liposomal fluoroorotate effectively inhibited retinal detachment in an experimental model of PVR (231). Finally, in a study by Hui et al. (16), daunomycin was encapsulated into liposomes and investigated in an experimental model of PVR. A prolonged half-life and minimized toxicity were reported following the encapsulation process.

Another approach of delivering local concentrations of a drug while lessening toxic effects at other sites is to administer liposomally encapsulated drugs by a systemic route. Various strategies have been attempted to target the released contents of liposomes. One approach has been to formulate liposomes that release their contents in response to hyperthermia (heat of 40–42°C). These liposomes are called "temperature-sensitive" and have been studied since 1984; Khoobehi et al. (232) delivered carboxyfluorescein and ara-C from temperature-sensitive liposomes, using a noninvasive microwave generator as an external trigger. Liposomes prepared from synthetic phospholipids rapidly released their contents at a phase-transition temperature of 41°C; however, in the presence of serum, the transition temperature decreased to approximately 40°C. The amounts of dye and drug released were different owing to the different physicochemical characteristics of both substances. Khoobehi et al. (233) further investigated the release of drugs from temperature-sensitive liposomes, ara-C, and 5-fluorouridine. A microwave-generated hyper-

thermia was applied to the rabbit eye, and the intravitreal release of the drugs was measured. The amounts were all higher in the heated eyes. The application of heat did not cause any damage to the ocular tissues. Ogura and coworkers (234) managed to deliver a model substance, carboxyfluorescein, to selective areas of the retina. As penetration of the drug into the retinal tissue is significantly restricted by intercellular tight junctions between vascular endothelial cells, retinal pigmented epithelial cells, and photoreceptors that form the blood–retinal barrier, the authors induced a breakdown of this barrier by laser pulses. The drug encapsulated in temperature-sensitive liposomes, situated in the lumen of the vessels, could then penetrate into the retina through areas where the barrier was disrupted. Liposomal encapsulation prevented any retinal toxicity compared with injection of the free drug. No evidence of retinal injury after laser exposure was found.

In summary, data generated in the last two decades clearly demonstrate that liposomes have great potential as novel drug delivery systems. The following advantages can be mentioned (207). First of all, liposomes can incorporate both hydrophilic and lipophilic compounds; therefore, even water-insoluble constituents can be administered in a liquid dosage form in which the therapeutic agent is dissolved. Composed of lipids similar to those present in biological membranes, liposomes are expected to be biocompatible and biodegradable. Liposomes can provide slow or controlled release and consequently prolonged action of encapsulated drugs. As long as the drug is incorporated within the liposomes, it cannot be metabolized. The rate of drug release can be influenced by selecting appropriate lipid components of the liposomal membrane, such as cholesterol or hydrogenated phospholipids. Finally, there is considerably reduced retinal toxicity of intravitreally injected drugs when they are encapsulated within liposomes.

Drug delivery using liposomes may be useful for the treatment of posterior segment diseases; however, there are also inherent problems encountered with these methods. One of the major problems limiting the widespread use of liposomes is both chemical and physical stability. Chemical instability may be due to hydrolysis or oxidation of the lipid components; physical instability may be caused by drug leakage from the vesicles and/or aggregation or fusion of the vesicles into larger particles. All these processes influence the bioavailability of encapsulated drugs. Some of these stability problems can be overcome by lyophilization; if the finished product is preserved in a relatively more stable dry state, its shelf life is longer. Sterilization is often difficult because most methods are unsuitable for liposomal products; phospholipids are thermolabile and sensitive to sterilization procedures involving the use of heat, radiation, and/or chemical sterilizing agents. The method available for sterilization of liposomes is filtration through 0.22-μm membranes; however, filtration is not suitable for LUV and does not remove viruses or pyrogens (207). Finally, intravitreally administered liposomes tend to spread diffusely within the vitreous cavity and cause cloudiness, interfering with the patient's visual acuity and the ability of the ophthalmologist to examine the fundus until complete biodegradation of the formulation has occurred (217,235).

Iontophoresis

Iontophoresis, from the Greek *ionto*, ion, and *phoresis*, to bear, is a process that allows increased penetration of ionized molecules across or into tissues by application of a low electric current (mA) (236). The drug is applied with an electrode carrying the same charge as the drug, while the ground electrode, which is of the opposite charge, is placed elsewhere on the body to complete the electric circuit (236) (Fig. 11).

The factors governing the penetration of drugs by iontophoresis have been studied by Hughes and Maurice (238); the penetration of a drug is proportional to the current and to the duration of its application, whereas the concentration of the drug solution does not seem to be an important factor (239). Other factors are the design of the electrode and the physicochemical properties of the drug, such as its charge (it should be ionized at a physiological pH and soluble in water) and its size (the drug should have a relatively small molecular size, <600 Da [24]).

Two types of iontophoresis are performed in the eye, namely, transcorneal and transscleral iontophoresis (237). Although transcorneal iontophoresis is capable of producing high and sustained levels of drug in the cornea and the aqueous humor, thus allowing the treatment of anterior segment diseases, only meager concentrations are achieved in the vitreous humor. This is due to the iris–lens diaphragm, which limits the penetration of the drug into the vitreous cavity. Incidentally, significant drug concentration levels were achieved in aphakic eyes, as reported by Fishman and colleagues (241). To circumvent the iris–lens barrier, transscleral iontophoresis is applied through the pars plana rather than the cornea. Because it is as effective in phakic as in aphakic eyes, it provides therapeutic vitreous drug levels to treat posterior segment disorders. Transscleral iontophoresis may thus replace or supplement intravitreal injections. This procedure has gained interest as a local drug delivery system for sub-

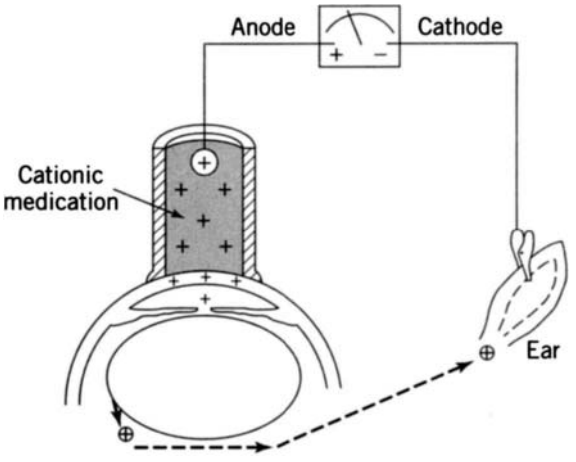

Figure 11. Ocular iontophoresis in the rabbit. *Source:* Reproduced from Ref. 237 with permission.

stances that are not amenable to topical delivery and require repeated administration over an extended period of time, such as antibiotics, antifungal, antiviral, antimetabolite, and steroid drugs (242) (Table 9).

The first application of transscleral iontophoresis was carried out by von Sallman as early as 1943; atropine and scopolamine were introduced in the vitreous humor by using an electrode circling the sclera (243). Since that time, iontophoretic delivery of antibiotics has been successful in providing vitreal therapeutic levels of drugs. Burstein et al. (243) administered gentamicin to rabbit eyes by means of transscleral iontophoresis. After the application of current for 3 minutes, a depot of gentamicin was introduced into the vitreous humor, which allowed therapeutic levels to be maintained in the adjoining ocular tissues for more than 24 h. Grossman and coworkers (245) compared transcorneal and transscleral iontophoresis of gentamicin to each other and with respect to subconjunctival injection. The highest intravitreal levels were achieved by transscleral iontophoresis, 53.4 μg/mL after 16 h, whereas the peak level achieved through transcorneal iontophoresis was 0.5 μg/mL after 30 min, and through subconjunctival injection, 2.6 μg/mL after 30 min. The vitreal levels remained within the therapeutic range for 24 h. Barza et al. (239) delivered iontophoretically three antibiotics, cefazolin, ticarcillin, and gentamicin, to rabbit eyes. Three hours after application of a current for 10 min over the *pars plana*, mean vitreal concentration of the antibiotics reached 94 to 207 μg/mL. Drug penetration showed a correlation with the current intensity and the duration of iontophoresis but not with the concentration of the drug solution. The procedure caused focal damage to the retina, for example, hemorrhagic necrosis, edema, and infiltration by polymorphonuclear cells, but the authors supposed that such an amount of injury is no greater than that caused by an intravitreal injection or surgical implantation of a sustained-release drug delivery device. Transscleral iontophoresis of gentamicin was also found effective in monkeys (244). Vitreal levels achieved were similar to those obtained in rabbit eyes with a lower current (239). The procedure was well tolerated, and the small burns produced by the electric current were over the *pars plana*, an area of the eye not critical for vision. The authors concluded that transscleral iontophoresis could be applied in humans with topical anesthesia only. Vancomycin is an antibiotic compound bearing two positive charges and having a relatively high molecular weight of 1,448 Da. It is very effective against gram-positive bacteria and *Bacillus* species. After application of 3.5 mA for 10 min, vitreal levels of vancomycin were well above the minimal therapeutic concentration of 5 μg/mL 8 h after treatment (240). Ciprofloxacin, a zwitterionic molecule, was investigated by Yoshizumi et al. (246). After transscleral iontophoresis, higher vitreal concentrations were achieved when the negatively charged form of ciprofloxacin was used rather than the positively charged form. However, aqueous levels were higher than vitreous levels, which were under the MIC_{90} of several organisms commonly causing endophthalmitis.

Grossman and Lee (247) attempted to deliver ketoconazole, an antifungal agent, to the vitreous of rabbits by transscleral iontophoresis. The water solubility of this drug is relatively low. The peak concentration achieved in the vitreous was not sufficient for therapeutic fungicidal activity. Transscleral iontophoresis is consequently not an effective means to deliver this antifungal drug for the treatment of endogenous endophthalmitis.

Lam and coworkers (248) performed transscleral iontophoresis of dexamethasone sodium phosphate into rabbit eyes and obtained high and long-lasting therapeutic

Table 9. Ocular Iontophoretic Drug Delivery

Drugs	Current (mA)	Duration (min)	Peak level (μg/mL)	Animal model	Year	Author (et al.)	Ref.

[a]Given as a supplementation of intravenous foscarnet.

concentrations of this antiinflammatory drug, maybe owing to pools of dexamethasone that would have accumulated in the different ocular tissues. In an experimental model of uveitis, Behar-Cohen et al. (249) investigated iontophoresis of dexamethasone by applying the electrode on both sclera and cornea of rat eyes. This procedure allowed the reduction of inflammation in both anterior and posterior segments of the eye as efficiently as systemic corticotherapy without any clinical or histological damages to the eyes.

Transscleral iontophoresis of antiviral agents such as ganciclovir could be useful for the treatment of CMV retinitis. Lam et al. (250) showed that a single iontophoretic application of ganciclovir over the *pars plana* may deliver a therapeutic dose of this drug into the vitreous, resulting in significant levels even 3 days after its administration. Foscarnet was also successfully delivered by transscleral iontophoresis (251). The peak concentration achieved 4 h after the administration of the current was below the concentration reported to cause retinal toxicity, and therapeutic levels could be maintained up to 60 h after iontophoresis.

The advantages of iontophoresis include the minimization of systemic exposure to the drug; the delivery of high concentrations of the drug directly to the targeted site; a minimal discomfort for the patient, only under topical anesthesia; and improved consistency in the penetration of the drug (238). It is a noninvasive procedure that may replace or supplement intravenous therapy or intravitreal injection of drugs (252).

Nevertheless, iontophoresis is not a harmless procedure. Transscleral iontophoresis might be associated with damage to the retina and the choroid, as described by Maurice (253). He observed destruction of most of the layers of the retina, with an engorgement of the choroid. Barza et al. (240,245) noticed hemorrhagic necrosis; edema; inflammatory infiltration of the retina, the choroid, and the ciliary body; and retinal burns. Lam and coworkers (254) presented a detailed description of the pathologic features occurring after transscleral iontophoresis. The pathologic changes varied with the duration of application. In contrast to the extensive retinal changes caused by 2 to 25 min of transscleral iontophoresis, a short application period ($\leq$1 min) did not result in histopathologic changes. Although the mechanism of retinal damage caused by transscleral iontophoresis is not known, it is suspected to be produced by heat or by the directly applied electrical current. On the other hand, during iontophoresis, electrolysis takes place in the electrode chamber, and the pH of the solution is sharply raised (or decreased, depending on the polarity of the electrode). Hence, negatively charged hydroxide ions may be driven into the vitreous and accumulate in the vicinity of the area undergoing iontophoresis toward the end of the procedure, causing chemical burns.

Prodrugs and Codrugs

The term *prodrug* was first introduced in 1958 by Albert (255) to describe an inactive compound, formed by linking a drug to an inert chemical, namely, the promoiety, by a covalent bond that could be broken in vivo by any mechanism, spontaneously or enzymatically, to yield the active drug substance. Furthermore, the prodrug should possess better delivery properties than the parent drug molecule (256). The use of prodrugs for ocular delivery has been reviewed by Lee and Li (257). Prodrugs are mainly used topically to increase corneal drug absorption to enhance efficacy, reduce the incidence of systemic side effects by lowering the required dose, and prolong the duration of action and thereby improve patient compliance. In the case of intravitreal delivery, the main advantage of prodrugs is that they prolong the action of drugs that are rapidly cleared out from the vitreous when administered in a conventional dosage form.

Steffansen and coworkers (258) developed a drug delivery system of 5-FU prodrugs suspended in silicone oil to maintain therapeutic intravitreal levels of 5-FU over several days for the treatment of PVR. They synthesized several lipophilic *N*-alkoxycarbonyl derivatives of 5-FU, with alkyl chain lengths ranging from 6 to 18 carbon units. All prodrugs hydrolyzed quantitatively to the parent 5-FU in aqueous buffer. Hydrolysis was accelerated in the presence of plasma or rabbit vitreous, which exhibited an enzymatic contribution, but in all cases the reaction followed first-order kinetics. The release rate of 5-FU depended on the alkyl chain length; the more lipophilic the prodrug, the more sustained the release rate.

Taskintuna and associates (259) investigated a lipid prodrug, acyclovir diphosphate dimyristoylglycerol (ACVDP-DMG). ACVDP-DMG represents the combination of acyclovir with cytidine diphosphate diacylglycerol (Fig. 12), a naturally occurring phospholipid, and it is very active against HSV and CMV. ACVDP-DMG is the prototype of a class of liposome prodrugs that the authors term *prosomes*. This compound makes up part of a liposome wall together with naturally occurring phospholipids, as opposed to conventional liposomes in which the drug is placed inside the liposomes. This prosome was found superior to both ganciclovir and acyclovir in a rabbit model of HSV retinitis. The ACVDP-DMG seemed to be specifically absorbed by the retina following intravitreal injection in rabbits, because the liposome walls seemed to fuse with the retinal cell membranes, allowing incorporation and progressive release of the drug into the retinal cells. This system did not seem to cause any toxic effects to the retina or the lens. In a pharmacokinetic study (260), liposomal ACVDP-DMG provided therapeutic levels of acyclovir for 18 days.

The use of a conjugate drug, a so-called codrug, is a novel approach that allows sustained release of two drug entities. These two drugs become relatively insoluble when covalently linked, and hydrolysis of the chemical bond allows both drugs to be released slowly in equimolar quantities. The codrug has a distinct advantage over the use of either drug alone because it incorporates the properties of both parent compounds while allowing a sustained delivery over an extended period of time. Consequently, a controlled release is achieved without recourse to more traditional polymeric drug delivery systems, some of which have been shown to induce a mild, localized foreign-body reaction with glial proliferation and inflammation.

A study by Berger and coworkers (261) was designed to evaluate the efficacy of two codrugs in preventing the de-

Next Page

velopment of PVR in a rabbit model. The codrugs are composed of an antimetabolite, 5-FU, covalently linked to a corticosteroid, dexamethasone (DEX) or triamcinolone acetonide (TA), by a carbonate bond (Fig. 13). After synthesis of the codrugs by chemical reaction, the authors prepared pellets by direct compression of the DEX–5-FU powdered codrug and a suspension of the TA–5-FU codrug. The DEX–5-FU pellet released the drugs over 1 week in vitro. Using an experimental model of PVR in rabbits, the authors implanted the pellet intravitreally and observed a reduction of the incidence of retinal detachment from 70 to 20% until day 13, after which by day 20 the retinal detachment was up to 40%. The TA–5-FU codrug in suspension is more hydrophobic and provided considerably longer sustained release in vitro than the more soluble DEX–5-FU codrug. The TA–5-FU suspension reduced the incidence of retinal detachment from 89 to 30% from day 14 until day 28. Corelease occurs in two steps. The first step, codrug dissolution, is determined by the solubility of the compound and is the rate-determining step. The second step, codrug hydrolysis, occurs rapidly. This may explain why the more hydrophobic drug was the more effective in inhibiting experimental PVR.

In another investigation by Guo (262), an intravitreal device composed of the prodrug acyclovir–flurbiprofen was developed for the treatment of acute retinal necrosis (ARN), a disease that is accompanied by severe vasculitis. Treatment of inflammation can cause difficulty as steroids may induce a flare of viral activity. In AIDS-associated ARN, patients frequently respond poorly to systemic acyclovir, necessitating intravitreal injections. However, the damaged blood–retinal barrier enhances the clearance of acyclovir, requiring more frequent drug administration. A system capable of maintaining sustained therapeutic levels of acyclovir and flurbiprofen would thus be a real advantage. Pellets of codrug released both parent drugs in vitro following a zero-order kinetics. The release rate increased in the presence of proteins and enzymes. Bearing in mind that inflammation can elevate ocular protein concentrations by a factor of 10, this would result in accelerated drug release from this codrug system. The codrug delivery system may therefore form the basis of a disease-regulated delivery system, increasing release rate to match the severity of the condition and then decreasing to preserve the life span of the device (262).

CONCLUSION

In the past, most intraocular diseases, including sight-threatening endophthalmitis, devastating CMV retinitis, proliferative vitreoretinopathy, and uveitis, were treated by systemic and subconjunctival administration of drugs. These routes of treatment led, in the majority of cases, to the loss of the eye owing to the poor penetration of the various drugs into the vitreous cavity. This can be explained by the tight junctional complexes that interconnect cells of the retinal pigment epithelium and also tightly bind together the endothelial cells forming the walls of the retinal capillaries. These surfaces form the so-called blood–retinal barrier and prohibit passage of substances across the cells. In diseases such as endophthalmitis, the inflammation breaks down this barrier, but at this stage of the disease the retina has already been irreversibly damaged. The means of bypassing physiological and anatomical barriers and achieving high vitreous concentrations is through intravitreal administration. The use of intraocular drugs had formerly been restricted to the treatment of endophthalmitis. Nowadays, it is also considered for disorders that have been described in this article such as CMV retinitis, proliferative vitreoretinopathy, and uveitis. All these clinical conditions require frequent and repeated intravitreal injections of drugs, which may cause severe complications such as retinal detachment, vitreous hemorrhage, or intraocular infections. That is why sustained delivery systems have been developed recently to prolong the therapeutic levels of these drugs in the vitreous and thus diminish the frequency of the injections. This article has reviewed some of these systems (Table 10).

Biodegradable polymers have an advantage over other controlled-release systems in obviating the need to surgically remove the drug-depleted device. Potentially, biodegradable matrix systems also enjoy a number of other advantages in terms of simplicity in design and predictability of release if the latter is controlled solely by the erosion of the matrix. In many cases, however, the release occurs also by diffusion through the matrix, making the process more difficult to control—particularly if the matrix is hydrophilic and thereby absorbs water, promoting degradation in the interior of the matrix. To maximize control over the release process, it is desirable to have a polymeric system

velopment of PVR in a rabbit model. The codrugs are composed of an antimetabolite, 5-FU, covalently linked to a corticosteroid, dexamethasone (DEX) or triamcinolone acetonide (TA), by a carbonate bond (Fig. 13). After synthesis of the codrugs by chemical reaction, the authors prepared pellets by direct compression of the DEX–5-FU powdered codrug and a suspension of the TA–5-FU codrug. The DEX–5-FU pellet released the drugs over 1 week in vitro. Using an experimental model of PVR in rabbits, the authors implanted the pellet intravitreally and observed a reduction of the incidence of retinal detachment from 70 to 20% until day 13, after which by day 20 the retinal detachment was up to 40%. The TA–5-FU codrug in suspension is more hydrophobic and provided considerably longer sustained release in vitro than the more soluble DEX–5-FU codrug. The TA–5-FU suspension reduced the incidence of retinal detachment from 89 to 30% from day 14 until day 28. Corelease occurs in two steps. The first step, codrug dissolution, is determined by the solubility of the compound and is the rate-determining step. The second step, codrug hydrolysis, occurs rapidly. This may explain why the more hydrophobic drug was the more effective in inhibiting experimental PVR.

In another investigation by Guo (262), an intravitreal device composed of the prodrug acyclovir–flurbiprofen was developed for the treatment of acute retinal necrosis (ARN), a disease that is accompanied by severe vasculitis. Treatment of inflammation can cause difficulty as steroids may induce a flare of viral activity. In AIDS-associated ARN, patients frequently respond poorly to systemic acyclovir, necessitating intravitreal injections. However, the damaged blood–retinal barrier enhances the clearance of acyclovir, requiring more frequent drug administration. A system capable of maintaining sustained therapeutic levels of acyclovir and flurbiprofen would thus be a real advantage. Pellets of codrug released both parent drugs in vitro following a zero-order kinetics. The release rate increased in the presence of proteins and enzymes. Bearing in mind that inflammation can elevate ocular protein concentrations by a factor of 10, this would result in accelerated drug release from this codrug system. The codrug delivery system may therefore form the basis of a disease-regulated delivery system, increasing release rate to match the severity of the condition and then decreasing to preserve the life span of the device (262).

CONCLUSION

In the past, most intraocular diseases, including sight-threatening endophthalmitis, devastating CMV retinitis, proliferative vitreoretinopathy, and uveitis, were treated by systemic and subconjunctival administration of drugs. These routes of treatment led, in the majority of cases, to the loss of the eye owing to the poor penetration of the various drugs into the vitreous cavity. This can be explained by the tight junctional complexes that interconnect cells of the retinal pigment epithelium and also tightly bind together the endothelial cells forming the walls of the retinal capillaries. These surfaces form the so-called blood–retinal barrier and prohibit passage of substances across the cells. In diseases such as endophthalmitis, the inflammation breaks down this barrier, but at this stage of the disease the retina has already been irreversibly damaged. The means of bypassing physiological and anatomical barriers and achieving high vitreous concentrations is through intravitreal administration. The use of intraocular drugs had formerly been restricted to the treatment of endophthalmitis. Nowadays, it is also considered for disorders that have been described in this article such as CMV retinitis, proliferative vitreoretinopathy, and uveitis. All these clinical conditions require frequent and repeated intravitreal injections of drugs, which may cause severe complications such as retinal detachment, vitreous hemorrhage, or intraocular infections. That is why sustained delivery systems have been developed recently to prolong the therapeutic levels of these drugs in the vitreous and thus diminish the frequency of the injections. This article has reviewed some of these systems (Table 10).

Biodegradable polymers have an advantage over other controlled-release systems in obviating the need to surgically remove the drug-depleted device. Potentially, biodegradable matrix systems also enjoy a number of other advantages in terms of simplicity in design and predictability of release if the latter is controlled solely by the erosion of the matrix. In many cases, however, the release occurs also by diffusion through the matrix, making the process more difficult to control—particularly if the matrix is hydrophilic and thereby absorbs water, promoting degradation in the interior of the matrix. To maximize control over the release process, it is desirable to have a polymeric system

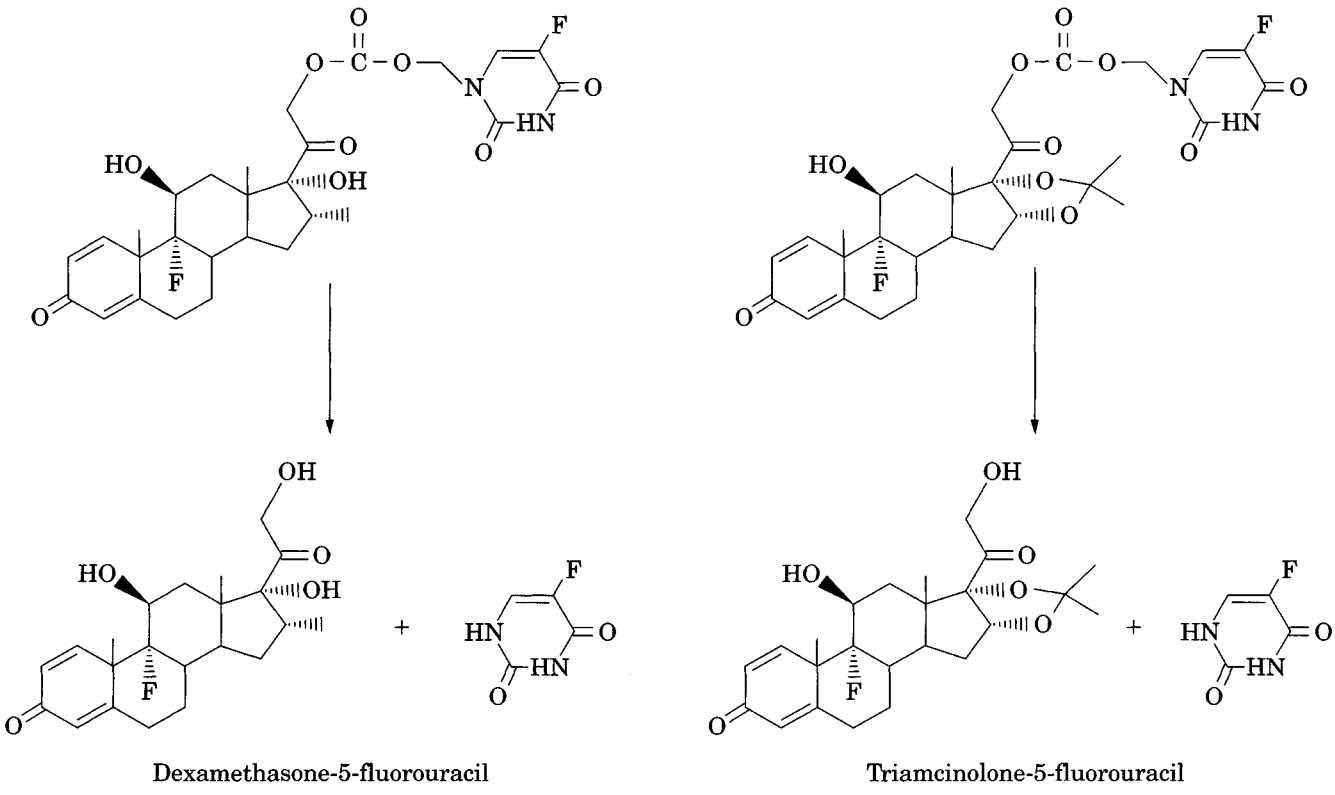

Figure 13. Chemical structures of dexamethasone–5-fluorouracil and triamcinolone–5-fluorouracil codrugs and hydrolysis to the parent drugs. *Source:* Ref. 261.

that degrades only from the surface and delays the permeation of drug molecules. Achieving such a heterogeneous degradation requires the rate of hydrolytic degradation on the surface to be much faster than the rate of water penetration into the bulk. The ideal polymer would have a hydrophobic backbone but with a water-labile linkage. Many classes of polymers have been designed with these considerations in mind. Among them, polyanhydrides and POEs erode from surface. Taking advantage of the pH dependence of the rate of ortho ester cleavage, preferential hydrolysis at the surface is obtained by either addition of basic substances to suppress degradation in the bulk or incorporation of acidic catalysts to promote degradation on the surface.

Devices that are not biodegradable such as the EVA–PVA implants are of clinical utility for chronic, sight-threatening diseases such as CMV retinitis and uveitis. These conditions are likely to require long-term drug therapy; therefore, any device may need to be replaced once depleted of drug. On the other hand, in diseases such as PVR, which requires relatively short-term therapy (weeks or months), a biodegradable system is clearly more desirable.

Microspheres and liposomes have been shown to increase the efficacy, reduce the toxicity, prolong the activity, and provide site-specific delivery for many drugs when administered to the eye. However, liposomes tend to have a short shelf life and to migrate within the eye (possibly to unwanted locations) following intraocular injection. Furthermore, the intravitreal injection of a liposome preparation always disturbs the patient's vision. Microspheres are more stable, their production is reproducible, and the release rate is controllable; but the injection of microspheres in the vitreous is always followed by an impairment of the visual acuity.

Transscleral iontophoresis has proved to be fast and painless and in most cases results in the delivery of a high and long-lasting vitreal concentration of the drug. However, several authors have noticed damage to the retina such as burns and disorganization of the retinal cell layers. These lesions are probably as harmful as those created by an intravitreal injection or surgical implantation of a sustained-release drug delivery device.

The prodrug or codrug approach, on the other hand, is a good method of providing sustained release of one or more drugs. The main advantage of this system is the absence of any polymeric material that might cause problems of biocompatibility.

The ideal drug release system should then fulfill the following criteria: (*1*) the systems should provide a sustained therapeutic concentration of drug in a reliable and predictable way over an adequate period to obtain the desired clinical response: inhibition of the inflammation or prevention of proliferation and contraction of epiretinal membranes in the case of proliferative vitreoretinopathy; (*2*) the concentration of drug should be relatively uniform over the administration period, with no early or late excessive release of the drug; (*3*) the device should be easily

Table 10. Advantages and Drawbacks of the Drug Delivery Systems Described in this Article

Pros	Cons
Biodegradable polymeric systems	
No need to be removed	Possible toxicity of breakdown products
No impairment of the clarity of ocular media	Rapid degradation
For *short-term* therapy (weeks to months)	Often sterilization problems
Controllable release rates	
Eventually injectable through a needle	
Nonbiodegradable polymeric systems	
No degradation products	To be removed after depletion
No impairment of the clarity of ocular media	Risk of encapsulation
For *long-term* therapy (months to years)	
Controllable release rates	
Nanoparticles, microspheres	
Injectable through needle	Vitreal haze after injection
Long shelf life	Initial burst effect
Good control over release	
Liposomes	
Good biocompatibility	Vitreal haze after injection
Reduction of drug toxicity	Short shelf life
Injectable through needle	Difficult to sterilize
Iontophoresis	
Noninvasive	For ionized drug
	Damages to the eye (burns)
Prodrugs and codrugs	
Concomitant equimolar release of both drugs from the codrug	No tailored release from the codrug
No need for polymeric carrier material	
Good tolerance	

implantable or injectable but must remain stable and nonmigratory within the eye; (*4*) the device should be totally biodegradable to avoid the need for explantation at a later date; (*5*) the device should have a long shelf life, should be easily handled by surgeons and operating room personnel, and should be easily sterilized; and (*6*) there should be no toxic effect from sustained exposure to the drug or degradation products of the device.

None of the sustained-delivery systems introduced to date fulfill all these criteria. Yet all of the exciting approaches described in this article may lead to the improvement of vision in patients with severe posterior segment diseases.

INTRODUCTION

This article intends to update the state of the art of nasal drug delivery from a pharmaceutical and technological point of view. Many important contributions can be found in literature on the subject, focusing on different aspects of interest to researchers, such as the Proctor edited book (1), the edited and directly contributed books of Chien (2,3), and the reviews of Illum (4), Wilson (5), Edman (6), Merkus (7), Gizurarson (8), Duchene (9), Harris (10), Buri (11), and Alpar (12).

A Nasal Drug Delivery Focus Group, organized in an American Association of Pharmaceutical Scientists section (13), has also been constituted as well as an Open Forum for free exchange and information in all R and D areas ranging from the formulation to the marketing of nasal preparations.

NASAL DELIVERY: HISTORICAL AND BEHAVIORAL USE

New materials and new technologies have stimulated pharmaceutical researchers to identify and use alternatives to the classical oral and injectable routes. One of the routes currently being studied is the nasal way, even though the physiological evolution of the nose followed the olfactive and respiratory necessity to provide humid, warmed, and filtered air for the lungs. In fact, nasal mucosa evolved in order to have a wide surface, large blood supply, and efficient filtering system. Because the mucosa is often affected by various diseases that alter its functionality, the first nasal drug delivery system was for restoring normal nasal conditions. Man discovered the possibility of using nasal mucosa for absorbing substances giving systemic effects. Unfortunately, the most convincing examples of systemic effects obtained by administering active principles inside the nose were those which misused the nose, such as the behavioral habit of sniffing cocaine or tobacco. An instructive behavioral employment of the nose for drug absorption, usually in order to have hallucinations or more general mental effects, is the religious rite of the Amazonian population of Yanomamo to assume *epenà*, that, is a powdered mixture of different plant parts like *Mimosa acacioides*, *Piptadenia peregrina*, and others not identified (14). The interest of this rite for pharmaceutical researchers is linked to the administration devices the natives use in order to deposit the powdered drug in the nose (Fig. 1). The devices consist of an insufflator having the form of a long linear pipe activated by an assistant or, alternatively, a Y-shaped curved tube which allows for self-administration. These "medical devices" focalize the typical aspect of nasal delivery that is the need for a nebulizer or an insufflator for depositing solid or liquid formulations into the nose.

All these uses, or misuses, of the nose for systemic drug delivery have provided a lot of important information as to the employment of the nasal route for therapeutically drug delivery. The effects, and in particular, the toxicity manifested by the mucosa in response to drug deposition are of paramount importance for setting the therapeutical delivery of drugs in terms of safety and efficacy. From these experiences it is worthwhile underlining some aspects that are particularly useful for the design of therapy and dosage form for the nose. The rapid onset of the effect is linked to high mucosa permeability and indicates using the nose for therapies requiring prompt response. Then, the maniacal use of the nose because of the effects involving the brain opens the possibility of directly reaching the brain after deposition on the olfactory mucosa. Finally, the fact that drugs are successfully administered in powder form increases the formulation possibilities for designing the appropriate dosage form.

ANATOMY AND PHYSIOLOGY OF THE NOSE

The nose is characterized by two nasal cavities, separated by a septum and divided into three main regions: vestibule (nostril), atrium (or preturbinate region), and turbinate region (15). The last region is composed of an olfactory upper part and of two respiratory medium and lower parts that join together in the rhinopharynx. The turbinate region is characterized by cornets and meati, gaps situated between cornets and the nasal external part. The nostrils are the entry of the nasal cavity.

The nose presents sensitive, vegetative, and sensorial nervous conduction. The trigeminal nerves respond to al-

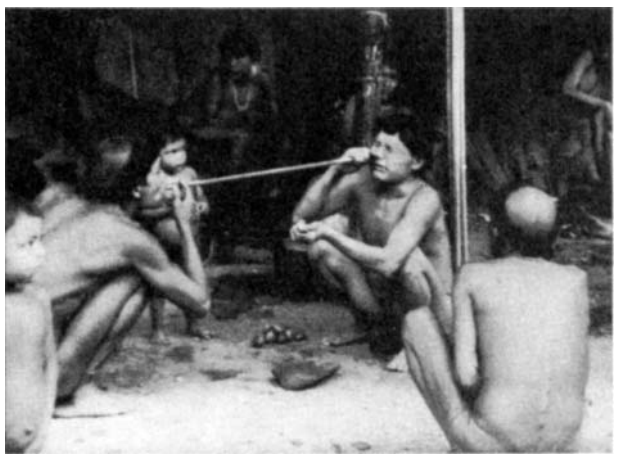

Figure 1. Yanomano Indian tribe using the insufflator pipe for *epenà* nasal administration.

lergic stimulus causing sneezing; the vegetative system provides secretory and vasomobility functions, and particular elements of the olfactory mucosa control the activity of sensorial nerves.

Nasal cavities are covered by respiratory mucosa that, within the nostrils, is characterized by a stratified, squamous and keratinized epithelium, with hairs, called vibrissae. Beyond the limen nasi, the epithelium loses its keratin cover and becomes the respiratory mucosa with pluristratified cylindrical epithelium. It is provided with vibratile cilia and other mucus secreting cells. Goblet cells and submucosa glands produce a high amount of mucus, which is the protective barrier against external agents. The continuous film of mucus is structured in two layers: the lower one is smooth with low viscosity, the upper one is more viscous and elastic and moves following the cilia movements.

The nose, which has an extensive vascular network, has two main functions: the sense of smell given by the olfactory mucosa and the inspired air conditioning by purification, heating, and moisture regulation. The greatest particles are removed by the vibrissae of the vestibule. Other particles are removed by the anatomic structures of the nasal cavities. The combined action of the cilia and mucus layer is called mucociliary clearance, an important defense mechanism against inhaled dust, allergens, and microorganisms. The coordinated beating of the cilia results in the movement of the upper mucus layer towards the nasopharynx, where it is swallowed. Finally, there is an air flow control because the respiratory air volumes are monitored by the cornets, which alternatively change their volume, giving a variable resistance to the breathed air.

TOXICOLOGICAL CONSIDERATIONS

The poor nasal bioavailability of many substances (in particular, peptide and protein drugs) can be substantially improved by the use of absorption enhancers. The acceptability of these enhancers is not only dependent on their promoting effect but also on their safety profile for systemic and local adverse effects (16–21). Nasal drug formulations must not alter the histology and physiology of the nose in the sense that the mucosa must retain its functionality as a barrier toward external substances and microorganisms. In any case, damage induced must be reversible. The histological toxicity refers to the alteration of mucosa, including membrane protein removal, cell loss, excessive mucus discharge, ciliotoxicity, and disturbance of the normal enzymatic balance (22,23). In addition, the dosage form and its components should not interfere with the mucociliary clearance.

Various methods have been used to test the toxicity of drugs and additives on the nasal mucosa and the mucociliary system. Traditionally, histopathological examination of a prefixed membrane specimen by light and scanning electron microscopy is regarded as the indicator of cytotoxicity. These methods suffer from inspector subjectivity and the impossibility of highlighting subtle changes in nasal mucosa and do not provide the nasal sensitivity tolerance measurement in response to a particular formulation. Therefore, in order to determine minute changes occurring in the mucosal tissue due to exposure to formulations, a biochemical approach has been developed (24). The extent of the release of total proteins, although not very specific as to the type of damage, provides a general indication about the extent of irritation.

The release of enzymes lactate dehydrogenase (LDH) and 5′nucleotidase (5′-ND), directly indicate the extent of damage suffered by the mucosa. Membrane-bound 5′-ND release in the nasal perfusate gives an indication of the level of membrane perturbation, whereas the cytosolic enzyme LDH indicates cell leaching and/or lysis (25).

Mucociliary transport and clearance interferences can be measured in vivo (26,27) or in vitro (28). Determination of ciliary beat frequency in vitro has been carried out on explants of ciliated mucosa from human adenoid tissue (29), from the trachea of different animal species (30,31), or from chicken embryo trachea (32). The frog palate preparation as an ex vivo model for the mucociliary transport velocity study has also been proposed for the indication of topical tolerability of different substances (33). Effects on the ciliary beat frequency detected in vitro may be more pronounced than the influence in vivo. In vitro experiments directly expose ciliated epithelia to test solution, whereas in vivo the cilia are protected by mucus (34). Therefore, in vitro ciliary beat frequency tests should be used as indicators for potential damage to nasal epithelium, rather than proof of such damage occurring in the in vivo situation. One of the best known in vivo tests is the saccharin transit time, i.e., the time required for the subject to taste a saccharin particle placed on the inferior turbinate of the naris (35). However, the most powerful method used for measuring the deposition and clearance of drugs in the nasal cavity remains scintigraphy.

DOSAGE FORMS AND MATERIALS

Nasal dosage forms consist of preparations containing dispersed or dissolved drugs, filled in a container designed to be squeezed or spray activated (36). The aim of delivery is to deposit the formula on the mucosa and coat the available surface, in particular the respiratory part, which is the major absorption site for drugs. Other therapeutic situations must require a localized accumulation of the product in certain districts of the nasal cavity. This can be achieved through an appropriate design of the insufflator and of the formulation to produce a fine dispersion of droplets or particles capable of sticking to the mucosa (37). This avoids the coalescence of the mist with a backflow of product and limits a fast transport to the pharynx by mucociliary clearance. Therefore, dispersion pattern and bioadhesion are the two key factors to be considered during the development phase of the formulation.

At present, the application of the product by spraying is very elegant and accepted. Therefore, the objective of formulation design is to obtain an aerosol useful for inspiration and deposition in the upper airways. In the past, drops were often instilled in the nose, but the advancement of insufflator technology has made this form obsolete and limited to pediatric use or to patients less able to perform

the insufflative maneuvers. Liquid preparations are common dosage forms for nasal delivery. Because the nasal epithelium is essentially a lipophilic transport barrier, transnasal transport is related to the nasal mucosa tissue–water partition coefficient, suggesting also an important role of the stereochemical conformation during membrane transport (38). Therefore, aspects such as formula pH, ionic strength, surface active agents, viscosity, and drug concentration have to be considered in order to facilitate the transport (39). However, from a technological point of view, the liquid preparations present problems linked to formula stability, low drug concentration at the absorption site, and short residence time in nasal cavity.

These drawbacks accelerated the development of nasal powders as alternative nasal dosage forms with improved chemicophysical and microbiological stability. Furthermore, drug dissolution on nasal mucosa provides elevated drug concentration at the deposition site, giving rise to a high flux of active ingredient. In many cases the superiority of nasal powder compared with nasal liquid was demonstrated, in particular with peptidic drugs (40–42). Administration of powders requires a nasal insufflator for dose emission and deposition of particles in the nose. It has been assessed that the site and pattern of inhalatory powder deposition in the respiratory tract are affected by the aerodynamic properties of the powder (43). Moreover, the formalities of dose delivery control the deposition mechanisms, i.e., inertial impacting, sedimentation, and diffusion. It could be postulated that efficient nasal delivery of powder from a spraying device requires impacting with adhesion and/or sedimentation of particles on nasal mucosa; therefore, powder properties such as particle size, shape, surface, density, and flow must be optimized to activate the proper mechanism for therapeutic treatment. The number of drugs directly administrable to the nose in powder form is limited because of unsuitable characteristics such as large particle size, low solubility, poor absorption, and irritability. These limits can be overcome through the use of a suitable solid excipient as carrier. Such a carrier must be compatible, hydrophilic, soluble, and of an aerodynamic particle size favorable to nasal deposition. The most common material used are sugars, β-cyclodextrin, cyclodextrin derivatives, phospholipids, starches, cellulose derivatives, poly(vinylpyrrolidone) and others. Swellable polymers proved very useful as nasal carriers, because the swelling phenomenon was added as a transport enhancing effect. Particle size is the main parameter affecting nasal drug delivery. It was found that powders around 100 μm in size are efficiently delivered in terms of amount and type of delivery, when an insufflator device using a gelatin capsule as reservoir was used (44). In the particle size range between 150 and 50 μm there was an evident change in the insufflation behavior: for size over 150 μm, the spray pattern suggested more favorable conditions for impacting the nasal mucosa; below 50 μm, a more uniform deposition by sedimentation is expected, but the possibility of particle respirability can increase as well. Other formulations used for nasal delivery involve nasal gels; one example is vitamin B_{12} gel, which provides a superior bioavailability compared with oral delivery (45). A scopolamine gel is expected to be filed soon for approval (46).

METERING AND INSUFFLATORS

Devices for nasal delivery differ according to the formulation to be dispensed. Liquid solutions are delivered using metered atomizing pumps, metered-dose pressurized nasal inhalers, rhinal tubes for variable volume delivery, and plastic spray or squeeze bottles (47). Pumps and squeeze bottles operate by mechanical actuation to sample a liquid volume from a reservoir and to produce a mist cloud having the shape of an inverse cone or of a sagittal plume. The use of these devices is usually extensively explained in the product leaflets, and the intervention of a pharmacist for assembling the nasal spray device is often requested.

Quantity dispensed and reproducibility are the major points to be assessed. Pumps, both mechanically or gas actuated, are very precise and accurate in delivery, provided that they are primed according to the indications of the producer. The delivery rate is very fast because emission is usually completed in less that one second. The size of droplets produced with these devices prevents the entrance of the preparation into the lung, and their size and velocity provide an impacting on the nasal mucosa with a distributed deposition. The multidose preparations require preservatives in the solution that can alter the mucosa. Metered unidose insufflator devices are the technological solution to avoiding preservative use. An example of these is reproduced in Figure 2. However, considering that there are two nostrils and that deposition carried out in both nostrils doubles absorption, bidose devices have been developed and marketed both by the Pfeiffer (48) and Valois (49) companies.

Powder delivery requires different types of insufflators, which can be mechanically or respiratory actuated. The user requests are for a small-sized portable device, with high spraying performance and visible feedback, moisture protected and easy to handle. The mechanically designed devices consist of a rubbery bulb connected through the dose reservoir to a nasal adapter (Fig. 3). The squeezing of the rubbery bulb provides a stream of air capable of emitting the appropriately loaded powder in the insufflator. The insufflators designed to be used by breathing through

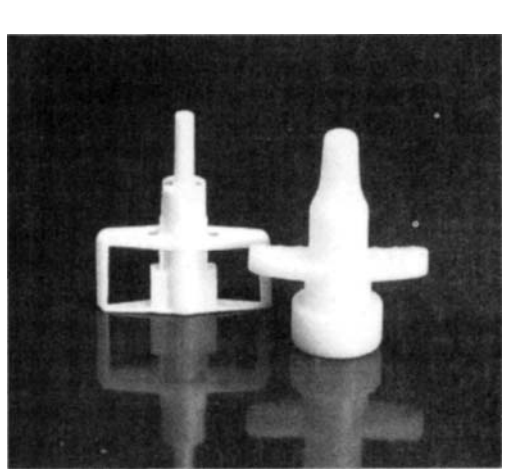

Figure 2. Monospray systems for nasal administration of monodose of liquid formulation (Valois Pharm, France).

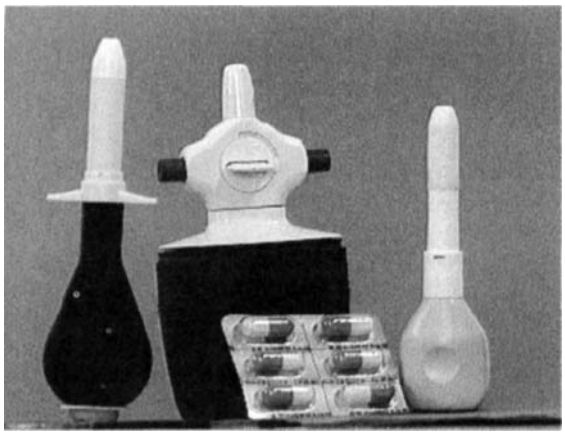

Figure 3. Different insufflators for nasal administration of powdered formulations. From left to right: Rinoflatore® (Fisons, Rome, Italy), Miat Nasal Insufflator® (Miat, Milan, Italy), Puvlizer® (Teijin, Tokyo, Japan).

the nose are a nose adapted version of the dry powder inhalers, designed for lung delivery. With both types of devices, the drug unidose is loaded in a gelatin capsule that is pierced just before activation. Because the capsule is located between the air jet producer and the nose adapter, the air stream that flows through creates a turbulence inside the capsule, capable of aerosolizing and emitting the amount of powder contained. This phenomenon, called "dancing cloud" by the Hovione company (50), causes a complete, gradual, and efficient emission of the powder content of the motionless capsule. The devices loaded with gelatin capsule can deliver different amounts of powder without adversely affecting their behavior (51).

QUALITATIVE AND QUANTITATIVE ASPECTS OF NASAL DOSE DELIVERY

Nasal delivery of a drug requires metering of the dose and its emission by means of a device capable of producing an aerosol suitable for deposition on nasal mucosa. The words *cloud, plume*, or *puff* are used indifferently for indicating the nasal aerosol. The goal of puff production is to appropriately deposit the drug according to the pathology to be treated, which could be for localized or systemic effects. For example, a disease such as rhinitis requires a deposition on the total area of the mucosa, whereas a targeting to the brain would require localized deposition at the roof of the nose. Other therapeutic possibilities require the adaptation of the puff for deposition at different sites.

In any case, nasal delivery of drug involves both qualitative and quantitative aspects of drug delivered. The qualitative aspect refers to the aerodynamic behavior of the cloud produced and is described by the spray pattern and the cloud geometry, whereas the quantitative aspect is linked to the dose of drug sprayed per puff. The qualitative aspect is assessed by photographic technique in order to obtain the sequence of dose emission from the pump or insufflator and to collect information on spray pattern and geometry. Plume shape, height, area, density, particle size, and velocity are the parameters involved in the spray pattern and geometry determination.

In the case of liquid preparations, the qualitative aspect is primarily dependent on the device used for insufflation. The spray geometry in the case of pump metered-dose insufflators or squeeze plastic bottles is totally different. It is not surprising to find that different geometry can result in different bioavailability of the drug. This is probable not only when comparing two different types of nasal insufflators but also in the case of the same type manufactured by different producers. As an example, Figure 4 shows two mists of the same liquid formulation produced using two similar pumps manufactured by different producers. The two preparations were not bioequivalent, because delivery with one pump gave a bioavailability 30% lower than the reference (C. Vecchio and R. Bettini, University of Parma, Department of Pharmacy, personal communication, 1998). Registrative health authorities require for droplet size distribution determination using two different methods, such as laser scattering and cascade impactor. In addition, the spray pattern and plume geometry must be compared for bioequivalence studies.

In the case of nasal powder, the powder cloud, which looks like a plume emerging from a chimney, grows in dimension during emission, with a maximum height and width depending on the characteristics of the product sprayed and the device used. The cloud aspect is mainly dependent on the formulation's characteristics and, particularly, on the fundamental (size and shape) and derived (packing and flow) properties of the powder (44). Using a rubbery bulb insufflator, the clouds originating from small particle size powder are fluffy and homogeneous in density, whereas the clouds obtained from large particle size powders are characterized by visible individual particle trajectories (Fig. 5). The rate of particle delivery decreased with decreasing size, whereas the time needed to completely emit the dose through the nose adapter of the insufflator increased with decreasing size. For nasal impacting, the powder cloud should remain as compact as possible to

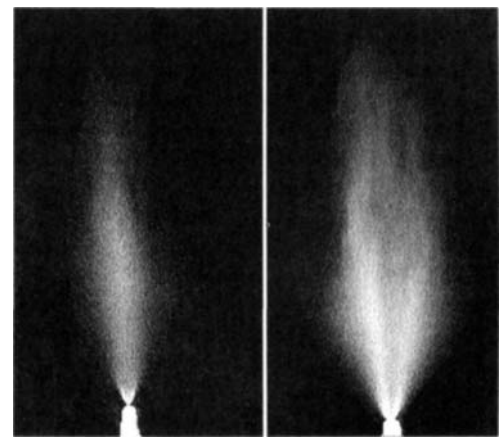

Figure 4. Nasal puffs obtained by spraying the same desmopressin nasal solution through two different metered-dose pumps. Puff (**a**) provided a superior bioavailability compared with puff (**b**). The amounts emitted were not significantly different.

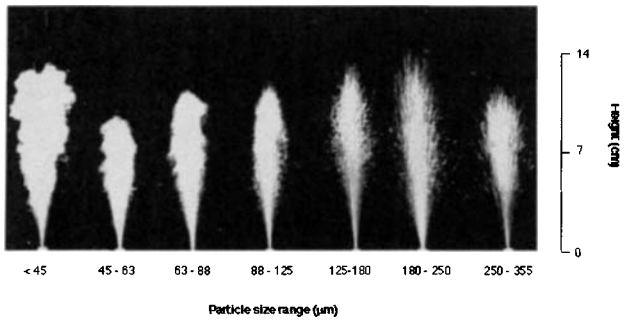

Figure 5. Influence of nasal powder particle size on the puff appearance (Miat Nasal Insufflator).

achieve an efficient shot of powder to the nasal mucosa, whereas for sedimentation a larger cloud would be preferred. The measurement of the expansion area of the axial section of the clouds during emission evaluates the packing of the cloud: as the particle size decreased below 100 μm, the area of the puff increased (44). Serum progesterone levels following nasal administration in rabbits of two powder mixtures containing co-ground progesterone-β-cyclodextrin or co-lyophilized progesterone and β-cyclodextrin showed rapid increase (52). Progesterone co-grounded powder exhibited a significantly higher extent of bioavailability, without a significant difference in rate compared with the co-lyophilized powder. The progesterone-β-CD co-ground powder was ejected by the insufflator at higher speed and as a compact cloud.

The quantitative aspect of nasal delivery is different according to the physical state of the preparation, i.e., liquid or solid, and it is largely dependent on the type of device used for spraying. In the case of liquid preparations, there are obviously different delivery behaviors according to the device used. Metered pumps are designed for delivering a very precise and accurate amount of nasal solution. The alternative, the squeeze bottle, suffers from a strong dependence on the energy used in squeezing the bottle in order to emit the dose. Therefore, the device affects the accuracy of delivery. As an example, a solution of xylometazoline was delivered in different amounts from squeeze bottle by different patients. Figure 6 shows the behavior of successive sprays performed by male or female patients: it is evident that the males exert more strength in spraying than females, because they sprayed out more product per shot. The same solution charged in a metered pump device is less dependent on the varying strength of the patient, as Figure 6 shows as well. Finally, metered pumps are regularly used in prescription preparations, and the squeeze bottle is the choice for over-the-counter preparations.

The quantitative aspect of a nasal solution filled in multidose reservoir is first tested by the labeled number of sprays that must be available using the preparation completely. It is also required that the number of priming operations to be performed before the device is ready for use should be declared. After this preliminary characteristic, the content uniformity per spray is a regulatory requisite. This must be checked from dose to dose, from container to container, and from batch to batch, considering

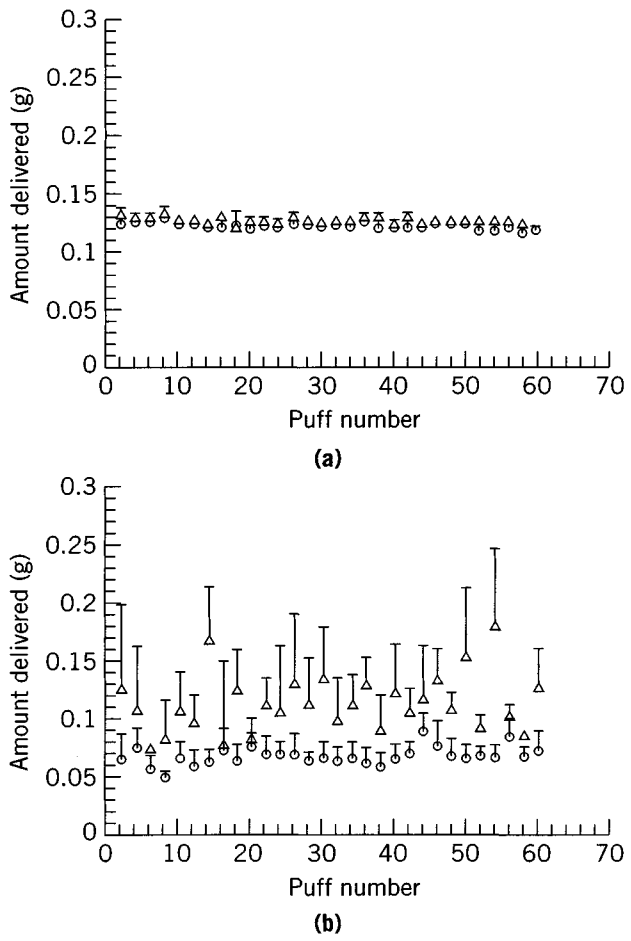

Figure 6. Differences between women (○) and men (△) in delivering the same xylometazoline nasal solution from (**a**) metered-dose pump and (**b**) squeeze bottle.

that the accepted variability is established between 85 and 115% of the labeled dose.

Nasal inhalation powders are delivered using insufflators that generally work on a unidose basis. The drug is dosed in a hard gelatin capsule and the capsule is loaded and pierced in the insufflator. The production of the puff is done by squeezing the rubbery bubble that produces the air stream necessary for nebulizing the powder. The dimension of the rubbery bubble determines the amount of the emitted powder and the complete delivery of the dose from the capsule. This aspect is strictly dependent on the properties of the formulation inside the capsule. Successive generations of powder insufflators were proposed with the aim of allowing depositing the dose in the two nostrils. This quantitative problem was solved by using insufflators that have a small bubble, so determining the need to squeeze the bubble many times to completely emit the amount loaded into the capsule, alternating the nostril involved in the insufflation. The amount of dose emitted by this sequence of insufflation is reported in Figure 7, where it can be appreciated that the successive squeezing allow sharing the amount deposited in the two nostrils and the delivery depends on particle size of powder.

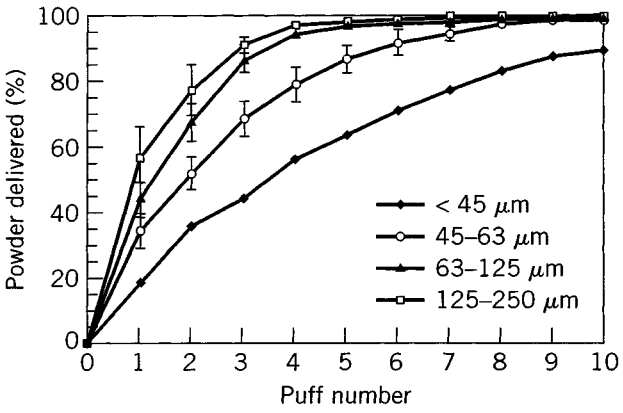

Figure 7. Cumulative percentage of nasal powder delivered from Puvlizer nasal insuffiator as a function of the puff number (powder loaded; 25 mg).

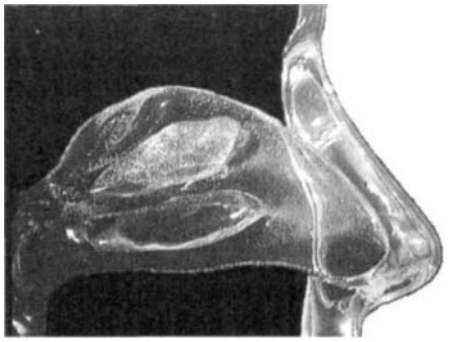

Figure 8. Powder deposition in the left section of the artificial nasal cavity showing a large coating of atrium and superior cornet.

Deposition of emitted dose in the nasal cavity was studied using various techniques both in vivo and in vitro. Scintigraphic techniques are the most powerful for determining the site of dose deposition and were used to show the influence of dosage form and device. One of the first papers published on the subject compared in vivo the sites of deposition and the patterns of clearance following intranasal administration of nasal spray and nasal drops. It was found that spray was deposited anteriorly in the nasal cavity, with little dose reaching the turbinates, whereas drops dispersed the drug throughout the length of the cavity. A substantial difference was also observed in terms of clearance, evidentiating that the spray was cleared more slowly (53).

Technological tests of pattern deposition have been suggested by health authorities and consist of spraying the product against a flat surface, such as a Kieselgel sheet, to highlight the printing of the droplets sprayed by the pump. This test is requested as quality control and must be effected using the same device at two distances from the sheet, in order to have a printing of the distribution of droplets at different levels of cloud. In vitro studies were also done using a cast of the human nose. A significant difference was observed among the deposition of liquid solution applied by a drop bottle, a squeeze bottle, a metered pump, and a pressurized inhaler. This study also provided indications on the method of delivery, because it was observed that in the case of pressurized aerosols, a double delivery in each nostril effected in different directions provided better distribution of the product (54).

Few data are available concerning the deposition of powder in the nose (55). The requisite particle size for nasal deposition has been stated as less than 10 μm (1). An unpublished work correlated the deposition pattern in a silicone cast of the human nose with the particle size of the powder sprayed. It was found that atrium deposition was predominant independently of particle size (Fig. 8). Other authors have investigated the use of a glass model of the nasal cavity, without the turbinate presence, to estimate nasal deposition (56, 57). Recently, using a silicone model including the turbinate structure, good nasal deposition was obtained despite the fact that the particle size measured with aerodynamic methods was less than optimal. The model with turbinates gave higher deposition in the nasal cavity, as well as reducing the fraction penetrating the nose (58).

PENETRATION ENHANCERS AND BIOADHESION

A drug given by the nasal route is absorbed very quickly, entering the bloodstream similarly to an injection. Therefore, the nasal route must be primarily considered for rapid effect. However, this effect is also transient, because the efficient clearance mechanisms of the nose rapidly activate as well, so limiting the absorption time. Therefore, employing nasal delivery for prolonged release requires the development of particular strategies in order to keep the substance on the mucosa for a long time without altering the functionality of the nose.

Mucociliary clearance is the most significant physiological factor that affects nasal drug absorption, because it determines the time a drug remains at the absorption site. Some pathophysiological conditions, such as rhinitis, the common cold, hay fever, sinusitis, asthma, and nasal polyposis, may affect the retention of drugs in the nasal cavity. Environmental factors such as humidity, temperature, airborne toxins and chemicals, and many pharmaceutical excipients may also affect the clearance (59, 60). In order to achieve high absorption with only minimal effects on the mucociliary mechanism, the absorption process must be rapid, preferably within the first 15 minutes after administration (61). If the rate of clearance could be slightly decreased or halted in a reversible manner, then such retardation would be useful in increasing the contact time between the active drug and nasal mucosa, thereby increasing bioavailability.

Nasal mucosa allows effective absorption of a variety of lipophilic drugs and hydrophilic drugs, such as peptides and proteins (62). The major difficulty in administering those drugs intranasally is their low nasal bioavailability due to enzymatic degradation, mucociliary clearance, and poor mucosal membrane permeability. The attempts made to overcome these problems include coadministration of absorption enhancers and/or mucoadhesive substances.

The influence of the enhancers on the absorption of the drug across the nasal membrane is related to a direct effect on the drug and/or to an influence on the mucosa. For some drugs the solubilizing or stabilizing effect is of major importance. With regard to mucosa, enhancers may act by alterating the properties of the mucus layer, by opening the tight junctions between epithelial cells, increasing membrane fluidity, creating disorders in the phospholipid of membrane, and facilitating the leaking of proteins and lipids from the membrane. The improvement of peptide and protein absorption is probably due to one or a combination of these mechanisms.

The most evaluated compounds as enhancers are surfactants (laureth-9), bile salts (glyco-taurocholate, deoxycholate), chelators (EDTA, citric acid), fatty acid salts (oleic, caprylic, capric, and lauric), phospholipids (L-α-lysophosphatidylcholine [DDPC], didecanoyl-PC), fusidates (sodium taurodihydrofusidate, STDHF), glycyrrhetinic acid derivatives (carbenoxolone, glycyrrhizinate), cyclodextrins (α-, β-, γ-cyclodextrins), hydroxypropyl-β-cyclodextrin and dimethyl-β-cyclodextrin (DMβCD), randomly methylated β-cyclodextrin (RAMEB), chitosan, and particulate carriers (microcrystalline cellulose, starch microspheres, and liposomes).

Nasal absorption enhancers differ substantially in efficacy and safety. Bile salts, surfactants, Ca^{2+} chelators and STDHF have been assumed to increase nasal drug transport, but they have shown morphological damage and severe inhibition of nasal ciliary movement. In vivo laureth-9 and sodium deoxycholate are associated with nasal irritation, and STDHF leads to painful stinging and lacrimation (1). Calcium chelators penetrate into the cells where they interact with intracellular Ca^{2+}, causing severe damage or even cell death. Therefore, research has been focusing on new classes of promoters of nasal drug absorption. Controlled studies in humans using medium-chain phospholipid DDPC as insulin enhancer have shown that nasal mucosal physiology was unaffected after intranasal administration, but that insulin bioavailability was low, despite intranasal doses about 20 times higher than subcutaneous doses (63). Cyclodextrins (CDs) are cyclic oligosaccharides showing a polar outer surface and an apolar interior cavity able to include lipophilic guest molecules. CDs can enhance lipophilic drug absorption by solubilization and protection against physicochemical and enzymatic degradation. Thus, CDs are also able to enhance hydrophilic drug absorption by the extraction of specific lipids from biological membranes, leading to an increase in membrane permeability and fluidity. The extent of protection and absorption enhancement seems to depend strongly on the nature of the drug used as well as on the CD used. For example, in vivo studies in rats have demonstrated that the addition of 5% α-CD to a nasal preparation of insulin resulted in an absolute bioavailability of approximately 30%; on the contrary, β- and γ-CDs did not affect insulin absorption. However, DMβCD gave rise to a large increase in insulin absorption, with a bioavailability of 100%. In contrast to the result obtained in rats, experiments in rabbits and human volunteers showed no absorption-enhancing effect of CDs for insulin, with a bioavailability of approximately 3–5% (64). Studies in rabbits have concluded that α-CD is able to increase nasal absorption of human growth hormone (hGH). In fact, it has been seen that the presence of 30% α-CD in a powder formulation of hGH raises the nasal bioavailability from 8% to 23–25% (65). RAMEB enhanced dihydroergotamine (DHE) nasal absorption when administered by liquid and powder formulations including CD (RAMEB:DHE ratio 10:1), showing a bioavailability of 50% and 56%, respectively (66).

New compounds recently studied, chitosans are biodegradable high weight cationic polysaccharides. Their mechanism of transport enhancement is a combination of bioadhesion and transient opening of the tight junctions in the membrane. The cell-binding activity of chitosans is related to electrostatic interactions between cell surfaces charged negatively and the cationic polyelectrolyte structure. Chitosans have no arresting effect on the mucociliary clearance, and they do not cause significant changes in nasal mucosa histology. Medium molecular weight chitosans are able to enhance the nasal absorption in animals and human volunteers of polypeptides and other polar drugs, such as insulin, salmon calcitonin, and morphine metabolites (67). Because rapid mucociliary clearance decreases the time of drug contact with the absorbing regions of nasal mucosa, the use of compounds having bioadhesion properties has been revealed as very efficient in overcoming this problem. It has been shown that formulations including bioadhesive materials are retained in the nasal cavity with half-life clearance of 3 h or longer, compared with 15–20 minutes for usual formulations (68). Mucoadhesives are synthetic or natural polymers that interact with the mucus layer. Recently, bioadhesive microspheres based on materials such as starch, albumin and Sephadex, with particle sizes of 40–60 μm, have been developed. Starch microspheres are able to increase considerably the nasal absorption of insulin in rats and sheep, and of hGH and salmon calcitonin in sheep (69,70). The absorption enhancement by starch microspheres is not only related to their mucoadhesive properties but also to their capability of opening tight junctions by the dehydration of mucosal cells. The use of degradable starch microspheres as a nasal delivery system for hGH resulted in an increase of plasma peak height from 1.0 to 9 ng/mL and of area under the curve (AUC) from 28 to 892 ng min/mL, with a relative bioavailability of 2.7%.

Other bioadhesive polymeric systems have also been used in nasal peptide drug delivery (71). Microcrystalline cellulose was suggested to provide prolonged residence time due to its insolubility (41). Recent studies concluded that the absorption-enhancing effect of particulate carriers correlates directly with their Ca^{2+} binding capacity. In fact, the opening of the tight junctions may also be explained by a local decrease in Ca^{2+} concentration (72). There are many ongoing investigations to improve nasal bioavailability by a combination of microcrystalline cellulose (MCC) with permeation enhancers (sodium taurocholate [ST], ammonium glycyrrhizinate [AG], and glycyrrhetinic acid [GA]). Insulin absolute bioavailability from a 1.5% w/v suspension resulted in 1.96%. The presence of ST, AG, and GA in the MCC suspension provided bioavailabilities of 8.36, 7.83, and 2.15%, respectively. Thus, the combination of a bioadhesive polymer and permeation

relatively nontoxic enhancers can be of promising potential for developing a nasal spray formulation for peptide drugs (73).

Finally, liposomes are attracting considerable interest for drug delivery to nasal mucosa. In fact, they are known to sustain the release of the entrapped drugs and to decrease the mucociliary clearance of the drugs due to their surface viscosity. Their action on nasal mucosa is related to the incorporation of phospholipids in the membrane, opening "new pores" in the paracellular tight junction (74). Proliposomes, i.e., a free-flowing powder immediately forming a liposomal dispersion on adding water, have also been manufactured for nasal delivery with the intention of sustaining the delivery of propanolol through nasal mucosa (75).

DRUGS DEVELOPED FOR NASAL ADMINISTRATION

Nasal preparations for local effect have been available over-the-counter for a long time. Recently the nose was considered for delivering drugs with systemic effects, and appropriate products were marketed. The products described here, delivered under prescription, are examples of systemic effect nasal preparations and include also some relevant products for topical effect. Oxytocin and nafarelin nasal sprays have not been reviewed.

Butorphanol

Butorphanol is a potent synthetic mixed agonist-antagonist opioid analgesic. Butorphanol is well absorbed orally, but due to extensive first-pass metabolism, oral bioavailability is very low. Alternative nonparenteral routes of administration, such as transnasal, sublingual, and buccal have been developed. The biopharmaceutical evaluation of the transnasal formulation discovered significant advantages over sublingual and buccal formulations (76). Butorphanol administered intranasally showed linear pharmacokinetics for doses ranging from 1 to 4 mg; the bioavailability and the maximum concentration were higher than those found after administering the drug via sublingual and buccal routes. Because both sublingual and buccal dosage forms are physically placed in the mouth, some portion of the dose is swallowed, absorbed orally, and subject to first-pass metabolism. In contrast, little butorphanol can escape from the sinus cavity after nasal administration, so that the majority of the dose is absorbed through the desired route. Therefore, butorphanol intranasal administration is a useful tool for the treatment of moderate to severe pain. The most frequently reported adverse effects with butorphanol administered nasally were congestion and insomnia.

Butorphanol for nasal administration is marketed as Stadol NS Nasal Spray (Bristol Myers Squibb Co.) (77). It is an aqueous solution of butorphanol tartrate for nasal administration as a metered spray. Each bottle contains 2.5 mL of a 10 mg/mL solution of butorphanol tartrate with sodium chloride, citric acid, and benzethonium chloride in purified water, with pH 5.0. Stadol NS is used in postoperative analgesia, mainly in the treatment of migraine pain. Onset of analgesia, which is within a few minutes for intravenous administration and within 10–15 minutes for intramuscular injection, is within 15 minutes for the nasal spray doses. Peak analgesic activity occurs within 30–60 minutes following intravenous and intramuscular administration and within 1–2 hours following nasal spray administration. Compared with the injectable form, Stadol NS has a longer duration of action (4–5 hours). Mean peak blood levels of about 1 ng/mL occur at 30–60 minutes after 1 mg dose administered nasally. The absolute bioavailability of Stadol NS is 60–70% and does not change in patients with allergic rhinitis. The fraction of Stadol NS absorbed is unaffected by the concomitant administration of a nasal vasoconstrictor, but the rate of absorption is decreased. Therefore, a slower onset can be anticipated if Stadol NS is administered concomitantly with or immediately following a nasal vasoconstrictor.

The patient should be instructed on the proper use of Stadol NS. The pump reservoir must be fully primed prior to initial dose. After priming, each metered spray delivers an average of 1.0 mg of butorphanol tartrate, and the 2.5 mL bottle delivers an average of 14–15 doses of Stadol NS. If not used for 48 hours or longer, the unit must be reprimed.

Calcitonin

Calcitonin is a 32 amino acid polypeptide hormone secreted by the parafollicular cells of thyroid glands. It provides the right bone growth by regulating Ca^{2+} turnover in cells. Nowadays it can be successfully employed in the treatment of osteoporosis and in Paget's desease, characterized by abnormal bone formation. The synthetic salmon calcitonin is currently formulated in several ways. Oral administration is contraindicated because the hormone is subjected to digestive degradation. Injectable calcitonin has been available on the market since 1984. Because of injection inconvenience to patients, intranasal administrations seemed to be more attractive. Many studies have been carried out to demonstrate the efficiency of nasal delivery, and the benefits have been compared with the parenteral route. The drug has been delivered as snuff, drops, and nebulized sprays. In late 1995 a new nasal spray was approved by the U.S. FDA.

Data obtained in experiments comparing the nasal with subcutaneous administrations have shown an equivalence, because both preparations were capable of alleviating pain and reducing bone disorder in the population of osteoporotic patients (78). Nasal calcitonin delivery is safe, preventative, and may increase bone mass of the lumbar spine. Fracture efficacy data are not yet available, although preliminary results are promising. Nasal calcitonin may be an analgesic to bone and of benefit in glucocorticoid-induced osteoporosis (79). The dose of nasal calcitonin for the treatment of established osteoporosis is 200 international units daily.

Although compliance problems are bypassed, by nasal administration low bioavailability increases the amount of dose administered. Results regarding the bioavailability of calcitonin nasal spray (Miacalcin®, Sandoz) have shown a great variability. Miacalcin is rapidly absorbed by nasal mucosa, and the plasma concentration peak appears after

31–39 minutes, which is twice as long as the 16–25 minutes found for the parenteral route. In volunteers approximately 3% of nasal dose, compared with intramuscular injection, is available (data ranged between 0.3 and 30.6%) (80). Adverse effects, which include nausea, rhinitis, and nasal discomfort, are generally mild and transient and always less common than others related to parenteral formulations. The nasal spray has been reported as having no serious adverse reactions associated with high doses. An increase in the bioavailability may be obtained using enhancers and proteolitic enzyme inhibitors (81), which improve the transport of the hormone through the nasal epithelium.

The delivery device is basically a pump system, which must be primed before the first use. The pump is activated once a faint spray is emitted, and it does not need to be reactivated before each successive use.

Dihydroergotamine

DHE is an ergot alkaloid used for the treatment of orthostatic hypotension and mainly for the prophylactic therapy of migraine. DHE was mainly available in parenteral dosage forms. The oral route is not suitable due to very low bioavailability (1%) caused by incomplete absorption and, particularly, to a high first-pass effect by the liver. However, alternative routes of administration that result in plasma levels comparable to the intramuscular route have been investigated (82). It has been demonstrated that intranasal administration provides a feasible delivery of DHE into systemic circulation. In fact, pharmacokinetic studies performed on humans show that DHE administered intranasally presents rapid absorption with a bioavailability, relative to intramuscular injection, of approximately 38%. A linear kinetics in the dosage range of 1 to 4 mg was observed (83). Another important pharmacokinetic result, concerning the reliability of this route of administration of DHE for the treatment of migraine, was that the vasomotor phenomena which could affect the nasal mucosa during a migraine attack, rhinitis, or the simultaneous administration of a local vasoconstrictor, had little or no influence on the bioavailability of DHE administered intranasally.

The first nasal solution consisted of an ampoule with DHE methanesulfonate salt at 4 mg/mL, and caffeine as enhancer. The ampoule had to be placed into a nebulizer when the migraine attack occurred, and after it was opened, it had to be used within 24 hours due to limited pharmaceutical and microbiological stability. Furthermore, the low concentration of DHE required large volumes to be sprayed into the nostrils, causing a spillage of solution from the nose. To overcome these drawbacks and to improve the nasal formulation, a pharmaceutically more stable nasal spray of higher concentration of DHE, able to administer a intranasal dose in a much smaller spray volume, was developed. Recently, the nasal spray (Migranal, Novarti's) was approved by the FDA (84). In two recent clinical trials of nasal spray, patients experienced headache relief as early as 30 minutes after treatment. Up to 60% of patients had responded within 2 hours, and up to 70% within 4 hours, following a single 2 mg treatment.

An interesting work in rabbits was carried out comparing two different formulations, liquid and lyophilized powder, containing a concentration of DHE of 10 mg/mL and RAMEB (66). It was assessed that the amount of RAMEB in liquid sprays did not affect the bioavailability of DHE. Nevertheless, by adding RAMEB to liquid, DHE solubility was increased. This allowed for more concentrated formulations and made possible administering higher doses in one puff, avoiding the spillage of liquid from the nasal cavity. Furthermore, the presence of RAMEB also increased the stability of the drug. Different results have been obtained from powdered formulations in which the DHE absorption was dependent of the amount of β-cyclodextrin and of the powder volume. The addition of CD seemed to improve absorption by enabling a rapid dissolution in the mucus layer of the DHE powder sprayed into the nostril.

Sumatriptan

Sumatriptan is a serotonin receptor agonist used in the treatment of migraine and cluster headache. It is available in a subcutaneous injection form or as tablets for oral dosage, but recently also as a nasal spray. The rationale of the nasal form is that the subcutaneous form is difficult to be self-administered for several patients, the oral route provides low bioavailability (14%), and administration during nausea or vomiting due to migraine may be unpleasant. The nasal spray is generally well tolerated; the most frequently reported events are transient disturbance of taste and nausea or vomiting.

The nasal formulation (Imigran, Glaxo Wellcome) is a solution of sumatriptan hemisulphate (10 mg/250 μL), buffered at pH 5.5, considering this pH within the normal range of nasal secretions. The solution is hypertonic. A high concentration is required for administering the dose in a small volume, suitable for spraying into the nostrils. Because of the low solubility of sumatriptan succinate used in the subcutaneous form, the hemisulphate salt has been preferred for the nasal form. Sumatriptan is a basic compound (pK_a 9.63), so it is almost completely ionized at pH 5.5. The good absorption at this pH supports the hypothesis of a paracellular mechanism driving the absorption (85).

The bioavailability and the rate of absorption are intermediate between the values observed after subcutaneous and oral administration. The times to peak plasma concentrations are 12 min for a 6 mg subcutaneous dose, 2 h after a 100 mg oral dose, and 1 h for a 20 mg intranasal dose. Following the latter route, sometimes a secondary peak was observed after 1.5–2 h. It is likely that part of the dose runs out of the back of the throat and is swallowed with the saliva, becoming a second oral dose. After 2 h from a 20 mg dose, more than 50% of the patients reported headache relief. A second administration at this time is effective in two-thirds of the nonresponders (86).

Desmopressin

Desmopressin, the synthetic analogue of the naturally occurring antidiuretic hormone, vasopressin, has for many years been the drug of choice in the treatment of diabetes

insipidus. Traditionally, it has been delivered by the intranasal route using the rhinyle catheter method, and was one of the first examples of a peptide that could be given systematically by the nasal route. Desmopressin solution was administered intranasally as a spray, using a metered-dose pump, or as drops, using a rhinyle catheter. Plasma levels showed that desmopressin was absorbed to a greater extent after administration of the spray, with a two- to three-fold increase in the relative bioavailability compared with the drops. Moreover, the use of an intranasal spray device can deposit well-controlled doses within the nasal cavity, which remain there sufficiently long to provide a clear enhancement in absorption and bioavailability (26).

DDAVP® Nasal Spray (desmopressin acetate) or DDAVP® Rhinal Tube (Rhône-Poulenc Rorer Pharmaceutical, Inc.) are available as aqueous solution for intranasal use (87). Each milliliter contains desmopressin acetate 0.1 mg, chlorbutanol, and sodium chloride. Intranasal DDAVP provides a prompt onset of antidiuretic action with a long duration after each administration. Its antidiuretic effect is about one-tenth that obtained with an equivalent dose administered by injection.

Cromolyn Sodium

Cromolyn sodium is indicated for the prevention and treatment of the symptoms of allergic rhinitis, because it inhibits the degranulation of sensitized mast cells and the release of histamine. The available product is a nasal solution (Nasalcrom® Nasal Solution, FISONS Pharmaceuticals) (88). Each milliliter of Nasalcrom contains 40 mg cromolyn sodium in purified water with benzalkonium chloride to preserve and EDTA to stabilize the solution.

Cromolyn sodium is poorly absorbed from the gastrointestinal tract. After instillation of Nasalcrom, less than 7% of the total dose administered is absorbed and is rapidly excreted unchanged in the bile and urine. The remainder of the dose is either expelled from the nose or swallowed and excreted via the alimentary tract.

Another nasal dosage form of cromolyn available on the market is formulated as nasal powder (Lomudal®, Fison Italchimici). It is presented as capsules containing 20 mg powder cromolyn sodium. The nasal powder administration requires the use of a special insufflator called Rinoflatore (see Fig. 3).

Steroid Drugs

Oral biavailability of steroid drugs is extremely low due to extensive elimination by hepatic first-pass metabolism. Nasal absorption of steroids, including progesterone, estradiol, and testosterone, has resulted in systemic bioavailability comparable with intravenous administration in rats and rhesus monkeys. For example, progesterone oral systemic bioavailability was approximately 7.9%, which is significantly less than the bioavailability achieved by nasal route (72–82%). The results demonstrate that nasal delivery can result in as much as a 10-fold reduction in the hepatogastrointestinal first-pass elimination of progesterone (89).

Other steroid drugs (i.e., glucocorticoids), such as budesonide, dexamethasone, flunisolide, fluticasone propionate, triamcinolone acetonide, and beclomethasone dipropionate are administered in the nasal cavity to obtain a local effect. Budesonide is an antiinflammatory glucocorticosteroid marketed as Rhinocort® Nasal Inhaler (Astra) (90). It is a metered-dose pressurized aerosol unit containing a suspension of micronized budesonide, indicated for the management of symptoms of seasonal or perennial allergic rhinitis in adults and children. A 3-week clinical study with placebo in seasonal rhinitis, comparing Rhinocort and orally ingested budesonide in 98 patients with allergic rhinitis due to birch pollen, demonstrated that the therapeutic effect of budesonide can be attributed to its topical effects. Only about 20% of an intranasal dose from the Rhinocort inhaler reached the systemic circulation. Biopsies of the nasal mucosa of 50 adult patients after 12 months of treatment and of 10 patients after 3–5 years of therapy showed no histopathological evidence of adverse effects. Rhinocort Nasal Inhaler is supplied in a 7 g canister containing 200 metered doses, provided with a metering valve and nasal adapter, together with patient's instructions for use. Each activation delivers approximately 32 μg of micronized budesonide to the patient.

Beclomethasone diproprionate (BDP) is another antiinflammatory steroid. Beconase® AQ Nasal Spray (Glaxo Wellcome, Inc.) or Vancenase® AQ nasal spray (Schering Plough Corp.) is a metered-dose, manual pump spray unit containing a suspension of BDP in an aqueous medium containing microcrystalline cellulose, carboxymethylcellulose sodium, dextrose, benzalkonium chloride, polysorbate 80, and phenylethyl alcohol (91). After initial priming (3–4 activations) each activation of the pump delivers from the nasal adapter 100 mg of suspension containing 42 μg of BDP. Beconase AQ Nasal Spray is indicated for the relief of the symptoms of seasonal or perennial allergic and nonallergic (vasomotor) rhinitis. The mechanism of the aerosolized drug's action in the nose is unknown. When given by nasal inhalation, the drug is deposited primarily in the nasal passages. Only about 20–25% of the dose is absorbed. A portion of the drug is swallowed. Biopsies of nasal mucosa obtained during clinical studies showed no histopathologic changes. Rino Clenil® (Chiesi Farmaceutici) is another metered-dose pressurized aerosol containing BDP 0.01 g, sorbitan trioleate, and propellant.

THE INSULIN CASE AND FUTURE DEVELOPMENTS: VACCINES AND BRAIN TARGETING THROUGH THE NOSE

Intranasal administration of drugs is likely to gain further importance in time. A large number of experiments on nasal drug delivery have used insulin as a model drug. The high interest in this drug itself makes it a suitable molecule to check the efficacy of nasal formulation. Despite the fact that insulin nasal delivery is not yet a reality, a very important challenge in the field of nasal drug delivery is the total or partial substitution of insulin daily injections with an intranasal therapy for diabetes mellitus. Up to now, several trials with different intranasal formulations have resulted in low and variable bioavailability and in uncertainty about long-term safety. Therefore, an intra-

nasal therapy is not likely to be available in the near future (63). Moreover, considerations exist as to whether the oral form of insulin would be more convenient. The reasons are based on the fact that the intestinal administration of insulin showed that the drug is absorbed via the liver. This is the same as insulin produced by the pancreas and is different from the injected or inhaled insulin that goes directly into the circulation. Obviously, an ideal diabetes mellitus therapy should be capable of simulating the profile of normal insulin secretion (92,93). As mentioned earlier, high and predictable bioavailability and long-term safety are the main conditions for an intranasal formulation to be introduced into therapeutic practice. At present, neither a liquid nor a solid dosage form can assure both. We refer to the review of Merkus et al. (64) for a deeper evaluation of the mechanisms by which the adjuvants improve absorption of insulin.

New results are expected in the fields of vaccination and brain targeting (94). The first effective immunizations by this route were demonstrated in the late 1920s. Immune reactions develop in two different ways depending on the site of the first contact with the antigen. If the antigen directly enters the bloodstream, B-lymphocytes are primed to express specific antibodies and to release them into systemic circulation. If otherwise the infective agent (or the exogenous substance) is contacted by a mucosal surface, a different mechanism is activated. The antigen is picked up by specific M-cells of the epithelium and presented to T- and B-lymphocytes located in follicles forming the so-called mucosal associated lymphoid tissue (MALT). Thereafter, the primed lymphocytes migrate from the original MALT (e.g., the nasal associated lymphoid tissue) to the regional lymph nodes; here they get into further differentiation and then reach, by means of the systemic circulation, all the other mucosal surfaces, where both humoral and cellular immunity is provided. Vaccination by parenteral injection provides effective systemic immunity, but also implies high costs, low patient compliance, and several side effects. Some of these disadvantages could be avoided by immunization via mucosal surfaces. Future vaccination must be inexpensive, easy to distribute and administer. These are exactly the possibilities offered by intranasal vaccination. For the time being, no intranasal vaccine has yet been licensed. However, a wealth of studies have been undertaken in this direction. In particular, intranasal vaccines against the influenza virus have been found to be highly effective in several experiments in humans. Very interesting results have been obtained in the research for a vaccine against human immunodeficiency virus (HIV). In experiments on mice, intranasal immunization was superior to vaginal, gastric, or rectal immunization for the induction of systemic and mucosal anti-HIV antibody responses (95). Other investigations have been devoted to herpes virus, *Helicobacter pylori, Streptococcus pneumoniae*.

Finally, the nasal mucosa is also a very suitable site for the administration of peptides and small proteins to the brain that do not diffuse through the blood-brain barrier. An interesting summary on this subject has been reported by Sakane et al. (96). Many studies have demonstrated the presence of a particular transport mechanism from the olfactory mucosa to the brain, exploiting an easier access to the cerebrospinal fluid (CSF). The nerves coming from the olfactory bulb spread out in bundles close to the cribriform plate (the part of the ethmoid bone constituting the roof of the anterior cranial fossa). The bundles cross this bony wall and enter the nasal cavity, ending in many small protrusions of the mucosal surface. Each nervous bundle is surrounded by supporting cells and by a space containing CSF; this space is probably an extension of the subarachnoid space, and its presence provides a reliable explanation of the high rate of absorption from the olfactory region to the CSF.

As demonstrated by Gizurarson et al. (97), after instillation to the olfactory region of the nasal cavity, a significantly higher concentration of insulin reaches the brain as compared to subcutaneous administration. The relative bioavailability (intraolfactory versus subcutaneous) was 370%, with high differences between the administration techniques used. Based on these results, peptides and small proteins are the most interesting molecules for drug delivery to the brain exploiting intranasal administration.

ACKNOWLEDGMENTS

This article has been made possible thanks to the collaborative work of the young researchers active in nasal delivery studies at the Pharmaceutical Department of the University of Parma: Daniela Cocconi, Elena Pasini, Angela Armanni, Stefano Cagnani, Monica Sala, and Stefano Bonfante. Professor Dimitri Rekkas of the University of Athens must to be thanked as well for his helpful suggestions.

INTRODUCTION

Historically, the use of topical devices for eye treatment is mentioned in Assyrian medical texts. Vegetable drugs (e.g., caraway, cassia, onions) were commonly prescribed and were applied as powders, ointments, or washes mixed with water, milk, wine, or oil (1). As an example, it was suggested to treat purulent conjunctivitis with "a local application of tanner's verdigris on vellum with copper dust, arsenic and yellow sulphide of arsenic mixed in curd" (1).

Actually, topical delivery of eyedrops into the lower cul-de-sac is the most common method for the administration of therapeutic agents in the treatment of ocular diseases and in diagnostics. However, one of the major problems encountered with solutions is the rapid and extensive elimination of drugs from the precorneal lachrymal fluid by solution drainage, lachrymation, and nonproductive absorption by the conjunctiva or the nasal mucosa, which may cause undesirable side effects (2,3) (Fig. 1). It must be noted that this high drainage rate is due to the tendency of the eye to maintain its residence volume at 7–10 μL permanently, whereas volumes topically instilled range from 20 to 50 μL. In fact it has been demonstrated in vivo that 90% of the dose was cleared within 2 min for an instilled volume of 50 μL and, within 4 min for an instilled volume of 10 μL (4). Consequently, the ocular residence time of conventional solutions is limited to a few minutes, and the overall absorption of a topically applied drug is

INTRODUCTION

Historically, the use of topical devices for eye treatment is mentioned in Assyrian medical texts. Vegetable drugs (e.g., caraway, cassia, onions) were commonly prescribed and were applied as powders, ointments, or washes mixed with water, milk, wine, or oil (1). As an example, it was suggested to treat purulent conjunctivitis with "a local application of tanner's verdigris on vellum with copper dust, arsenic and yellow sulphide of arsenic mixed in curd" (1).

Actually, topical delivery of eyedrops into the lower cul-de-sac is the most common method for the administration of therapeutic agents in the treatment of ocular diseases and in diagnostics. However, one of the major problems encountered with solutions is the rapid and extensive elimination of drugs from the precorneal lachrymal fluid by solution drainage, lachrymation, and nonproductive absorption by the conjunctiva or the nasal mucosa, which may cause undesirable side effects (2,3) (Fig. 1). It must be noted that this high drainage rate is due to the tendency of the eye to maintain its residence volume at 7–10 μL permanently, whereas volumes topically instilled range from 20 to 50 μL. In fact it has been demonstrated in vivo that 90% of the dose was cleared within 2 min for an instilled volume of 50 μL and, within 4 min for an instilled volume of 10 μL (4). Consequently, the ocular residence time of conventional solutions is limited to a few minutes, and the overall absorption of a topically applied drug is

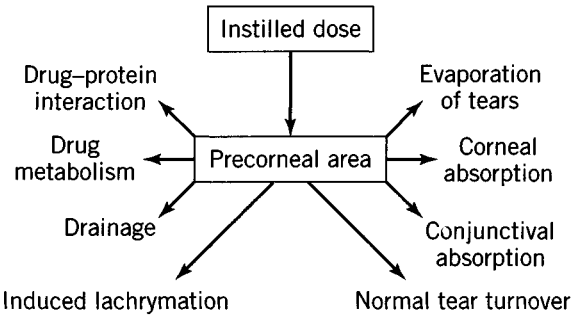

Figure 1. Drug elimination pathways from the precorneal area.

limited to 1–10% (5,6). Drug uptake occurs as a massive pulse entry, followed by a rapid decline, which means a short initial period of overdosing, followed by a long period of underdosing (7).

Initial attempts to overcome the poor bioavailability of topically instilled drugs typically involved the use of ointments based on mixtures of white petrolatum and mineral oils (8,9) and suspensions (10,11). Ointments ensure superior drug bioavailability by increasing the contact time with the eye, minimizing the dilution by tears, and resisting nasolachrymal drainage. Because these vehicles have the major disadvantage of providing blurred vision, they are nowadays mainly used for either nighttime administration or for treatment on the outside and edges of the eyelids (12). Use of suspensions as ophthalmic delivery systems relies on the assumption that particles may persist in the conjunctival sac. The efficiency of suspensions has shown high variability, which occurred as a result of inadequate dosing, probably mainly due to the lack of patient's compliance in adequately shaking the suspension before administration (13). These disadvantages have led to other approaches being investigated. One of the common methods to optimize prolonged precorneal residence time is to use hydrogels (14,15), liposomes (16), micro- and nanocarrier systems (16–19), and inserts (20,21). In comparison with traditional formulations, these systems have the following advantages:

- Increased contact time
- Prolonged drug release
- Reduction of systemic side effects
- Reduction of the number of applications
- Better patient compliance

A rapid overview of the most common diseases, e.g., ocular inflammations, glaucoma, and dry eye syndrome, treated with the ophthalmic dosage forms reviewed in this article is briefly provided here. Ocular inflammations are triggered by trauma, viral or bacterial infections, immunorelated phenomena, or corneal ulceration. Depending on the etiologic agent, the treatment of ocular inflammations consists of a topical steroidal therapy (dexamethasone) in combination with nonsteroidal antiinflammatory drugs (diclofenac), immunosuppressive agents (azathioprine), antimicrobial agents (tobramycin), and mydriatic-cycloplegic drugs (pilocarpine) (22).

Glaucoma results from the impairment of the aqueous humor flow and is characterized by an elevation of the intraocular pressure, progressive optic neuropathy, visual impairment, and eventually blindness (22). The most frequent drug therapy is based on the use of parasympathomimetics (pilocarpine), with or without adrenergic agonists (epinephrine) or β-blockers, including timolol, betaxolol, carteolol, and metipranolol.

Dry eye syndrome and keratoconjunctivitis sicca (KCS) are ocular surface pathologies concerned with reduction and unstability of the precorneal tear film. KCS is associated with local symptoms such as irritation, photophobia, foreign body sensation, and burning (23). The treatment of this disease relies on the use of artificial tear formulations able to fulfill the physicochemical role of normal tear including lowering the surface tension of the tear film, forming a hydrophilic layer compatible with adsorbed mucin, and enhancing the tear volume when necessary (23).

The aim of the following article is to describe the various polymeric systems used to achieve prolonged contact time of drugs with the cornea and increase their bioavailability. Advantages and shortcomings of the different systems reviewed are discussed as well as their characteristics and their in vivo applications.

HYDROGELS

Definition and Classification

The most common way to improve drug retention on the corneal surface is undoubtedly by using polymers to increase solution viscosity. Previous studies on rabbits by Robinson et al. (24,25) established that the rate of drainage from the eye of an instilled solution is markedly reduced as the viscosity of the solution is increased. More recently, the approach to improve precorneal retention is based on the use of mucoadhesive polymers. The principle for use of bioadhesive vehicles relies on their ability to interact with the mucin coating layer present at the eye surface (26).

Kim et al. (27) define hydrogels as polymers endowed with the ability to swell in water or aqueous solvents and induce a liquid–gel transition. However, in ophthalmology the limit between actual hydrogels and highly viscosified solutions is not clearly established. According to Plazonnet et al. (28), aqueous gels are at the upper limit of viscous preparations, and they are formed when high molecular weight polymers or high polymer concentrations are incorporated in the formulations.

Currently, two groups of hydrogels are distinguished, namely preformed and in situ forming gels (Fig. 2). Preformed hydrogels can be defined as simple viscous solutions which do not undergo any modifications after administration. In situ forming gels are formulations, applied as

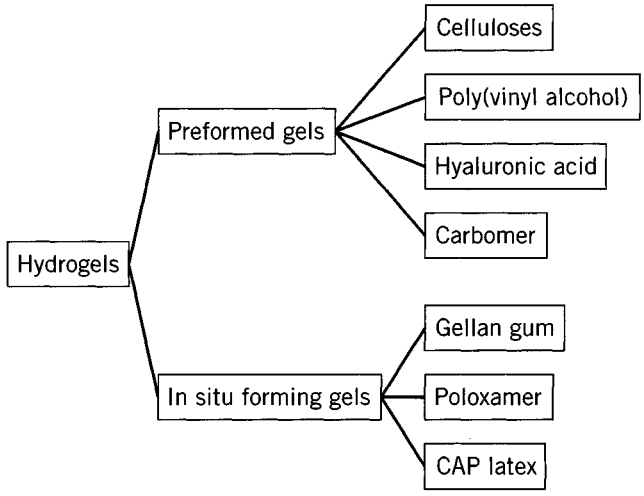

Figure 2. Classification of ophthalmic hydrogels. *Source:* Adapted from Ref. 29.

solutions, sols, or suspensions, that undergo gellation after instillation due to physic-chemical changes inherent to the eye (29).

The polymers chosen to prepare ophthalmic hydrogels should meet some specific rheological characteristics. It is generally well accepted that the instillation of a formulation should influence tear behavior as little as possible (6). Because tears have a pseudoplastic behavior, pseudoplastic vehicles would be more suitable as Newtonian formulations, which have a constant viscosity independent of the shear rate, whereas pseudoplastic solutions exhibit decreased viscosity with increasing shear rate, thereby offering lowered viscosity during blinking and stability of the tear film during fixation. The importance of the rheological properties of topical semisolid preparations regarding ocular tolerance and thus, good efficacy, has been reviewed by Zignani et al. (30).

Preformed Hydrogels

Preformed hydrogels for topical administration in the eye can be based on natural, synthetic, or semisynthetic polymers. Some characteristics of the more commonly used polymers are listed in Table 1.

Cellulose Derivatives. Because pure cellulose is not water soluble due to its relatively high crystallinity, cellulosic derivatives have been used for a long time as viscosifiers in collyria. Methylcellulose (MC) was first introduced in ophthalmic formulations in the 1940s as a mean of decreasing their fluidity (31). Some years later, Mueller and Deardorff (32) showed in man that solutions of homatropine hydrobromide exhibited enhanced cycloplegic and mydriatic activity in the presence of MC. Further promising results were obtained in 1962 by Haas and Merrill (33), who reported a lowered intraocular pressure in man after administration of pilocarpine incorporated in an MC vehicle. Since then, cellulosic polymers have been extensively studied as vehicle for ocular drug delivery. Currently, a large number of commercial formulations contain cellulosic viscosifiers, including Adsorbotear® (Alcon, Fort Worth, Texas) and Tears Naturale (Alcon, Fort Worth, Texas).

The cellulosic derivatives most commonly used in ophthalmology are:

- Methylcellulose (MC)
- Hydroxyethylcellulose (HEC)
- Hydroxypropycellulose (HPC)
- Hydroxypropylmethylcellulose (HPMC)
- Sodium carboxymethylcellulose (CMC Na)

The boundary between viscous solutions and gels for cellulosic derivatives is particularly difficult to define, because data regarding the hydrocolloid concentration or the viscosity of the final formulation are not always available. Therefore, some studies listed in Table 2 deal more with viscous solutions than with actual hydrogels.

Comparing the performance of three different cellulosic derivatives, namely HEC, HPC, and HPMC, Ludwig et al. (41) reported that HEC solutions were the most effective in reducing the elimination rate of sodium fluorescein from the cornea, probably due to a better tolerance. In fact, HEC was rated as the most comfortable by the volunteers, whereas HPC and HPMC gave rise to complaints of irritation and blurred vision. Several studies have clearly demonstrated the efficacy of cellulosic polymers in increasing ocular availability of numerous drugs when compared with simple saline solutions by decreasing the drainage rate from the eye (25,40,44). For example, Chrai and Robinson (25), using MC as the viscosity-inducing polymer, found a 10-fold decrease in the drainage rate constant for a 100-fold change in viscosity. However, they reported that increasing the viscosity above 15–20 cps, which appeared as the optimum viscosity, did not lead to a proportional improvement.

Subsequent advances in the polymers field with respect to ocular drug delivery have led to the use of poly(vinyl alcohol) (PVA); sodium hyaluronate, and carbomer, which often give better results (35,38,44,47) than celluloses.

Poly(vinyl alcohol). PVA is a synthetic polymer commercially obtained by polymerization of vinylacetate to poly(vinyl acetate) and subsequent hydrolysis to PVA (49).

Table 1. Characteristics of Polymers Used To Prepare Preformed Hydrogels for Ophthalmic Applications

Polymer	Origin	Characteristics
Cellulosic derivatives	Semisynthetic	Good tolerance Optical clarity Newtonian behavior Similar refractive index as the cornea
Poly(vinyl alcohol)	Synthetic	Newtonian behavior Wetting agent
Sodium hyaluronate	Skin, connective tissues, muscles, tendon, vitreous body, aqueous humor	Biocompatible Mucoadhesive Pseudoplastic behavior Viscoelastic behavior
Carbomer	Synthetic	Good tolerance Bioadhesion Possibility to be neutralized by the active compound in its basic form

PVA was introduced in the early 1960s (50) and has been reported to have corneal contact time superior to MC when tested on rabbits. Conflicting results were obtained by Linn and Jones (51), who found that PVA exhibited a significantly shorter elimination time than another cellulosic derivative, namely HPMC (Fig. 3). Numerous authors (46,52,53) reported quite similar results in favor of 0.5% MC over 1.4% of PVA in rabbits or humans. These last findings seemed more reasonable than those of Krishna and Brow (50) because 0.5% MC solutions exhibit significantly greater viscosity compared with 1.4% solutions based on PVA. Patton and Robinson (24) highlighted those presuming contradictory results. By testing solutions based on MC and PVA, the authors concluded that two vehicles exhibiting or at least approximating to Newtonian behavior in the same viscosity range could not have significantly different effects on ocular drug bioavailability. Moreover, they established that an optimal viscosity range (12–15 cps) also existed for PVA as demonstrated for MC (25).

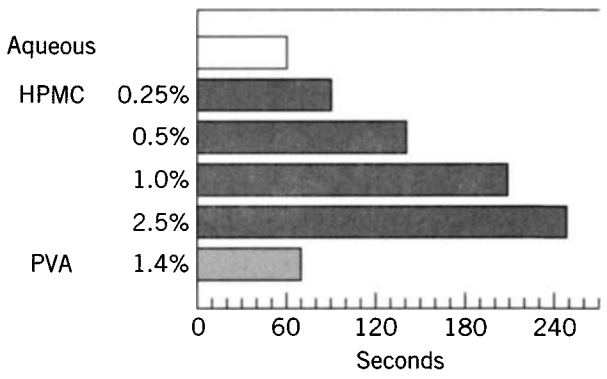

Figure 3. Lachrymal excretion time of various vehicles. Average of 20 separate instillations of each vehicle. *Source:* Adapted from Ref. 51 with permission.

Since then, numerous studies have been conducted, mostly comparing celluloses with PVA in an effort to determine the ideal ophthalmic vehicle. Some drugs tested in formulations containing PVA as well as the subsequent observations are listed in Table 3.

Lachrymal drainage evaluations of PVA formulations by γ scintigraphy (35,54) have demonstrated a significant delay of the drainage in man and rabbits, when compared with a saline solution. Hardberger et al. (35) have reported that the average $T_{1/2}$ for saline was markedly shorter (4.2 minutes) than for 1.4% PVA solutions (24 minutes).

Some commercial products, particularly for the treatment of dry eye, are based on PVA, including HypoTears® (IOLAB Corp., Claremont, California) and Liquifilm® (Allergan, Irvine, California).

Sodium Hyaluronate. The sodium salt of hyaluronic acid (SH) is a high molecular weight biological polymer composed of repeating disaccharide units of glucuronic acid and *N*-acetylglucosamine, a specific ultrapure fraction being patented as Healon® (Kabi Pharmacia, Sweden) by Balazs (57) in 1979. Its use as a vehicle in ocular drug delivery has been extensively reviewed by Bernatchez et al. (58). The efficacy of SH to increase precorneal residence time of ophthalmic formulations in humans has been investigated by several authors using different methods summarized in Table 4.

γ scintigraphic data of Snibson et al. (60) pointed out a very interesting phenomenon. They demonstrated that the residence times of 0.2% and 0.3% SH solutions on the cornea were significantly longer for patients having dry eye syndrome than in healthy subjects. The rationale for such a result was that the alteration of tear mucin in dry eyes might have modified the interaction of SH with the ocular surface.

An extended residence time is one of the factors used to select artificial tears for the therapy of KCS. At present, the therapeutic schedule in the treatment of dry eye implies frequent instillations, which lead to two major shortcomings: patient discomfort and side effects due to preservatives used in multiple dosage forms such as benzalkonium chloride, well known for their potential toxicity to the corneal epithelium. Because SH can protect against damages caused by benzalkonium chloride (62), it has been frequently proposed as a vehicle of choice in tear substitutes (61,63–65) and all the studies reported improvement of several symptoms associated with KCS, such as blurred vision, pain, photophobia, with this kind of

treatment. A further advantage of SH in this application is its pseudoplastic behavior.

The ability of SH to prolong drug release by increasing precorneal drug residence time has been studied (mostly in animals) for several ophthalmic compounds such as pilocarpine (66–71) or, more recently, gentamicin (72). Residence time of gentamicin in humans was found to be 2.23-fold superior when instilled in 0.25% SH formulations than in an isotonic phosphate buffer solution, and drug bioavailability was significantly improved for at least 10 minutes.

Carbomer. Cross-linked poly(acrylic acid) of high molecular weight, commercially available as Carbopol® (B.F. Goodrich Chemical Company, Cleveland, Ohio), is widely used in ophthalmology to enhance precorneal retention to the eye.

Preparation of Carbopol hydrogels is simply based on the dispersion of the polymer in water at room temperature, followed by a neutralization process with agents such as sodium hydroxide, triethanolamine, or directly with active basic compounds. The maximal viscosity is obtained at neutral pH.

Carbopol offers the advantage of exhibiting excellent mucoadhesive properties when compared with others polymers (e.g., cellulose derivatives, PVA and SH). The mechanisms involved in the mucoadhesion ability of Carbopol have been investigated previously (73,74). Four mechanisms of interaction between mucin and poly(acrylic acid) have been described (73,74):

- Electrostatic interaction
- Hydrogen bonding
- Hydrophobic interaction
- Interdiffusion

These mechanisms can be explained by the similar features of the mucus network and the cross-linked poly(acrylic acid):

- Macromolecular expanded network
- Negative charges
- Significant hydratation in aqueous media
- Significant number of carboxyl groups

The efficacy of Carbopol in enhancing precorneal residence time has been extensively studied by incorporating tracers such as sodium fluorescein (75) or active compounds such as pilocarpine or prednisolone (47,76–78). Some in vivo studies on rabbits or humans are reported in Table 5.

Comparing different types of poly(acrylic acid) (Carbopol 940, 934, 941, and 910), Unlü et al. (81) concluded that Carbopol 940 showed superior appearance and clarity. The results reported in these studies showed the superiority of poly(acrylic acid) as a sustained release agent over reference solutions (77,82) or over some hydrogels (47,56,79). However, the majority of authors avoided tolerance evaluations. Only Ludwig et al. (75) noted some differences in acceptability of Carbopol formulations (0.1 and 0.2%) from one patient to another; some volunteers complained of blurred vision. This result was confirmed by a clinical trial in human by Amin et al. (83), who observed a slight irritation after administration of Carbopol 940 gel, whereas the Draize test on rabbits showed no ocular irritation.

Table 5. Preformed Ophthalmic Hydrogels Based on Carbopol

Carbopol type	Concentration (%)	Drug	Reference
Carbopol 934	N.A.	Prednisolone sodium phosphate	77
Carbopol 940		Prednisolone acetate	
Carbopol 940	1.0–6.0	Pilocarpine	47
Carbopol 941			
Carbopol 940	1.0–4.0	Flurbiprofen	79
Carbopol 940	0.3	Tropicamide	80
Carbopol 934	0.49	Pilocarpine nitrate	56

A large number of commercial ophthalmic preparations contain Carbopol, including tear substitutes such as Lacrigel® (Europhta, Monaco), Lacrinorm® (Chauvin, Montpellier, France) or formulations containing active compounds such as Iduviran® (Chauvin, Montpellier, France) and Pilopine® (Alcon, Fort Worth, Texas).

Other natural or synthetic polymers have also been evaluated as potential vehicles to prolong the residence time of drugs at the surface of the eye but are currently being further investigated. Therefore, they are not extensively discussed in this article but are principally mentioned here for reference: chondroitin sulfate (63,67), xanthan gum (40,83,84), poly(vinylpyrrolidone) (44,85,86), and chitosan (87). Briefly, xanthan gum and chitosan are both polysaccharides of natural origin, being respectively obtained by an aerobic fermentation of a carbohydrate with *Xanthomonas campestris* and by deacetylation of chitin. An important difference between the two polymers is the anionic character of xanthan gum, whereas chitosan exhibits positive charges. Xanthan gum has been proposed as a material for artificial tears preparations (83) as well as vehicle for drug delivery (40,84). The possible advantage of chitosan over xanthan gum lies in the presence of positive charges at physiological pH on the sugar backbone of chitosan, which are supposed to interact with the negative charges of the mucus, thereby confering a bioadhesive property to this polysaccharide. Therefore, chitosan has attracted attention for topical ophthalmic applications, for example to enhance tobramycin delivery to the eye (87). γ scintigraphic evaluations have shown that the presence of chitosan was efficient to prolong precorneal residence time of formulations based on this polysaccharide, when compared with a commercial solution (87).

In Situ Forming Gels

The use of preformed hydrogels still has drawbacks that can limit their interest for ophthalmic drug delivery or as tear substitutes. They do not allow accurate and reproducible administration of quantities of drugs and, after administration, they often produce blurred vision, crusting of eyelids, and lachrymation. A new approach is to try to combine advantages of both solutions and gels, such as accuracy and facility of administration of the former and prolonged residence time of the latter. Thus, in situ hydrogels can be instilled as eyedrops and undergo an immediate gelation when in contact with the eye. The liquid to semisolid phase change can be triggered by:

- Increased temperature
- Increased pH
- Ionic strength of the tear film

Thermoreversible Hydrogels. These hydrogels are liquid at room temperature (20–25°C) and undergo gelation when in contact with body fluids (35–37°C), due to an increase in temperature.

Different thermal setting gels have been described in the literature, including for example acrylic acid copolymers (84,88) and *N*-isopropylacrylamide derivatives (89,90). However, specific requirements inherent to ophthalmic administration such as tolerance have limited the choice of such polymers.

Poloxamers, commercially available as Pluronic® (BASF-Wyandotte, USA), are the most commonly used thermal setting polymers in ophthalmology. They are formed by a central hydrophobic part (polyoxypropylene) surrounded by hydrophilic part (ethylene oxide). Depending on the ratio and the distribution along the chain of the hydrophobic and hydrophilic subunits, several molecular weights are available, leading to different gelation properties. Pluronic F-127, which gives colorless and transparent gels, is the most commonly used polymer in pharmaceutical technology. Briefly, hydrogels based on Pluronic are commonly prepared (91,92) by solubilization of the polymer in cold water (5–10°C) followed by gelation upon warming to ambient temperature.

Three principal mechanisms have been proposed to explain the liquid–gel phase transition after an increase in temperature, including the gradual desolvation of the polymer, increased micellar aggregation, and the increased entanglement of the polymeric network (93–95). Furthermore, Miller and Drabik (93) have suggested that intramolecular hydrogen bonds might promote gelation. The importance of the entanglement process in the gelation phenomenon of poloxamers has been confirmed by Gilbert et al. (96), who used a fluorescent probe technique to evaluate the hydration and diffusion processes in Pluronic F-127 solutions. A schematic representation of the gelation process, proposed by Waring and Harris (95) is shown in Fig. 4. The mucomimetic property of poloxamers is supposed to be due to their hydrophobic and hydrophilic sequences simulating mucin action by adsorption of the aqueous layer of tears on the hydrophobic epithelium (Fig. 5). Owing to their protective and mucomimetic action, poloxamers have also been evaluated for the treatment of dry eye (95,97). For example, Flow Base® (95), containing 18% of poloxamer 407, sodium chloride, and potassium chloride

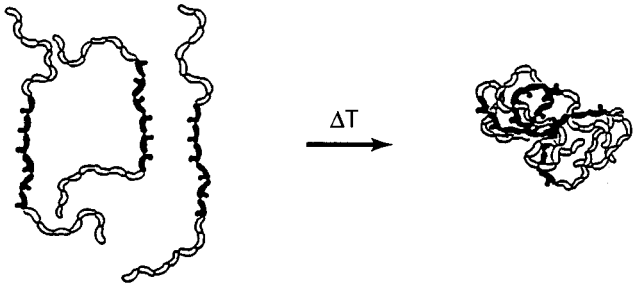

Figure 4. Liquid–gel transition of formulations based on poloxamers. *Source:* From Ref. 95 with permission.

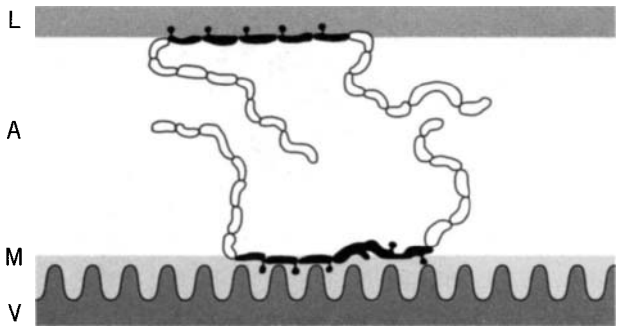

Figure 5. Model of the supposed action of poloxamers as tear substitutes. L, lipophilic phase; A, aqueous phase; M, mucus; V, villosities. *Source:* From Ref. 95 with permission.

has been shown to possess clinically advantageous properties as a tear substitute. The major drawback of this product is the formation of solid residues on the eyelids after instillation of 50 μL of solution, this problem being overcome by instillation of smaller volumes.

Poloxamers have also been widely investigated as ocular drug delivery systems. Miller and Donovan (98) reported enhanced activity of pilocarpine in poloxamers 407 gels when compared with a simple solution, whereas Dumortier et al. (99) have shown that a thermoreversible gel does not improve the kinetic profile of morphine over a reference solution. It must be noted that in both investigations the same polymer was used but not at the same concentrations (25% (98) and 20% (99), respectively), which might explain the discrepancies of the results.

Studying the influence of some parameters on the release rate of solutes from Pluronic F-127 hydrogels in vitro, Gilbert et al. (100) pointed out that increasing polymer concentration decreased the release rate of the drug, whereas increasing drug lipophilicity decreased the release rate. A recent γ scintigraphic study (101) on a semi-interpenetrating network based on poloxamer and poly(acrylic acid), Smart Hydrogel™, has been shown to remain significantly longer at the surface of the eye than a reference solution ($t_{50\%}$ about 25-fold higher).

Some applications of thermoreversible hydrogels in ophthalmology refer to the use of other polymers, the poloxamines, which are copolymers of poly(ethylene oxide) and poly(propylene oxide) obtained from a precursor, commercialized as Tetronic® (102).

Despite all the promising results obtained with thermoreversible gels, there remains an important drawback associated with the use of these hydrogels; the risk of gelling before administration by an increase in the ambient temperature during packaging or storage.

Pseudolatexes: pH-Induced Gelation. El-Aasser (103) defined pseudolatexes as artificial latexes prepared by the dispersion of a preexisting polymer in an aqueous medium. In situ gelling pseudolatexes for ophthalmic use can be described as aqueous colloidal dispersions of polymer, which become viscous gels after instillation in the conjunctival cul-de-sac due to modification of the pH (104).

Pseudolatexes are obtained by dispersion of an organic solution of a preformed polymer in an aqueous medium, leading to an O/W emulsion. Solvents from the internal phase are then evaporated to obtain a fluid dispersion of polymeric particles with a size generally smaller than 1 μm (104). Two principal methods are commonly used to prepare ophthalmic pseudolatexes, the solvent evaporation process (105–107) and the salting out process (106,108,109). Both methods allow the production of a lyophilized and easily redispersible powder. Thus, pseudolatexes have the advantage of ensuring the physical stability of the latex as well as the stability of active compounds such as pilocarpine, which is sensitive to aqueous media. In addition, such systems represent an interesting technological alternative that avoids the use of organic solvents, which can cause problems such as toxicity and pollution. Bioactive materials can be added into these systems at various times of the preparation: in the aqueous or in the organic phases during preparation or by adsorption on the final latex (105).

Ibrahim has listed (104) some prerequisites necessary for an optimal formulation of ophthalmic pseudolatex:

- Solubility of the polymer selected in organic solvents as well as insolubility in water
- Existence on the macromolecule of ionizable groups, which can react with the electrolytes of the lachrymal fluid
- Use of a high molecular weight polymer
- Rapid coagulation process after instillation to avoid precorneal drainage of the instilled formulation before the phenomenon of gelation appears
- Compatibility of the different components of the colloidal dispersion with precorneal tissues

First preliminary investigations of pH-sensitive nanoparticulate systems (latex) for ophthalmic administration began in the early 1980s (110) and have been extensively studied by Boye (19). He proposed the preparation of latexes containing pilocarpine with cellulose acetate phthalate (CAP). The choice of this polymer was determined by the compatibility of the polymer with the active compound, the ability of the CAP latex to be a free-running solution at pH 4.2 and a gel at 7.2, and finally, the latex stability at relatively low pH which is a prerequisite to ensuring the stability of pilocarpine.

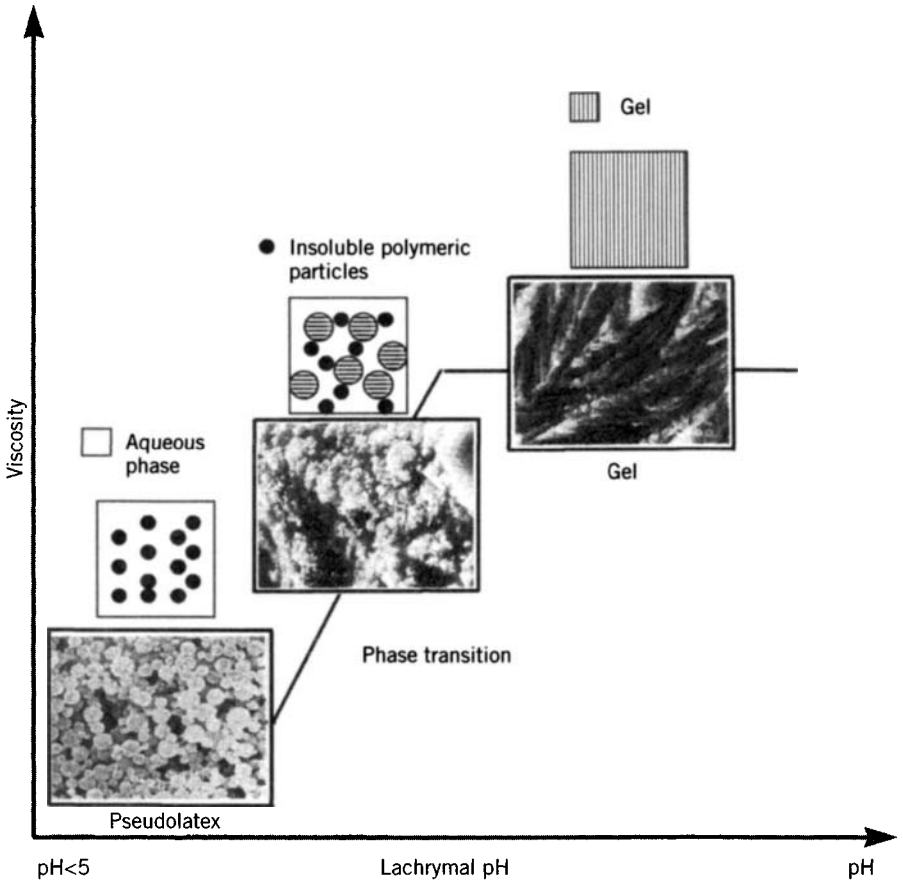

Figure 6. Transformation of the colloidal dispersion in gel. *Source:* From Ref. 111 with permission.

The principle of the sol–gel transition of the polymer CAP is shown schematically in Fig. 6. The gelation capacity of CAP latexes has been visualized in vitro by scanning electron microscopy and in vivo in rabbits by incorporating methylene blue in the ophthalmic formulations (106).

The efficacy of a preparation based on a pseudolatex has been evaluated by measuring pharmacological responses (19,105) and precorneal residence time by γ scintigraphy (19,111). This technique has clearly demonstrated the superiority of CAP latex over a solution to prolong the corneal residence time of pilocarpine, as shown in Fig. 7.

Finally, it is important to note that irritation tests (19) on rabbits including examination of the cornea, the iris and the conjunctiva have demonstrated that the investigated pseudolatexes did not induce visible irritation. However, a sensation of discomfort seems to be unavoidable after the coagulation of the solution in the conjunctival cul-de-sac as is the case for any semisolid preparation.

Ionically Induced Gelation: Gellan Gum. Gellan gum is an anionic exocellular polysaccharide produced by the bacterium *Pseudomonas elodea*, having the characteristic property of cation-induced gelation (112,113). The acetylated form is commercially available as Gelrite® (Kelco Division of Merck and Co, USA). The sol–gel transition process is induced by the presence of monovalent or divalent ions such as Na^+ and Ca^{2+}. Some other parameters influence the phase transition, e.g., the concentration of polysaccharide, the temperature of the preparation, and the nature and the concentration of cations. Kang et al. (114) have determined that divalent ions such as magnesium or calcium were superior to monovalent cations in promoting the gelation of the polysaccharide (Fig. 8). However the concentration of sodium in tears (2.6 g/L) is quite sufficient to induce the gelation (115). Because the presence of lach-

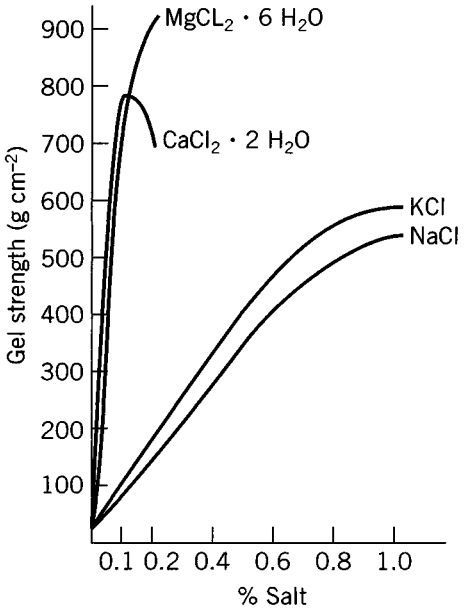

Figure 8. Effects of cations on gel strength of deacetylated gellan gum. *Source:* From Ref. 114 with permission.

rymal fluid is required to induce gel formation, accidental gelation during storage does not occur as with thermoreversible gels. The gelling mechanism is based on a modification of the conformation of the polysaccharide. It corresponds to the formation of double-helical junction zones in the presence of cations, followed by aggregation of the double-helical segments, leading to a three-dimensional network (116).

Corneal contact time of formulations based on gellan gum has been investigated using two main methods, which are fluorometry (117,118) and γ scintigraphy (40,119). Both techniques have demonstrated improved residence times with Gelrite when compared with saline or various commercial solutions. Gelrite has also provided corneal residence times superior to those of other hydrogel preparations based on polymers such as cellulosic derivatives or xanthan gum (Fig. 9) (40). A γ scintigraphic study by Greaves et al. (119) analyzing three formulations has pointed out the defectiveness of the gel in rabbits. In the case of humans, Gelrite showed longer contact time with the cornea than HEC, whereas a contradictory observation was noted in rabbits (119). This result is explained by the lower basal turnover and the slower blink rate in rabbits compared with man.

Efficacy of gellan gum has been also evaluated by measuring pharmacokinetic parameters (115) and pharmacological response (40,120). Rozier et al. (115) found an increased ocular bioavailability of timolol maleate when incorporated in Gelrite formulations versus the commercial Timoptic® solution. This result was confirmed by Vogel et al. (120), who observed a twofold decrease of the intraocular pressure of patients after administration of Gelrite-containing timolol.

Sanzgiri et al. (14) proposed a mechanism of drug release in vitro from gellan matrices of methylprednisolone (MP). The data suggested that MP release was influenced by the dissolution of the drug, its diffusion from the matrix, and possibly by erosion of the matrix; the combination of the three processes resulting in overall diffusion-controlled release kinetics as shown by the release index of the drug.

Exceptional rheological properties of gellan gum such as thixotropy, pseudoplasticity, and thermoplasticity (116) are further advantages for its use in ophthalmology: the fluidity of the solution can be increased simply by shaking or slightly warming the preparation.

Recently two other natural polymers believed to be able to form in situ gels by interacting with the lachrymal fluid have been evaluated as potential adjuvants in ophthalmic formulations (121,122). Carrageenans, a group of water-soluble sulphated galactans extracted from red seaweed, showed similar features to gellan gum regarding their rheological behavior, gelling properties (114), and tolerance. This suggested that they could be interesting polymers for prolonging the residence time of topical ocular formulations (121). Some alginates, rich in guluronic acid residues, have been demonstrated to exhibit reversible liquid–gel transition after administration and to be efficient in reducing intraocular pressure when carrying pilocarpine (122).

DISPERSED SYSTEMS

Liposomes

Liposomes are microscopic vesicles composed of alternating aqueous compartments and lipid bilayers (mainly

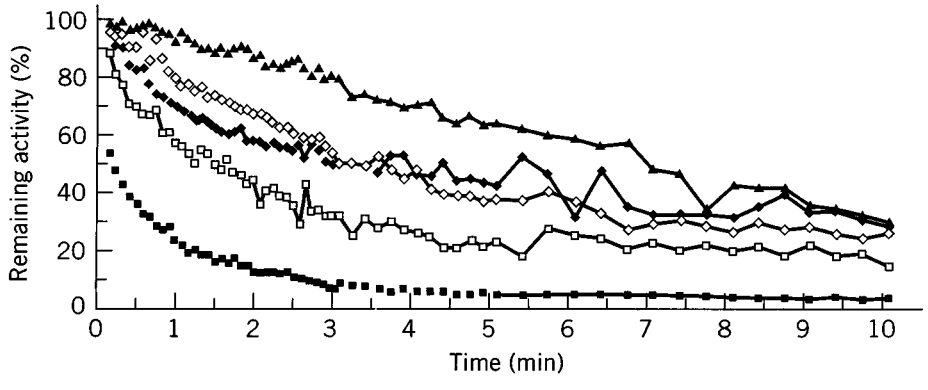

Figure 9. Precorneal drainage of ^{99m}Tc-DTPA incorporated in various formulations containing pilocarpine nitrate 2%. (■) Reference solution (n = 13), (□) HEC 0.325% (n = 9), (◆) HEC 0.5% (n = 8), (◇) xanthan gum 0.3% (n = 9), (▲) Gelrite 0.6% (n = 9). *Source:* From Ref. 40 with permission.

phospholipids and cholesterol). Liposomes are classified in three categories according to their size and the number of bilayers: (*1*) small unilamellar vesicles (SUV), (*2*) large unilamellar vesicles (LUV), and (*3*) multilamellar vesicles (MLV). Depending on their composition liposomes can have a positive, negative, or neutral surface charge.

The efficacy of liposomes in ophthalmic therapy depends on several parameters, including (*1*) the drug encapsulation efficiency, (*2*) the size and the charge of the vesicles, (*3*) the distribution of the drug in the liposomes, (*4*) the stability of the liposomes after instillation, (*5*) the residence time of the liposomes in the conjunctival sac, and finally, (*6*) the affinity of the liposomes for the cornea (123). Of these, a major factor affecting ocular drug bioavailability is the unstability of liposomes to the proteins in the conjunctival sac. Tall et al. (124) reported that proteins exert a destabilizing effect on the integrity of liposomes. However, Stratford et al. (125) have studied in vitro the effect of tears proteins on the release of epinephrine and inulin from liposomes. They reported only a slight increase of drug concentration in the release medium containing the simulating composition tears (126) when compared with a simple phosphate buffer solution.

The use of liposomes as ocular delivery systems was first reported by Smolin et al. (127) and Schaeffer and Krohn (128). Animal studies by Smolin et al. (127) demonstrated that entrapping idoxuridine in liposomes was more effective than the free drug in the treatment of acute and chronic herpetic keratitis. Studying the corneal uptake of penicillin G and indoxole with different types of liposomes, Schaeffer and Krohn (128) reported that corneal uptake of drugs was largely increased with positively charged liposomes. This suggests that the interaction between the cornea and liposomes is probably based on an electrostatic interaction, owing to the negatively charged epithelium at physiological pH. This in vitro study determined that the degree of association of liposomes with the corneal surface is decreasing as follows: $MLVs^+ > SUVs^+ > MLVs^- > SUVs^- > MLVs = SUVs$. Fitzgerald et al. (129) similarly reported that positively charged egg lecithin MLVs were retained markedly longer in the precorneal region than neutral or negative MLVs. However, γ scintigraphy experiments have demonstrated that vesicle retention occurred mainly in the inner canthus as well as in other extraocular regions, but not on the corneal surface where significant absorption takes place (129).

Various investigations concerning different liposome–ophthalmic drug combinations are reported in Table 6. The various studies concerning the use of liposomes in ophthalmic field have been also extensively reviewed by Lee et al. (123) and Mezei and Meisner (130,131).

Contradictory results were obtained from the studies listed in Table 6, suggesting high entrapment efficacy of lipophilic drugs in liposomes compared with hydrophilic compounds. Singh and Mezei (141) have tested triamcinolone acetonide and dihydrostreptomycin sulfate as lipophile and hydrophile model drugs, respectively. Concentrations of triamcinolone acetonide in different ocular tissues were markedly increased with liposomes, compared with a control suspension. On the other hand, the hydrophilic drug dihydrostreptomycin sulfate showed reduced ocular concentrations when associated with liposomes. Meisner et al. (135) also reported that atropine salt was less promising than free base to achieve a long-acting drug delivery. Schaeffer and Krohn (128) obtained a 10-fold enhancement of the corneal penetration of the hydrophilic penicillin G entrapped in liposomes over polysorbate 80 solutions. This can be explained, in part, by the amphiphilic behavior of penicillin G, which is not completely internalized in the aqueous phase but intercalates into liposomal membranes by insertion of its hydrophobic moiety.

More recently, the use of polymer-coated liposomes, which are expected to achieve superior precorneal retention time when compared with uncoated vesicles, has been investigated. Surprisingly, both cationic and anionic mucoadhesive polymers, namely chitosan (137) and Carbopol (142), failed to improve the corneal retention (137) or the drug bioavailability (142).

The ocular irritability of neutral and positive liposomes has been assessed by Draize test, histological examination, and rabbits blinking test (143,144). The two former methods indicated that irritation induced by each type of liposome might be considered as negligible, whereas the blinking method of Tanaka et al. (144) confirmed the safety of neutral liposomes but demonstrated that positive liposomes may cause pain or discomfort.

The use of liposomes in ocular drug delivery is still at an experimental stage and no liposomal ocular commercial products are available. This is due to a number of remaining limitations to their routinal use. Several shortcomings are inherent to liposomes such as their short shelf life, their limited drug loading capacity, as well as sterilization difficulties, because most of the methods can cause irreversible damage to the liposomes (123,131). Furthermore, the improvement of liposomes as drug carrier systems in ophthalmology requires a good understanding of the mechanisms involved in their interaction with the cornea. For instance, endocytosis is considered by most investigators as the dominant mechanism of interaction between liposomes and cells over fusion, adsorption, or lipid exchange processes (145). However, the cornea has been shown to exhibit only slight phagocytic activity (146), and endocytosis is probably not the main mechanism of interaction of the vesicles with corneal cells. Therefore, adsorption or lipid exchange is believed to be the major mechanism of interaction between the liposomes and the corneal cells (147).

Microparticles and Nanoparticles

Microparticles and nanoparticles are colloidal drug carriers in the micrometer and submicrometer range, which have been evaluated for ophthalmic drug delivery purposes over the past 15 years (148). Micro- or nanoparticles are divided in two groups, micro- or nanospheres and micro- or nanocapsules. Microspheres are monolithic particles possessing a porous or solid polymer matrix, whereas microcapsules consist of a polymeric membrane surrounding a solid or a liquid drug reservoir (148). Practically, the term nanoparticles is applied to nanospheres and nanocapsules because it is often difficult to determine if they are real capsules or matrix-type particles.

Table 6. Ocular Liposomal Formulations for Topical Application

Drug	Liposomal characteristics: Type	Liposomal characteristics: Size	Subject	Parameter(s) examined	Refs.

The application of such systems in the ophthalmic field has been extensively reviewed by Kreuter and colleagues (148–150). Upon topical instillation of a particulate suspension in the cul-de-sac, the drug is slowly released in the lachrymal pool by dissolution and mixing, diffusion, or mechanical disintegration or erosion of the polymeric matrix (149). The upper size limit for microparticles for ophthalmic administration is about 5–10 μm. The ophthalmic administration of particles of higher size can result in an itching sensation and can induce lachrymation, with the possible consequence of reducing drug bioavailability.

The manufacturing methods used to produce micro- and nanoparticulate carriers are numerous, such as interfacial polymerization (151,152), desolvatation (153,154), or aggregation by pH adjustment and heat treatment (155). Nanoparticles for ophthalmic drug delivery have been mainly produced by emulsion polymerization and are based on several synthetic or natural biocompatible polymers, as shown in Table 7. The active compound can be dissolved, trapped, encapsulated, adsorbed or linked to these colloidal systems (148). The various fabrication processes have been extensively reviewed in specialized books or reviews (156–158) and in the chapter NANOPARTICLES of this encyclopedia.

As shown in Table 7, the principal materials used so far to prepare colloidal systems for ophthalmic drug delivery have been synthetic biodegradable polymers belonging to the group of poly(alkyl cyanoacrylate). These polymers can be degraded following two concomitant metabolization pathways, which are the erosion of the polymer backbone leading to the formation of formaldehyde (187) or the cleavage of the ester inducing the formation of a water-soluble polymer backbone and the corresponding alcohol (188). In vivo, the presence of enzymes favors the second pathway, which is quite convenient because it reduces the production of the toxic formaldehyde under physiological conditions. The nontoxicity of nanoparticles based on some polymers has been demonstrated in vivo, i.e., poly(isobutyl cyanoacrylate) and poly(hexyl cyanoacrylate) were found to be well tolerated after topical application in rabbits (148) and empty poly(butyl cyanoacrylate) nanoparticles in saline did not induce adverse effect in humans (189).

Drug release from poly(alkyl) cyanoacrylate nanoparticles can occur by different isolated or concomitant mechanisms (29):

- Degradation of the polymer (rate depending on the length of the alkyl chain)
- Desorption of the active compound adsorbed from the surface of the nanoparticles
- Diffusion through the polymeric matrix

Precorneal elimination and penetration of particles in the cornea have been evaluated using various labeling methods with radioactive tracers such as ^{141}Ce (190), ^{99m}Tc (183), ^{14}C (191,192), ^{111}In (193), or ^{3}H (165), or with fluorescent probes (194–196). Initial attempts to evaluate res-

idence time were made in the early 1980s by Sieg and Triplett (190), who labeled polystyrene microspheres of 3 μm and 25 μm diameter with ^{141}Ce. They found that precorneal elimination of smaller particles was dependent on the volume instilled, unlikely for the 25 μm diameter particles. The washout phase was greatly enhanced after administration of 50 μL of 3 μm particles instead of 25 μL. Hence, this indicated that there was a lower limit for particle-size retention in the eye, in addition to the well-recognized upper size limit for preventing the onset of irritation. The study of Wood et al. (191), evaluating the disposition of poly(hexyl cyanoacrylate) nanoparticles, showed that colloidal particles were rapidly removed from the precorneal area in a similar way to aqueous solutions but were better retained, which was attributed to mucin binding or buoyancy of the nanoparticles.

Diepold et al. (192) and Zimmer et al. (165) have reported that the residence time of nanoparticles was significantly higher in inflamed ocular tissues than in healthy eyes. The increased retention of nanoparticles is probably due to some peculiar physiological modifications accompanying the inflammatory process. One can cite as possible causes an increased cell permeability (165), a secretion in the precorneal area of substances (e.g., albumin, fibrin) that can bind with nanoparticles, and a partial blockade of the nasolachrymal duct due to the swollen conjunctival tissue (192). These studies suggest that colloidal carriers could considerably improve the therapeutic index of some antiinflammatory, antibacterial, or antiviral drugs (150).

Calvo et al. (196), using confocal laser scanning microscopy, have observed ex vivo and in vivo that poly(ϵ-caprolactone) (PCL) nanocapsules penetrated the corneal epithelial cells by an endocytic mechanism. Furthermore, PCL nanocapsules (196) exhibited a selectivity for the cornea versus the conjunctiva, which means that such systems could reduce systemic absorption. This result was in accord with the in vivo data of Losa et al. (17), who found reduced cardiovascular side effects of metipranolol when incorporated in PCL nanocapsules.

Most applications of drug-loaded ophthalmic delivery systems involve glaucoma therapy, using either cholinergic agonists like pilocarpine (11,18,169,174,181) or β-blockers such as betaxolol (161–163) or carteolol (163). Zimmer et al. (171), evaluating miotic response and intraocular pressure (IOP) of rabbits after administration of pilocarpine-loaded microspheres and nanospheres based on albumin, reported a great improvement of the bioavailability of the drug, when compared with a reference solution. These particles increased the ocular bioavailability by 50–90% when considering the miotic response and by 50–70% when considering the IOP-lowering effect. Furthermore, the authors have shown that this result could be improved by coadministering these particles with bioadhesive polymers such as hyaluronic acid, mucin, sodium carboxymethylcellulose, or poly(acrylic acid) (172).

INSERTS

Definition

This section is devoted to solid devices delivering drugs to the anterior segment of the eye that are denoted by the general name *insert*, originating from the Latin *inserere*, to introduce. Historically, the first solid medication precursors of the present insoluble inserts were described in the nineteenth century. They consisted of squares of dry filter paper, previously impregnated with drug solutions (e.g., atropine sulfate, pilocarpine hydrochloride) (197); small sections were cut and applied under the eyelid. *Lamellae*, the precursors of the present soluble inserts, consisted of glycerinated gelatin containing different ophthalmic drugs (197). However, the use of lamellae ended when more stringent requirements for sterility of ophthalmic preparations were enforced. Nowadays, ophthalmic inserts are again provoking great interest, as evidenced by the increasing number of publications in the field in recent years. Table 8 gives an overview of the different drugs applied with inserts.

The uses of ocular inserts have been extensively reviewed by Bawa (198), Saettone (197), Saettone and Salminen (199), Khan and Durrani (200), and Shell (201,202). Gurtler and Gurny (203) have reviewed ophthalmic inserts in the patent literature, and Baeyens et al. (22) have described inserts as ocular drug delivery devices in veterinary medicine.

Ophthalmic inserts are defined as preparations with a solid or semisolid consistency, the size and shape of which are especially designed for ophthalmic application (i.e., rods or shields) (203). These inserts are placed in the lower fornix and, less frequently, in the upper fornix or on the

INSERTS

Definition

This section is devoted to solid devices delivering drugs to the anterior segment of the eye that are denoted by the general name *insert*, originating from the Latin *inserere*, to introduce. Historically, the first solid medication precursors of the present insoluble inserts were described in the nineteenth century. They consisted of squares of dry filter paper, previously impregnated with drug solutions (e.g., atropine sulfate, pilocarpine hydrochloride) (197); small sections were cut and applied under the eyelid. *Lamellae*, the precursors of the present soluble inserts, consisted of glycerinated gelatin containing different ophthalmic drugs (197). However, the use of lamellae ended when more stringent requirements for sterility of ophthalmic preparations were enforced. Nowadays, ophthalmic inserts are again provoking great interest, as evidenced by the increasing number of publications in the field in recent years. Table 8 gives an overview of the different drugs applied with inserts.

The uses of ocular inserts have been extensively reviewed by Bawa (198), Saettone (197), Saettone and Salminen (199), Khan and Durrani (200), and Shell (201,202). Gurtler and Gurny (203) have reviewed ophthalmic inserts in the patent literature, and Baeyens et al. (22) have described inserts as ocular drug delivery devices in veterinary medicine.

Ophthalmic inserts are defined as preparations with a solid or semisolid consistency, the size and shape of which are especially designed for ophthalmic application (i.e., rods or shields) (203). These inserts are placed in the lower fornix and, less frequently, in the upper fornix or on the

cornea. They are usually composed of a polymeric vehicle containing the drug and are mainly used for topical therapy.

Further advantages of inserts over other drug delivery systems discussed already are (22):

- accurate dosing
- absence of preservatives
- increased shelf live, due to the absence of water

However, they have one significant disadvantage, their solid consistency, which means that they are perceived by patients as a foreign body in the eye (199). Besides the initial discomfort, other potential disadvantages arising from their solid state are possible movement around the eye, occasional inadvertent loss during sleep or while rubbing the eyes, interference with vision, and difficult placement (and removal for insoluble types) (199). Most of the ongoing research is therefore dedicated to improving ocular retention and to ensure an easy placement by the patient, while reducing the foreign body sensation in the eye. Ophthalmic inserts are generally classified according to their solubility behavior and their possible bioerodibility (203) (Fig. 10).

Soluble Inserts

Soluble inserts are the most frequently investigated class of ophthalmic inserts (see Table 8). Their main advantage relies on their complete solubility compared with their insoluble counterparts, so that they do not need to be removed from the eye after deposition. They are usually divided into two categories according to their polymer composition. The first type is based on natural polymers whereas the second is derived from synthetic or semisynthetic polymers.

Natural Polymers. Natural polymers include collagen, which was the first ophthalmic insert excipient described in the literature. Inserts containing collagen were first developed by Fyodorov (198,240) as corneal bandages following surgical operations and eye disease. Later, collagen shields as drug carriers were suggested by Bloomfield et al. (223). As described for contact lenses, the therapeutic agents are generally absorbed by soaking the collagen shield in a solution containing the drug and, once placed in the eye, the drug is gradually released from the interstices between the collagen molecules, as the collagen dissolves. Accordingly, the residence time of drugs (241) such as antibacterials (222,242), antiinflammatory agents (234,236), antivirals (239,243), or combination drugs (230) was increased when compared with traditional eye drops (see Table 8). However, as observed for contact lenses, most drugs are released quite rapidly by a diffusion process, whereas dissolution requires a much longer time. The corneal shields, currently available for clinical use, do not contain drugs but are designed as disposable therapeutic corneal bandages (199). For example, Bio-Cor® (developed by Bausch and Lomb, Clearwater, Florida) is made of porcine scleral collagen, whereas Medilens® (developed by Chiron Ophthalmics, Irvine, California) and ProShield® (developed by Alcon Surgical, Forth Worth, Texas) are prepared from bovine corium tissue (243–245).

The main advantages of collagen shields over contact lenses is their solubility and that they do not need to be removed. However, collagen may cause an inflammatory response in the ocular tissues. Also, if shields are not used in association with antibacterials, a secondary infection may occur (239). Nowadays, these devices have the further disadvantage of not being well accepted by the authorities, because of possible prion-based infection.

Synthetic and Semisynthetic Polymers. Ophthalmic inserts containing synthetic, i.e., poly(vinyl alcohol) (205, 233), and semisynthetic, i.e., cellulose based (204,205,208, 209,216,225,233), polymers are frequently described in the literature (see Table 8). This stems in part from their advantage of being based in products well adapted for ophthalmic use and their ease of manufacture by conventional methods, including extrusion (225), compression (204), and compression molding (246). Drug release from such systems is generally characterized by two phases (203,247). The first corresponds to the penetration of tear fluid into the insert, which induces a rapid diffusion of the drug and forms a gel layer around the core of the insert. This external gelification induces the second phase corresponding to a decreased release rate, again controlled by diffusion. The major problems of these soluble inserts are the rapid penetration of the lachrymal fluid into the device, the blurred vision caused by the solubilization of insert components, and the glassy constitution of the insert increasing the risk of expulsion. Ethylcellulose, a hydrophobic polymer, can be used to decrease insert deformation and therefore prevent blurred vision (225,228,233). Regarding the risk of expulsion, several authors (217,218,225,228) have incorporated carbomer, which is at low concentrations a strong, but well-tolerated bioadhesive polymer. Recently, Baeyens et al. (226,228) and Gurtler et al. (225,248) have used CAP in combination with gentamicin sulfate to decrease drug solubility. Prolonged release of the drug above the minimal inhibitory concentration (MIC) was obtained for more than 50 h, whereas gentamicin incorporated without CAP was released for less than 24 h. Subsequently, a new insert providing release of gentamicin and dexamethasone at different rates was developed. The prolonged release of gentamicin—an antibacterial agent—is combined with the immediate release of dexamethasone—an antiinflammatory agent—against structural damage that can be caused by the infection (Fig. 11). The release rate can also be decreased by using Eudragit as an insert coating agent (204,205,216). This polymer is normally used for enteric coating, and Saettone et al. (204) have observed in rabbits that Eudragit-coated inserts containing pilocarpine induced a miotic effect of longer duration, compared with the corresponding uncoated products.

Lacrisert® is a soluble insert that was successfully commercialized by Merck Sharp and Dohme in 1981 (198). The device weighs 5 mg, measures 1.27 mm in diameter with a length of 3.5 mm, and is composed of HPC and is useful in the treatment of dry eye syndrome. The device is placed in the lower fornix where it slowly dissolves over 6–8 h to stabilize and thicken the tear film (249).

New Ophthalmic Delivery System (NODS®), originally patented by Smith & Nephew Pharmaceuticals, Ltd., in 1985, consists of a medicated flag (4 mm × 6 mm, thickness 20 μm, weight 0.5 g) that is attached to a paper-covered handle by means of a short (0.7 mm) and thin (3–4 μm) membrane (Fig. 12) (206). All components (flag, membrane, and handle) are made of the same grade water-soluble poly(vinyl alcohol). For use, the flag is touched onto the surface of the lower conjunctival sac. The membrane dissolves, rapidly releasing the flag, which swells and dissolves in the lachrymal fluid, delivering the drug. When evaluated in humans, NODS produced an increase in bioavailability for pilocarpine and chloramphenicol with respect to standard eyedrop formulations (206).

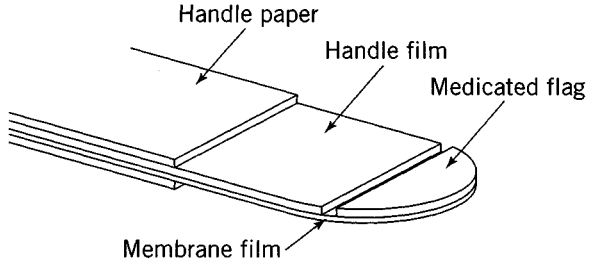

Figure 12. Schematic representation of the NODS system. *Source:* Adapted from Ref. 198.

Insoluble Inserts

Insoluble inserts can be classified into three categories (203): diffusional and osmotic systems, and hydrophilic contact lenses. Each class of insert shows a different drug release profile. Diffusional and osmotic systems contain a reservoir that is in contact with the inner surface of the drug rate controller to which its supplies the drug. The reservoir contains, respectively, a liquid, a gel, a colloid, a semisolid, a solid matrix, or a carrier containing drug. Carriers are made of hydrophobic, hydrophilic, organic, natural, or synthetic polymers. The third category, contact lenses, is a particular group of insoluble ophthalmic devices. However, the main disadvantage of these devices is their insolubility, because they need to be removed from the eye after treatment.

Diffusional Inserts. Diffusional inserts consist of a central reservoir of drug enclosed in specially designed semipermeable or microporous membranes allowing the drug to diffuse from the reservoir at a precisely determined rate. Drug release from such a system is controlled by the lachrymal fluid permeating through the membrane until a sufficient internal pressure is reached to drive the drug out of the reservoir. These diffusional systems prevent a continuous decrease in release rate by the use of a barrier membrane of fixed thickness, resulting in a zero-order release pattern.

Ocusert® (developed by Alza Corporation, Palo Alto, California) is undoubtedly the most commonly described insoluble insert in the literature (199,202,211,250–256) (Fig. 13). This flat, flexible, elliptical device consists of a pilocarpine reservoir with alginic acid, a mixture surrounded on both sides by a membrane of ethylene-vinyl acetate copolymer. The device is encircled by a retaining ring impregnated with titanium dioxide. The dimensions of the elliptical device are: major axis, 13.4 mm; minor axis, 5.7 mm; thickness, 0.3 mm. Two types of Ocusert are available for humans: the Pilo-20® and Pilo-40®, providing two different release rates for pilocarpine (20 μg/h and 40 μg/h, respectively) over a period of seven days (211).

Osmotic Inserts. The osmotic inserts are mostly described in the patent literature, and in vivo tests are rarely reported (203). They are generally made up of a central core surrounded by a peripheral component. The central part can consist of a single reservoir or two distinct compartments (Fig. 14). The single reservoir contains the drug, with or without an additional osmotic solute dispersed through a polymeric matrix, so that the drug is surrounded by the polymer as discrete small deposits. If the central part is made up of two compartments, the drug and the osmotic solute are placed in separate chambers, the drug

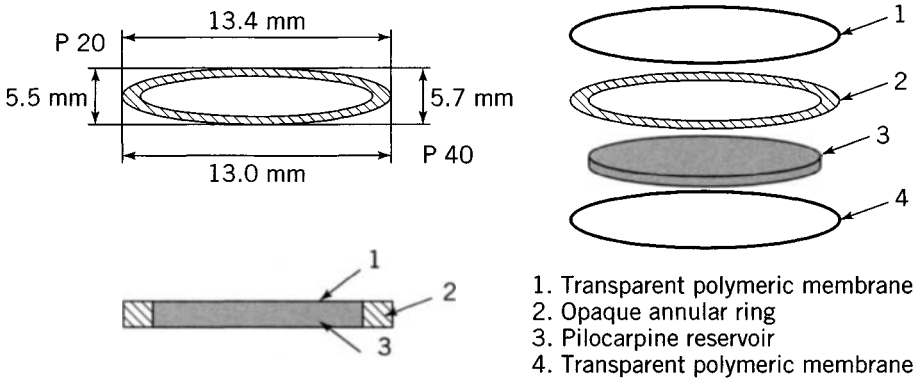

Figure 13. Schematic representation of the Ocusert system. *Source:* Adapted from Ref. 198.

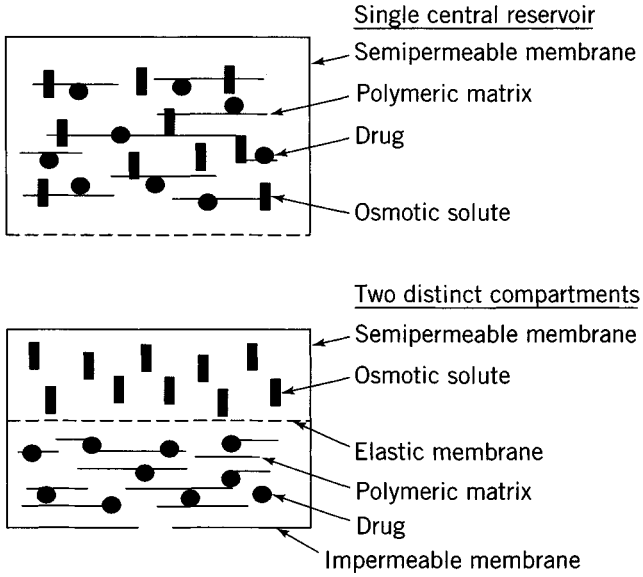

Figure 14. Schematic representation of the two types of osmotic inserts.

reservoir being surrounded by an elastic impermeable membrane, and the osmotic solute reservoir by a semipermeable membrane. The peripheral part of these osmotic inserts comprises in all cases a covering film made of an insoluble semipermeable polymer.

The majority of patents deal with systems having a unique central reservoir (215,237). The release of drug from these inserts can occur via two distinct release mechanisms: an osmotic and a diffusional release (203). When the insert is placed in the ocular environment, this starts the osmotic release, meaning tear fluid diffuses to the peripheral deposits through the semipermeable polymeric membrane, wets them, and induces their dissolution. The solubilized deposits generate a hydrostatic pressure against the polymer matrix triggering its rupture in the form of pores releasing the drug. This osmotic part of the release is characterized by a zero-order release profile. Ideally, the drug is continuously released from the osmotic insert by the increasing formation of apertures in the device forming a lattice of composition dispensing paths in the polymer on all sides of the inserts. In fact, these paths are interconnected, forming tortuous microchannels of irregular shapes and size causing a second drug release corresponding to a diffusional nonconstant release.

The release of drug from systems having a central reservoir subdivided into two compartments (257,258) starts as soon as the device is placed in the eye. Tears diffuse into the osmotic compartment, inducing osmotic pressure that stretches the elastic membrane and contracts the compartment containing the drug, so that the active compound is forced through the single drug release aperture. Thus, these systems are characterized by two distinct compartments and a single aperture having a very small diameter.

Contact Lenses. The initial use of contact lenses was for vision correction. The use of contact lenses has been extended as potential drug delivery devices by presoaking them in drug solutions. The main advantage of this system is the possibility of correcting vision and releasing drug simultaneously. Contact lenses are composed of a hydrophilic or hydrophobic polymer that swells by absorbing water. The swelling, caused by the osmotic pressure of the polymer segments, is opposed by the elastic retroactive forces arising along the chains as cross-links are stretched until a final swelling (equilibrium) is reached.

Refojo (259) has proposed a subdivision in five groups of contact lenses, namely rigid, semirigid, elastomeric, soft hydrophilic, and biopolymeric. Rigid contact lenses have the disadvantage of being composed of polymers (e.g., PMMA) hardly permeable to moisture and oxygen. Moreover, these systems are not suitable for prolonged delivery of drug to the eye and their rigidity makes them very uncomfortable to wear. The permeability problem was resolved using gas permeable polymers such as cellulose acetate butyrate. However, the discomfort associated with the foreign object and long adaptation period remain the shortcomings of rigid contact lenses. For this reason, soft hydrophilic contact lenses were developed for prolonged release of drugs such as pilocarpine (212), chloramphenicol and tetracycline (232), and prednisolone sodium phosphate (235) (see Table 8). The most commonly used polymer in the composition of these types of lenses is HEMM copolymerized with PVP or EGDM. PVP is used for increasing water of hydration, whereas EGDM is used to decrease the water of hydration.

Shell and Baker (247) have shown that drug release from presoaked contact lenses was extremely rapid, with

Table 9. Advantages and Shortcomings of Some Topical Ocular Drug Delivery Systems

Drug delivery system	Advantages	Shortcomings
Hydrogels	Reduction of the number of applications	Slight blurred vision
	Good compliance	No true sustained release effect
	Better tolerance than ointments	
Liposomes	Accurate dosing	Insufficient stability
	Improved bioavailability for lipophilic drugs	Short shelf life
		Limited drug loaded capacity
Micro- or nanoparticles	Accurate dosing	Too slight improvement for heavy processes of fabrication
	Slight increased ocular bioavailability	
Inserts	Accurate dosing	Difficulty of placement
	Absence of preservatives	Foreign body sensation
	Increased shelf life, due to the absence of water	

an in vivo residence time in general not longer than 24 h (200). In addition, preservatives, such as benzalkonium chloride, cannot be avoided and they have greater affinity with the hydrophilic contact lens material than for the aqueous drug solution (198). Bawa has described other approaches to decrease drug release rate from contact lenses. These include the introduction of the drug into the monomer mixture followed by polymerization of the monomers in the presence of the drug. This procedure removes the need for preservatives and consequent eye sensitization, because the drug is added in the matrix as a solid (213,214). However, the main problem associated with all contact lenses is their high cost of manufacture, and the difficulty of incorporating a precise amount of drug into the matrix. Disposable contact lenses have been commercially available for many years already, and the continued progress made in polymer chemistry should facilitate the development of this type of inserts.

Bioerodible Inserts

These inserts are formed by bioerodible polymers, i.e., materials that undergo hydrolysis of chemical bonds and hence dissolution (cross-linked gelatin derivatives, polyester derivatives) (209,211,233,238,260). The great advantage of these inserts is the possibility of modulating their erosion rate by modifying their final structure during synthesis, and by addition of anionic or cationic surfactants. However, erodible systems can have significantly variable erosion rates based on individual patient physiology and lachrymation patterns, whereas degradation products and residual solvents used during the polymer preparation can cause inflammatory reaction.

In conclusion, the majority of therapeutic agents can be delivered using inserts which are a promising alternative administration route, because of their various advantages compared with classical dosage forms. However, only few of these compounds have been commercialized. This can be attributed to the reluctance of ophthalmologists and patients to replace the traditional ophthalmic solutions as well as the cost and the need to train both the prescribers and the patients to place the inserts correctly in the eyes.

In the future, the use of ophthalmic inserts will certainly increase because of the development of new polymers, the emergence of new drugs having short biological half-lives or systemic side effects, and the need to improve the efficacy of ophthalmic treatments by ensuring an effective drug concentration in the eye for several days.

CONCLUSION

Although the various systems described in this article have been generally demonstrated to be successful approaches for prolonged ocular therapy, they all fall short of the ideal for a variety of reasons (Table 9). For example, the use of hydrogels remains associated with possible blurring vision, liposomes are often insufficiently stable after sterilization, and inserts are subject to a lack of patient compliance, due to their difficulty of placement in the eye (particularly for the elderly) and the sensation in the eye of foreign body. For these reasons, new polymers are currently under investigation to improve such systems and new approaches are being developed. Some authors have proposed the incorporation of lectins (261) or cyclodextrins (262,263) in ophthalmic formulations, or the use of codrugs (264) and prodrugs. Lectins have shown to bind to corneal and conjunctival surfaces as well as to the constituents of the tear film. Therefore, they are currently being investigated in the formulation of drug carrier complexes, where they could anchor the dosage form to the epithelial surfaces. The principle of using cyclodextrins in ophthalmic formulations relies on their ability to solubilize water-insoluble drugs and on capacity to reduce local drug irritation in the eye, which could, in turn, result in an improved bioavailability.

INTRODUCTION AND OVERVIEW

Products for women are on the rise in part because of gender equality issues and in part because of new drugs and/or delivery systems. Given the convenience of the oral route of administration, this is still the preferred route of drug delivery. However, many drugs are intended for local treatment and still other drugs are susceptible to first-pass metabolism; hence, the vaginal route of drug delivery is a more common site of drug application today than it was in the recent past.

Vaginal delivery of treatment modalities for local conditions is both understandable and expected whereas using the vaginal portal for systemic drug delivery carries with it both cultural and therapeutic issues. As will become clear in this article, the vaginal route is a very attractive route for drug delivery despite the presence of significant biological barriers.

A cartoon depiction of the reproductive organs is shown in Figure 1. Note the location of the vagina leading to the cervix. Dimensions of the vaginal cavity vary with age and tissue thickness and also varies with hormonal status. These changes present a challenge in the design of an appropriate drug delivery system that is effective across all age patients irrespective of their hormonal status.

VAGINAL ANATOMY AND PHYSIOLOGY

Premenopausal State

The vagina is a thin-walled, fibromuscular tube extending from the body exterior to the uterus. In the adult premenopausal female, the vagina is approximately 7 to 10 cm in length and 2 cm in width. The vagina may be segmented into the anterior wall (8 cm) and the posterior wall (11 cm), which combine to form two ridges of folds imparting a cross-sectional H-shaped appearance (1).

The vaginal wall consists of three principal layers: the epithelial layer, the muscular coat, and the tunica externa (adventitia). The inner mucosal layer may be further subdivided into the epithelium and lamina propria (2). The outermost epithelium is situated above the basement membrane and consists of noncornified, stratified squamous epithelium subdivided into four distinct layers: (*1*) a superficial layer consisting of large, flat cells with pyknotic nuclei; (*2*) an intermediate layer of larger and flatter nucleated cells; (*3*) a parabasal layer of polyhedral cells; and (*4*) a monolayer of cuboidal basal cells closely apposed to the basement membrane (3,4). A depiction of vaginal cell histology is shown in Figure 2. The first three cell categories are frequently exfoliated. Cuboidal cells are typically not sloughed off the vaginal wall unless undergoing extensive trauma. The epithelium overlies and is supported by the lamina propria, a region of dense connective tissue intertwined with a network of elastic fibers. The epithelium is drawn into numerous longitudinal and transverse muscular folds called rugae serving to increase the vaginal surface area (5). The vaginal wall does not contain mucus glands, but is continuously covered by a thin layer of protective moisture, some of which is obtained from Skene's and Bartholin's glands located near the vaginal orifice.

INTRODUCTION AND OVERVIEW

Products for women are on the rise in part because of gender equality issues and in part because of new drugs and/or delivery systems. Given the convenience of the oral route of administration, this is still the preferred route of drug delivery. However, many drugs are intended for local treatment and still other drugs are susceptible to first-pass metabolism; hence, the vaginal route of drug delivery is a more common site of drug application today than it was in the recent past.

Vaginal delivery of treatment modalities for local conditions is both understandable and expected whereas using the vaginal portal for systemic drug delivery carries with it both cultural and therapeutic issues. As will become clear in this article, the vaginal route is a very attractive route for drug delivery despite the presence of significant biological barriers.

A cartoon depiction of the reproductive organs is shown in Figure 1. Note the location of the vagina leading to the cervix. Dimensions of the vaginal cavity vary with age and tissue thickness and also varies with hormonal status. These changes present a challenge in the design of an appropriate drug delivery system that is effective across all age patients irrespective of their hormonal status.

VAGINAL ANATOMY AND PHYSIOLOGY

Premenopausal State

The vagina is a thin-walled, fibromuscular tube extending from the body exterior to the uterus. In the adult premenopausal female, the vagina is approximately 7 to 10 cm in length and 2 cm in width. The vagina may be segmented into the anterior wall (8 cm) and the posterior wall (11 cm), which combine to form two ridges of folds imparting a cross-sectional H-shaped appearance (1).

The vaginal wall consists of three principal layers: the epithelial layer, the muscular coat, and the tunica externa (adventitia). The inner mucosal layer may be further subdivided into the epithelium and lamina propria (2). The outermost epithelium is situated above the basement membrane and consists of noncornified, stratified squamous epithelium subdivided into four distinct layers: (*1*) a superficial layer consisting of large, flat cells with pyknotic nuclei; (*2*) an intermediate layer of larger and flatter nucleated cells; (*3*) a parabasal layer of polyhedral cells; and (*4*) a monolayer of cuboidal basal cells closely apposed to the basement membrane (3,4). A depiction of vaginal cell histology is shown in Figure 2. The first three cell categories are frequently exfoliated. Cuboidal cells are typically not sloughed off the vaginal wall unless undergoing extensive trauma. The epithelium overlies and is supported by the lamina propria, a region of dense connective tissue intertwined with a network of elastic fibers. The epithelium is drawn into numerous longitudinal and transverse muscular folds called rugae serving to increase the vaginal surface area (5). The vaginal wall does not contain mucus glands, but is continuously covered by a thin layer of protective moisture, some of which is obtained from Skene's and Bartholin's glands located near the vaginal orifice.

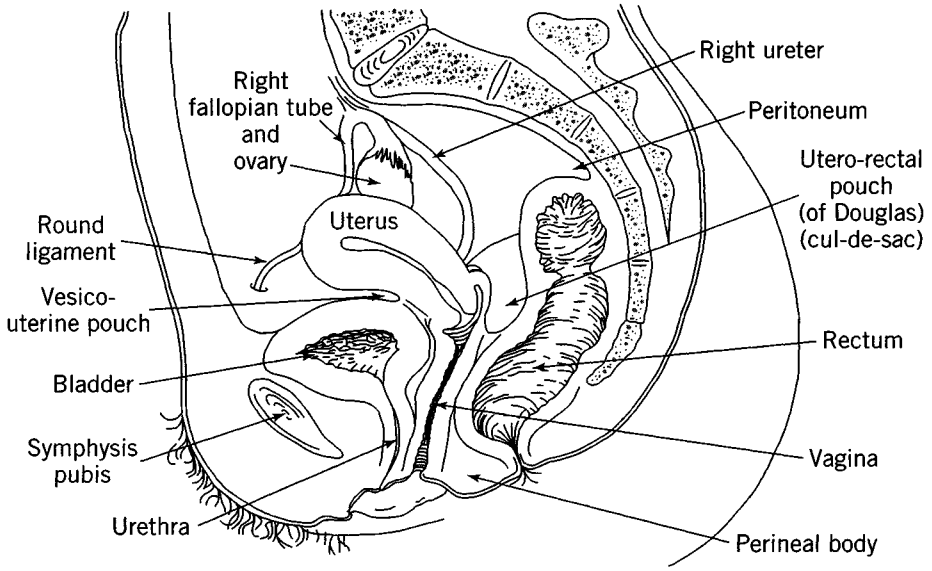

Figure 1. A depiction of the human reproductive system.

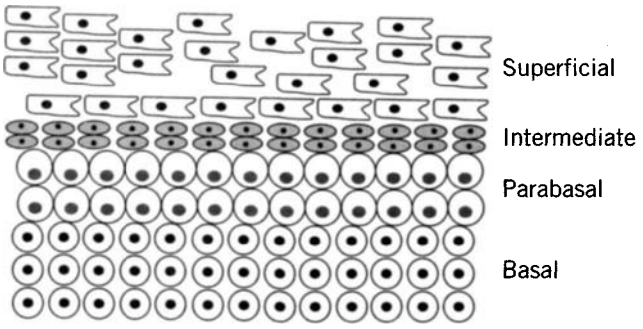

Figure 2. Depiction of vaginal histology.

Most vaginal secretions originate from cervical mucus glands and/or exuded fluid from the highly vascularized lamina propria (transudation) as well as cells sloughed off from the vaginal mucosa (3,6). Cervical mucus is a primary source of vaginal moisture and acts as a barrier layer protecting the underlying epithelium. During a woman's reproductive years, approximately 1 to 3 g/day of total fluid is secreted. Increased blood vessel dilation due to sexual stimulation leads to enhanced blood flow to the vaginal region and increases the production of this vaginal fluid. The volume and viscosity of cervical mucus undergoes significant changes during the menstrual cycle. Estrogen dominates during the first half of the cycle, which at ovulation induces large quantities of mucus secretion and is characteristically thin and alkaline. During the luteal phase, in which progesterone levels are high, mucus secretion decreases and is more viscous.

The muscular layer, lying distal to the epithelium, consists of smooth muscles and elastic fibers. The latter are primarily arranged in longitudinal fashion with a small inner portion of fibers arranged circularly. This organization imparts great elasticity to the vagina. The outer tunica adventitia consists of dense, loose connective tissue and provides a region of attachment of the vagina to surrounding organs.

Vaginal blood perfusion is supplied from uterine and pudendal arteries, which branch from the internal iliac arteries. Subsequently, these arteries form the cervicovaginal artery supplying the cervix and vaginal surfaces. The vaginal, uterine, and vesicle veins allow drainage of the rich plexus surrounding the vagina with eventual emptying into the internal iliac veins (3,7). Suffice it to say that the vagina is well endowed with a blood supply.

Vaginal fluid is acidic due to the presence of Döderlein's lactobacilli, which convert luminal carbohydrates such as glycogen secreted from exfoliated epithelial cells into lactic acid (8). A newborn child's vaginal pH ranges from 5.5 to 5.8, which is attributable to alkalinity of the amniotic fluid. During the first week of life, Döderlein's bacilli appear within the vaginal cavity dropping the pH to approximately 5.0. This value rises to neutrality within the first month and persists until puberty (9). During the years between the initial menstrual period (i.e., menarche) and menopause, pH for a healthy vagina drops to 4.0 to 5.0 with considerable fluctuation, dependent upon the menstrual cycle. The lowest pH values occur midcycle, whereas higher values are obtained during the period immediately prior to or preceding menstruation (9,10). A pH gradient also exists within the vagina, in which the lowest and highest values are obtained as one moves towards the cervix and vaginal vestibule, respectively (9). Sexual stimulation or enhanced blood flow stimulate an increase in vaginal pH.

The vaginal mucosa has been observed to undergo cytological changes influenced by the level and type of hormones present. Thus, due to a high concentration of maternal estrogen within the neonate, the vaginal epithelium is quite thick. Within three weeks, the epithelium flattens and remains relatively thin until puberty, at which time the epithelium thickens to normal levels ranging from 200 to 300 μm depending upon estrogen levels during the menstrual cycle.

Vaginal fluid consists primarily of cervical secretions and transudation from blood vessels through intercellular channels into the vagina. Thus, these secretions are dependent on blood flow rate. The weight of vaginal discharge in premenopausal women is 3–4 g/4 hours, whereas estrogen-deprived postmenopausal women have discharges that are 50% less. Table 1 shows typical vaginal discharges for women.

Peri- and Postmenopausal State

Perimenopause is the 3 to 5 years preceding menopause during which there is a reduction in estrogen levels. The perimenopause period typically begins during the midforties and is characterized by menstrual cycle irregularity (12). During a normal menstrual cycle, 6 to 12 follicles mature and proliferate in response to follicle-stimulating hormone (FSH) and luteinizing hormone (LH), but only a single follicle releases an ovum (13). The remaining follicles degenerate and by inception of menopause, a limited number of follicles are present in the ovary. During perimenopause, the reduction in functional follicles precipitates an alteration in ovary hormone secretion. Typically, the ovaries secrete high concentrations of estrogen during the follicular phase of the menstrual cycle. The menstrual cycle depends upon the presence of estrogen for development of theca and granulosa cells, which are involved in the production of estrone, estradiol-17 β, and also induce an LH surge required for ovulation (13,14). As the menstrual cycle becomes more irregular, the ovaries become unresponsive to higher FSH levels. By the end of perimenopause, estrogen production has declined 70–80% of its original concentration, leading to a subsequent decrease in estradiol production and thus removing an important negative feedback control to FSH production. The decline in estrogen levels also prevents LH production necessary for ovulation. Therefore, the initial clinical evidence of perimenopause is a shortened menstrual cycle precipitated by high FSH secretion creating rapid follicular development (14).

Menopause is defined as the last spontaneous episode of uterine bleeding in which the ovaries stop producing hormones (15). Histologically, the vaginal epithelium changes and returns to conditions similar to prepuberty. The epithelium thickness is reduced, corresponding to a shedding of the outer superficial and intermediate cell layers, in which vaginal smears of menopausal women primarily show the presence of basal cells and leukocytes (16). In premenopausal women, the vaginal mucosa may be as thick as 45 cell layers during the first half of the menstrual cycle. In comparison, the vaginal mucosa of postmenopausal women becomes fragile and may be composed of only three to four cell layers. Figure 3 represents a section of normal vaginal tissue compared with estrogen-deficient tissue. Along with epithelial thinning, there is a subsequent drop in glycogen and Döderlein's bacilli levels precipitating alterations in bacterial flora and an increased alkalinity to pH 7.0 (4). The pH change leads to an enhanced opportunity for bacterial and fungal infections due to the loss of acidic organisms within the vaginal cavity.

In postmenopausal women, there is a decrease in the size of the vagina in comparison to menstruating women. The average vaginal length and width decrease to 6.0 and 1.0 cm, respectively. The vagina also loses its elasticity and vascularity, the latter of which precipitates a reduction in vaginal secretions, which become increasingly watery after menopause (1).

Table 1. Vaginal Discharge Rates

Subjects	Rate of Discharge	Refs.
Reproductive Age		
Including cervical secretions	3–4 g/4 h	11
Without cervical secretions	2.7 g/24 h	10
Postmenopausal, no estrogen supplement	1.7 g/4 h	11
Hysterectomized		
Ovarectomized	1.56 ± 0.05 g/24 h	10
Intact ovaries	1.89 ± 0.12 g/24 h	10
Ovarectomized with estrogen supplement	1.97 ± 0.05 g/24 h	10

DESIRABLE FEATURES OF A VAGINAL DRUG DELIVERY SYSTEM

An ideal vaginal drug delivery system must be functionally effective and aesthetically pleasing to the patient. From a functional point of view, its purpose is to deliver drug at an effective rate over a predefined period of time. Because of patient compliance issues for every route of administration, the dosing interval should be as long as possible and preferably not less than once daily. A longer interval would be preferable provided it is not so unusual as to be confusing to the patient. Drug metering from the vaginal delivery system is determined by the pharmacodynamic response but minimally the drug delivery system must be sufficiently flexible to accommodate different drugs and different rates of release.

The aesthetic or patient-related issues can be prominent and must be considered. Such factors as vaginal leakage of the system and staining of undergarments are important concerns. It also goes without saying that the

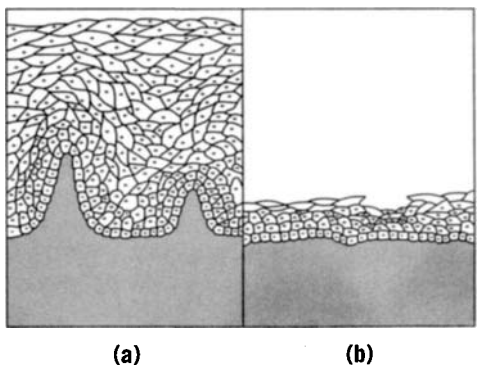

Figure 3. (**a**) Normal vaginal mucosa and (**b**) estrogen-deficient mucosa.

system must not be irritating or interfere with normal physiological processes.

A significant issue for chronically administered drugs is whether or not the system interferes with sexual intercourse. To this end, insoluble inserts, or bulky erodible systems, are likely to be less well accepted by the patient. Gels and creams must be odorless and not create a sticky sensation during sexual intercourse.

A concern for any product to be commercialized is the ease and cost of manufacturing. A unit dose system does not need a preservative but the microbial bioburden must be low. Methods to process the drug delivery system to ensure low bioburden are often limited by the physical nature of the system or the physicochemical stability of the system to sterilizing techniques. A multidose system does require a preservative, and this can require substantial development effort to find a suitable chemical preservative.

REPRODUCTIVE SYSTEM PATHOLOGIES AND TREATMENT

Vaginal Dryness

As the estrogen level begins to decline at the onset of menopause, subsequent vaginal anatomical and physiological changes occur such as vaginal atrophy and a lack of tissue hydration. A reduction in circulating estrogen levels precipitates vasoconstriction leading to less blood flow and consequently less fluid transudation to the vaginal tissue (6). Five years after the last menstrual period, only 25% of women complain of vaginal dryness, with the percentage of complaints increasing to 65% by 60 years of age. Vaginal dryness is more commonly a problem for postmenopausal women who are not sexually active or not undergoing drug therapy. The reduction of the epithelium to 4 or 5 cell layers and the lack of tissue hydration results in the vagina becoming predisposed to a greater likelihood of irritation with subsequent inflammation. Common complaints caused by vaginal dryness include a burning sensation, postcoital bleeding, purulent discharge, a decrease in lubrication with sexual arousal, and dyspareunia (6).

Vaginal dryness is typically not a serious problem and can often be treated with either hormone replacement therapy or topical lubricants. Estrogen replacement therapy has been shown to increase vaginal hydration to levels of the premenopausal state, but may be contraindicated in certain patients such as breast cancer patients who are likely also taking tamoxifen, an estrogen blocker. Therefore, the development of a nonhormonal therapeutic would be advantageous. A microparticulate system called Replens®, which incorporates a cross-linked bioadhesive polymer, polycarbophil, was introduced into the market. The topical moisturizer remains within the vagina for 3 to 4 days and has been shown to impart greater lubrication efficacy in comparison with other lubricants (17).

A study on breast cancer patients, a group for which estrogen replacement therapy is contraindicated, found that vaginal dryness was relieved with use of Replens as well as returning vaginal pH to premenopausal levels (6). Of 25 postmenopausal patients, the vaginal dryness index as described in Table 2 improved after the first month of treatment ($P < .001$). Other studies have also indicated the safety and efficacy of Replens compared with local estrogen therapy. Nachtigall showed that in a randomized study of 30 women, over one year past their last menstrual period, Replens was an alternative therapy to estrogen vaginal cream (18). This therapy induced significant enhancement in vaginal moisture, lubrication, and vaginal elasticity with concomitant reduction in pH to premenopausal levels.

Bioadhesive gels induce tissue hydration by increasing localized vaginal blood flow by 25%, leading to an increase in vaginal fluid transudation. Estrogen induces similar vaginal blood flow enhancement when used alone. If combined with a bioadhesive gel, an increase in vaginal blood flow of 50% has been exhibited. The exact mechanism for the blood flow increase is unknown, but it has been postulated that the bioadhesive polyelectrolyte on the tissue surface creates ion movement into the tissue. Subsequently, greater blood flow is observed. This is similar to the mechanism of tissue hydration induced by the mucus layer lining epithelial surfaces (6).

Menopausal Stress Incontinence

Given that both vaginal and urethral blood flow increased following application of Replens, it is expected that the same product might be useful to treat patients with menopause-related stress incontinence. As with vaginal dryness, there are a number of women, such as breast cancer patients, who cannot use estrogen replacement therapy and thus a nondrug alternative is attractive.

The lower urinary tract contains the urethra, a tubular structure that allows urine to exit from the urinary bladder. The urethra is composed of estrogen-sensitive tissues similar to those found in the vagina, due to the presence of estrogen receptors located in the mucosa and connective tissue (20). Urethral cells, like vaginal mucosa, mature and proliferate upon estrogen exposure. During menopausal and postmenopausal years, the reduction in estrogen levels lead to marked changes in the urinary system such as the inability for effective urine control. Urinary stress incontinence is a condition resulting in urine leakage due to physical stress such as heavy lifting, coughing, or laughing. In postmenopausal years, the urethral mucosa atrophies to a state in which the urethra is primarily lined with immature parabasal cells (19). Additionally, the lack of estrogen promotes a weakening and relaxation of urethra musculature and ligaments, while also diminishing the level of blood flow to the region. These three factors combine to contribute to the loss of urinary continence inducing a 30% drop in urethral closure pressure in postmenopausal women (19). Studies have shown a significant correlation between menopause and the onset of urinary stress incontinence with 70% of postmenopausal women in one study suffering from incontinence due to the initiation of menopause (20,21).

Estrogen replacement therapy is the most common form of treatment for urinary stress incontinence. Increased estrogen levels cause thickening of the mucosa, increased blood supply, and enhanced muscle tone to the urethra. Recently, it has been shown that bioadhesive gels may provide not only an enhancement in vaginal blood flow, but

Table 2. Vaginal Health Index

	1	2	3	4	5
Elasticity	None	Poor	Fair	Good	Excellent
Fluid volume (pooling of Secretions)	None	Scant amount, vault not entirely covered	Superficial amount, vault entirely covered	Moderate amount	Normal amount
pH	6.1 or above	5.6–6.0	5.1–5.5	4.7–5.0	4.6 or below

Moisture (coating)	None, surface inflamed	None, surface not inflamed	Minimal	Moderate	Normal

Source: From Ref. 19.

also induce a doubling of suburethral blood flow leading to the elimination of urinary stress incontinence (6). This result has been substantiated in double-blind cross-over studies.

Bacterial Vaginosis

Trichomoniasis, candidiasis, and bacterial vaginosis are several forms of vaginitis that commonly occur within the female population. Bacterial vaginosis, formerly named nonspecific vaginosis or *Gardnerella*-associated vaginitis, is the most prevalent vaginal infection among women of childbearing age, 16–48 years (22,23). Bacterial vaginosis is not a true infection but a condition in which there is an alteration in the balance of vaginal bacteria without inflammation. Under normal conditions, the vagina is heavily populated with lactobacilli bacteria, which help to maintain vaginal acidity. Bacterial vaginosis is characterized by a reduction in lactobacilli concentration with subsequent increases in aerobic and anaerobic bacteria including, *Gardnerella vaginalis*, *Mycoplasma hominis*, *Ureaplasma urealyticum*, and *Bacteroides* species (24,25).

Women with bacterial vaginosis often have a fish-like vaginal odor, a thin milky-grey homogenous vaginal discharge, vaginal pH > 4.5, and a positive test for clue cells in the vaginal fluid. An increase in vaginal pH liberates amines such as putrescine, trimethylamine, and cadaverine leading to the fish-like odor. Because semen is also slightly alkaline, women with bacterial vaginosis commonly complain of an enhanced odor following sexual intercourse (26).

Bacterial vaginosis commonly occurs in sexually active women with no convincing evidence that it should be categorized as a sexually transmitted disease. It is more common in women who use nonbarrier contraceptive methods but less common in postmenopausal women and prepubescent girls (27,28). These observations led to the theory that hormonal factors play a role in the condition. However, hormones have never been associated with the disease, and in many cases, there are no obvious factors predisposing women to bacterial vaginosis.

Since 1978, metronidazole has been the treatment of choice for bacterial vaginosis. Various studies have shown that oral metronidazole (500 mg twice daily for 7 days) is the preferred treatment (24,29,30) but other regimens consisting of single-dose metronidazole (2 g), 2% clindamycin vaginal cream, and oral clindamycin are effective treatments (31). Other alternatives to metronidazole delivery systems are needed due to unpleasant side effects and contraindications during the first trimester of pregnancy.

Recently, increased interest in the development of localized drug delivery systems within the vaginal cavity has been shown due to the advantage of localized drug levels, which reduces dosing frequency, drug administration, and side effects (32). Treatment of bacterial vaginosis with bioadhesive gels with pH-reducing properties would be expected to eliminate the characteristically fishy odor within a short time period due to the conversion of polyamines to nonvolatile salt forms. Additionally, the return of the vaginal environment to acidic pH would favor a higher lactobacilli population (6).

In a double-blind, placebo, crossover study consisting of women with vaginal odor, the bioadhesive gel product was locally applied every third day. The study showed two effects upon application: (*1*) a reduction in vaginal pH and (*2*) a concomitant decrease in vaginal odor when compared with the placebo group. The bioadhesive gel is not an antimicrobial gel but it potentiates an unfavorable condition for continued microbial growth (6).

Recently, there has also been interest in the development of a metronidazole bioadhesive tablet. Studies were performed to determine the efficacy of treatment between a localized metronidazole bioadhesive and oral tablets for the treatment of bacterial vaginosis (32). In a double-blind study, patients were randomly given a bioadhesive tablet with or without 100 mg metronidazole. The bioadhesive consisted of a modified starch–polyacrylic acid combination. The two groups were compared with patients given two 500 mg doses of oral metronidazole for 7 days. Similar cure rates were obtained with the metronidazole bioadhesive tablet and oral treatment groups with only one-seventh of the dose given with localized treatment.

Sexually Transmitted Diseases

There are an estimated 333 million new cases of sexually transmitted diseases (STDs) that occur worldwide each year. The United States leads the industrialized world with an STD rate that is 50–100 times greater than other industrialized countries with an estimated 10 to 12 million new cases annually (33). Women, adolescents, young children, and substance abusers are most susceptible to the

spread of STDs. Of the new cases, greater than 3 million occur in children and young adults 13 to 19 years of age. A recent Centers for Disease Control and Prevention (CDC) report indicated that of the common U.S. infectious diseases, 85% originated from sexual transmission (34).

Some of the most common STDs include chlamydia, gonorrhea, syphilis, human papillomavirus, genital herpes, and human immunodeficiency virus (HIV). Chlamydia is ranked by the CDC as the most prevalent with an estimated 4 million new cases annually. Gonorrhea is the next most prevalent with new cases occurring at a rate of 800,000 per year. In 20–40% of women who obtain inadequate treatment of chlamydia and gonorrhea, the disease leads to a more serious disease state, namely pelvic inflammatory disease. Inadequate treatment may also result in fatal ectopic pregnancies (34).

HIV infection has been reported in over 160 countries with 75% of the population infected via sexual transmission of the virus (35). Estimations are anywhere between 40,000 to 80,000 new HIV infections per year in the U.S. with an average of 500,000 to 2.3 million adult AIDS deaths worldwide between 1992 and 2000 (36).

Overcoming STDs is one of the greatest concerns and challenges facing the world today due to the health impact on infected individuals and the tremendous economic consequence associated with treatment. In the U.S. alone, STDs add between 15 and 18 billion dollars annually to the cost of the nation's health care system (34).

One potential method for controlling the spread of STDs is preventing the transmission of the infecting organism. Nonoxynol-9 (N-9) is a nonionic surfactant that exerts both spermicidal and antiviral/antibacterial activities by damaging cell membranes of spermatozoa and microorganisms. This agent is the only chemical currently used in the U.S. as the active substance in topically applied contraceptives. In vitro, N-9 has been shown to have activity against organisms responsible for STD pathogenicity such as *Neisseria gonorrhoeae*, *Trichomonas vaginalis*, *Treponema pallidum*, herpes simplex, *Chlamydia trachomatis*, and HIV (37–39). In vitro studies have indicated that 0.1–1.0% N-9 inactivates cell-free and cell-associated HIV (40). In concentrations of 5% or greater, N-9 kills lymphocytes containing the HIV virus. Because gonococcal, chlamydial, and trichomonal infections have been correlated with an increased risk of HIV transmission, the reduction in the spread of these diseases would also indirectly reduce the number of HIV infections.

Clinical trials have established that N-9 preparations can decrease the transmission of STDs such as gonococcal, chlamydial, and trichomonal infections (41–43). An N-9 film, when used in combination with condoms, in a single-blind randomized study of 343 women reduced the rate of cervical infections of *Chlamydia trachomatis* and *Neisseria gonorrhoeae* by 25% (40% if used in >75% coital acts). In a study by Rosenberg et al., N-9 (1.0 g) in a contraceptive sponge decreased the prevalence of gonorrhea and chlamydia infection in Thai women by 70% and 30%, respectively (36).

There is some controversy whether N-9 used in vivo is effective in HIV inactivation. A contraceptive vaginal sponge containing N-9 (1.0 g) did not protect women prostitutes against being infected with HIV (10). However, in a second study using an N-9 suppository with a lower N-9 dose (150 mg), there was evidence of a protective effect against HIV infection among women prostitutes (44).

One of the problems associated with N-9 administration is the potential for N-9 toxicity to the genital tract epithelium when frequently administered or used in high doses. Under these conditions, the vaginal mucosa may become irritated increasing the risk for women to be infected with HIV due to small lesions or disruptions within the vaginal lining.

The use of a bioadhesive gel in combination with N-9 would be advantageous particularly due to the fact that the spermicide would remain localized within the vaginal cavity for 1 to 3 days providing localization of N-9 for greater time periods in addition to a reduced N-9 concentration within the vaginal cavity. The gel allows intimate contact with the tissue with preferential binding to damaged tissue enabling an additional use as a barrier to systemic invasion of HIV viruses. The complex of N-9 and bioadhesive polymer has also been shown to increase N-9's antiviral and spermicidal activity. The Today Sponge and other nonbioadhesive topical spermicidal preparations contain anywhere between 1.0 g and 100–200 mg N-9, respectively. The combined bioadhesive spermicidal preparation contains a lower concentration of N-9 preventing cervical or vaginal epithelial ulceration while still having spermicidal, antiviral, and antimicrobial activity (45).

In studies at the Pasteur Institute in Paris, France, researchers have shown that N-9 can kill the free AIDS virus, but not when the virus is attached to a lymphocyte. If N-9 is combined with a bioadhesive, the bioadhesive attaches to the lymphocyte for a period of time allowing N-9 to kill the lymphocyte and subsequently the AIDS virus (44). However, clinical studies have yet to be performed that confirm these results.

Advantage 24, a topical contraceptive, contains N-9 in a bioadhesive gel composed of polycarbophil. The product adheres to the epithelium and remains localized allowing for once-a-day application. Advantage 24 forms a temporary barrier over the cervix and contains the lowest dose of N-9 (52.5 mg) of any product on the U.S. market (46). The frequency of sexual intercourse does not affect localization of the delivery system nor the dosing interval.

A randomized, placebo-controlled, double-blind crossover study of 60 female prostitutes in Mombasa, Kenya, was conducted to establish the safety and toxicity of Advantage 24 administration (47). Advantage 24 or a placebo gel was applied vaginally once daily for 2 weeks. The study concluded that Advantage 24 did not induce epithelial toxicity.

The Joint United National Programme on HIV/AIDS has recently announced that Advantage 24 was shown to inhibit STD transmission (HIV included) during intercourse (46). Due to the prospect that women may want to increase the N-9 dose or possibly decrease the potential for condom usage, the CDC will not accept N-9 as an alternative method for combating or preventing HIV/STD infection. Currently, additional Phase III studies of Advantage 24 for HIV are underway in Thailand and South Africa (46).

Endometriosis

The inner portion of the uterus is lined with endometrial tissue that responds to hormonal stimulation by proliferating prior to each menstrual period with subsequent shedding as menstrual flow during the latter portion of the menstrual cycle. Endometriosis is a benign disease in which the endometrial tissue migrates to areas outside the uterine cavity such as the ovaries, fallopian tubes, pelvic cavity, vagina, and large bowel (48). The invasive tissue is sensitive to hormonal stimulation with resultant breakdown and bleeding confined to a localized area with no outlet, leading to tissue irritation and inflammation (22,49). This may initiate scar tissue development with subsequent lesion, nodule, or growth formation resulting in pain or sexual discomfort.

Menstrual cramping (i.e., dysmennorrhea), an important diagnostic symptom, is the most frequently experienced pain associated with endometriosis. Endometriosis is found in 10–15% of menstruating women between the ages of 25 and 44 (50). Women may also experience pain associated with sexual activity (i.e., dyspareunia) and chronic midline pelvic pain (48,51). Bladder and large bowel lesions may cause pain upon defecation or abdominal bloating, or produce rectal bleeding (50). In 30–40% of cases, endometriosis may be severe enough to cause infertility (49). For women under 35 years of age, surgery may restore or maintain fertility in 25–50% of the cases. For women over 35, removal of the ovaries and uterus may be recommended.

There are various treatment options depending on the age, symptoms, desire for pregnancy, and disease extent. Typically, treatments include either drug therapy to suppress the growth and differentiation of the displaced tissue, surgery, or abdominal hysterectomy (50).

Drug therapy is used as a means for palliation and is very often not a cure. The standard for drug therapy is danazol, a drug that decreases estradiol concentration by reducing the frequency of estradiol pulses. Disease recurrence occurs between 20 and 30% per year and side effects include nausea, weight gain, and hot flashes (51). Gonadotropin-releasing hormone agonists (e.g., nafarelin, leuprolide) are used to control the release of anterior pituitary hormones producing a state of reversible hypoestrogenemia (50). There are concerns over the long-term usage of these medications due to an increase in low density lipoprotein (LDL) levels and/or a greater chance of developing osteoporosis.

Progestin agents have been shown to decrease the risk of estrogen-precipitated endometrial hyperplasia by promoting the transformation of the endometrium into a secretory mucosa, but their use has been limited due to promotion of irregular vaginal bleeding, depression, and enhanced LDL levels (52).

In order to reduce these unwanted side effects, strategies were developed aimed at looking toward new delivery routes and using natural progesterone to reduce side effects. Natural progesterone is problematic when administered orally due to rapid prehepatic and hepatic metabolism leading to insufficient endometrial effects (53). The production of metabolites also leads to symptomatic side effects, in particular, drowsiness. Vaginal administration of natural progesterone induced higher plasma concentrations reached later after dosing and reduced side effects than when administered orally due to a reduction in prehepatic metabolism (21).

Crinone®, a biocompatible bioadhesive gel incorporating natural progesterone (90 mg), was developed as a delivery system to circumvent oral delivery problems. The bioadhesive gel adheres to the vaginal epithelium imparting prolonged release properties. The gel may be administered once daily with peak progesterone plasma levels occurring 6 hours after application (29). Crinone given every 48 hours induced an effective secretory endometrial transformation usually encountered with oral progesterone (300 mg) administration or with 150–600 mg vaginal tablets (37). The explanation for the effectiveness of Crinone is the bioadhesive vehicle allows for greater absorption of progesterone by promoting enhanced contact time with vaginal epithelium. Although not approved for endometriosis at this time, but approved for in vitro fertilization patients, Crinone has shown the potential for use of a vaginal bioadhesive delivery system providing prolonged release of progesterone at lower doses which results in fewer side effects, reduced dosing frequency, and improved patient compliance and acceptance.

TOPICAL CONTRACEPTIVES

Prevention of pregnancy, i.e., population control, is a global problem. Oral contraceptives have been the treatment of choice since their introduction in the 1950s. However, for many individuals, because of their inability to use hormone products, or the cost of such products, topical contraceptives are a reasonable alternative. For a topical contraceptive to be effective, its active ingredient, usually N-9, must be placed in the vaginal cavity to immobilize or destroy the approximately 40 million sperm in a typical ejaculate. If not destruction of these sperm then elimination of those sperm prevents them from the cervical canal (Figure 4). This is a formidable challenge.

Present topical contraceptives have label instructions to the patient that the product must be inserted 10 minutes before sexual intercourse. Presumably the clearing mechanisms of the vagina are sufficiently robust to remove applied material, which is a strong argument for using a bioadhesive product that may keep the product in place for 3–4 days.

The more difficult issue is how to place and maintain the spermicidal product at the opening of the cervical canal both during and after sexual intercourse. At midcycle, when the egg is available for fertilization, there is a change in consistency of cervical mucus and subsequent leakage of this material out through the opening of the cervical canal, i.e., the os. This flow of mucus will hinder retention of a liquid or semisolid material from remaining at the site of expected maximal need.

Current topical contraceptives are reasonably unreliable, as compared with oral contraceptives. The need to use the product 10 minutes before sexual intercourse and thus no overnight protection is a significant liability. A bioadhesive polymer can indeed provide extended duration of action and thus elevate the reliability of bioadhesive-

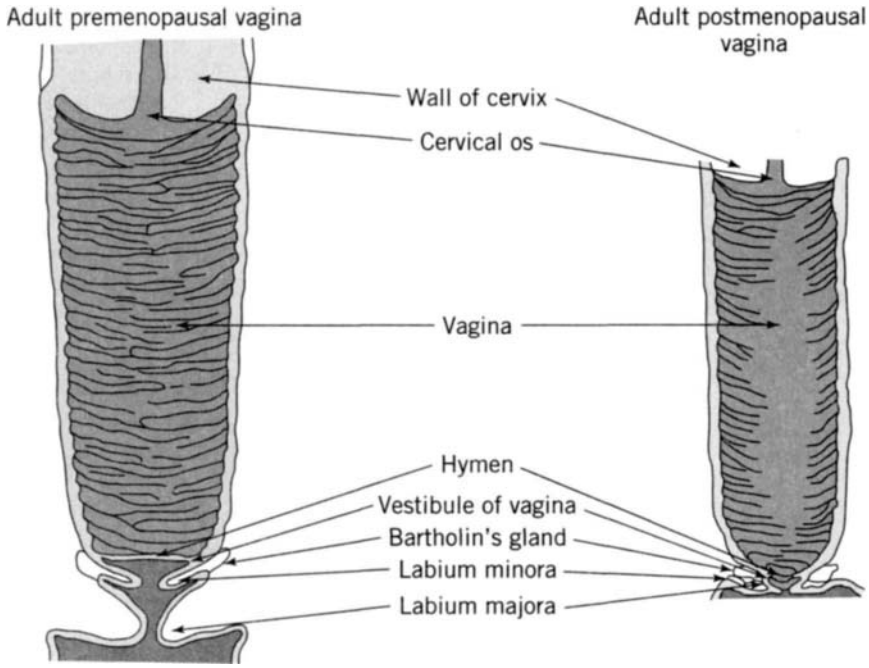

Figure 4. Depiction of vaginal anatomy.

based topical contraceptives. However, until a product can be made that will remain at the opening of the os, to serve as both a physical and chemical barrier, topical contraceptives will remain less reliable than oral contraceptives.

OTHER VAGINAL DRUG DELIVERY SYSTEMS

Many dosage forms have been used for vaginal drug delivery with the most common being pessaries (suppositories), gels, and foams. Early work by Masters and Johnson showed that vaginal distribution of these dosage forms varied considerably with the nature of the system and method of instillation.

Table 3 gives a summary of vaginal delivery systems using hydrogel polymers. The forms of these vaginal products include rod-shaped monolithic devices (54), gels (20), and discs.

VETERINARY APPLICATIONS

Current commercially available controlled release drug delivery systems intended for intravaginal use in animals are restricted to the delivery of compounds used to control the estrus cycle (55–57). These compounds include progesterone, fluorogestone acetate, and methyl acetoxy progesterone (55–57). A further drug, estradiol benzoate, is also administered intravaginally in a commercially available product (58,59); however, it is administered to cattle as a 10 mg hard gelatin capsule that does not include any controlled release component. Following administration and release, the estradiol is immediately available for absorption (58,59).

Table 3. Hydrogen-Based Vaginal Delivery Systems

Drug	Hydrogel[a]	Test animal	Refs.
Bleomycin	HPC/C-934	Human	15
Insulin	PAA	Rats/rabbits	20
Progesterone	MEEMA/HEMA/MEMA	Not tested	54
Progesterone	Noveon AA1/C-934	Human	35
Prostaglandin E_2	HEMC	Human	31
Prostaglandin E_2	Unspecified	Human	31
Prostaglandin E_2	Cross-linked PEG	Human	43,44

[a]HPC, hydroxypropyl cellulose; PAA, poly(acrylic acid); MEEMA, (methyl ethyl)ethyl methacrylate; HEMA, hydroxyethyl methacrylate; MEMA, methyl ethyl methacrylate; HEMC, hydroxy ethyl methyl cellulose; PEG, poly(ethylene)glycol.

Possible reasons for the area of controlled release intravaginal drug delivery focusing on compounds for the control of the estrus cycle include (*1*) the demand for improved herd or flock management techniques coupled with the need to control the estrus cycle for more economic animal production, which was confounded by the inability of the compounds used to control the estrus cycle to be effective orally (due to extensive hepatic metabolism) and therefore the need for an alternate route of administration; (*2*) the need for rapid termination of drug delivery to allow a sharp decline in progestagen plasma levels to induce an estrus response, which requires a route of administration that allows ready access and easy removal of a delivery system; (*3*) the inabilities of other routes of administration to achieve these requirements (the one exception being the ear flap for which a small subcutaneous ear implant containing norgestomet was developed) (60–69); (*4*) the ideal physicochemical properties of the compounds that control the estrus cycle, which was reflected in their ability to be rapidly absorbed across the vaginal mucosa; and (*5*) the conductive pharmacokinetic properties of the compounds that control the estrus cycle, i.e., the small minimum effective concentrations that are associated with these compounds to maintain control over follicular growth, coupled with their rapid elimination kinetics, which facilitate the sharp drop in plasma levels which is needed to induce estrus.

Several commercially available intravaginal veterinary drug delivery systems have been marketed. These include PRID, CIDR-S (no longer available), CIDR-G, CIDR-B and polyurethane sponges of various sizes and densities (Fig. 5). None of these delivery systems impart a true controlled release over the drugs they contain; all simply allow the incorporated drug to slowly leach out with time. Recently a sophisticated microchip-controlled intravaginal drug delivery system was introduced onto the New Zealand market. This delivery system was designed to allow a constant daily release of a progesterone for 10 days, and a pulsed release of estradiol and prostaglandin 1 hour and 6 days, respectively, after insertion. In addition to commercially available products, several conceptual intravaginal veterinary drug delivery systems have also been described in the literature (17–24). These include Rajamahendrans Rubber Tubing device (cattle) (70–72), the Plasthyd Device (sheep) (73), and Kabadi and Chiens silicone sheets (sheep) (74–77).

Animals species in which these intravaginal drug delivery systems are used are currently limited to cattle, sheep, and goats. This is a reflection of several reasons including the conducive management practices associated with these animals; the needs and demands of the end user; the economics associated with the unit cost of the intravaginal drug delivery system versus the value of the animal concerned; the high progestagen requirements that are needed to control the estrus cycle of some animals, e.g., pigs; and the laws governing artificial insemination procedures in some animals (e.g., until recently artificial insemination in horses was banned). The availability of cheaper technologies and delivery systems, changes to artificial insemination laws, and innovative delivery systems that can deliver greater quantities of progestagen may see an expansion in the types of animals in which intravaginal veterinary drug delivery systems are developed and used.

Other species have been investigated for the potential application of intravaginal drug delivery. These include deer (78–95), horses (96–103), and buffalo (104–109). The commercially available sponges designed for use in sheep and goats have been investigated in deer (78–81) and horses (96–99). The probable reasons for these delivery

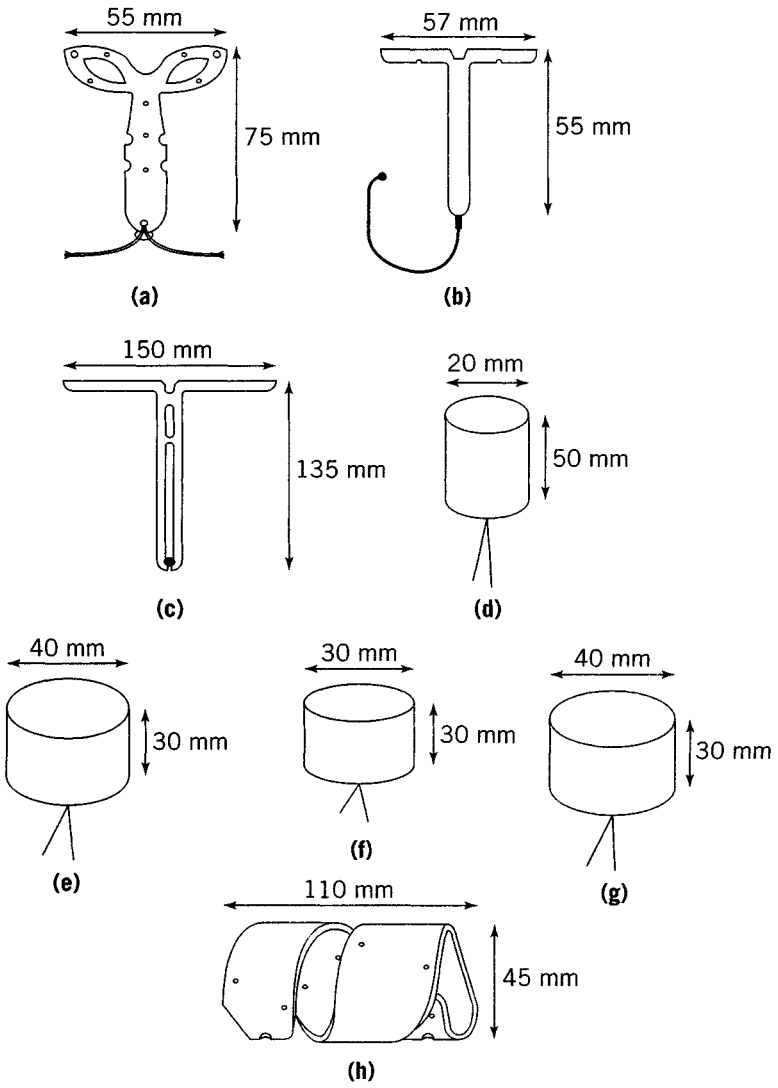

Figure 5. Commercially available estrus-synchronizing controlled release intravaginal drug delivery systems used in cattle, sheep, and goats. (**a**) CIDR-S (0.465 g progesterone; sheep) (no longer commercially available); (**b**) CIDR-G (0.33 g progesterone; sheep and goats); (**c**) CIDR-B (1.9 g progesterone; cattle); (**d**) Repromap sponge (60 mg methyl acetoxy progesterone; sheep); (**e**) Chronogest sponge (30 mg fluorogestone acetate; sheep); (**f**) Chronogest sponge (40 mg fluorogestone acetate; goats); (**g**) Chronogest sponge (45 mg fluorogestone acetate; goats); and (**h**) PRID (1.55 g progesterone; cattle). Delivery systems E and G are manufactured from sponges of different density.

Table 4. Factors To Consider When Designing an Intravaginal Veterinary Drug Delivery System for Estrus Control

Factor	Objective	Reason
Size	Optimize: Length Diameter Width	Animal comfort Ease of insertion Ease of removal
Shape	Optimize: Overall spatial geometry	Impel retention characteristics Prevent animal discomfort and damage Impel a means for insertion and removal
Retention	Maintain device inside vagina for entire treatment period	Ensure continuity of drug delivery over required insertion period
Release characteristics	Meet clinical requirements	Maintain sufficiently high progestagen plasma levels to prevent ovulation
Removal	Ability to: Terminate delivery at will Remove easily	Impel sudden drop in progestagen levels to induce estrus
Adverse effects	Avoidance of: Damage to mucosa Damage to cervix Irritation to vaginal mucosa	Reduce discharge formation Eliminate membrane perforation

Table 5. Polymers, Drugs, Manufacturing Methods and in vitro and in vivo Release Characteristics of Commercially Available Controlled Release Intravaginal Veterinary Drug Delivery Systems

Delivery system	Drug	Polymer	Manufacturing technique	Type of delivery system	Release characteristics	
					in vitro	in vivo
Sponge	FGA[a] MAP[b]	Polyurethane	Single application of drug dissolved in ethanol	Matrix	$t^{1/2}$ (21)	$t^{1/2}$ (142–144)
PRID	Progesterone	Silicone	Low temperature injection molding[c]	Matrix	$t^{1/2}$ (94)	$t^{1/2}$ (145)
CIDR-S	Progesterone	Silicone	High temperature (190°C) injection molding[d]	Matrix	Not reported	Not reported
CIDR-G	Progesterone	Silicone	High temperature (190°C) injection molding[d]	Matrix	$t^{1/2}$ (Personal results)	Not reported
CIDR-B	Progesterone	Silicone	High temperature (190°C) injection molding[d]	Matrix	$t^{1/2}$ (146)	Not reported

[a]PGA, Fluorogestone acetate
[b]MAP, Methyl acetoxy progesterone
[c]Progesterone/silicone mixture around a stainless steel sheet
[d]Progesterone/silicone mixture around a nylon spine

systems not being successful in these animals may include the excessive amount of discharge associated with sponges (which may be acceptable by sheep and goat farmers but not by owners of these other species) and poor retention rates. CIDR-G have been inserted into deer with success both in terms of estrus synchrony and suitability of the delivery system design with respect to animal comfort, retention, etc. (86–95). Both PRID and CIDR-B have been investigated in horses (100–103) and buffalo (104–109). The probable reason for these delivery systems not being completely successful in these animals is the inappropriate design for these species (i.e., overall dimensions), which results in either straining following insertion (100,101) or the need to adapt the dimensions of the device before insertion to improve retention characteristics (103).

Brief History

Controlled drug delivery has a long history in the animal reproduction field. Polyurethane sponges were first investigated in sheep in the early 1960s as a delivery system for the administration of synthetic progestagens to control the estrus cycle (110–112). T.J. Robinson successfully demonstrated the worth of this delivery system in large sheep trials under Australian farming conditions (110–112). Shortly afterwards, D.F. Wishart demonstrated that the sponge was equally effective in sheep farmed under British conditions (113–124). In the 1970s, J.F. Roche in collaboration with Abbott Laboratories developed the PRID device for use in cattle (116–123). In the 1980s, R.A.S. Welsh in collaboration with D. Miller developed the CIDR-S (124,125) and shortly afterwards the CIDR-G (for sheep and goats) (126–130). Rapid development resulted in the CIDR-G technology being extended to the design and development of a device for use in cattle called the CIDR-R (131–141). Interdispersed with these developments were conceptual approaches of Rajamahendran (cattle) (70–72), the Plasthyd Device (sheep) (73) and Kabadi and Chiens silicone sheets (sheep) (74–77).

DESIGN FACTORS IN CONTROLLED RELEASE INTRAVAGINAL VETERINARY DRUG DELIVERY SYSTEMS

A number of factors should be considered when designing a controlled release intravaginal veterinary drug delivery system (M.J. Rathbone et al., unpublished data, 1998). These are summarized in Table 4. Ease of insertion, retention characteristics, ease of removal, animal comfort, and achievement of clinical objectives (through release rates) are the key aspects that need to be considered and tailored to a particular animal species if an intravaginal veterinary drug delivery system is to be successfully developed.

INTRAVAGINAL VETERINARY DRUG DELIVERY SYSTEMS

Currently available intravaginal veterinary drug delivery systems are shown in Figure 5 together with their dimensions. A brief description of the delivery system, polymer used to manufacture it, and the type of release characteristics are given in Table 5.

FUTURE DEMANDS AND REQUIREMENTS OF INTRAVAGINAL VETERINARY DRUG DELIVERY SYSTEMS

The future demands for intravaginal veterinary drug delivery for animal health and production are dependent upon the perception in some circles for the need to eliminate the adverse and unwanted effects which intramuscular and subcutaneous injection cause on administration such as ulcer formation and hide damage. Alternate routes for drug administration may be necessary to limit the occurrence of these problems and the intravaginal route offers advantages for some compounds. Future demands on the intravaginal veterinary drug delivery scientist will be influenced by the extent to which this concept is pursued and the suitability of the physicochemical and pharmacokinetic properties of the drugs which need to be delivered. In addition intravaginal veterinary drug delivery system design will be influenced by the requirements of the reproductive physiologists and endocrinologists who are currently defining the types of drugs and their delivery patterns for "ideal" synchrony programs (55–58).

Bibliography

The challenge of modern drug therapy is the optimization of the pharmacological action of drugs coupled with the reduction of their toxic side effects in vivo. One response is the use of colloidal drug carriers that can provide site-specific or targeted drug delivery combined with optimal drug release profiles. Among these carriers, liposomes and nanoparticles have been the most extensively investigated. In the late seventies, because liposomal formulations started to face some technological limitations including poor stability and low drug entrapment efficiency, polymeric nanoparticles were proposed as alternative drug carriers. Nanoparticles are solid colloidal particles ranging in size from 10 to 1,000 nm. They are made of a macromolecular material which can be of synthetic or natural origin. Depending on the process used for their preparation, two different types of nanoparticles can be obtained, namely nanospheres and nanocapsules. Nanospheres have a matrix-type structure in which a drug is dispersed, whereas nanocapsules exhibit a membrane-wall structure with an oily core containing the drug. Because these systems have very high surface areas, drugs may also be adsorbed on their surface. The general structure and drug association modes of nanoparticles are illustrated in Figure 1 (1).

MANUFACTURE OF NANOPARTICLES

Numerous methods exist for the manufacture of nanoparticles, allowing extensive modulation of their structure, composition, and physicochemical properties. The choice of the manufacturing method essentially depends on the raw material intended to be used and on the solubility characteristics of the active compound to be associated to the particles. Regarding the raw material, criteria such as biocompatibility, the degradation behavior, choice of the administration route, desired release profile of the drug, and finally, the type of biomedical application determine its selection. From these considerations, it is clear that nanoparticle formulation requires an initial and very precise definition of the needs and objectives to be achieved.

Historically, the first methods used to produce nanoparticles were derived from the field of latex engineering developed by polymer chemists. These methods were based on the in situ polymerization of a monomer in various me-

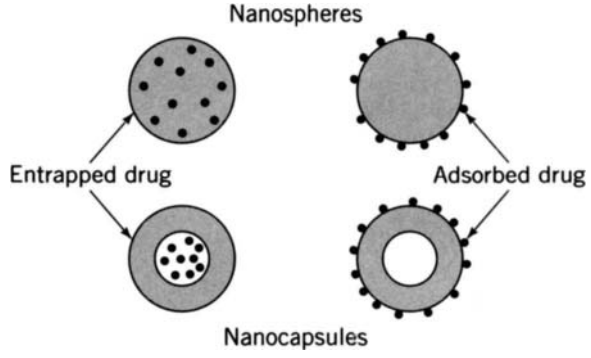

Figure 1. Various types of drug-loaded nanoparticles. *Source:* From Ref. 1.

dia. Pioneers in this field were Birrenbach and Speiser (2) who produced in the early seventies the very first polymerized nanoparticles for pharmaceutical use. Since that time, in situ polymerization-based methods have been widely developed, allowing a great diversity of nanoparticulate formulations to be obtained, as well as a better understanding of the mechanisms involved in these processes. In spite of real technological advances realized in this field, polymerization-based methods may present some drawbacks and limitations, which have made the development of new methods necessary. Thus, alternative methods based on the dispersion of well-characterized preformed polymers or natural macromolecules have been proposed, enlarging the field of possibilities for nanoparticulate formulations. As with polymerization-based methods, these new techniques allow the production of both nanospherical and nanocapsular systems. The most important milestones in the development of nanoparticulate systems are summarized in Table 1 (2–13).

In Situ Polymerization

Nanospheres. Two different approaches have been considered for the preparation of nanospheres by in situ polymerization, depending on whether the monomer to be polymerized is emulsified in a nonsolvent phase (emulsification polymerization), or dissolved in a solvent that is a nonsolvent for the resulting polymer (dispersion polymerization).

General Aspects of Emulsification Polymerization. Depending on the nature of the continuous phase in the emulsion, it is traditional to distinguish conventional emulsification polymerization from inverse emulsification polymerization. In the former case, the continuous phase is aqueous (o/w emulsion), whereas in the latter process it is organic (w/o emulsion). In both cases the monomer is emulsified in the nonsolvent phase with surfactant molecules, leading to the formation of monomer-swollen micelles and stabilized monomer droplets. The polymerization reaction (consisting of a nucleation and a propagation stage) takes place in the presence of a chemical or physical initiator. The energy provided by the initiator creates free reactive monomers in the continuous phase which then collide with the surrounding unreactive monomers and initiate the polymerization chain reaction. The reaction generally stops once full consumption of monomer or initiator is achieved. The drug to be associated to the nanospheres may be present during polymerization or can be subsequently added to the preformed nanospheres, so that the drug can be either incorporated into the matrix or simply adsorbed at the surface of the nanospheres.

Table 1. Milestones in the Field of Nanoparticle Manufacture

Year	Milestone	Refs.
	Nanoparticles formed by polymerization	
1976	Polyacrylamide nanospheres	2
1976	Poly(methyl methacrylate) nanospheres	3
1979	Poly(alkyl cyanoacrylate) nanospheres	4
1986	Poly(alkyl cyanoacrylate) nanocapsules	5
	Nanoparticles from preformed polymers	
1972	Albumin nanospheres by heat denaturation	6
1978	Gelatin nanospheres by desolvation	7
1979	Albumin nanospheres by cross-linking	8
1981	Poly(lactic acid) nanospheres by emulsification-solvent evaporation	9
1986	Poly(lactic acid) nanospheres by direct precipitation	10
1987	Poly(lactic acid) nanocapsules by interfacial deposition	11
1988	Poly(lactic acid) nanospheres by salting-out process	12
1995	Poly(lactic acid) nanospheres by emulsification-diffusion	13

Far from being totally elucidated, the mechanism by which the polymeric particles are formed during emulsification polymerization is not as simple as it was first believed, being initially described as a simple polymerization within the stabilized monomer droplets (14). Indeed, it is well established that the particles obtained by emulsification polymerization are generally much smaller (100–300 nm) than the original stabilized monomer droplets in the continuous outer phase (1–10 μm) (15). Other mechanisms, involving sites of nucleation other than the monomer droplets, have been considered to explain the particle formation process (16–19). First, the so-called micellar polymerization mechanism was proposed, involving the swollen-monomer micelles as the site of nucleation and polymerization. Swollen micelles exhibit sizes in the nanometer range and thus have a much larger surface area in comparison with that of the monomer droplets. It was assumed that, once generated in the continuous phase, free reactive monomers would more probably initiate the reaction within the micelles. Being slightly soluble in the surrounding phase, the monomer molecules reach the micelles by diffusion from the monomer droplets through the continuous phase, thus allowing the polymerization to be pursued within the micelles. So, in this case, monomer droplets would essentially act as monomer reservoirs (Fig. 2).

A second mechanism, called the homogeneous nucleation and polymerization process, has been proposed (16–19). If the monomer is sufficiently soluble in the continuous outer phase, the nucleation and polymerization stages can occur directly in this phase, leading to the formation of primary polymer chains called oligomers. In this case, throughout polymer chain growth, both the micelles and the droplets play the role of monomer reservoirs (Fig. 3). When the oligomers have reached a certain length, they precipitate and form primary particles which are stabilized by the surfactant molecules provided by the micelles and the droplets. Depending on the bulk conditions and system stability, the end-product nanospheres are formed either by additional monomer input into the primary particles or by fusion of the primary particles.

Whatever the mechanism involved (droplet, micellar, or homogeneous polymerization) each terminal nanosphere formed by emulsification polymerization usually consists of a large number of polymeric chains (18,19).

Emulsification Polymerization in an Organic Continuous Phase. According to certain authors (2,20–22), the previously described mechanisms are only applicable when the polymerization process involves an aqueous continuous outer phase. It was assumed that in the case of inverse emulsification polymerization, in which the continuous phase is an organic one, the very water-soluble monomers used in this system cannot diffuse from the micelles through the organic phase because of their very low partition coefficient. As a result, particle formation would only result from the fusion of small nucleated micelles of constant size (Fig. 4). For this reason, this process is generally mentioned as an inverse "microemulsification" polymerization. The resulting nanospheres would contain fewer polymeric chains and a narrower distribution size, in contrast to the particles obtained by conventional emulsification polymerization (20–22). This theory has been debated by Kreuter (16) assuming that, whatever the partition coefficient of the monomer, the latter should still be slightly soluble in and diffuse through the organic phase. According to this author the mechanism of polymerization in an inverse emulsion is not qualitatively different from that in a conventional emulsion.

As previously mentioned, the first report concerning the use of nanoparticles for pharmaceutical applications was made by Birrenbach and Speiser in the seventies (2). These earliest nanoparticles were polyacrylamide nanospheres prepared by inverse emulsification polymerization and were intended to incorporate water-soluble antigenic material for vaccination purposes. Typically, water-soluble acrylamide monomers and human immunoglobulin G (IgG) were emulsified in *n*-hexane in the presence of a crosslinker (*N*,*N*′-methylene bisacrylamide) and large amounts of anionic surfactants (bis-(2-ethylhexyl)-sodium sulfosuccinate and poly(oxyethylene)-4-lauryl ether). The polymerization was initiated by γ-, ultraviolet, or visible light ir-

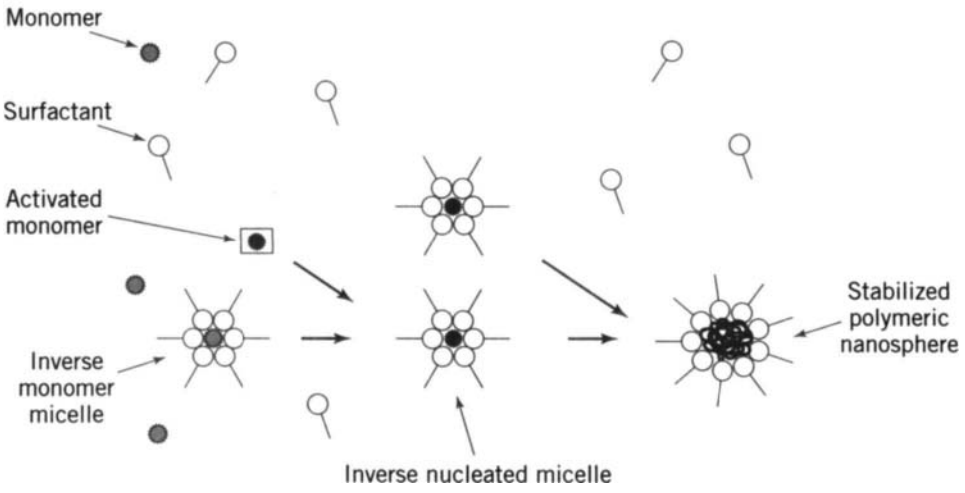

Figure 4. Mechanism of inverse emulsification polymerization. *Source:* Adapted from Ref. 18.

radiation, leading to the formation of IgG-loaded polyacrylamide nanospheres in the organic phase. Subsequently, several authors (20–25) used variants of this technique for the production of polyacrylamide nanospheres, but only a few produced nanospheres containing an active substance. Kopf et al. (23) succeeded in entrapping 96% of norephedrine HCl in polyacrylamide nanospheres. Labhasetwar and Dorle (25) produced polyacrylamide nanospheres incorporating metronidazole and primaquine but in this case the entrapment efficiency was low (<6%). In fact, these formulations have not been further developed for medical purpose, due, in particular, to the nonbiodegradable nature of this acrylic material. The use of polyacrylamide nanospheres as vaccine adjuvants is still being considered, but the large amounts of solvents and surfactants required for their production limit somewhat the interest of this application. However, these initial nanoparticle formulations allowed a better understanding of polymerization processes and opened up new prospects in the field of drug targeting.

The inverse emulsification polymerization process was rapidly adapted for the production of biodegradable poly(alkyl cyanoacrylate) (PACA) nanospheres (26–30). In these studies, the drug was dissolved in a small volume of water or hydrophilic solvent (methanol) and emulsified in an organic phase (e.g., isooctane, cyclohexane-chloroform, hexane) in the presence of large amounts of surfactants. Alkylcyanoacrylate monomers were then added directly or dissolved in an organic solvent to the preformed w/o emulsion under stirring. It was initially claimed that due to this subsequent addition of the monomers, particles with a shell-like wall (nanocapsules) were formed, resulting from the interfacial polymerization of monomers at the surface of the water-swollen micelles containing the drug. In fact, on the basis of transmission electron microscopy observations, it was later shown that the presence of nanocapsules was only occasional in the final nanoparticulate suspension and that most of the particles formed during this process were true nanospheres (19,26). Hydrophilic compounds such as doxorubicine (27,29,30), fluorescein (27), and methylene blue (28), as well as lipophilic compounds such as triamcinolone acetonide (26), were efficiently incorporated into PACA nanoparticles using this technique. As with former polyacrylamide nanospheres, PACA nanoparticles were finally obtained in the form of an organic dispersion containing large amounts of potentially toxic surfactants. In view of their therapeutic use, a tedious and extensive washing of the particles was required, making the overall manufacturing procedure long and difficult. This drawback has placed this process at a disadvantage with respect to polymerization in an aqueous phase for the production of PACA nanospheres.

Emulsification Polymerization in an Aqueous Continuous Phase. A major improvement was the preparation of nanospheres by emulsification polymerization in an aqueous continuous phase using no, or very little, surfactant. In this process, the surfactant acts mainly as stabilizer of the polymerized particles rather than emulsifier. Emulsification polymerization in a continuous aqueous phase is actually the most important method for the production of nanospheres.

A simple emulsification polymerization procedure was proposed in 1982 by Couvreur et al. (4) for the production of biodegradable PACA nanospheres. Since that time, these nanospheres have been the object of the most extensive investigations in the field of submicroscopic polymeric carriers. PACA nanospheres are produced by emulsifying water-insoluble alkylcyanoacrylate monomers in an acidic aqueous phase containing the drug and nonionic surfactants (e.g., poloxamer 188, polysorbate 20) or steric stabilizers (e.g., dextran 70). An anionic micellar polymerization takes place after diffusion of the monomer molecules through the aqueous phase. Once the polymerization is fully completed, the particle suspension is neutralized with NaOH, brought to isotonicity by glucose, and filtered. In contrast to other polymerization systems requiring an energy input that can affect the stability of the incorporated drug, the polymerization here is spontaneously initiated at room temperature by the hydroxide ions present in water, under vigorous stirring. The pH of the medium determines

the polymerization rate. The pH has to be acidic in order to prevent excessively rapid polymerization and enable the formation of monodispersed (nonagglomerated) nanoparticles. At pH values below 3, the size of the nanospheres obtained is approximately 200 nm with a narrow size distribution. Nanospheres with diameters as small as 30 nm can be produced by increasing the concentration of the surfactant or the pH of the polymerization medium in the pH range from 1 to 3 (31). Even smaller nanospheres can be obtained using sulfur dioxide as polymerization inhibitor (32). Among other parameters, the pH of the polymerization medium also has a major influence on the molecular weight of the polymer forming the nanospheres. This effect is generally described as being complex and is related to the antagonist action of initiator (OH^-) and terminator (H^+) during the polymerization process. As a result of the termination mechanism by H^+ ions, the molecular weights after anionic polymerization are generally very low and decrease with decreasing pH (33,34). To control the molecular weight of the polymer forming the nanospheres is important given the great influence of this parameter on the degradation rate of the particle, on the resulting drug release kinetic, as well as on the biodistribution of the particles. Consequently, optimization of the polymerization conditions (pH, temperature, stirring rate, type and concentration of monomer, surfactant, stabilizer, and acidifying agent) has been the object of very extensive investigations (33–36). It has been shown that such formulations were very reproducible in term of size and drug content, even after preparation at a semiindustrial level. Since the early patent of Couvreur et al. (4), a wide variety of drugs have been efficiently incorporated into PACA nanospheres. Most of them are hydrophilic and display cytostatic or antibiotic activities (1).

A major advantage of PACA nanospheres is their very rapid elimination from the body, within a few days, as a result of their very rapid degradation in vivo (37). The degradation mechanism of PACA nanospheres in biological conditions is complex. It involves at least two pathways, a chemical process (the so-called formaldehyde-producing pathway) and an enzymatic process, which was shown to be dominant and to occur through the hydrolysis of the ester side chains of the polymer (37–39). The incidence of the resulting degradation products (specially formaldehyde) in vivo is still a matter of debate. Toxic effects have been shown to occur toward a number of cells in vitro, with a clear relationship between the toxicity graduation and the alkyl chain length of the polymer (39–41). PACA nanospheres with long side chains (butyl, isobutyl, and isohexyl cyanoacrylates) generally exhibit a lower toxicity, which is attributed to their slower degradation, compared with nanospheres with short side chains (methyl and ethyl cyanoacrylates) (39,40). In addition, nanospheres with long alkyl chains are generally characterized by higher entrapment efficiencies and, as a result of slower degradation, slower drug release profiles (39). Although the bioacceptability of PACA nanospheres has to be considered carefully, they are actually considered as one of the most promising candidates for drug delivery in humans. A Phase I clinical trial using doxorubicin-loaded PACA nanospheres has been performed and revealed an improvement of the doxorubicin therapeutic index, illustrating the potential of these formulations as drug delivery systems (42).

The acidic nature of the polymerization medium can represent a major drawback when the drug intended to be incorporated into PACA nanospheres is labile at low pH. This problem can be overcome by using slightly different monomers such as the methylidene malonate derivatives. Those monomers have been proposed for the production of nanospheres in polymerization media having higher pH values. Developed on the same basis as alkylcyanoacrylates, alkyl methylidene malonic acid esters present an alkyl oxycarbonyl group instead of a cyano group, which is less electrophilic and thus less reactive in the presence of nucleophilic hydroxide ions (43). Diethyl methylidene malonate monomers were successfully used for the production of nanospheres by anionic polymerization in aqueous media (pH 6.7 to 8.7) (43,44). Unfortunately, poly(diethyl methylidene malonate) nanospheres could not be considered as suitable systemic drug carriers given their demonstrated nonbiodegradability both in vitro and in vivo (43). A new methylidene malonate derivative, methylidene malonate 2.1.2. was designed to overcome the lack of degradation of the former polymeric derivative. Poly(methylidene malonate 2.1.2.) (PMM 2.1.2.) nanospheres could be produced through anionic polymerization at pH values from 4 to 9, with an excellent batch to batch reproducibility in the pH range from 5 to 6 (45,46). In addition to the fact that these newly developed nanospheres may be useful for the incorporation of acid labile drugs, they have also been shown to exhibit satisfactory degradability and erodability (46,47), low in vitro (46,47), and in vivo (48) toxicity as well as a satisfactory shelf life (49). Although the production of drug-loaded PMM 2.1.2. nanospheres has not been described yet, these formulations appear to be promising alternative tools for the intravenous delivery of drugs, as well as good candidates for targeting purposes (50).

Numerous other derivatives have been used to prepare polymerized nanospheres in situ. The production of polyglutaraldehyde, poly(vinyl pyridine), poly(acroleine) and polystyrene nanospheres has been described by different authors (19). Although the lack of biodegradability of these systems compromises their clinical use as drug carriers, they could be potentially useful as adjuvants in vaccines (19).

Dispersion Polymerization in Water for Production of Polymethacrylic Nanospheres. The term *emulsification polymerization* is used when the monomer is emulsified in a nonsolvent by mean of surfactants. In the case of dispersion polymerization, the monomer is no more emulsified but dissolved in an aqueous medium which acts as a precipitant for the polymer to be formed. The nucleation is directly induced in the aqueous monomer solution and the presence of stabilizers or surfactants is not absolutely necessary for the formation of stable nanospheres. This method was developed in the mid-seventies by Kreuter and Speiser (3) for the production of very slowly biodegradable poly(methyl methacrylate) (PMMA) nanospheres. The aim of these authors was to propose a simplified manufacturing procedure based on the method previously developed by Birrenbach and Speiser (2) but avoiding the use of large

amounts of organic solvents and surfactants. In this method, water-soluble methyl methacrylate monomers are dissolved in an aqueous medium and polymerized by γ-irradiation (3,51) or by chemical initiation (ammonium or potassium peroxodisulfate) combined with heating to temperatures above 65°C (52,53). In the case of chemical initiation, the aqueous medium must be previously flushed with nitrogen for 1 h in order to remove its oxygen content, which could inhibit the polymerization by interfering with the initiated radicals. Whatever the type of initiation used, oligomers are formed and above a certain molecular weight precipitate in the form of primary particles which may or may not be stabilized by surfactant molecules. Finally, nanospheres are obtained by the growth or the fusion of primary particles in the aqueous phase (Fig. 5).

The possible production of PMMA nanospheres by surfactant-free polymerization is very advantageous because, as previously mentioned, the removal of detergents is generally very cumbersome. Being very slowly biodegradable and biocompatible (54), PMMA nanoparticles have been shown to be an optimal material for vaccination purposes. For this application, initiation by γ-irradiation can be useful for the production of PMMA nanospheres by polymerization in the presence of antigenic material, because it can be carried out at room temperature or below, thus preventing the destruction of these heat-sensitive substances (51). Antigens may be present during polymerization (3,55) but can also be added to the preformed nanospheres (3,53,55,56). The antigenic materials used to produce nanoparticulate PMMA adjuvants were influenza virions (3,55), influenza subunit antigens (53), bovine serum albumin (52,53), and more recently HIV-1 and HIV-2 antigens (56,57). For the particles produced in the presence of influenza virions, a shell-like structure was proposed (55,58). Because of their large dimension (~80 nm), the virions are more probably coated by a shell of polymerized monomers initially adsorbed at their surface, than strictly incorporated in a polymeric matrix.

Besides PMMA nanospheres, copolymer methacrylic nanospheres can also be produced by the dispersion polymerization process using blends of methyl methacrylate with one or several other acrylic acid derivatives (e.g., hydroxyethyl methacrylate, methacrylic acid, ethylene glycol dimethacrylate, sulfopropylmethacrylate) (53,59–61). These copolymer nanospheres were developed with the intention of modifying the surface properties of the nanospheres, namely the hydrophilicity but also the charge (61) which are important parameters governing the body distribution of the particles.

Various types of drugs have been linked to PMMA and polymethacrylic nanospheres (1). Rolland (62) performed extensive investigations with doxorubicin-loaded polymethacrylic nanospheres suggesting that, in spite of their very low biodegradability, these particles could be used in humans for cancer treatment using a monthly intravenous injection protocol. Nevertheless, compared with some other colloidal systems, the use of such practically nonbiodegradable particles appears to be very limited, if not precluded when regular therapeutic administration is desired. Essentially suitable as adjuvants for vaccination purpose, PMMA and polymethacrylic nanospheres are also of great value for fundamental studies on the in vitro and in vivo behavior of particles remaining intact in biologic media over extended time periods (59,63–66). In providing general information about the interactions of the nanospheres with cells or opsonins, their biodistribution and bioelimination, these studies allow a better understanding of the mechanisms regulating the biological fate of nanoparticulate drug carriers.

Nanocapsules

PACA Nanocapsules. On the basis of the method proposed by Couvreur et al. (4) for preparing PACA nanospheres, Al Khouri-Fallouh et al. (5) developed a new method leading to the production of nanocapsules, a new type of colloidal carrier with a capsular structure consisting of a polymeric envelope surrounding an oily central cavity. The aim was to produce a nanoparticulate formulation with high entrapment efficiency for lipophilic drugs. This could be hardly achieved with PACA nanospheres prepared by anionic emulsion polymerization because this method required dissolution of the drug in an aqueous polymerization medium, precluding the incorporation of poorly water-soluble compounds.

In the procedure described by Al Khouri-Fallouh et al. (5), the monomer (isobutyl cyanoacrylate) and a lipophilic drug (lomustine, progesterone) are dissolved in an ethanolic phase containing an oil (Myglyol®, Lipiodol®) or a non-

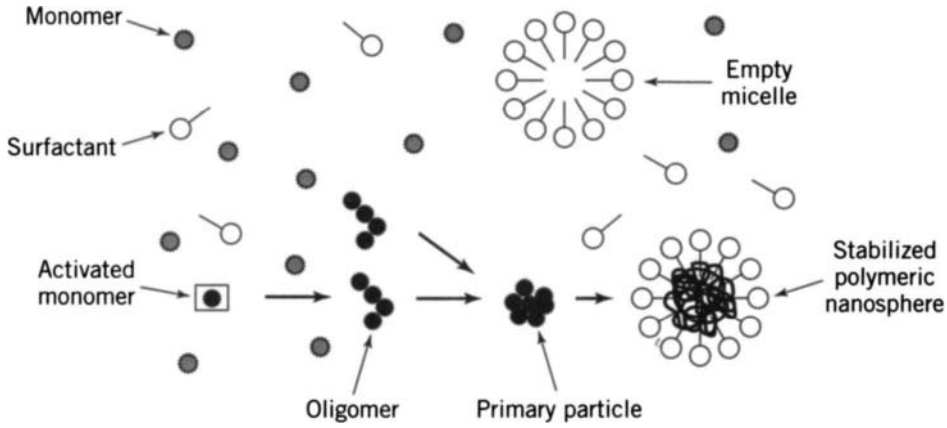

Figure 5. Mechanism of dispersion polymerization. *Source:* Adapted from Ref. 18.

miscible organic solvent (benzylic alcohol). This mixture is slowly injected through a needle into a magnetically stirred aqueous phase (pH 4–10) containing a nonionic surfactant (poloxamer 188). The mixture immediately becomes milky and nanocapsules with a mean diameter of 200–300 nm with a narrow polydispersity are formed. The colloidal suspension can then be concentrated by evaporation under reduced pressure and filtered through sintered glass before redilution with a physiological buffer. Examination by transmission electron microscopy, after negative staining of the particles, demonstrated the existence of a polymeric wall with a mean thickness of about 3 nm (5,67). On the basis of these observations, it was assumed that formation of nanocapsules resulted from the so-called interfacial polymerization mechanism. This mechanism was described as a spontaneous and rapid process: upon mixing with the aqueous phase, ethanol rapidly diffuses out of the organic phase giving rise to spontaneous emulsification of the oil/monomer/drug mixture. Due to their interfacial properties (67), the monomer molecules spontaneously locate at the surface of the oil nanodroplets and, upon contact with aqueous hydroxide anions, immediately polymerize at the water–oil interface, leading to the formation of solid wall-structured particles. The speed of magnetic stirring has no influence on the particle size, which depends solely on the nature and the volume of the oil, and on the volume of the diffusing organic phase (68). The presence of surfactant in the aqueous phase is not necessary for the successful formation of nanocapsules but does guarantee the physical stability of the preparation. For efficient encapsulation, the lipophilic drug must have a partition coefficient which favors its location in the oil, and the oil must then be chosen accordingly (68). Since the early description of this new process, numerous workers have used it as such or with slight modifications to produce nanocapsules incorporating a wide variety of lipophilic drugs with high entrapment efficiencies (1).

Extensive investigations have been performed to determine the influence, on PACA nanocapsule morphology and structure, of parameters such as the nature and pH of the aqueous phase, composition of the organic phase (solvent, oil, monomer), surfactant and emulsification conditions (67,69–72). In particular, in a very interesting study employing freeze-fracture electron microscopy, Fresta and Puglisi (71,72) showed that, depending on the type of organic solvent used for the nanocapsule preparation, heterogeneous systems consisting of a mixture of nanocapsules and nanospheres could be obtained. When protic water-miscible organic solvents such as ethanol, *n*-butanol, or isopropanol were used in the preparation, both types of particles were formed in the suspension, whereas when aprotic water-miscible organic solvents such as acetone and acetonitrile were used, only true nanocapsules were obtained. It was assumed that protic solvents, with a certain nucleophilic character, could give rise to the polymerization of the monomer molecules initially in the organic mixture, before emulsifying it in the aqueous phase. Evidence of initial polymerization in an organic protic phase was supported by the fact that when the monomer was dispersed, for example, in pure ethanol, cloudy suspensions were observed, whereas when it was added to acetone or acetonitrile the resulting solutions remained absolutely clear. On the basis of these observations, Fresta and Puglisi (71,72) assumed that upon contact with the aqueous phase, oligomers, preformed in the protic organic phase, may precipitate and lead to the formation of nanospheres in the final suspension. As to the nanocapsules, they may be formed according to two different mechanisms: (*1*) by normal polymerization of the monomers at the water–oil interface and (*2*) by deposition at the interface of the preformed oligomers present in the organic phase (interfacial deposition of a preformed polymer theory). When an aprotic solvent is used, only interfacial polymerization may occur, allowing the production of true nanocapsule suspensions. Accordingly, the use of acetone was shown to provide high-quality nanocapsules, with regular wall thickness and homogeneous size distribution (32).

Slightly different theories have been proposed by other investigators to explain the presence of both nanospheres and nanocapsules in the suspensions prepared with nucleophilic solvents (73,74). Whatever the real nature of the mechanism involved, it clearly appears that when the production of a true nanocapsule formulation is desired, the most suitable conditions of preparation have to be established, especially with regard to the organic solvent to be chosen. In addition, a selective characterization of the resulting particles should be systematically conducted in order to assess the real homogeneity of the system. In good accordance with these considerations, Chouinard et al. (69) described the preparation of poly(isohexyl cyanoacrylate) nanocapsules using an ethanolic oily phase. In order to prevent immediate polymerization in ethanol, the monomer was initially saturated with a polymerization inhibitor (sulfur dioxide) prior to mixing with the ethanolic oily phase. Upon contact with the aqueous phase, sulfur dioxide rapidly diffuses into water, allowing interfacial polymerization to occur and nanocapsules to be formed. Evidence of the homogeneous capsular morphology of the particles was assessed by freeze-fracture microscopy, as well as by density measurements (69).

Several authors have reported the production of nanocapsules by interfacial polymerization of cyanoacrylate monomers using a inverse emulsification polymerization procedure. This technique was used to encapsulate hydrophilic compounds such as doxorubicin (27,29,30), fluorescein (27), or methylene blue (28), as well as the lipophilic drug triamcinolone acetonide (26). In this procedure, the drug was dissolved in a small volume of water (or methanol in the case of triamcinolone acetonide) and emulsified in an organic external phase (e.g., isooctane, hexane) containing a surfactant. Then, an organic solution of cyanoacrylate monomers was added to the preformed w/o emulsion. It was generally assumed that, using this procedure, nanocapsules were formed, resulting from an interfacial polymerization process around the nanodroplets. However, it was showed by Krause et al. (26) by transmission electron microscopy that, in fact, following this procedure, a mixture of nanospheres and nanocapsules was formed, with a predominance of nanospheres. A rational explanation for the formation of nanocapsules is that the polymerization process in some cases is so rapid that an impermeable poly-

mer wall may be formed at the interface, preventing the diffusion of further monomers into the interior of the particles. However, in most cases, the interior of the particles is also polymerized and solid monolithic nanospheres are formed (19). For this reason, this particular technique is sometimes classified in the literature with other related methods allowing the preparation of PACA nanospheres by inverse emulsification polymerization (1,19).

Poly(N^{α},N^{ϵ}-L-lysinediethylterephthaloide) Nanocapsules by Interfacial Polycondensation Using Electrocapillarity Emulsification. Arakawa and Kondo (75) proposed an original technique for the preparation of blood hemolysate–loaded nanocapsules. These hemoglobin containing nanoparticles were intended to be used as artificial red blood cells. Poly(N^{α},N^{ϵ}-L-lysinediethylterephthaloide) nanocapsules containing sheep hemolysate are prepared by interfacial polycondensation of L-lysine with terephthaloyl dichloride in an emulsion made by electrocapillarity. A water phase containing the hemolysate and L-lysine is slowly injected into an organic solution of terephthaloyl dichloride containing a surfactant. During the injection, an electrical potential difference is applied between the two phases. When this potential reaches a certain value (850 V), the interfacial tension is reduced to zero and spontaneous emulsification occurs. The polycondensation between the monomers should be expected to occur exclusively at the water–oil interface, leading to the formation of wall-type nanoparticles. However, formation of true nanocapsules still remains to be proven by electron microscopy analysis (19). In addition, as for other preparation methods implying a w/o emulsion, these particles must be subsequently transferred to an aqueous phase by successive washings.

Dispersion of a Preformed Polymer

As described already, since the early description of polymerization processes for the production of latex in the polymer industry, extensive efforts have been made to adapt this technology for the production of polymeric colloids that meet pharmaceutical requirements. Although real technological advances have been achieved, allowing for example the fulfillment of the submicroscopic size criteria, most of the polymeric carriers prepared by polymerization still encounter major drawbacks (74). With the exception of PACA and recently developed PMM 2.1.2. nanoparticles, most of the carriers produced by polymerization have inadequate biodegradability properties precluding their use for regular therapeutic administration. Only for vaccination purposes can very slowly biodegradable PMMA systems be considered as being suitable adjuvants when achievement of a very prolonged immune response is desired. In addition, due to the multicomponent nature of the polymerization media, it is generally very difficult to predict the molecular weight of the resulting polymerized material. This is a major drawback because the molecular weight greatly influences the biodistribution and release behavior of the polymeric carrier. Another drawback is the possible inhibition of drug activity due to interactions with activated monomers or with the numerous H^+ ions present in anionic polymerization processes. Finally, the main limitation to the use of polymerized carriers is related to the presence of toxic residues, namely the unreacted monomer, initiator, and surfactant molecules whose elimination requires time-consuming and not always efficient procedures.

In order to circumvent those limitations and extend the manufacturing possibilities for the achievement of biodegradable, well-characterized, and nontoxic nanoparticles, new methods involving the use of already polymerized materials have been developed. These materials include natural macromolecules (biopolymers) and synthetic polymers.

Nanospheres Prepared From Natural Macromolecules. Among the natural macromolecules available for the manufacture of nanospheres, proteins such as albumin, gelatin, legumin, or vicilin, as well as polysaccharides like alginate or agarose have been evaluated (Table 2). These macromolecules have attracted wide interest as biomaterials due to their intrinsic properties of biodegradability and biocompatibility. Of the previously mentioned macromolecules, albumin and gelatin have been the most extensively used. Two main manufacturing techniques have been reported to produce nanospheres from natural macromolecules. The first technique is based on the formation of a w/o emulsion and subsequent heat denaturation or chemical cross-linking of the macromolecule. The second approach involves a phase separation process in an aqueous medium that may be followed by chemical cross-linking (see Table 2). The term cross-linking is used to describe the formation of covalent bonds between the lysine amino groups of proteins and an aldehydic compound, leading to the hardening and stabilization of the formed particles.

Emulsification-Based Methods. The emulsification technique was initially introduced by Scheffel et al. (6) for the production of albumin nanospheres and was later optimized by Gallo et al. (76). In this process, an aqueous solution of albumin is emulsified at room temperature in a vegetal oil (cottonseed oil) and homogenized either by mean of a manual (6) or mechanical high pressure homogenizer (77) or by mean of ultrasonication (76). Once a high degree of dispersion is achieved, the emulsion is added dropwise to a large volume of preheated oil (>120°C) under stirring. This leads to the immediate vaporization of the water contained in the droplets and to the irreversible denaturation of the albumin which coagulates in the form of solid nanospheres (18) (Fig. 6). The suspension is then allowed to cool down at room temperature or in an ice bath. Subsequently, the particles are submitted to several washings using large amounts of organic solvent (e.g., ether, ethanol, acetone) for complete removal of the oil. This purification step represents a main drawback in terms of manufacturing wastes, especially in view of large scale particle production. In addition, the hardening step by heat denaturation may be harmful to heat-sensitive drugs. To circumvent this latter problem, the use of a cross-linking agent was proposed by Widder et al. (8) for the chemical hardening of the albumin nanodroplets. Surprisingly, although the cross-linking agent (2,3-butanedione or formaldehyde) was added only after the washing and resuspension of the system in ether, no coalescence of the soft

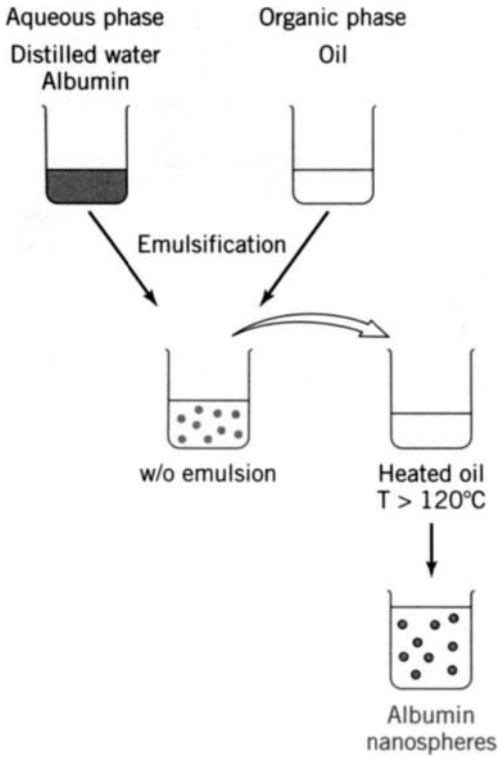

Figure 6. Preparation of nanospheres by thermal denaturation of albumin.

non-cross-linked albumin droplets was reported during these experiments (16).

Another method for preparing cross-linked albumin nanospheres has been proposed using a polymeric phase (ethylcellulose in toluene or hydroxypropylcellulose in chloroform) instead of an oily dispersing phase (78,79). It was asserted that, after purification and drying, the resulting particles were more easily redispersed and also exhibited narrower size distributions compared with particles produced with an oily dispersing phase (79). Nevertheless, with this particular method, the elimination of the polymeric dispersing agent still remains a problem, requiring several washings with large amounts of organic solvent (78,79), and thus it does not offer any advantage over the previously described techniques.

Gelatin and, more recently, polysaccharidic agarose nanospheres have been produced using an emulsification-based method involving the gelation of the macromolecule (80,81). In this process, the w/o emulsion was cooled (0–5°C) below the gelation temperature of the macromolecule, leading to the complete gelation of the macromolecule droplets. The resulting hydrogel nanospheres were further stabilized by cross-linking (80) or directly washed with an organic solvent (81).

Phase Separation-Based Methods in an Aqueous Medium. As previously mentioned, the main disadvantage of emulsification methods is that large amounts of organic solvents are required to obtain nanospheres free of any oil or dispersing agent residues. Another disadvantage is that it is very difficult to produce small nanospheres (<500 nm) with narrow-size distributions, due to the intrinsic instability of the emulsion prior to hardening by heat or cross-linking (19). Coacervation or controlled desolvation methods have been developed to circumvent these problems. In this case, the particles are formed in an aqueous medium by a phase separation process and are subsequently stabilized by cross-linking with glutaraldehye.

A now traditional method was proposed by Marty et al. (7), based on the desolvation and resolvation properties of proteins. In this process, gelatin and albumin nanospheres can be produced by the slow addition of a desolvating agent (neutral salt or alcohol) to the protein solution. Upon this addition, a progressive modification of the protein tertiary structure is induced leading, when a certain degree of desolvation is obtained, to the formation of protein aggregates. The nanospheres are obtained by subsequent cross-linking of these aggregates with glutaraldehyde. To obtain small and monodispersed particles, it is important to maintain the system at a point just before coacervation is initiated (7,16). The addition of the desolvating agent is monitored by turbidimetry measurements of the system and must be stopped as soon as the turbidity increases, otherwise aggregates that are too large will be formed. Alternatively and for optimal monitoring of the process, the system can be desolvated until the coacervation state is reached, and then rapidly reverted to the precoacervated

state by adding a very small amount of resolvating agent (7,16) (Fig. 7).

Other phase separation-based methods have been developed in recent years for the production of other protein and polysaccharide nanospheres, as shown in Table 2 (82–86). In these processes, phase separation could be induced by changes in the pH or temperature, or by addition of appropriate counterions in the protein or polysaccharide aqueous solution. In the latter case, for example, alginate nanospheres were formed by controlled gelation of an alginate solution. The alginate gelation was induced by divalent cations (calcium chloride) and the resulting gelated nanospheres were subsequently stabilized by polyelectrolytic complexation with a polyamine (poly(L-lysine)) (82).

Several drugs or tracers have been successfully combined with natural macromolecular nanospheres, either by incorporation (codissolution with the macromolecule), chemical coupling on the surface (reaction with free functional groups of the cross-linking agent), or by simple adsorption on preformed nanospheres (1). The emulsification-based methods can be considered especially suitable for the incorporation of hydrophilic drugs in term of loading capacity. With regard to the phase separation-based techniques, the entrapment efficiency for hydrophilic drugs can be strongly affected depending on the drug affinity which is partitioned between the macromolecular particle and the aqueous environment (87). In general, highly water-soluble drugs are less well incorporated by these methods, because they interact more strongly with water than with the macromolecule and are readily washed out of the particles (7). Nevertheless, the major concerns with techniques involving natural macromolecules lie in the necessity for using hardening agents (most frequently glutaraldehyde) that may react with the drug and may also confer some toxicity to the nanoparticle formulations (87).

Nanospheres Prepared From Synthetic Polymers. Among the numerous synthetic polymers available for the preparation of nanospheres, the most commonly used are poly(lactic acid) (PLA), poly(glycolic acid) (PGA), poly(lactic-*co*-glycolic acid) (PLGA), poly(ϵ-caprolactone) (PCL), and poly(β-hydroxybutyrate) (PHB). Belonging to the family of polyesters, these polymers are known to exhibit adequate biodegradability and biocompatibility. Under physiological conditions, polyesters are generally degraded by hydrolysis into products which are well tolerated by various tissues. For example, the degradation products of PLA, PGA, and PLGA, namely glycolic acid and lactic acid, are physiologic substances easily eliminated through the Krebs cycle (41,88). The safety of polyesters is illustrated by their extensive use as sutures and orthopedic implants for approximately two decades, and more recently by their use as controlled delivery devices for drugs. At present, a number of microparticle and implant formulations composed of PLGA copolymers are available on the market, for human use (e.g., Decapeptyl retard®, Zoladex®). Being directly related to the rate of degradation, the drug release capabilities of polyesters can be easily tailored, depending on the monomer composition and the polymerization conditions (88,89). Consequently, polyesters make possible the preparation of delivery systems from which the drug is released in a controlled way, over days to months. Polyesters nanoparticles can be produced using two different approaches. The first approach is based on the emulsification of an organic solution of the polymer in an aqueous phase containing surfactants, stabilizers, or electrolytes, and subsequent precipitation of the polymer by removal of the organic solvent. A second approach is based on the direct precipitation of the solubilized polymer upon addition of a nonsolvent.

Emulsification-Based Methods. Different emulsification-based methods have been described depending on the miscibility of the organic solvent in the aqueous phase. Some methods involves volatile and water-immiscible solvents which can be extracted by simple evaporation, leading to polymer precipitation (emulsification-solvent evaporation method). In other methods, partially or fully water-miscible organic solvents are used and polymer precipitation occurs as a result of controlled diffusion processes (salting-out and emulsification-diffusion methods).

The emulsification-solvent evaporation method was first used by Gurny et al. (9) in the early eighties for the preparation of PLA nanospheres, based on a patent filed by Vanderhoff et al. (90). This method was later adopted for the production of nanospheres with a wide range of polymers including PLGA, PCL, and PHB, as well as methacrylic acid copolymers and cellulose derivatives (1,19,87). The preformed polymer is dissolved in a volatile organic solvent (e.g., chloroform, methylene chloride, ethyl acetate), and the organic solution is dispersed in an aqueous phase to form an o/w emulsion, in the presence of a surfactant (e.g., polysorbate, poloxamer, sodium dodecyl sulfate) or a stabilizer such as poly(vinyl alcohol) (PVA). Continuous emulsification under stirring prevents coalescence of the organic droplets and can be further improved by sonication or microfluidization with a high pressure homogenizer. The extraction of the solvent from the nanodroplets

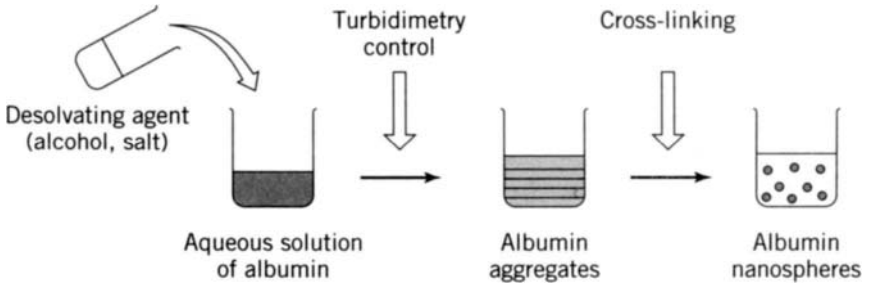

Figure 7. Preparation of nanospheres by desolvation of albumin.

is achieved by evaporation at room temperature under stirring or in a rotary evaporator under reduced pressure. As a consequence of this extraction, the polymer precipitates, leading to the formation of nanospheres (Fig. 8). The technique was later optimized by Julienne et al. (91), who investigated the influence of various parameters on the resulting particle size, such as the nature and concentration of the surfactant and stabilizer, the conditions of emulsification, the polymer concentration, and the phase volume ratio.

The emulsification-solvent evaporation method generally allows efficient entrapment of lipophilic compounds (e.g., testosterone, indomethacin), which can dissolved in the polymer solution (1). Recently, the encapsulation of a model amphiphilic protein, bovine serum albumin, was achieved by a slight modification of the technique (92). An aqueous solution of bovine serum albumin and poloxamer 188 was emulsified in a solution of PLGA in ethyl acetate by sonication. Then, this pre-emulsion was added to an aqueous phase containing PVA as stabilizer, resulting in a (w/o)/w emulsion which was sonicated again, diluted, and finally introduced in a rotavapor to eliminate the solvent. Entrapment efficiencies up to 70% could be achieved using this procedure (92).

Another modification of the technique was proposed to achieve the entrapment of water-soluble compounds in PLGA nanospheres, based on the use of a mixture of a chlorinated solvent and polar solvents (acetone, methanol) to dissolve the polymer and the drug (93). Due to their polarity and water miscibility, the admixed polar solvents were shown (*1*) to improve the dissolution of a water-soluble drug (5-fluorouracil) in the organic phase and (2) to promote the emulsification of the system by rapid diffusion out of the nanodroplets upon addition of the aqueous phase (93).

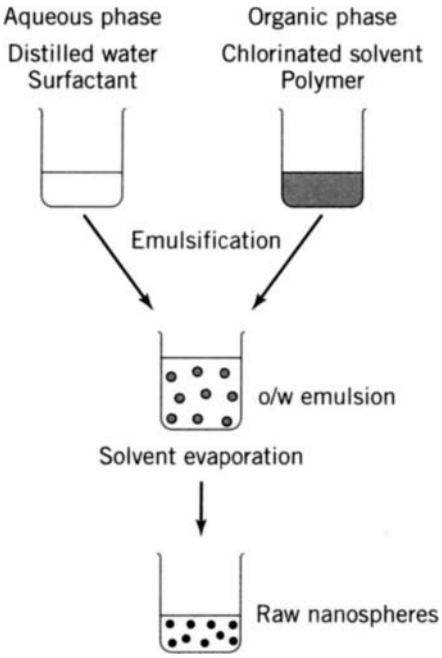

Figure 8. Emulsification-solvent evaporation method.

Although less toxic solvents such as ethyl acetate can be used, the emulsification-solvent evaporation method generally requires the use of toxic chlorinated solvents and surfactants, which constitute a major drawback for this method. In addition, the possibility to efficiently entrap water-soluble compounds remains very limited.

The salting-out procedure was proposed by Bindschaedler et al. (12) in the late eighties. This technique makes use of acetone, a water-miscible solvent, instead of the chlorinated solvents previously used and, furthermore, avoids the use of surfactants. An aqueous phase saturated with electrolytes (e.g., magnesium acetate, magnesium chloride) and containing PVA as a stabilizing and viscosity increasing agent is added under vigorous stirring to an acetone solution of polymer. In this system, the miscibility of both phases is prevented by the saturation of the aqueous phase with electrolytes, according to a salting-out phenomenon. The addition of the aqueous phase is continued until a phase inversion occurs and an o/w emulsion is formed. Then, a sufficient amount of pure water is added to disrupt the equilibrium between the two phases and to allow complete diffusion of acetone into water, leading to polymer precipitation in the form of spherical nanospheres (Fig. 9). Optimization of the method was performed by Allémann et al. (94) and the influence of various manufacturing parameters on the particle size was investigated. Furthermore, it was shown in this study that solvents other than acetone (e.g., tetrahydrofuran) as well as nonelectrolytic salting-out agents (e.g., sucrose) could be also used to produce nanospheres, demonstrating the relative versatility of the method (94). A wide variety of polymers can be used with this technique including PLA, methacrylic acid copolymers, and cellulose derivatives (1). High

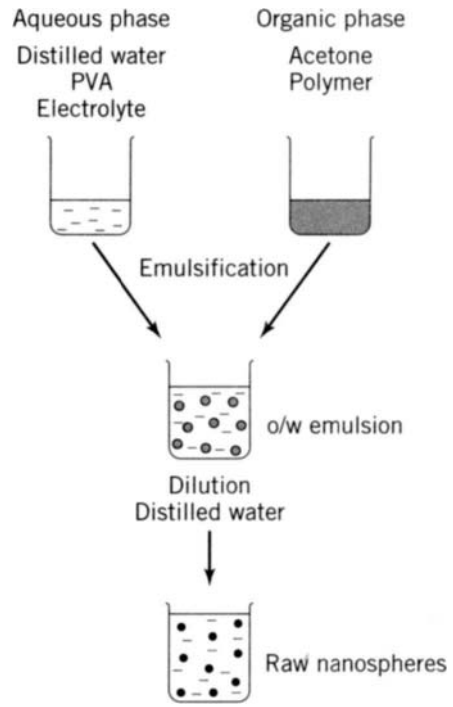

Figure 9. Salting-out process.

drug loadings can be achieved, depending on the solubility of the drug in acetone and on the nature of the salting-out agent used. For instance, savoxepine, a neuroleptic drug (pK_a 8.3), was loaded in PLA nanospheres either in the form of a free base or as a salt, the salt being much less soluble in acetone. Two different salting-out agents, magnesium chloride and magnesium acetate, were used, providing an acidic or a basic aqueous phase, respectively (95). The highest entrapment efficiency (95%) was achieved with the formulation involving savoxepine base and a basic aqueous phase (pH 8). Having minimal affinity for the aqueous phase under these conditions, the drug remains within the organic phase, leading to very efficient entrapment in the resulting nanospheres.

Although the salting-out process has proved suitable for the production of large quantities of highly drug-loaded nanospheres, the use of acetone and large amounts of salts may raise some concern about recycling of the salts and about compatibility with active compounds. Recently, Leroux et al. (13) developed a new method called emulsification-diffusion, which involves the use of benzyl alcohol as organic solvent. The originality of this method is based on the partial miscibility of benzyl alcohol with water. An aqueous phase containing a stabilizing agent (PVA or gelatin) is added to a solution of polymer in benzyl alcohol under mechanical stirring. Because benzyl alcohol is only miscible at a ratio of 1:25 (m/v) with water, a two-phase system is formed and an o/w emulsion is obtained upon complete addition of the aqueous phase. Then, the emulsion is diluted with a large amount of pure water in order to overcome the 1:25 miscibility ratio of benzyl alcohol. The precipitation of the polymer occurs as a result of the diffusion of benzyl alcohol into water, leading to the formation of nanospheres. By increasing the percentage of PVA in the external phase, it was possible to produce nanoparticles as small as 70 nm in diameter, whereas with gelatin the smallest nanoparticles obtained had an average size of 700 nm. The polymers used were PLA, PLGA, PCL, and methacrylic acid copolymer Eudragit® S100. Chlorambucil, a cytostatic drug with a very slight water solubility, was successfully entrapped into PLA nanospheres (13). In a recent study, the potential use of other partially water-soluble solvent and stabilizing agents was investigated, and a mechanism based on interfacial phenomena was proposed to explain the formation of nanospheres (96).

Direct Precipitation-Based Method. This technique, proposed by Fessi et al. (10), involves the use of an organic solvent that is completely miscible with the aqueous phase, typically acetone, but ethanol or methanol can also be used. This method allows nanospheres to be obtained without prior emulsification. In this case, the polymer precipitation is directly induced in an aqueous medium (containing or not a surfactant) by progressive addition under stirring of the polymer solution (Fig. 10). After nanoparticle formation, the solvent is removed by vaporization under reduced pressure. The usefulness of this method is limited to drugs that are highly soluble in polar solvents, but only slightly soluble in water (e.g., indomethacin), to avoid extensive loss of the drug during the solvent diffusion (87). In fact, the main limitation of this method is that it is not easy to choose a polymer/drug/solvent/nonsolvent system allowing high entrapment efficiencies and production yields. In general, this method has to be carried out with low concentrations of polymer in the organic phase. In this case, polymer dispersion and small particle size can be obtained easily. In contrast, when it is necessary to increase the amount of polymer in the organic phase (e.g., for the preparation of large-scale batches), large aggregates tend to form, resulting in poor production yields (97). Recently, it was shown that changing the nature of the organic phase could reduce the polymer loss. For example, the use of mixtures of acetone and water instead of acetone alone was shown to favor the dispersion of the polymer and to increase the production yield (97).

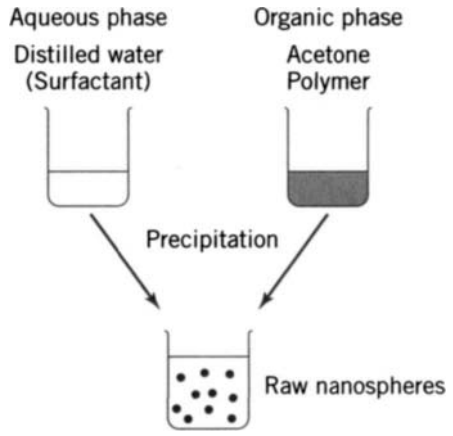

Figure 10. Direct precipitation method.

Nanocapsules Prepared From Synthetic Polymers. Nanocapsules can be produced from synthetic polymers by a very similar procedure to that already described. This method was also proposed by Fessi et al. (11) and is generally called the interfacial deposition technique. It differs from the nanosphere preparation method by the introduction of an oily component into the polymer organic solution. First, the polymer is dissolved in acetone, then a phospholipid mixture (e.g., Epikuron®) and benzyl benzoate are added to this solution. The resulting organic solution is poured into an aqueous phase containing a surfactant (e.g., poloxamer 188) under moderate stirring. Acetone diffuses immediately into the aqueous phase, inducing the deposition and the precipitation of the polymer around the oily droplets (Fig. 11). Once the nanocapsules are formed, acetone is eliminated under reduced pressure. Drugs intended to be encapsulated by this method must have a high solubility in the organic-oily phase, otherwise they diffuse from the oily solution and precipitate in the aqueous medium during particle formation (11,98). For example, as a result of the poor solubility of indomethacin in organic-oily phases, very poorly loaded PLA nanocapsules (0.25% w/v) could be produced with this drug (11). The production of cyclosporin A–loaded nanocapsules made of PCL was recently reported (98). Under optimized conditions, drug loadings as high as 50% could be obtained, but because no data about production yields were provided, it is not clear

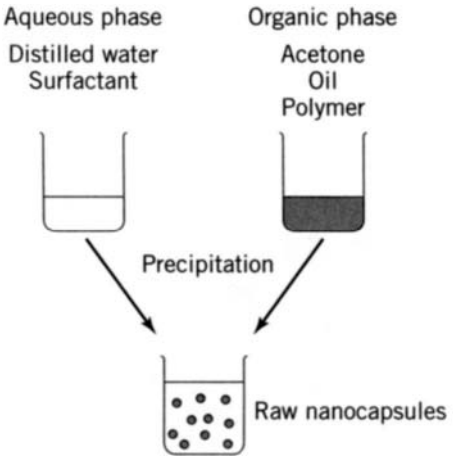

Figure 11. Interfacial deposition technique.

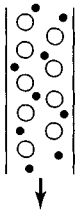
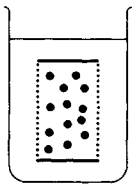
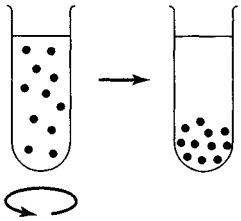
whether this procedure is suitable for the production of large-scale batches.

Pharmaceutical Aspects

Because nanoparticles are intended to be used as pharmaceutical dosage forms in humans, among other requirements, they are required (*1*) to be free of any potentially toxic impurities, (*2*) to be easy to store and to administer, and finally (*3*) to be sterile if parenteral use is envisaged.







Purification. Depending on the preparation method, various potentially toxic impurities can be found in the nanoparticulate suspensions including organic solvents, residual monomers, polymerization initiators, electrolytes, surfactants, stabilizers, and large polymer aggregates. The necessity for and degree of purification are dependent on the final purpose of the formulation developed. For example, the stabilizer PVA, frequently used to prepare polyester nanoparticles, is not acceptable for parenteral administration, whereas it is not so critical for oral and ocular administration (87). Although polymer aggregates can be easily removed by simple filtration through sintered glass filters, the removal of other impurities requires more sophisticated procedures. The most commonly reported procedures are gel filtration, dialysis, and ultracentrifugation (7,69,99–101). However, these methods are not entirely satisfactory because they are restricted to the laboratory scale or they are incapable of eliminating molecules with high molecular weight (Table 3). The necessity of finding an efficient purification technique that can be scaled up from an industrial standpoint led to the development of the cross-flow filtration method. In this technique, first used by Allémann et al. (99), the nanoparticle suspension is filtered through membranes, with the direction of the fluid being tangential to the surface of the membranes. In contrast to perpendicular filtration modes, the clogging of the filters is thereby avoided (Fig. 12). Depending on the type of membrane used, either microfiltration or ultrafiltration can be performed. The suspension is submitted to several filtration cycles, while the filtrate, containing components smaller than the pores of the membrane as well as soluble impurities, is discarded. First, concentration of the suspension is achieved. Then, pure water is added to the system at the same rate as the filtration rate, thus allowing the circulation volume to remain constant (diafiltration step). Simple to use, this technique allows the fast purification of large amounts of nanoparticles with no alteration of their size. For example, it was shown that by using a microfiltration membrane (porosity of 100 nm), approximately 6 g of PLA nanoparticles produced by the salting-out process could be purified in less than 3 hours, with complete removal of the salts and PVA macromolecules (99). In addition, scale-up is feasible by enlarging the filtering surface.

Freeze-drying. If nanoparticles are stored as aqueous suspensions, degradation and/or solubilization of the polymer, drug leakage, drug desorption, and/or drug degradation may occur. Freeze-drying (lyophilization) probably represents one of the most useful methodologies to ensure the long-term conservation of polymeric nanoparticles (102). This technique involves the freezing of the suspension and the subsequent elimination of its water content by sublimation under reduced pressure. After complete desiccation, nanoparticles are obtained in the form of a dry powder that is easy to handle and to store. Freeze-dried nanoparticles are usually readily redispersible in water without modification of their physicochemical properties (1). Because nanoparticles are usually produced with surfactants or stabilizers (e.g., polysorbate, poloxamer, PVA), the residual presence of these compounds generally favors the redispersion of the particles. However, in some specific cases, full redispersion of the system may be difficult to achieve. For example, nanocapsules composed of an oily core surrounded by a tiny polymeric wall tend to aggregate during the freeze-drying process (67,102). Similarly, aggregation problems have been reported with nanospheres made of various materials (102–104). This problem can be circumvented by desiccating these systems in the presence of an appropriate lyoprotective agent such as mono- or disaccharides (e.g., trehalose, sucrose, glucose) (102,104). The mechanisms by which sugars protect nanoparticles during freeze-drying are frequently referred to as "poorly understood" in the literature. However, very detailed and useful information about these mechanisms can be found in a number of articles dealing with lyoprotection and cryoprotection of liposomes and proteins (105,106). In these studies, it is commonly suggested that during freeze-drying sugars may interact with the solute of interest (e.g., liposome, protein) through hydrogen-bonding. As a result, the solute might be maintained in a "pseudo-hydrated" state during the dehydrating step of freeze-drying, and would therefore be protected from damage during dehydration and subsequent rehydration. Such a protective interaction is made possible by the ability of sugars to remain amorphous during freeze-drying (105,106). It has to be kept in mind that the addition of sugar may affect the isotonicity of the final nanoparticulate suspension, and that a subsequent step of tonicity adjustment may be required prior to any parenteral or ocular administration.

Sterilization. Nanoparticles intended to be used parenterally are required to be sterile and apyrogenic. Surpris-

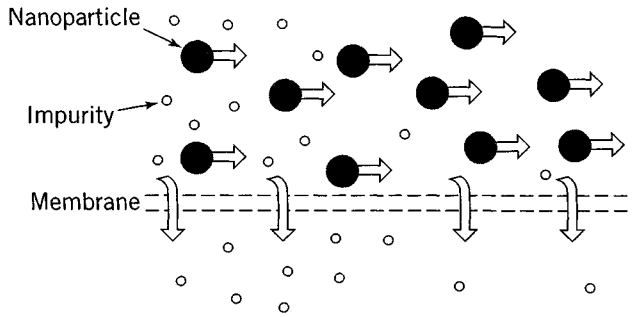

Figure 12. Cross-flow filtration technique.

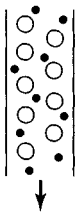

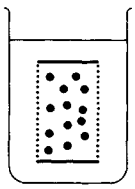

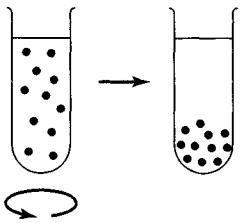

ingly, few authors have addressed this question. Sterile filtration on 0.22 μm filters is not adequate for nanoparticle suspensions because microorganisms and nanoparticles are generally similar in size (0.25–1 μm). Sterilization may be achieved, as for other microparticulate systems, either by using aseptic conditions throughout formulation, or by subsequent sterilizing treatments such as autoclaving or γ-irradiation (1,87). Production under aseptic conditions is possible but not very realistic, because it is complex, expensive, and inherently not safe. A terminal sterilization step will always be required to ensure the microbiological safety of the finished product. The choice of the sterilizing treatment depends on the physical susceptibility of the system. Autoclaving (moist heat sterilization) and γ-irradiation were shown to have an impact on the physicochemical properties of the particles in several systems, as illustrated by modification of the particle size, stability, and drug release characteristics (1,107). Most of the time, these modifications occur as a consequence of the cleavage or cross-linking of the polymeric chains, but can also result from alterations of other constituents such as the surface agents or the drug itself (107,108). It is apparent from these considerations that the sterilization of nanoparticulate formulations is a very critical step that should be systematically investigated early in the development program for an eventual optimization of the formulation. For example, the chemical stability of the polymeric matrix may be markedly improved by optimization of the polymer molecular weight (108). The final formulation would therefore result from a rational balance between conditions maintaining the formulation integrity upon sterilization and the final purpose of the formulation.

MODULATION OF THE IN VIVO FATE OF NANOPARTICLES

There are many ways to administer colloidal drug carriers including the intravascular, oral, ocular routes as well as intramuscular and subcutaneous injections. The main challenge for administering nanoparticles into the vascular compartment is the targeting of active compounds to the desired organs or cells, allowing a site-selective action of the compound and minimization of side effects. Another aim is related to the sustained delivery of drugs, in particular the increase of the therapeutic availability of drugs normally rapidly degraded or excreted in their free form, for various administration routes.

ingly, few authors have addressed this question. Sterile filtration on 0.22 μm filters is not adequate for nanoparticle suspensions because microorganisms and nanoparticles are generally similar in size (0.25–1 μm). Sterilization may be achieved, as for other microparticulate systems, either by using aseptic conditions throughout formulation, or by subsequent sterilizing treatments such as autoclaving or γ-irradiation (1,87). Production under aseptic conditions is possible but not very realistic, because it is complex, expensive, and inherently not safe. A terminal sterilization step will always be required to ensure the microbiological safety of the finished product. The choice of the sterilizing treatment depends on the physical susceptibility of the system. Autoclaving (moist heat sterilization) and γ-irradiation were shown to have an impact on the physicochemical properties of the particles in several systems, as illustrated by modification of the particle size, stability, and drug release characteristics (1,107). Most of the time, these modifications occur as a consequence of the cleavage or cross-linking of the polymeric chains, but can also result from alterations of other constituents such as the surface agents or the drug itself (107,108). It is apparent from these considerations that the sterilization of nanoparticulate formulations is a very critical step that should be systematically investigated early in the development program for an eventual optimization of the formulation. For example, the chemical stability of the polymeric matrix may be markedly improved by optimization of the polymer molecular weight (108). The final formulation would therefore result from a rational balance between conditions maintaining the formulation integrity upon sterilization and the final purpose of the formulation.

MODULATION OF THE IN VIVO FATE OF NANOPARTICLES

There are many ways to administer colloidal drug carriers including the intravascular, oral, ocular routes as well as intramuscular and subcutaneous injections. The main challenge for administering nanoparticles into the vascular compartment is the targeting of active compounds to the desired organs or cells, allowing a site-selective action of the compound and minimization of side effects. Another aim is related to the sustained delivery of drugs, in particular the increase of the therapeutic availability of drugs normally rapidly degraded or excreted in their free form, for various administration routes.

Mechanisms Regulating Body Distribution of Nanoparticles

Mononuclear Phagocytic System. At the present time, the ideal aims mentioned earlier have still not been adequately achieved with nanoparticles. As every other colloidal systems (e.g., liposomes, niosomes, microemulsions), intravascularly injected nanoparticles are rapidly detected as foreign products and quickly removed from blood circulation by the action of the mononuclear phagocytic system (MPS), which is also known as the reticuloendothelial system. The MPS is a collective name for a group of highly phagocytic mononuclear cells found throughout the body, either at fixed sites (tissular macrophages) or free in the bloodstream (circulating monocytes). Large concentrations of these cells are found in the liver (macrophages called Kupffer cells), spleen, and to a lesser extent, in the bone marrow. Because of the rich blood supply and specialized architecture of these organs, intravenously injected nanoparticles are extensively taken up by the liver (up to 90%) and the spleen (2–5%) within minutes or seconds following administration (109,110). Phagocytosis of particles by macrophages involves two steps: attachment of the particles to the cell membrane and ingestion of the particles. The attachment of the particles to macrophages is generally mediated through the action of serum proteins, called opsonins, which after adsorption onto the surface of the particles make any foreign material (immune complex, microorganisms, or particulate drug carrier) recognizable to the phagocytic cells of the MPS. Opsonization is a dynamic, complex and not fully elucidated process involving a great diversity and number of serum proteins, among which immunoglobulins and components of the complement system (particularly C3 and C5) have been shown to play a predominant role (111). Short half-lives are commonly observed whatever the chemical composition of the injected particles (e.g., albumin, polystyrene, PLA, PLGA, PACA). Therefore, using these types of systems, site-specific or sustained delivery of drugs is not readily achievable using the intravascular route, except in the MPS organs where the sequestration of these systems may be of clinical value. The exploitation of such "passive targeting" has led to some therapeutic advantages as illustrated by the use of nanoparticles for the treatment of some MPS-located diseases and intracellular infections, especially in the liver. This aspect will be developed in more detail in the section entitled "Parenteral Administration." However, for targeting to organs other than those of the MPS, the natural homing of nanoparticles to elements of the MPS is a serious obstacle which must be overcome. One of the earliest strategies was through suppression of the MPS phagocytic function by saturating it with high amounts of colloidal particles (e.g., plain polystyrene nanoparticles) or by use of phagocytosis depressants such as dextran sulfate, methyl palmitate, or gadolinium chloride (112). However, the concept of MPS blockage is not clinically acceptable, because it would rapidly lead to impaired MPS function and suppress the essential defense system of the body.

Factors Affecting the Biodistribution of Nanoparticles. It is now well established that the extent and nature of opsonin adsorption at the surface of colloidal particles depend on the physicochemical properties of the particles such as the size, surface charge, and surface hydrophobicity (111,113). In general, the adsorption of opsonins preferentially occurs onto hydrophobic rather than hydrophilic surfaces. The higher the particle hydrophobicity, the faster the particles are removed from the circulation and taken up by the cells of the MPS. The charge carried by the colloidal particles can also have an important role in determining the clearance and fate of the particles. It is generally accepted that negative surface charge increases the clearance of particulates, relative to neutral or positively charged surfaces. Together with the surface characteristics, the size of the nanoparticles also greatly influences their biological fate. Particles larger than 5,000 nm are normally entrapped in the capillary network of the lungs, whereas nanoparticles less than 100 nm may be able to leave the circulation through gaps or fenestrations in the endothelial cells lining the blood vessels.

Surface Engineering of Nanoparticles

The development of colloidal carriers with appropriate size and protein-resistant surfaces such that opsonization is minimized is currently the subject of great interest. Several approaches have been proposed during the last decade to achieve long-circulating nanoparticles, based on appropriate modifications of the nanoparticle surface.

Biomimetic Nanoparticles. The biomimetic approach is illustrated by the coating of a nanoparticles by sialic acids or plasma proteins such as albumin or inactivated complement moieties. Such surface modification was proposed as an elegant way to mimic the biological environment and make the foreign surface invisible to the MPS (66,114–116). The rationale for using albumin and complement moieties are the following: albumin is the main protein present in the blood (40 g/L), whereas complement moieties are among the most important opsonins involved in clearance mechanisms. As to the sialic acids, they may be components that are able to prevent the drug carrier surface from being recognized by the MPS, by imitating the sialylated cell surface. Human orosomucoid, a sialic acid-rich serum glycoprotein, has been used recently to coat PACA nanoparticles (116). The nanoparticles are generally coated by simple incubation (12 to 24 h) with a solution of the protein (66,116) or by direct incorporation of the protein during the production process (114,115). Unfortunately, so far none of these biomimetic coatings has provided adequate protection against opsonin adsorption and MPS phagocytosis, presumably due to rapid desorption of the coat (114–116) or insufficient mimetic ability (66).

Sterically Stabilized Nanoparticles. Most of the previously described polymeric materials forming nanoparticles are relatively hydrophobic with regard to opsonin adsorption. Creation of a new surface by coating the particle with a hydrophilic and nonionic macromolecule was suggested to be an efficient means to prevent recognition of the particles by the cells of the MPS and prolong their systemic circulation time. The concept of surface hydrophilization was rapidly extended to the concept of steric stabilization

when it was shown that hydrophilicity alone could not provide antiphagocytic effect. Indeed, highly hydrophilic macromolecules or polymers such as dextran, gelatin, or PVA failed to prevent the massive capture of colloidal carriers by phagocytic cells of the MPS (110). It has been proposed that besides hydrophilicity, high flexibility of the coating chains is another major requirement to provide effective protection against opsonization. Among the nonionic hydrophilic polymers fulfilling this criteria, poly(ethylene oxide) (PEO), also commonly named poly(ethylene glycol), has been the most successful synthetic materials used to alter the opsonization process. The protein-resistant nature of PEO chains is attributed to their unique solution properties and molecular conformation in aqueous solutions. Highly hydrated PEO chains produce a surface which is in a liquid-like state and thereby minimizes the tendency to make hydrophobic interactions (117). The considerable flexibility and mobility of the chains result in the sampling of a large number of possible conformations at the particle surface. This highly dynamic state may prevent interactions with approaching opsonins (111,117).

The surface modification of particles using PEO derivatives has been achieved using two main approaches. In a first attempt, preformed particles were modified by physical adsorption of amphiphatic PEO-based compounds including commercially available ethoxylated surfactants and, more recently, new block copolymers with a tailored composition and a R-PEO structure (where R is a synthetic polymer similar to the polymer forming the particle core). In this first approach the PEO moieties are maintained around the particle through intermediate hydrophobic interactions of noncovalent nature. The main concern was to ensure the coating stability, which through the adsorption process was shown to be somewhat limited. As a result, a second approach was recently developed involving use of the previously mentioned R-PEO copolymers and leading to PEO-grafted nanoparticles.

PEO-Coated Nanoparticles. The adsorption approach was initially based on the use of commercially available PEO-based surfactants, such as ethoxylated nonyl phenol (Antarox®), polysorbates (Tween®), PEO-24-laurylether (Brij® 35), perethoxylated castor oils (Cremophor®) (110,118), or different PEO homopolymers (119,120).

However, during the last decade, the most popular and promising coating surfactants have been ethylene oxide (EO) and propylene oxide (PO)-based copolymers, the so-called poloxamers and poloxamines. In contrast to the previously mentioned compounds, these surfactants are available in a very wide range of molecular weights and hydrophilicity, allowing a real modulation of the surface modification and an optimal efficacy in terms of steric stabilization. Poloxamers are linear ABA block copolymers with the general structure $(EO)_n$-$(PO)_m$-$(EO)_n$, where n and m are the numbers of (EO) and (PO) units, respectively. Poloxamines are also ABA block copolymers, but instead of being linear, they present a branched tetrafunctional structure with a central ethylene diamine bridge: $\{(EO)_n$-$(PO)_m\}_2$-N-CH_2-CH_2-N-$\{(EO)_n$-$(PO)_m\}_2$. Due to their original structure, these amphiphatic surfactants attach themselves onto the surface of nanoparticles through their central hydrophobic portion (i.e., $(PO)_m$ or $(PO)_m$ ethylene diamine, respectively), whereas the hydrophilic $(EO)_n$ portions protrude into the surrounding medium, forming a brush-like coat around the particle. The adsorption of surfactant molecules onto the particles is generally performed by 24 hours' incubation of equal volumes of nanoparticle suspension (2.5%) with a coating solution of the relevant surfactant (0.05–2.5% w/w) (121).

Within the poloxamer and poloxamine series, only polymers with a certain optimal molecular weight and n/m ratios have an ability to provide efficient protection against phagocytosis (121,122). The length of the protruding $(EO)_n$ chains determines the coating layer thickness around the particle and their ability to cover the hydrophobic $(PO)_m$ anchoring parts. Another prerequisite is a sufficient length of the anchoring $(PO)_m$ block to preclude the desorption/displacement of the coat upon contact with dynamic biological environments. In this respect, poloxamer 407 (69 PO and 2 × 98 EO), poloxamer 338 (54 PO and 2 × 128 EO) and poloxamine 908 (4 × 17 PO and 4 × 119 EO) were shown to be the most efficient products in diverting model polystyrene or PMMA nanoparticles from the liver and in providing extended circulation times after intravenous administration in different animal models (112,122). In some cases, the foregoing polymers led not only to the decrease of particle uptake by liver macrophages but also to the redirection of the nanoparticles to other organs such as the bone marrow, spleen, and lymph nodes (112,122). In addition to the intrinsic properties of the coating material, other parameters such as the particle size (curvature) and the surface characteristics have been shown to strongly influence the final conformation of the adsorbed polymer and thereby its ability to alter the biological fate of the particles (111,121,122). Although the correlations between these different factors have not been clearly established yet, particle size has been shown to affect the adsorbed amount of polymer, the coating layer thickness, as well as the mobility of the protruding PEO chains (111,121,122). Together with the particle size, the nature of the surface to be coated also determines the final conformation of the coating polymer. Until recently, the promising in vivo results achieved with poloxamer- and poloxamine-coated polystyrene and PMMA particles could not be transferred to biodegradable drug carriers. In general, the surface of biodegradable particles is distinctly less hydrophobic than that of nonbiodegradable model particles, leading to no or weak adsorption of poloxamer and poloxamine surfactants to the particle surface (110). In the latter case, a rapid desorption of the coating layer can be expected to occur upon contact with biological media, or even before when a washing procedure is performed to remove excess of free surfactant molecules prior to biological testing. In addition, the production of biodegradable nanoparticles frequently involves the use of a hydrophilic stabilizer (e.g., dextran or PVA) whose residual presence on the particle surface can further inhibit surfactant adsorption (123,124). As a result, attempts to provide a steric protection to biodegradable particles using poloxamers and poloxamines have usually failed (111,123,124). Recently, these surfactants were used to stabilize PLGA nanoparticles prepared by a emulsifier-free nanoprecipitation method (125,126). In vitro, different particle uptake and protein resistance abil-

ities were observed between PLGA and polystyrene model nanoparticles modified in the same manner. This was attributed to distinct conformations of the coating layer on the two different surfaces. However, following intravenous administration to rats, PLGA-coated nanoparticles were shown to exhibit slightly prolonged circulation times and reduced accumulation in liver and spleen, comparable, surprisingly, to that obtained with polystyrene nanoparticles tested in parallel that had been modified in the same manner. Furthermore, when the PLGA-coated particles were washed of excess surfactant before intravenous administration, prolonged circulation times, although slightly reduced, were still observed. A relative stability of the coatings could obviously be achieved in this study. Although this point was not discussed by the authors, this might be partly explained by the absence of emulsifier in the preparation process.

New amphiphilic R-PEO diblock copolymers were recently proposed for the advantageous replacement of the surfactants previously used. The advantage of the R-PEO copolymers over the poloxamers and poloxamines is in replacing the poly(propylene oxide) (POP) moiety of the latter polymers with a biodegradable and biocompatible R chain. Indeed, the R moiety can be chosen among the family of the hydrophobic polymers generally used to produce biodegradable nanoparticles. In addition to its safe nature, the R part of the R-PEO copolymers is expected to be a better anchor group when adsorbed onto a surface of a similar nature. These polymeric materials are generally synthesized by ring-opening polymerization or by melt condensation, with tailored molecular weights and R/PEO ratios (127,128). In a recent study, a PLA-PEO block copolymer was adsorbed onto both PLGA and polystyrene nanoparticles (129). Following intravenous administration into rats, the PLGA modified particles were shown to exhibit extended circulation levels, whereas the coated polystyrene particles, after one hour of effective blood circulation, were suddenly massively taken up by the MPS. These distinct behavior patterns of the two systems have been attributed to a difference in the stability of the PLA-PEO coatings on polystyrene and PLGA nanoparticles, the affinity of the PLA anchor moity presumably being higher for the PLGA surface than for that of polystyrene.

PEO-Grafted Nanoparticles. It is evident from results with both model nonbiodegradable and biodegradable systems that the stability of the coating layer is an essential feature in modifying particle interaction with the biological environment. Although the adsorption approach undoubtedly provided information on the in vivo behavior of sterically stabilized nanoparticles, the relative unreliability of the resulting steric barrier was soon considered a limitation, especially in terms of interpreting the results. Theoretically, whatever the affinity between the surface and the coating material, the desorption of the latter is always possible in vivo.

The introduction of novel R-PEO block copolymers provided a very interesting alternative to the adsorption approach for surface modification. As a matter of fact, due to their peculiar amphiphatic structure and composition, these copolymers can be used as the main material to produce, in a single-step procedure, nanoparticles with the R blocks forming the central core and the PEO blocks forming a hydrophilic shell covalently linked to the core. Recently, several authors reported the production of PEO-grafted nanoparticles using emulsification-solvent evaporation, direct precipitation, or the salting-out process. In these procedures, the R-PEO copolymer is dissolved in an organic phase which is subsequently mixed with an aqueous phase. Due to their high affinity for the aqueous phase, the PEO blocks are presumed to migrate to the water interface, whereas the hydrophobic R blocks remain within the nanodroplets and subsequently form the solid core of the particles after organic solvent removal. So far the copolymers used have been PLA-, PLGA-, PCL- and poly(sebacic acid)-PEO diblock copolymers (104,115,128,130–136). The resulting PEO-grafted nanoparticles exhibited sizes between 100 and 300 nm. It has to be emphasized that, in most studies, the particle size was determined directly after purification of the raw nanoparticle suspensions, avoiding the possible effects of a freeze-drying step on the resuspension ability of the PEO surface-modified nanoparticles. It was shown recently that the presence of PEO at the nanoparticle surface could severely impair the redispersion of the freeze-dried particles after rehydration (104). This effect may be attributed to the well-known tendency of PEO to crystallize during freeze-drying (106,137) and can be circumvented using an appropriate lyoprotectant additive (e.g., trehalose) (104,106,137). It appears that the use of a lyoprotectant additive should be systematically considered when PEO surface-modified nanoparticles are intended to be freeze-dried.

The blood clearance and biodistribution of the R-PEO based systems have been studied (Table 4). It was demonstrated that the protective effect of PEO depends on both the chain length and the surface density of the PEO chains, although it is still not clear which parameter is the most dominant (104,111). Nevertheless, results from the literature indicate that, above a certain threshold, increase of the PEO density no longer prevents phagocytosis (111,133). Similarly, there appears to be an optimal chain length (around 2,000 Da) that is necessary to achieve efficient protection (111,129). To further improve the performance of PEO-coated nanoparticles, new copolymers presenting more than one PEO block have been recently proposed (128,138). These so-called R-$(PEO)_n$ multiblock copolymers would allow the production of nanospheres with optimal PEO surface-densities.

Various drugs were successfully entrapped into PEO-grafted nanospheres such as lidocaine (128,131), prednisolone (128), ibuprofen (115), as well as oligonucleotides (139). The entrapment efficiency and in vitro drug-release patterns were shown to depend strongly on the chemical nature of the hydrophobic core, as well as the molecular weight and surface density of the hydrophilic PEO chains (128). The fact that the PEO chains might be involved in the release process was unexpected for the authors. However, some studies performed on various PLA/PLGA-PEO copolymers have shown that the PEO segments can greatly influence the physical properties of the polymer, such as its degradation behavior and its degree of swelling and permeability in water (140,141). Therefore, depending

Table 4. In vivo Studies with R-POE–Based Nanoparticles

Copolymer	Method[a]	Size (nm)	Animal	Comment	Reference
PLGA-PEO	ESE	<200	Mouse	Significant increase of AUC vs. control	130,131
PLA-PEO	DP	60–200	Rat	Significant increase of AUC vs. control	115,133
PLA-PEO	DP	<200	Rat	No particle-induced inflammatory response contrary to control	134

[a]ESE, emulsification-solvent evaporation; DP, direct precipitation.

on the copolymer composition, a more or less pronounced modification of the release can be expected in the presence of PEO segments (140,141). From this outcome, it appears that tailor-made PEO-polyester copolymers have great potential as nanoparticulate delivery systems. Illustrating this consideration, the kinetic profile and biodistribution of a labeled drug (^{14}C-ibuprofen) were investigated after intravenous administration of 20% loaded PLA-PEO nanoparticles in rats. A sustained release profile was reported for the drug (plasma half-life of 2 h 30 min) as well as a widespread body distribution 6 h post injection, demonstrating that in addition to their long-circulating ability, the PLA-PEO nanoparticles tested could also behave as sustained delivery dosage forms in vivo (115).

Nanoparticles made of R-PEO preformed block copolymers are actually among the most extensively investigated systems for the achievement of prolonged circulation following intravenous administration (104,115,128,130–136). As previously mentioned, the possible tailoring and easy characterization of R-PEO block copolymers allow a rational modulation of nanoparticle physicochemical properties and thereby a more precise understanding of the relationship between the surface properties and the in vivo behavior of the particles. However, other types of PEO-grafted nanoparticles can be produced, based on in situ copolymerization reactions. Polystyrene-PEO (PS-PEO) nanoparticles were produced by copolymerizing styrene monomers with various amounts of methoxyPEO (142). These nonbiodegradable PS-PEO nanoparticles were designed as model particles to study the influence of surface density of PEO on the in vitro and in vivo behavior of the particles. In rats, the blood circulation time was shown to be increased with increasing surface densities of PEO (142). More recently, biodegradable PACA-PEO nanospheres were produced by emulsion polymerization of cyanoacrylate monomers in water, in the presence of homopolymer PEO 4,000 (143). The authors hypothesized that, in this process, the OH groups of PEO act as polymerization initiators. In addition, it was shown that the presence of PEO in the polymerization medium avoided the need for surfactant or stabilizer such as polysorbate or dextran. Data obtained from chemical analysis suggested that a covalent bond was formed between PEO and PACA during the anionic polymerization process (143). So far, the ability of these systems to avoid MPS recognition has not been reported.

Direct attachment of protective PEO chains onto the surface of preformed albumin nanospheres has been described (144). PEO grafting could be achieved through the carboxylic acid and amino functionalities of the chemically cross-linked albumin surface. The PEO protective effect against phagocytosis was demonstrated in vitro, as well as the clear influence on this effect of both the length and surface density of the PEO chains (144).

Targeting Strategies

Although PEO surface-modified nanoparticles can partially avoid the MPS and exhibit extended circulation times in the bloodstream, they are not able to target a specific site in vivo. Over the last decades, two main approaches have been investigated to provide a targeting ability to nanoparticulate systems.

External Magnetic Guidance. The concept of magnetically controlled targeting for particulate systems emerged in the seventies. It was proposed as a means to minimize nanoparticle uptake by the MPS and to enhance their access to extravascular sites, particularly to tumors. Nanoparticles are rendered magnetic by incorporating Fe_3O_4 particles (10–20 nm) simultaneously to the drug during the preparation process. The magnetic nanoparticles are then injected through the artery supplying the tumor tissue and are guided externally with a magnet to the target. This technique has been investigated with magnetic nanoparticles made of albumin but the production and testing of polyglutaraldehyde, PACA, and PMMA magnetic nanoparticles was also reported (1,19). The efficacy of this technique has been demonstrated by using readily accessible target areas with an abundant blood supply, such as the tail or the kidneys of rodents, and therefore should be considered with caution. In fact, the usefulness of this technique in treating dispersed metastatic neoplasms appears to be limited. Moreover, the feasibility of using magnetic nanoparticulate systems in humans strongly depends on the possibility of using low-strength magnetic fields which would not be harmful for the patient in case of prolonged treatment.

Nanoparticles Coated With Antibodies. Several authors have investigated the possibility of attaching antibodies to the nanoparticle surface to facilitate their direction to specific sites. The underlying rationale is the possibility of using monoclonal antibodies (MAb) with unique antigen specificity. MAb can be fixed on nanoparticles by direct adsorption or via a spacer molecule (protein A) as well as by covalent linkage (e.g., carbodiimide, cyanogen bromide, and glutaraldehyde reactions) (145). Whatever the procedure used, MAb must bind to the particle via their Fc part with their antigen binding site Fab protruding into the medium, free to interact with the antigenic target site. This technique has been applied to a wide variety of nanopar-

ticles including PACA, polymethacrylic, albumin, and recently PMM 2.1.2. nanoparticles (50,78,146,147). Some authors demonstrated the capacity of these immunospecific nanoparticles to bind specifically tumor cells in vitro, but failed to demonstrate a significant accumulation of the carriers in targeted tumors in vivo (78,146). A number of reasons for this failure have been proposed including the competitive displacement of the MAb by blood components, secondary coating processes where the MAb-coated particles receive an opsonic layer, and also insufficient access of the immunospecific nanoparticles to the target site (145). It clearly appears that the success of immunospecific targeting strongly depends on the potential of the drug carrier to overcome MPS recognition. Future strategies will probably be based on the development of nanoparticles combining long-circulating properties (surface modification with PEO surfactant or polymer) and targeting abilities (attachment of MAb) (112,148).

CHARACTERIZATION OF NANOPARTICLES

As any other dosage form intended to be use in medicine, nanoparticulate formulations are usually characterized in term of size, morphology, drug content, and in vitro drug release. The determination of these properties is of great relevance for quality control as well as for evaluating the influence of process parameters on the resulting formulation. In addition to these pharmaceutical considerations, a major challenge is to establish a correlation between the physicochemical properties of the systems and their interaction with blood components and resulting site deposition. Recently, the design of surface-modified nanoparticles for the avoidance of the MPS has promoted the development of sophisticated methods for surface chemical analysis, allowing, for example, the identification of specific chemical groups on the surface of the particles. A wide range of techniques is available for a comprehensive physicochemical examination of nanoparticle properties. The most widely used techniques are listed in Table 5. Detailed descriptions of each technique can be obtained in the references, which are either very complete review articles (19,110,149,150) or recent specific reports focusing on these techniques (60,72,126,128,131,143,151–155).

APPLICATIONS OF NANOPARTICLES

Parenteral Administration

Delivery of Anticancer Drugs. One of the most promising application of nanoparticles is their use as parenteral carriers for anticancer drugs. Interestingly, nanoparticles exhibit a significant tendency to accumulate in a number of tumors after intravenous administration. This particular behavior has been related to the frequently observed high endocytic activity of cancer cells. In addition, some tumors have been shown to exhibit an increased vascular permeability which may favor the accessibility of nanoparticles to extravascular tumoral cells (19,156,157). The binding of a variety of anticancer drugs (e.g., doxorubicin, 5-fluorouracil, dactinomycin, methotrexate), immunomodulators (muramyl dipeptide-L-analyl-cholesterol) or antisense oligonucleotides mainly to PACA or albumin nanoparticles enhanced their efficacy against experimental tumors in comparison to free compound (157). In a number of cases, a reduction of the general toxicity of anticancer drugs was also demonstrated. This is usually attributed to the modification of the drug pharmacokinetic parameters that correlate with the distribution profile of the carrier itself. When associated with nanoparticles, drugs concentrate mainly in liver and spleen and are precluded to exert their acute toxicity in other organs (156,157). One of the most promising applications of anticancer drug-loaded nanoparticles may be their use in the treatment of hepatic metastases. Intravenously injected nanoparticles are mainly taken up by the Kuppfer cells. These latter may act as a reservoir for the drug, allowing its massive and prolonged diffusion into the neighboring neoplastic cells (156,157). Besides the use of this passive targeting, the incorporation of magnetic particles into albumin nanoparticles and subsequent electromagnetic guidance has been shown to improve the antimetastatic potential of the anticancer drug carrier by facilitating the access to extravascular tumors (19,157). A different approach to achieve tumor-specific targeting was made using MAb-coated nanoparticles. These formulations should be able to recognize specific cell determinants belonging only to tumor cells. Unfortunately, contrary to the very promising results obtained in vitro, the MAb-coated nanoparticles did not exhibit any increased tumor location after intravenous administration and were rapidly cleared by the MPS (157). New and attractive possibilities have recently become available with the development of PEO surface-modified nanoparticles (see "Surface Engineering of Nanoparticles"). In a recent study involving PLA nanoparticles loaded with a photoactivable sensitizer ($ZnPcF_{16}$) (120), coating the nanoparticles with PEO 20,000 by adsorption was shown to significantly increase their blood circulation time and in turn their tumor accumulation in mice. Efficient photodynamic therapy could be performed, as demonstrated by significant tumor regression following light treatment (120).

Delivery of Antiinfectious Agents. Intracellular infections are another field of interest for the use of nanoparticles. Infectious diseases are caused by obligate or facultative intracellular pathogens which can be bacterial, parasitic, fungal, or viral in nature. Most antiinfectious agents display limited efficacies against intracellular infections. For example, antibiotics usually exhibit either a poor ability to penetrate the infected cells or a decreased activity in intracellular compartments. Antiparasitic agents have a limited efficacy due to their lack of selectivity for the infected cells, resulting in a poor therapeutic index. Finally, antiviral agents generally display very short plasma half-lives. Because most of the cells that are frequently infected include phagocytic cells, it was suggested that nanoparticles should be of great interest to improve antiinfectious chemotherapy. This approach has been extensively investigated with PACA nanoparticles loaded with ampicillin as a model of acidic antibiotic. The efficacy of this formulation against *Listeria monocytogenes*

and *Salmonella typhimurium* infections has been demonstrated in numerous studies, both in cell cultures and in mouse models (19,156). The effective uptake of ampicillin-loaded nanoparticles was demonstrated in murine macrophages by confocal and transmission electron microscopy studies. In addition, the authors reported that the nanoparticles were localized in the same vacuoles as the infecting bacteria (158).

Nanoparticles also hold promise as drug carriers for the treatment of parasitic infections such as visceral leishmaniasis. This infection is caused by *Leishmania donovani*, an intracellular parasite of the MPS. Most of the drugs usually used to treat this infection (e.g., primaquine, dehydroemetine) exert, apart from the desired activity, very toxic and adverse side effects. The binding of these drugs to various types of nanoparticles was shown to significantly increase their therapeutic index as a result of passive targeting to the MPS (19,159). Surprisingly, it was shown that unloaded PACA nanoparticles exhibited a significant antileishmanial activity on their own. In fact, it appeared that PACA nanoparticles could induce an activation of the respiratory burst in macrophages leading to the production of toxic oxygen metabolites (19,156). It is reasonable to think that this immunomodulation activity of plain nanoparticles may open interesting perspectives not only in the field of parasitic infections, but also in the treatment of other infectious or tumoral diseases.

In the field of viral infections, a very important challenge is the targeting of human immunodeficiency virus (HIV)-infected macrophages. Indeed, it is now well established that macrophages of the MPS play an important role in the immunopathogenesis of HIV infection by acting as a reservoir for the virus and its dissemination throughout the body (19). Therefore, nanoparticles represent an interesting system for the specific transport of antiviral agents displaying poor selectivity and/or short plasma half-life. Recently, PACA nanoparticles loaded with the protease inhibitor saquinavir were shown to be effective in HIV-infected human macrophage cultures (160). In another study, azidothymidine bound to PACA nanoparticles was successfully targeted into macrophage-rich organs in rats (161). These initial promising results suggest that new perspectives in the treatment of HIV-related diseases may be open. Substances whose development has been halted because of their unfavorable pharmacokinetic properties could be made efficient and available, using nanoparticulate technology.

Peroral Administration

Delivery of Poorly Absorbed Drugs. Some authors have supported the idea that nanoparticles may improve the bioavailability of peptide or protein drugs administered orally. The rationale for this approach is that nanoparticles can protect these labile drugs from extensive enzyme degradation in the gastrointestinal tract (GIT) and enhance their absorption (*1*) by optimizing their interaction with the absorption site in the gut wall or (*2*) by directly transporting them through the intestinal mucosa to the systemic circulation.

Precursors in this field, Maincent et al. (162) reported that the relative peroral bioavailability of vincamine in rabbits was considerably increased when this drug was associated with PACA nanoparticles. Later, Michel et al. (163) found that insulin encapsulated in PACA nanocapsules reduced glycemia by 50–60%, whereas free insulin did not affect glycemia when administered orally to diabetic rats. This effect was attributed to the protection of insulin from proteolytic degradation. It was also suggested that this effect could result from the retarded passage of intact nanocapsules through the rat mucosa (163). Although experimental evidence of such a mechanism was found in rodents, whether or not it plays a significant role in increasing the bioavailability of drugs is still a controversial issue. In fact, in many studies, the passage of nanoparticles across the gastrointestinal mucosa was shown to be very low (2–3% of the injected dose), leading to the conclusion that only very potent drugs would be able to exert

their activity by this specific route (1,164). In fact, the most probable mechanisms by which nanoparticles increase the oral bioavailability of drugs is by protecting them against degradation and by releasing them in the GIT in a way that favors their absorption. For example, in a study by Lenaerts et al. (165), the peroral efficacy of PACA nanoparticles loaded with vincamine was attributed to the bioadhesive behavior of the particles, allowing the slow release of the drug close to its absorption window and its subsequent diffusion into the vascular compartment. Similarly, Mathiowitz et al. (166) reported enhanced oral bioavailability for model proteins and gene (insulin, dicumarol, plasmid DNA) encapsulated into biologically adhesive nanoparticles made of polyanhydride copolymers of fumaric acid and sebacic acid. The latest developments in the field of bioadhesive particulate systems, involving for example the use of lectins as specific bioadhesive moieties, are described in the literature (167,168). Recently, it was demonstrated by our group that pH-sensitive nanoparticles could significantly increase the bioavailability of poorly water-soluble HIV-protease inhibitors in mice and dogs (169). These formulations are made of polymethacrylic copolymers which rapidly dissolve and release the poorly water-soluble drug at a specific level of the GIT. It was suggested that this rapid and specific release, combined with the very high level of dispersion provided by the nanoparticulate formulation, favored the solubilization of the drug in the intestinal fluid, resulting in a positive impact on drug absorption.

Delivery of Vaccines. As previously mentioned, although restricted, particulate uptake does take place in the intestinal mucosa (164). This uptake was shown to occur mainly in the lymphoid regions of the intestine called the Peyer's patches, through the action of specialized epithelial cells, called M cells. These cells play a determining role in the sampling and transport of luminal antigens into lymphoid tissues for immunologic surveillance and initiation of appropriate immunologic response. It is generally accepted that limited doses of antigen are sufficient to induce an efficient immunization. Thus, it has been postulated that the use of nanoparticles would be profitable for the oral delivery of antigens, because of their ability to control the release of proteins and to protect them from enzymatic degradation in the GIT. Biodegradable PACA nanoparticles have been shown to enhance the secretory immune response after their oral administration in association with ovalbumin in rats (170). PMMA nanoparticles appear to be promising nanoparticulate systems for this application. The very slow degradation rate (30–40% per year) of these particles seems to be particularly appropriate for vaccine purposes, because prolonged contact between the antigen and the immunocompetent cells favors the persistence of immunity. Factors affecting the efficacy of the immunoparticles include particle size, hydrophobicity, and the presence or absence of surface ligands. Indeed, by associating targeting agents such as MAb specific from M cells, it may be possible to increase the levels of absorption of nanoparticle vaccines and therefore the immune response (171). Coupled with advances in molecular biology, immunology, and virology, controlled delivery nanoparticulate systems may be the next generation of effective vaccines in the field of oral immunization.

Other Routes of Administration

Besides the previously described main applications, nanoparticles can be considered for the intramuscular and subcutaneous routes. Although these routes have been so far rarely employed with nanoparticles, they may present some advantages in the attempt to prolong the plasma level of drugs, to protect them from enzymatic degradation or to reduce their irritant effect when applied intramuscularly. Depending on the rate of release which is desired for the drug, PACA or polylactide (PLA, PLGA) nanoparticles appear to be particularly suitable for these routes, due to their particular and controllable degradation properties (1,172–174). Due to their very slow biodegradation rate, PMMA nanoparticles are very attractive for vaccine purposes using the intramuscular or subcutaneous routes. These nanoparticles were shown to exhibit very powerful adjuvant properties for a number of antigens either trapped in the polymer or adsorbed onto the particle surface (175) (see also "Dispersion Polymerization in Water for Production of Polymethacrylic Nanospheres").

Another possible route of administration for nanoparticles is their topical application to the eye. The use of nanoparticles by the ocular route has been investigated for the treatment of chronic diseases such as glaucoma, following the observation that various types of nanoparticles tend to adhere to the ocular epithelial surface. As a result, several authors have tried to take advantage of this prolonged residence time of nanoparticles, because most of the conventional ophthalmologic formulations failed so far in providing sufficient drug bioavailability (176). The polymers that seem to have the best potential for this application are PACA, PLGA, and PCL. They have been used in the form of either nanospheres or nanocapsules. Because of their low viscosity in suspension, these systems can be administered as easily as eye-drops with the advantage of having a reservoir-like behavior, that is, able to deliver the drug progressively (176–178, as well as MUCOSAL DRUG DELIVERY, OCULAR).

CONCLUSION

Nanoparticles represent very promising drug delivery systems which can be considered for a very wide range of applications. Optimization of earlier polymerization procedures combined with the development of new procedures using well-characterized and biodegradable polymeric materials has enabled the development of nanoparticulate systems with increased acceptance and potential. Although the entrapment of hydrophilic compounds (e.g., proteins, DNA, oligonucleotides) still faces some limitations, the many possible variations in structure and type of nanoparticles allow the efficient entrapment of a great number of molecules. The technology of nanoparticles being now quite well mastered, the main objective is the improvement of their targeting properties following intravenous administration. Although the massive uptake of nanoparticles by the MPS can be very advantageous for

the treatment of diseases associated to this system, the targeting to sites other than the MPS remains an exciting and major challenge. Several strategies have been developed to achieve this goal, relying on the considerable progress made in the field of nanoparticle characterization and the growing understanding of their in vivo behavior. The strategy that is actually gaining a widespread interest is based on the design of nanoparticules with tailored surface characteristics. More than ever, the achievement of pharmaceutical nanoparticle formulations for human use depends on the successful exploitation of multidisciplinary knowledge.

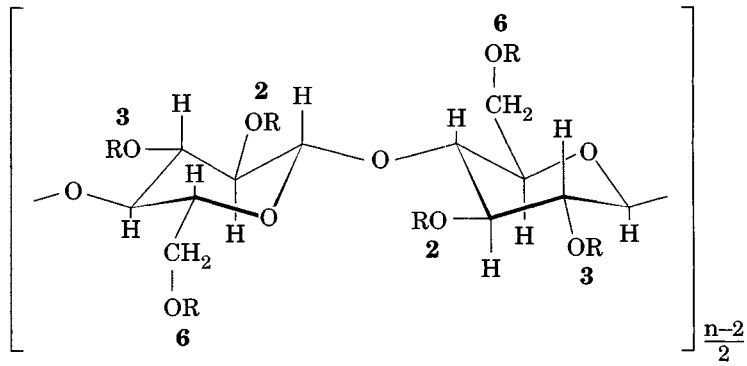
Bibliography

Polymers play a dominant role as carrier materials in drug delivery systems. The selection of a particular carrier is primarily determined by the intended use and the desired release profile. The polymer should be inexpensive, readily available, and easily processed on a large scale. When applied to an animal or human, it must be biocompatible and nontoxic. The route of administration also plays a decisive role: Polymers for parenteral use have to satisfy different requirements than polymers for oral use. This article reviews the most important nondegradable polymers used in drug delivery systems. They include the cellulose derivatives ethyl cellulose, cellulose acetate, cellulose acetate butyrate, cellulose acetate proprionate, and hydroxypropylmethyl cellulose; various acrylic polymers; silicones; poly(ethylene vinyl acetate); and poly(ethylene oxides). The physicochemical properties of the polymers are briefly discussed, followed by a review of various drug delivery systems in which the polymers have been incorporated.

ETHYL CELLULOSE



Ethyl cellulose is a cellulose ether prepared by the reaction of alkali cellulose with ethyl chloride; its chemical structure is shown in Figure 1. Its properties and applications have been reviewed recently (1). Its glass transition temperature is 120°C (2). It is characterized by the degree of ethoxy substitution and the solution viscosity. Commercial grades of ethyl cellulose have a degree of substitution between 2.25 and 2.58 (44 to 50% ethoxyl content) per anhydroglucose unit. Ethyl cellulose polymers are sold under the trade name Ethocel® by the Dow Chemical Company. Ethocel is available in six grades from standard 4 to 100, the numbers representing the viscosity of 5% w/v solutions in toluene ethanol (80:20) in cP, with the 7 and 100 grades also being offered with a fine particle size for applications in which the polymer is not dissolved in organic solvents but is used as a dry powder. A similar range of ethyl cellulose products is also offered by Hercules. Ethyl cellulose is water insoluble but soluble in a variety of organic solvents/solvent mixtures (3). The desired use of ethyl cellulose will determine the choice of a particular grade, for example, lower-molecular-weight grades are used for coating, and higher-molecular-weight grades are used for microencapsulation. Different grades can also be blended to obtain films with special properties. The polymer is tasteless and odorless, physiologically inert, stable in a pH range between 3 and 11, and, because of its nonionic character, compatible with most drug substances.

Ethyl cellulose has been used by the pharmaceutical industry for almost 40 years for the coating of solid dosage forms (tablets, pellets, granules); in matrix systems, which are prepared by wet granulation or direct compression; or in microencapsulation processes. It has excellent film-forming properties. Besides the predominant use as controlled-release barriers, thin films have been used as a moisture barrier to improve the stability of hydrolytically unstable drug substances or for taste-masking purposes.

Coated Systems and Films

Ethyl cellulose is one of the most widely used water-insoluble polymers for the coating of solid dosage forms. It can be applied as an organic solution or as an aqueous colloidal polymer dispersion. Many studies have been performed with ethyl cellulose films to predict properties of the coatings, for example, mechanical or permeability properties.

Various factors of the spraying process with organic polymer solutions, such as spraying distance, flow rate, and atomizing air pressure, affected the mechanical and release properties of ethyl cellulose films (4). It was pointed out that the variables governing solvent evaporation and spreading of the organic polymer solution droplets during the coating process are very important to obtain films with the desired properties. The selection of a suitable organic solvent system has been facilitated through the determination of the dilute solution properties of ethyl cellulose, namely the intrinsic viscosity and the interaction constant (5). Methylene chloride and ethanol in a ratio of 60:40% w/w were found to be optimal. Water concentrations in excess of 10% resulted in uncontrolled situations (e.g., polymer precipitation) during solvent evaporation. Based on tensile tests and thermal analysis, dibutyl sebacate and Myvacet were the most efficient plasticizers for ethyl cellulose films cast from ethanolic solution (6). The permeability of the polymeric films can be controlled by the molecular weight of the polymer or polymer blends or by the inclusion of additives like plasticizers or pore formers. The mechanical stability of the polymeric films increases with

Cellulose derivative	Substituent R (other than H)
Ethyl cellulose	$-CH_2CH_3$
Cellulose acetate	$-COCH_3$
Cellulose acetate propionate	$-CH_2CH_3$, $-COCH_2CH_3$
Cellulose acetate butyrate	$-CH_2CH_3$, $-COCH_2CH_2CH_3$
Hydroxypropylmethyl cellulose	$-CH_2CH(CH_3)OH$, $-CH_3$

Figure 1. Structure of a section of two anhydroglucose units (cellobiose) in a cellulose derivative. *Source:* Adapted from Doelker (117) with permission from Springer-Verlag.

increasing molecular weight. The release of drug from ethyl cellulose/hydroxypropylmethyl cellulose (HPMC) (9:1)–coated pellets decreased with increasing molecular weight of ethyl cellulose and increasing diethyl phthalate (plasticizer) concentration for the lower-molecular-weight ethyl cellulose grades (7). Above a molecular weight of 35,000 Da, the addition of a plasticizer had no effect on the drug release. The rapid release with the lower-molecular-weight grades was attributed to the weak mechanical properties of the coating, reflected by cracks and flaws in the film.

A porous ethyl cellulose film was obtained by spraying an ethyl cellulose–ethanol–water ternary mixture (8–10). The film porosity increased with increasing water content of the coating solution as a result of a phase separation process. The film porosity was also affected by the temperature and the relative humidity but was only slightly affected by the concentration of the polymer and its molecular weight. The increased film porosity resulted in increased permeation rates.

Although coating with organic polymer solutions is still widespread, aqueous ethyl cellulose dispersions have been developed to overcome problems associated with organic solvents (11). Two aqueous ethyl cellulose pseudolatexes are commercially available, namely Aquacoat®, manufactured by FMC, and Surelease®, by Colorcon®. Aquacoat® (30% solids content) is prepared by a direct emulsification–solvent evaporation method (12), whereby an organic polymer solution is emulsified into water to form an emulsion. The pseudolatex is obtained after homogenization and solvent removal. Sodium lauryl sulfate and cetyl alcohol are used as emulsifier and coemulsifier. The polymer dispersion must be plasticized to reduce its minimum film formation temperature (MFT). For coating purposes, 20–30% plasticizer is added, and the dispersion is diluted to a solids content between 10 and 25%. Surelease® (25% solids content) is a fully plasticized dispersion and is prepared by a phase inversion–in situ emulsification technique (13). Ethyl cellulose, dibutyl sebacate or fractionated coconut oil (plasticizer), and oleic acid (secondary plasticizer) are hot-melt extruded under pressure into water containing ammonia. Initially, a water-in-polymer dispersion is formed, which then inverts into a polymer-in-water dispersion. Ammonium oleate forms in situ as a stabilizer. Upon drying and film formation, ammonia evaporates, leaving oleic acid as an additional plasticizer within the film.

Various additives, which are present in the ethyl cellulose dispersions, will also be present in the final film or coating and can therefore affect film properties, such as mechanical properties or the permeability. Surfactants are necessary to physically stabilize the dispersion during preparation and storage. Plasticizers and antitacking agents or additives, which affect the permeability of the ethyl cellulose film (e.g., hydrophilic polymers such as HPMC), are added shortly before the application of the polymer dispersion.

Although a pH-independent drug release is expected with ethyl cellulose, several studies with Aquacoat®-coated beads showed a faster drug release in simulated intestinal fluid when compared to simulated gastric juice (14–17). This was caused by the presence of the anionic surfactant, sodium lauryl sulfate, which resulted in better wetting of the coated pellets in pH 7.4 buffer as indicated by contact-angle measurements (18) and not by residual acid/base groups in the ethyl cellulose polymer (19). Later, it was reported that the pH-dependent release could be circumvented by curing the coated dosage form above the glass-transition temperature of the plasticized polymer coating (20,21). During storage, sodium lauryl sulfate and cetyl alcohol were squeezed from the film, possibly changing the permeability (22). In addition, charged surfactants such as sodium lauryl sulfate could form insoluble complexes with cationic drugs present in the core (23,24).

Although the drug release from ethyl cellulose–coated multiparticulates such as pellets or granules is adequate, the release from tablets is often too slow. Water-soluble additives have therefore been incorporated into ethyl cellulose coatings to modify the drug release. They include low-molecular-weight materials including various sugars (e.g., sucrose, lactose, and sorbitol); salts (e.g., sodium chloride and calcium phosphate); surfactants such as sodium lauryl sulfate; or hydrophilic polymers including polyethylene glycol, polyvinyl pyrrolidone and, in particular, cellulose ethers (e.g., HPMC) (15,25–32). During dissolution studies, these additives leach from the coating membrane, or hydrate in the coating in the case of high-molecular-weight polymers, resulting in more permeable membranes and generally in a faster drug release. In addition, with thin coatings, hydrophilic polymers are added to increase the quantity of the coating to achieve a more uniform coating distribution on the pellet. Slight variations in the coating level will then not affect the release rate significantly.

The water-soluble high-molecular-weight polymers are usually not considered true pore-forming agents because they do not completely leach out from the coating to leave a well-defined pore structure. Ethyl cellulose/HPMC blends have shown phase separation with a limited degree of mixing between the polymers (33). Film studies revealed that HPMC-rich macroscopic polydispersed domains were dispersed within the ethyl cellulose–rich matrix. Complete leaching of HPMC was only observed at HPMC concentrations above 60% w/w; otherwise, some HPMC retention was observed. A critical HPMC concentration was identified below which very little polymer leached from the coating and no pores are formed. Above 24% HPMC, the polymer leaches from the ethyl cellulose films, resulting in pore formation and an increase in drug release (34,35). For the development of an osmotic system, the water permeability of pure ethyl cellulose was only about one-tenth of cellulose acetate but increased with HPMC in the film. At higher HPMC content, the initially semipermeable ethyl cellulose/HPMC film also became permeable for the drug (34). In an interesting experimental setup developed by the same research group, the permeability of ethyl cellulose/HPMC increased with increasing HPMC content as was shown with a pressurized cell device in which the permeability was measured in dependence to an applied tensile stress (36). Pellets coated with an aqueous ethyl cellulose dispersion containing HPMC initially formed water-filled pores after extraction of the HPMC at the beginning of the release process in the aqueous medium (37). However, after 2 h, these pores closed irreversibly as a result of fusion at temperatures above the MFT. The release was then as slow as without HPMC. A decrease in acetaminophen release with increasing HPMC concentration was contributed to the lower solubility of the drug in the HPMC-containing Aquacoat® film (38).

During coating with the HPMC-containing ethyl cellulose dispersion (Aquacoat®), a sediment formed in the colloidal dispersion upon standing, indicating destabilization of the colloidal ethyl cellulose particles by HPMC (39,40). The addition of HPMC to the ethyl cellulose pseudolatex resulted in the flocculation of the colloidal polymer particles above a critical HPMC concentration. The observed flocculation phenomena could interfere with the film formation of the colloidal polymer dispersion upon removal of water and thus could affect the drug release from the polymer-coated dosage forms.

A pore-forming agent, urea, was dissolved in the ethyl cellulose pseudolatex, Aquacoat®, to increase the release rate of drugs from coated osmotically active tablets (41). The release rates varied as a function of coating thickness, pore-former level and plasticizer type, and concentration. Scanning electron microscopy revealed that the urea was eluted from the coating, leaving a porous coating.

The drug release could also be increased by incorporating drug powder in the coating formulation (30). Theophylline was incorporated in the coating and resulted in faster drug release due to an increase in film porosity after dissolving from the coating. A gradient matrix system has been developed that consisted of an ethyl cellulose film with acetaminophen and xylitol coated on a core (42,43). A constant release could be obtained by increasing the drug concentration toward the core and having an inverse concentration gradient for xylitol. The drug release occurred through water-filled pores. Both compounds were soluble in the polymer, with acetaminophen acting as a plasticizer. Above a critical concentration, both the drug and xylitol crystallized, and the plasticizing effect disappeared.

Besides water-soluble additives, insoluble ingredients such as magnesium stearate or talc help reduce agglomeration or sticking of the coated particles during the coating process (15). The pigment concentration has a strong influence on the final film properties such as mechanical strength and permeability. Care must be taken when incorporating coloring agents into Surelease®, an aqueous dispersion of high pH value, because the basicity of the dispersion will destroy the dye–substrate complex (44). Colorants such as aluminum lakes should be replaced with inorganic pigments such as titanium dioxide.

With aqueous colloidal polymer dispersions, the addition of plasticizers is required for polymer dispersions having an MFT above the coating temperature. Water-soluble plasticizers are dissolved in the aqueous dispersions, whereas water-insoluble plasticizers are emulsified. Iyer et al. determined the uptake of the water-insoluble plasticizer, dibutyl sebacate, into Aquacoat® by using an alkaline partition column to separate the unbound plasticizer and gas chromatography for the plasticizer assay (45). The uptake of dibutyl sebacate was found to be complete within 30 min irrespective of the amount used; the uptake rate was faster with increasing solids content of the pseudolatex or when smaller quantities of plasticizer were incorporated. However, a previous study reported the presence of visible dibutyl sebacate droplets in Aquacoat® after 1 week of mixing, indicating incomplete plasticization after such a long plasticization time (17). Factors influencing the rate and extent of the plasticizer uptake by the colloidal particles, such as type and concentration of the plasticizer and type and solids content of the polymer dispersion, were investigated with Aquacoat® (46–48). The distribution behavior of the water-soluble plasticizers, triethyl citrate and triacetin, within Aquacoat® was virtually not affected by the mixing time or degree of agitation. The water-insoluble plasticizers were not completely taken up by the colloidal

polymer particles within a 24-h period. This may have important implications for the coating with aqueous polymer dispersions when compared to organic polymer solutions in which the plasticizer is completely dissolved. During coating, in addition to the plasticized polymer particles, the emulsified plasticizer droplets will be sprayed onto the solid dosage forms. This could result in an uneven plasticizer distribution within the film, potentially causing changes in the mechanical and especially release properties upon aging.

Plasticizers do not only affect the film formation from colloidal polymer dispersions or the mechanical properties of the resulting films; their choice will also affect the drug release from the coated dosage form (14,15,49). Increasing the concentration of dibutyl sebacate or triethyl citrate decreased the drug release from Aquacoat®-coated dosage forms (15), probably because of better fusion of the colloidal polymer particles. In general, water-insoluble plasticizers retard the drug release more than water-soluble plasticizers.

Process variables such as spray rate, droplet size, bed temperature, spray mode, chamber geometry, and so on can have a significant impact on the drug release (12–14,50). Dissolution data and morphological studies indicated differences in the nature of the coating, which was attributed to differences in particle motion in the bed, in particle distribution and density in the coating zone, and in the direction and distance the droplets had to travel prior to impinging on the particles (51). The coating temperature should be sufficiently high to achieve efficient water removal and subsequent particle coalescence. In general, it should be 10–20°C higher than the MFT of the polymer dispersion (52). The drug release with Surelease®-coated theophylline pellets decreased with increasing the product temperature from 32 to 48°C because of a more complete film formation. Coating at low product-bed temperatures prevents sufficient coalescence of the colloidal particles and promotes drug diffusion in the coating, resulting in a rapid release (53). Excessive temperatures resulted in porous films and poorly coalesced particles because of the high evaporation rate of water. Smaller nozzle diameters resulted in better coatings with fewer imperfections (54).

The coalescence of the colloidal ethyl cellulose particles into a homogeneous film is often incomplete after coating with aqueous polymer dispersions. As a consequence, changes in the drug release from the coated dosage form caused by further coalescence during storage have been observed as a function of storage temperature and time (12,16–18,55–57). A curing step or thermal treatment (storage of the coated dosage forms at elevated temperatures for short time periods) is often recommended to accelerate the coalescence of the ethyl cellulose particles prior to long-term storage. The storage temperature should be about 10°C above the MFT (16). Higher curing temperatures could cause excessive tackiness and agglomeration of the solid dosage forms. Curing was reported to be required with Aquacoat®-coated pellets but not with Surelease®-coated pellets (57).

Although curing at 40°C for 24 h was insufficient curing at either 50 or 60°C resulted in a significant reduction in drug release with Aquacoat®-coated pellets (18). The limiting drug-release pattern was approached after curing the beads for 1 h at 60°C. This value was also found by other authors (58). As an alternative to oven curing, Aquacoat®-coated beads have been cured directly in the fluidized bed after the coated beads have been applied with a thin layer of hydroxypropylmethyl cellulose (59). The hydrophilic overcoat prevented the sticking and agglomeration of the beads without altering the release profiles of the original coated pellets. The curing temperature had a more dramatic effect than curing time with Aquacoat®-coated pellets (60). An increase in drug release was observed with dibutyl sebacate, while a decrease was observed with tributyl citrate. The decrease was explained with a further gradual coalescence, while the increase was explained by either the plasticizer being squeezed from the coating or by drug being solubilized in the plasticizer at higher curing times. Although curing of the Aquacoat®-coated chlorpheniramine maleate beads produced a retarding effect in drug release, curing of ibuprofen beads coated with a comparable coating system resulted in more complex drug-release patterns (61). At curing times in excess of 4 h, the drug release increased. The increase in drug release (curing periods in excess of 4 h) could be explained by the migration of ibuprofen from the bead interior to the bead surface through the ethyl cellulose coating during the curing step. Large drug crystals could be observed throughout the coated surface by scanning electron microscopy. The drug–polymer affinity, coupled with the drug's low melting point, could thus serve as an explanation for the phenomenon of drug migration, a process that was accelerated at elevated temperatures. The diffusion of guaifenesin, another low-melting drug, through the vapor phase across the Aquacoat® coatings during storage of the coated beads has also been observed (17).

The ethyl cellulose pseudolatexes Aquacoat® and Surelease® resulted in very brittle films in the dry state and weak films in the wet state with low values for puncture strength and elongation (<5%) in both cases (62). In contrast, acrylic-based polymeric films were stronger and more flexible. Curing did not improve the mechanical properties of the Aquacoat® films. Ethyl cellulose films, when cast from organic solutions, were stronger (had higher puncture strength) in both the dry and wet state when compared with Aquacoat® films. However, the elongation values were still low. Interestingly, triethyl citrate leached almost completely from the pseudolatex-cast film, while more than 75% of the original plasticizer was still present in films cast from organic solutions. The higher leaching of triethyl citrate could have been the result of the anionic surfactant, sodium lauryl sulfate, being present in Aquacoat® films. The pseudolatex-cast films took up almost 43% water, compared with only 12% with the solvent cast films.

Most studies on the compaction of pellets coated with ethyl cellulose revealed a damage to the coating with a loss of the sustained release properties (63–69). This is not surprising because of the weak mechanical properties of ethyl cellulose.

Several articles discussed possible mechanisms by which drug release from multiparticulate dosage forms coated with water-insoluble polymers and in particular

ethyl cellulose might occur (70,71). The mechanism of drug release will be determined by the physicochemical properties of the drug, the polymer, and the dosage form. The possible mechanisms included solution/diffusion through a continuous polymer phase, solution/diffusion through plasticizer channels, diffusion through aqueous pores, and release driven by osmotic effects (70). Ozturk reported the release from ethyl cellulose–coated dosage forms to be a combination of osmotically driven release and diffusion through the polymer and or aqueous pores. To determine if the drug release was driven by osmosis or occurred primarily by diffusion through the polymer, the drug release from pellets and the drug diffusion across cast films was measured in diffusion cells (62). Ibuprofen had a significantly higher solubility in ethyl cellulose films than chlorpheniramine maleate. Ibuprofen, the water-insoluble drug, was released from the coated beads and diffused across free films, while chlorpheniramine maleate, the water-soluble drug, was released from the beads but did not diffuse across the polymeric film. Ibuprofen was released primarily by solution/diffusion through the hydrophobic polymer. On the other hand, chlorpheniramine maleate, the water-soluble drug, was not released by a solution/diffusion mechanism from the beads because of its negligible diffusion across cast films. Chlorpheniramine maleate was released through aqueous (micro)channels caused by osmotic effects with subsequent rupturing of the weak polymeric membrane. As described earlier, Aquacoat® films were extremely weak in the wet state (% elongation <1%).

The mechanism of release was reported to be different with pellets with lower coating levels and pellets with higher coating levels coated with Aquacoat® or Surelease® from diffusion through water-filled pores to diffusion of the drug through the membrane (57). Drug release from incompletely coated beads at low coating levels followed the square-root-of-time model, whereas the drug release at higher coating levels was best described with zero-order release kinetics (72). As with a typical reservoir system, three phases, an initial lag time, a constant-release phase, and a final declining-release phase, were observed (73). The major mechanism for release was reported to be diffusion and not osmotic pumping. The constant-release rate was proportional to the size (surface area) of coated pellets for metoprolol salts of different solubility. The zero-order release phase was shorter for more water-soluble drugs from Aquacoat®-coated pellets (74). Free films were not permeable for the water-soluble drugs, while the drugs were released from pellets through water-filled channels. The channels were attributed to artifacts of the coating process and not to the formation during contact with dissolution media. Each pellet was described to work like a mini–osmotic pump with multiple orifices (pores).

In addition to the colloidal ethyl cellulose dispersions, a micronized ethyl cellulose powder with an average particle size of a few μm is available in Japan from Shin-Etsu (54,75). The polymeric powder is dispersed in water with the addition of relatively large amounts of plasticizer prior to use. A comparative coating study of aqueous ethyl cellulose suspensions and pseudolatex dispersion revealed that the pseudolatex required less plasticizer for film formation than the aqueous polymer suspension. The average diameter of the ethyl cellulose particles in the suspension was 5.6 μm.

Matrix Systems

Ethyl cellulose can be incorporated as a carrier material into matrix preparations either by solution granulation or direct compression. Ethyl cellulose solutions were used for the preparation of granules by wet granulation, whereby the drug release was controlled by the amount of ethyl cellulose or the addition of a hydrophilic polymer (e.g., HPMC) to the granulation fluid. Ethyl cellulose has been used for solvent granulation of water-sensitive drugs. The resulting tablets have good physical properties. Controlled release theophylline tablets were prepared by fluid bed granulation of the drug and excipients with the aqueous dispersion, Surelease®, followed by compression of the granules (13). Because of its thermoplastic nature, ethyl cellulose can also be used for extrusion granulation.

Various studies have evaluated ethyl cellulose as a directly compressible excipient (76–81). The compressibility of ethyl cellulose has recently been reported (80). With directly compressible systems, the particle size of ethyl cellulose affected the release rate and the tablettability. Ethyl cellulose matrix controlled release tablets containing pseudoephedrine HCl were prepared by direct compression of different viscosity grades of ethyl cellulose (76). The lower viscosity grades produced harder tablets. Compared to HPMC matrix systems, matrix systems based on ethyl cellulose will release the drug faster at higher drug loadings because of a diffusion/erosion vs leaching drug release mechanism.

Microencapsulation

Ethyl cellulose microparticles can be prepared by various microencapsulation processes (see MICROENCAPSULATION). Depending on the microstructure of the microparticles, microcapsules (reservoir system) or microspheres (matrix system) can be distinguished.

Ethyl cellulose was one of the first polymers used for the microencapsulation of water-soluble drugs by the classical organic phase separation process (82). Phase separation can be induced by a temperature change in a cyclohexane system, whereby the drug is dispersed in a heated ethyl cellulose solution in cyclohexane at 80°C followed by gradual cooling of this solution to form the polymer coacervate to enclose the drug particles. In addition to the temperature change, the coacervation can be further induced by the addition of incompatible polymers, such as low-molecular-weight polyethylene or polyisobutylene. Polyisobutylene also acts as a protective colloid. As with aqueous phase separation techniques, the phase separation of ethyl cellulose can also be induced by the addition of nonsolvents, for example, in an ethyl cellulose–dichloromethane (solvent)-*n*-hexane (incompatible solvent) system.

Although microcapsules are formed primarily with the organic phase separation techniques, ethyl cellulose microspheres have been prepared with the solvent evaporation method, whereby the polymer is dissolved in an organic solvent followed by emulsification of this polymer–

drug solution into an external phase (83,84). The microspheres are obtained after solvent diffusion in the external phase and solvent evaporation. Depending on the solubility of the drug, either an external aqueous or oily phase can be used. Various modifications of this method have been developed, including multiple-emulsion (water-in-oil-in-water, W/O/W) and cosolvent methods. Water-soluble drugs were entrapped, whereby an alcoholic ethyl cellulose solution containing the active drug was emulsified into liquid paraffin followed by solvent evaporation (85).

Indomethacin polymeric nanoparticles were prepared by microfluidization, whereby the drug-containing solution was emulsified into an aqueous phase followed by microfluidization (86). The nanoparticles formed after solvent diffusion in the aqueous phase and solvent evaporation. For the drug to be encapsulated, it had to have a high solubility in the polymeric matrix. Otherwise, unwanted drug crystallization was observed in the aqueous phase.

Ethyl cellulose microparticles can also be prepared by spray-drying of organic polymer solutions or aqueous polymer dispersions. With organic polymer solutions, the drug is dissolved or dispersed in the organic ethyl cellulose solution, followed by spray-drying and removal of the organic solvent. The drug can be either dissolved or dispersed in a crystalline or amorphous state in the polymeric matrix. With aqueous polymer dispersions, the drug is dissolved or dispersed in the polymer dispersion; with plasticizer-free ethyl cellulose dispersions, a plasticizer has to be included to reduce the MFT of the dispersion, followed by spray-drying. The coalescence of the colloidal particles into microparticles has to be ensured.

Two microencapsulation methods that used the coalescence of colloidal particles into microparticles were recently developed. In the first method, the colloidal polymer particles were coalesced into microparticles by using the ionotropic gelation of polysaccharides with oppositely charged counterions as a process for the microparticle formation (87). In the second method, a drug-containing aqueous polymer dispersion was emulsified into a heated external oil phase to form a water-in-oil (W/O) emulsion. The colloidal polymer particles then coalesced into microparticles within the internal aqueous phase (88).

Naproxen microcapsules were prepared by a coacervation phase separation technique, and ibuprofen–ethyl cellulose microspheres were prepared by the solvent evaporation process (89). Both microparticles were compressed into tablets; the matrix-structure ibuprofen particles were intact after tabletting, whereas the coatings of the naproxen microcapsules were ruptured to some extend.

CELLULOSE ESTERS: CELLULOSE ACETATE, CELLULOSE ACETATE BUTYRATE, AND CELLULOSE ACETATE PROPIONATE

Cellulose acetate (CA), cellulose acetate butyrate, and cellulose acetate propionate are pharmaceutically used cellulose esters that are insoluble in physiological fluids. Their chemical structures are shown in Figure 1. Commercially available grades of the cellulose esters vary in their molecular weight, their degree of esterification, and their type of alcohol substitution, resulting in a wide range of polymers with different physicochemical properties, such as melting temperature, glass-transition temperature, mechanical properties, permeability characteristics, and solubility (90). A major supplier of these polymers is the Eastman Chemical Company; detailed information about important properties of the different polymer grades is given in the product literature (91).

CA is obtained by the controlled esterification of purified cellulose with acetic acid and anhydride. The acetylation of CA is carried out to completion followed by hydrolysis to obtain CAs with lower acetyl contents. Cellulose triacetate has the highest acetate content and the highest melting point of the cellulose esters and is therefore soluble in fewer organic solvents. It has only limited compatibility with plasticizers. Decreasing the acetyl content increases the hydrophilicity of CAs. The water or moisture permeability can therefore be controlled through the acetyl content. Cellulose acetate butyrate is soluble in a variety of organic solvents; it has a low water permeability and good mechanical properties. It is compatible with a wide number of plasticizers.

Cellulose esters have been used as coating materials, particularly in osmotically driven coated drug-release systems, as carrier materials in matrix systems, and in the area of microencapsulation.

Coated Systems

CA coatings have been used for many years in osmotically controlled drug delivery systems. A review of the patent literature on osmotic drug delivery systems has been recently published (92). The Theeuwes elementary osmotic pump consists of an osmotically active drug-containing core surrounded by a semipermeable membrane, usually CA, having an orifice (93). The polymeric membrane is impermeable for the drug but permeable for aqueous fluids. Water is osmotically attracted through the membrane into the core and dissolves the drug, which is then released through the orifice at a constant rate as long as solid excess drug and a constant osmotic pressure gradient are maintained. The CA coating is rigid and does not expand during the drug release. The drug release from the elementary osmotic pump depends on the surface area, the water permeability of the membrane, its wall thickness, and the osmotic pressure gradient.

CA coatings with a controlled porosity were formed by including water-soluble agents (e.g., sorbitol) in concentrations between 10 and 50% based on the polymer into the polymer solution (27,28,94). After contact with dissolution fluids, the water-soluble additives leached from the film, leaving a membrane with controlled porosity. The spongelike porous membrane was substantially permeable to both water and the drug. The drug is not released through a prefabricated orifice, as with the elementary osmotic pump, but through a porous network. Zero-order drug release was obtained, with the drug release being dependent on the level of pore former, the wall thickness, the drug loading, the solubility of the core, and the osmotic pressure difference across the membrane but being independent of the agitation and the pH of the medium. A microporous CA

coating was also prepared from CA pseudolatexes containing urea as the pore former (95). The tablets had to be cured to promote the coalescence of the polymer particles in a film.

Tablets were coated with an asymmetric CA membrane by first dip-coating the tablets in a solution of the polymer in acetone and a nonsolvent (formamide or glycerol), followed by air-drying the tablets 5 s and then immersing the coated tablets for 3 min in a water quench bath (96). The coatings have an asymmetric structure, similar to membranes used for reverse osmosis. The new membranes have several unique characteristics when compared with conventional osmotic tablets. Higher water fluxes can be obtained, allowing the release of low-solubility drugs or higher release rates. The permeability can be controlled by the membrane structure.

A multiparticulate delayed-release system consisting of an osmotically active core and a CA coating was developed (97,98). The membrane was initially semipermeable and then also became permeable for the drug after expansion of the osmotically active core and creation of pores in the coating induced by the osmotic pressure gradient and the water influx. The drug release could be controlled by the properties of the coating and the core.

CA is normally applied from organic solutions to the solid dosage forms. To avoid organic solvents, aqueous colloidal CA dispersions have been prepared and evaluated (99–101). The problems with aqueous CA dispersions are their high MFT, requiring high amounts of plasticizer, and the hydrolytic instability in aqueous media, requiring storage at low temperatures. Plasticizer levels between 160 and 320% based on the polymer were required to form adequate films. Volatile plasticizers, which evaporated to some extent during the coating process, gave stronger films when compared with films prepared with nonvolatile plasticizers. The water permeability of the membranes was strongly dependent on the type of plasticizer and the processing conditions. A high-performance liquid chromatography (HPLC) method was developed to determine the acidic degradation products, acetic, propionic, and butyric acid in aqueous pseudolatexes (102). The preparation of a redispersible polymer dispersion would overcome the stability and inconvenient storage problems.

With a CA pseudolatex, 150% triacetin and 120% triethyl citrate had to be used as plasticizers to obtain dense and homogeneous films after coating propranolol HCl tablets (103). The permeability of the coating was too low, and 40% sucrose and 10% polyethylene glycol (PEG) 8,000 were included as flux enhancers to provide macroporous membranes with adequate release characteristics. The thermal and mechanical properties of films cast from a CA latex were evaluated by thermal mechanical analysis by the FMC Corporation, the manufacturer of the dispersion. Various plasticizers in the range of 0–160% were evaluated, with glyceryl diacetate, glyceryl triacetate, and triethyl citrate being the most effective. The water permeability of CA decreased with increasing plasticizer concentration to a minimum and then increased at higher concentrations (104). An antiplasticization effect was responsible for the decreased water permeability. This effect disappeared at temperatures above the glass-transition temperature.

Matrix Tablets

Powdered cellulose esters have been evaluated as matrix materials for both immediate- and slow-release preparations (105,106). The tablets were prepared by direct compression, wet granulation with aqueous binders, and solvent wet-granulation processes. All three cellulose esters were directly compressible. Sustained release was especially obtained with the solvent granulation method, whereby the polymer partially dissolved in the organic solvent. Plasticized CA powder has been used as a direct compression vehicle to form sustained-release theophylline matrix delivery systems. The drug release decreased with increasing polymer/drug ratio and the inclusion of a plasticizer, triethyl citrate. The release was not strongly affected by the polymer molecular weight and the particle size distribution. In a related study, the plasticizer triacetin was incorporated into CA by film casting, particles were then prepared by grinding the film with dry ice. Blending the plasticizer with the polymer resulted in wet powders that had poor flow properties.

Microencapsulation

The water-insoluble cellulose esters have also been used as carrier materials for microparticles. A review of the different methods is given in the product literature of Eastman (107). The major methods used are organic phase separation and solvent evaporation techniques. Cellulose acetate butyrate microcapsules were formed by organic phase separation by the addition of heptane to a cellulose acetate butyrate solution in heptane/chloroform (108). Theophylline–cellulose acetate proprionate microspheres were formed by the solvent evaporation method, whereby a drug suspension in the acetonic polymer solution was emulsified into mineral oil followed by solvent evaporation and microsphere formation (109,110). The drug release from the microspheres depended on the type of polymer, its molecular weight, the particle size of the microspheres, and the drug loading. Cellulose acetate butyrate microspheres were prepared by a similar technique, whereby hexane was added to the oil to precipitate the polymer (111,112). The drug release could be accelerated through the inclusion of PEG. Drug-loaded ion-exchange resins were encapsulated from an acetonic cellulose acetate butyrate solution by the nonaqueous solvent evaporation method (113,114). Overcoating dried gelatin beads with cellulose acetate butyrate by the nonaqueous solvent evaporation reduced the drug release rate (115).

HPMC

The chemical structure of HPMC is given in Figure 1. The physicochemical properties of this substance strongly depend on the following parameters: (*1*) methoxyl content, (*2*) hydroxypropyl content, and (*3*) molecular weight. HPMC 2208 is a well-defined U.S. Pharmacoreial Convention (USP) type with a nominal methoxyl and hydroxypro-

pyl content of 22 and 8%, respectively. Dahl et al. (116) found broad variations concerning important characteristics of seven batches of HPMC 2208 provided by two different manufacturers. As can be seen in Table 1, three batches violated the USP specification with respect to the required methoxyl content (19–24%). Although all products were within the specified hydroxypropyl content limits of 4–12%, Dahl and coworkers presented relevant differences concerning the naproxen release rates from HPMC 2208 matrix tablets within this range (116). The observed differences (up to more than 100%) are of significant practical importance for the application of potent drugs. In conclusion, the USP specification concerning the hydroxypropyl content is insufficient and should be reinforced.

Grafting and cross-linking HPMC are common methods to achieve desired properties of the resulting polymer. To study these modifications in more detail, the reader is referred to numerous reviews and publications (117–120). A good summary of the work that has been done to determine the glass-transition temperature (T_g) of HPMC has been written by Doelker (117). He compares the results of various researchers and lists values ranging from 154 to 184°C (Table 2). Various techniques have been used to determine the T_g: differential scanning calorimetry (DSC), differential thermal analysis (DTA), thermomechanical analysis (TMA), torsional braid analysis (TBA), and dynamic mechanical analysis (DMA). Different techniques often lead to different T_g values, and usually only the results achieved with one special method can be compared directly. In addition, the variation of the degree of substitution and of the molecular weight (as discussed earlier) play a role in the observed variance of the T_g. Furthermore, a 57°C value was reported by Conte et al. (129), which seems to correspond to a low-energy secondary transition. The relevance of this low-temperature transition is unknown but could be of significance in the diffusion of oxygen and water.

The swelling and solubility behavior of HPMC strongly depends on the molecular weight, degree of substitution, cross-linking, and grafting. Non-cross-linked polymers absorb water, swell, and dissolve (erode); cross-linked HPMC swells to some equilibrium state, at which the retractive force of the network balances the swelling force. Recently, an excellent review concerning the quantitative treatment of these swelling processes has been written by Narasimhan and Peppas (130).

Talukdar and coworkers (131) investigated the rheological properties of HPMC by oscillatory as well as by steady shear measurements. The dynamic moduli, that is, storage modulus (G′) and loss modulus (G″), have been determined.

The formation of a gel layer is of evident importance for the drug release from HPMC systems. Initially, the polymer is in a glassy state. Upon exposure to the respective biological fluid, water penetrates into the device and decreases the T_g of HPMC (acting as a plasticizer). With increasing water concentration, this reduction of the T_g also increases. At a critical concentration of water, the T_g equals the temperature of the system, and the polymer undergoes the transition from the glassy to the rubbery state. The increasing mobility of the macromolecular chains results in drug-diffusion coefficients orders of magnitude higher than those in the glassy state. The kinetics of water penetration, swelling, and drug release have been studied extensively by Colombo and Peppas (132–135). Figure 2 shows the experimental as well as the theoretical concentration profiles of KCl (as a model drug), water, and HPMC 2208 in the gel phase of compressed tablets, 5 h (a) and 6 h (b) after exposure to water. The thickness of the swollen polymer changed from 1.75 mm at 4 h to 3 mm at 5 h and 5.25 mm at 6 h. In case of relevant dissolution of the polymer, the kinetics of this process must also be taken into account (136). In 1987 Lee and Peppas presented an appropriate model (137). The equilibrium swelling behavior of porous and nonporous hydrogels as well as their characterization has been reviewed by Brannon-Peppas and Peppas (138,139).

Table 1. Physicochemical Characteristics of Various Batches of HPMC 2208 15,000 mPa s

Batch number	Viscosity (mPa s)	Methoxyl content (%)	Hydroxypropyl content (%)

Uncoated Matrix Systems

A newly developed antihistaminergic drug, TA-5707F, has been released from HPMC matrix tablets by Yamakita et

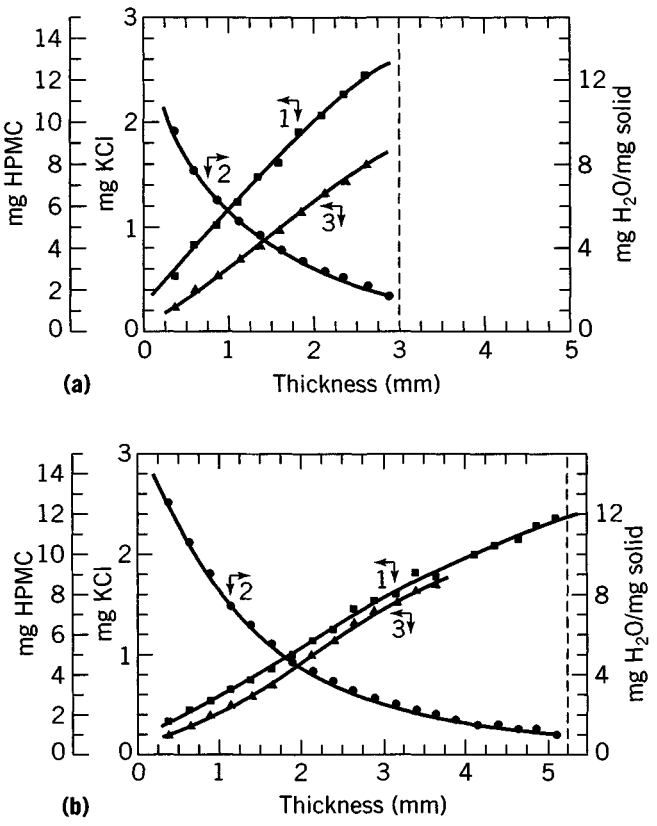

Figure 2. Concentration profiles of KCl (1), water (2), and HPMC 2208 (3) in the gel phase of compressed tablets after (**a**) 5 h and (**b**) 6 h. al. (140). They studied the in vitro as well as the (canine) in vivo kinetics. Liu and coworkers (141) presented the influence of the viscosity grade of HPMC on the release of diclofenac sodium in matrix tablets, performing in vitro and in vivo studies. The release mechanism of indomethacin containing HPMC matrix tablets in dependence on the initial drug loading and specific additives (e.g., starch) has been investigated by Xu and Sunada (142).

Pham and Lee (143) measured the transient dynamic swelling and dissolution behavior of HPMC matrices during drug release using a new flow-through cell (providing well-defined hydrodynamic conditions) and fluorescein as model drug. Studies of Ahlskog and Koller (144,145) deal with the treatment of Parkinson's disease, using a novel, potent, and selective dopamine D-2 agonist: MK-458 (PHNO; [+]-4-propyl-9-hydroxynaphthoxazine). The drug was administered in controlled-release devices (using HPMC matrices) as monotherapy in a double-blind, placebo-controlled, 12-week investigation.

Coated Matrix Systems

To achieve constant drug-release rates, Colombo and coworkers (146–148) covered different surface portions of an HPMC matrix tablet with an impermeable coating as can be seen in Figure 3. Systems prepared were uncoated matrix (Case 0), matrix with one base coated (Case 1), matrix with two bases coated (Case 2), matrix with lateral surface coated (Case 3), and matrix with one base plus lateral surface coated (Case 4). The applied coating modifies the relaxation rate of the polymer by affecting the dimension of the swelling of the plain matrix while leaving the diffusion characteristics of the active agent practically unchanged. The resulting drug release behavior is shown in Figure 4, for the case of diltiazem as active agent and Methocel® K100M as polymer. The release curves of cases 2–4 are nearly linear, except for a short period at the beginning of the experiment. These multilayer matrix systems for the controlled release of drugs have been patented by Colombo et al. (149) and are known as Geomatrix® systems. To facilitate the industrial production, the manual film-coating process can be avoided using press-coating techniques (150).

Polymer Blends

Perez-Marcos et al. (151) investigated the influence of the pH on the release of propranolol hydrochloride from matrices containing HPMC K4M and Carbopol® 974. At pH 1, the HPMC predominantly controlled the release of the drug, whereas at higher pH values, the Carbopol® became ionized and interacted with the active agent. In addition,

the interaction of the two polymers was significantly dependent on the pH. A controlled-release formulation for the α-MSH analog melanotan-I was developed by Bhardwaj and Blanchard (152) using HPMC and poloxamer 407. They characterized the release kinetics in vitro as well as in vivo (guinea pigs, intraperitoneal administration). Buccoadhesive morphine sulfate tablets have been developed and tested (in vitro and in vivo) by Anlar et al. (153). Carbomer (CP) served as the bioactive adhesive compound. The release behavior of systems containing 30 mg morphine sulfate and various amounts of HPMC and CP was found to be non-Fickian. The adhesion force was weakest at a ratio of 1:1 of the two polymers because of the formation of an interpolymer complex between HPMC and CP.

Poly(ethylene-vinyl acetate) (EVA) needle-shaped polymeric devices containing antitumor drugs may be applicable as drug carriers in cancer chemotherapy. Lin et al. (154) investigated the in vivo antitumor activity of adriamycin hydrochloride (ADH) in C3H mice bearing mammary carcinoma and nude mice bearing brain tumor. HPMC was used as a release rate regulator. Tumor growth was markedly inhibited by treatment with needle devices after being locally inserted into the solid tumor. Recent studies of Chowdary and Sankar (155) deal with solid dispersions of nifedipin in HPMC and microcrystalline cellulose (MCC). These systems gave a fast dissolution of the drug. However, when the dispersions were microencapsulated with Eudragit® RL PM, controlled, slow release was observed. The kinetics depended on the proportion of HPMC–MCC in the solid dispersion used as a core, on the coat/core ratio, and on the size of the microcapsules. The release was found to be independent of pH and ionic strength.

ACRYLIC POLYMERS

Besides cellulose derivatives, acrylic polymers are a popular choice for controlled-release dosage forms (156,157). Several derivatives of poly(methyl methacrylate) with different solubility properties were developed, predominantly for oral use. Enteric polymers were obtained by copolymerization of methyl methacrylate with methacrylic acid; polymers soluble at low pH by introducing dimethylaminoethyl methacrylate and water-insoluble but permeable polymers for diffusion-controlled drug delivery systems by the copolymerization of methyl methacrylate, ethyl acrylate, and small amounts of trimethylammonioethyl methacrylate chloride as monomers. The chemical composition of the commercially available poly(meth)acrylates, which are sold by Röhm under the trade name Eudragit®, is shown in Table 3. This review is limited to polymers insoluble in gastrointestinal fluids and used in controlled-release formulations and does not cover enteric polymers.

The poly(meth)acrylates were initially applied from organic solutions in alcohols, acetone, or solvent blends (156). Problems associated with the use of organic solvents led to the development of aqueous polymer dispersions. The water-insoluble methacrylate ester copolymers are neutral (Eudragit® NE 30D) or weekly cationic polymers (Eudragit® RS or RL 30D), which are insoluble in gastrointestinal fluids. The aqueous dispersions have a solids content of 30%. The residual monomer content in the Eudragit® products for pharmaceutical applications is below 0.1%. The shelf-life specifications for aqueous polymer dispersions do usually not exceed 1 year.

Eudragit® NE 30D (a copolymer of ethyl acrylate and methyl methacrylate in a ratio of 2:1) is produced by emulsion polymerization. It has an MFT around 5°C and does not require plasticizers. The latex forms soft and highly flexible films upon drying. Eudragit® NE 30D could be blended with Eudragit® L 30D (an aqueous dispersion of an enteric polymer) to form enteric coatings without the use of additional plasticizer.

The cationic polymers, Eudragit® RL 100 or RS 100, are obtained by bulk polymerization of ethyl acrylate, methyl methacrylate, and trimethylammonioethyl methacrylate chloride. RL 100 contains twice as many quaternary ammonium groups than RS 100 and is therefore more hydrophilic and more permeable. The commercially available aqueous polymer dispersions are prepared by directly emulsifying the solid polymer into hot water at 80°C, which is above its T_g of 55°C. The dispersion process and the stability of the resulting polymer dispersion is positively affected by the positive charges of the polymer. No emulsifier is needed for the emulsification process. 0.25% sorbic acid is added as preservative. Eudragit® RL 30D and Eudragit® RS 30D require the addition of plasticizer to reduce the MFT below the coating temperature. The most frequently used plasticizers for the polymers are triethyl citrate, triacetin, and acetyltributyl citrate. The polymer dispersions are compatible with additives such as talc, titanium dioxide, and pigments. A colorimetric ion-pair complexation method has been developed to rapidly quantify RS and RL in pharmaceutical dosage forms (158).

RL and RS pseudolatexes were also prepared by a solvent change technique, whereby the polymer was dissolved in a water-miscible organic solvent (e.g., acetone) or solvent system followed by dispersion of this polymer solution in deionized water under mild agitation (159). The pseudolatex formed spontaneously after the diffusion of the organic solvent in the aqueous phase and solvent evaporation.

In Table 4, the mechanical and thermal properties of films from methacrylic ester copolymer latexes are summarized.

Coated Systems

Methacrylates have been used in the coating of pharmaceutical dosage forms for several decades. They can be applied either as an organic solution or as an aqueous colloidal dispersion.

The permeability of Eudragit® NE 30D films can be increased by adding water-soluble substances, such as sugars or water-soluble polymers: (PVP), poly(vinyl alcohol) (PVA), and PEGs (156). The addition of water-soluble cellulose ethers, such as HPMC, is not recommended because they can result in flocculation. Theophylline tablets have been coated with NE 30D latexes containing dispersed pore formers (160). Normally, microporous coatings are

the interaction of the two polymers was significantly dependent on the pH. A controlled-release formulation for the α-MSH analog melanotan-I was developed by Bhardwaj and Blanchard (152) using HPMC and poloxamer 407. They characterized the release kinetics in vitro as well as in vivo (guinea pigs, intraperitoneal administration). Buccoadhesive morphine sulfate tablets have been developed and tested (in vitro and in vivo) by Anlar et al. (153). Carbomer (CP) served as the bioactive adhesive compound. The release behavior of systems containing 30 mg morphine sulfate and various amounts of HPMC and CP was found to be non-Fickian. The adhesion force was weakest at a ratio of 1:1 of the two polymers because of the formation of an interpolymer complex between HPMC and CP.

Poly(ethylene-vinyl acetate) (EVA) needle-shaped polymeric devices containing antitumor drugs may be applicable as drug carriers in cancer chemotherapy. Lin et al. (154) investigated the in vivo antitumor activity of adriamycin hydrochloride (ADH) in C3H mice bearing mammary carcinoma and nude mice bearing brain tumor. HPMC was used as a release rate regulator. Tumor growth was markedly inhibited by treatment with needle devices after being locally inserted into the solid tumor. Recent studies of Chowdary and Sankar (155) deal with solid dispersions of nifedipin in HPMC and microcrystalline cellulose (MCC). These systems gave a fast dissolution of the drug. However, when the dispersions were microencapsulated with Eudragit® RL PM, controlled, slow release was observed. The kinetics depended on the proportion of HPMC–MCC in the solid dispersion used as a core, on the coat/core ratio, and on the size of the microcapsules. The release was found to be independent of pH and ionic strength.

ACRYLIC POLYMERS

Besides cellulose derivatives, acrylic polymers are a popular choice for controlled-release dosage forms (156,157). Several derivatives of poly(methyl methacrylate) with different solubility properties were developed, predominantly for oral use. Enteric polymers were obtained by copolymerization of methyl methacrylate with methacrylic acid; polymers soluble at low pH by introducing dimethylaminoethyl methacrylate and water-insoluble but permeable polymers for diffusion-controlled drug delivery systems by the copolymerization of methyl methacrylate, ethyl acrylate, and small amounts of trimethylammonioethyl methacrylate chloride as monomers. The chemical composition of the commercially available poly(meth)acrylates, which are sold by Röhm under the trade name Eudragit®, is shown in Table 3. This review is limited to polymers insoluble in gastrointestinal fluids and used in controlled-release formulations and does not cover enteric polymers.

The poly(meth)acrylates were initially applied from organic solutions in alcohols, acetone, or solvent blends (156). Problems associated with the use of organic solvents led to the development of aqueous polymer dispersions. The water-insoluble methacrylate ester copolymers are neutral (Eudragit® NE 30D) or weekly cationic polymers (Eudragit® RS or RL 30D), which are insoluble in gastrointestinal fluids. The aqueous dispersions have a solids content of 30%. The residual monomer content in the Eudragit® products for pharmaceutical applications is below 0.1%. The shelf-life specifications for aqueous polymer dispersions do usually not exceed 1 year.

Eudragit® NE 30D (a copolymer of ethyl acrylate and methyl methacrylate in a ratio of 2:1) is produced by emulsion polymerization. It has an MFT around 5°C and does not require plasticizers. The latex forms soft and highly flexible films upon drying. Eudragit® NE 30D could be blended with Eudragit® L 30D (an aqueous dispersion of an enteric polymer) to form enteric coatings without the use of additional plasticizer.

The cationic polymers, Eudragit® RL 100 or RS 100, are obtained by bulk polymerization of ethyl acrylate, methyl methacrylate, and trimethylammonioethyl methacrylate chloride. RL 100 contains twice as many quaternary ammonium groups than RS 100 and is therefore more hydrophilic and more permeable. The commercially available aqueous polymer dispersions are prepared by directly emulsifying the solid polymer into hot water at 80°C, which is above its T_g of 55°C. The dispersion process and the stability of the resulting polymer dispersion is positively affected by the positive charges of the polymer. No emulsifier is needed for the emulsification process. 0.25% sorbic acid is added as preservative. Eudragit® RL 30D and Eudragit® RS 30D require the addition of plasticizer to reduce the MFT below the coating temperature. The most frequently used plasticizers for the polymers are triethyl citrate, triacetin, and acetyltributyl citrate. The polymer dispersions are compatible with additives such as talc, titanium dioxide, and pigments. A colorimetric ion-pair complexation method has been developed to rapidly quantify RS and RL in pharmaceutical dosage forms (158).

RL and RS pseudolatexes were also prepared by a solvent change technique, whereby the polymer was dissolved in a water-miscible organic solvent (e.g., acetone) or solvent system followed by dispersion of this polymer solution in deionized water under mild agitation (159). The pseudolatex formed spontaneously after the diffusion of the organic solvent in the aqueous phase and solvent evaporation.

prepared by dispersing water-soluble pore formers in organic polymer solutions followed by the coating step. The pore formers then leach from the coating into aqueous fluids, forming a microporous coating. With this novel system, a microporous membrane could be prepared without organic solvents by using pore formers with pH-dependent solubility properties (e.g., calcium salts), which were insoluble at the pH of the latex but were soluble in gastric juice. The pore former was dispersed in the coating and leached in aqueous media to form a multiporous coating through which the drug was released in a zero-order fashion.

Although the release from RS or RL-coated systems has been described to be pH-independent, a "pH-dependent" drug release was observed (161–163). This was actually caused by the presence in the release media of different anionic buffers species, which acted as counterions for the quaternary ammonium groups and replaced the chloride ion. The drug release correlated well with the hydration of the polymer films in different buffers (161). In another study, the release of theophylline from pellets coated with RS also showed a great dependence on the composition of the buffer solution. In contrast, the drug release from pellets coated with NE and the swelling of NE films was not significantly affected by the buffer species (162). Although the influence of buffer species can be diminished by the addition of NaCl (163), anionic species in the gastrointestinal tract, such as bile salts, have also been shown to have a dramatic effect on the drug release (164).

RS and RL 30D dispersions can be mixed in any ratio, with the coatings showing intermediate permeability properties (165,166). The addition of silica or talcum increased the drug release (166). The permeability of the films can also be influenced by the choice of plasticizer (167). An overcoat with the enteric polymer, Eudragit® S 100, eliminated the agglomeration of RS-coated pellets (167,168). Otherwise, talc or glycerol monostearate are used as antitacking agents (157).

The lag time prior to the diltiazem HCl release from RS-coated pellets could be controlled by varying the thickness of the coating (169). The drug release had a pattern of a lag period followed by an instantaneous release phase. A linear relationship was reported between the lag time and the square of the amount of polymer coated. High drug solubility was required for the rapid drug release after the lag period, which was caused by the time necessary for the polymeric film to hydrate. A sigmoidal release system (time-controlled drug delivery system) was developed, which consisted of a prolonged lag time followed by a rapid release phase (170–172). Because of the low water permeability of the RS film, the lag time could be varied by varying the thickness of the film. The drug release phase after the lag period could be enhanced by electrostatic or other physicochemical interactions between the polymer and organic acids such as succinic acid. The organic acid affected the hydration of the polymeric film. The drug release from beads coated with NE 30D, which has no quaternary ammonium group in the polymer chain, was not affected by succinic acid. Ion-exchange experiments revealed that organic acids interacted with the quaternary ammonium groups of RS by an ion-exchange mechanism.

A wide range of release rates can be obtained by adding additives to a single polymer or by blending different polymers. The membrane permeability of film-coated theophylline pellets was controlled by using blends of different aqueous acrylic polymer dispersions (173). A film with pH-dependent permeability was obtained by blending the neutral acrylic polymer, NE, with the enteric polymer, L, showing higher release rates at intestinal pH values. A wide range of dissolution profiles was obtained by blending the more permeable RL with the less permeable RS to obtain pH-independent permeabilities. Heterogeneous film structures were obtained by blending RS 30D and ND 30D, as indicated by two individual glass-transition temperatures. Enteric polymers can be incorporated into the water-insoluble polymers to develop pH-dependent systems for the linearization of release profiles or to adjust the drug release with drugs with pH-dependent solubility.

A model was developed that permitted the quantitative correlation of the release kinetics from coated pellets with the permeation properties of free films (174). The film data allow the prediction of the drug release from coated pellets, under the condition that the manufacturing process was kept constant and the cores of the coated pellets were identical.

Coated particles or pellets have also been compressed into tablets. Various formulation and process parameters have to be optimized to obtain tabletted reservoir-type pellets having the same properties, and, in particular, release properties as the original, uncompacted pellets. The most important variable is the type of polymer selected for the coating of the pellets. The polymer coating must remain intact during compaction. When compared to ethyl cellulose films, films prepared from acrylic polymers are more flexible and therefore more suitable for the coating of pellets to be compressed into tablets (62). Films of Eudragit® NE 30D were very flexible. The elongation was in excess of the elongation limit of 365% achievable with the puncture test device. With plasticized Eudragit® RS and RL 30D, flexible films were obtained with elongation values in excess of 125%. Crystals, granules, and pellets were coated with various aqueous acrylic polymer dispersions (Eudra-

git® NE 30D, RS/RL 30D, and L 30D-55) and compressed into fast-disintegrating tablets (156,175). Multiparticulates coated with flexible polymers (Eudragit® NE 30D and plasticized Eudragit® RS/RL 30D) could be compressed without significant damage to the coating. No or only small changes in drug release were found with coatings with elongation values in excess of 75%. These films have enough elasticity to deform on coated pellets during compression without rupture. Very little difference in drug release was observed between the compressed granules and the noncompressed granules, which contained theophylline and were coated with an Eudragit® RL/RS dispersion. Enteric coatings based on Eudragit® L 30D-55, a methacrylic acid–ethylacrylate copolymer, were brittle, and the compression of the pellets resulted in film damage. This damage could be avoided by mixing the enteric polymer with the flexible Eudragit® NE 30D. Heterogeneous films, which retained their enteric properties, were obtained after the addition of Eudragit® NE 30D.

The effect of compression force on the dissolution from Eudragit® NE 30D–coated theophylline pellets was evaluated in a range of 6–20 kN (176). The compaction-induced pellet deformation was practically complete at 6 kN, and no change in dissolution rate was observed upon increasing the compression force to 20 kN. The increase in drug-release rate was not attributed to rupturing of the polymeric film but to a thinning of the flexible film because of stretching. A recent review provides an update on the tabletting of coated pellets and discusses important formulation and process parameters necessary to obtain pellet-containing tablets, which, ideally, have the same properties—in particular, drug-release properties—as the individual coated pellets (177).

Films

Various release, permeability, and mechanical properties of drug-containing or drug-free films have been determined to predict primarily the properties of film-coated dosage forms. The films can be prepared either from organic polymer solutions or from the aqueous polymer dispersions. The drug has to be compatible with the polymer dispersion; for example, the addition of anionic drugs to the cationic polymer dispersion, RS 30D, results in flocculation.

The choice of organic solvents affected the permeability of cast Eudragit® RL and RS films. Including ethanol in the acetonic casting solution resulted in a greater permeability, which was caused by a decrease in pore size but an increase in pore number. The microstructure of the film was therefore strongly affected by the composition of the solvent mixture (178). Differences in the solute diffusion were also observed between the lower and upper surface of polymeric films (179,180). The lower film surface, which was in contact with the mold during casting, was more permeable than the upper surface.

The partition coefficients and diffusion coefficients of progesterone and a synthetic progestin were determined with drug-loaded Eudragit® RL films. The partition coefficients showed that both steroids were dissolved in the polymer films, and the values of the diffusion coefficients revealed that the mechanism of diffusion was a solution-diffusion and not a pore-diffusion mechanism (181).

RL and RS films containing salicylic acid and chlorpheniramine maleate were prepared by organic solvent casting (182,183). The drugs were soluble in the polymers and acted as plasticizers for the polymers, as shown by a decreased T_g. The addition of hydrophilic adjuvants increased the release rate. Salicylic acid interacted with the cationic groups of the polymers via electrostatic interactions. Increasing the ionic strength of the dissolution media increased the drug release from the matrix films (184).

Drug-containing films have been prepared by casting the aqueous colloidal polymer dispersions followed by drying. The propranolol HCl release from RS films increased with increasing RS-RL ratio (185). The drug-release rate was high at low plasticizer concentrations because of incomplete coalescence of the colloidal particles and film formation and then was constant in a plasticizer range between 10 and 30% and then increased at higher plasticizer concentrations because of the leaching of the plasticizer. The drug release from latex-cast films was faster when compared with that from solvent-cast films of the same composition. Films cast from organic polymer solution were less porous and denser than the comparable latex-cast films, as observed with scanning electron microscopy.

Depending on the solubility of the drug, it could be either dissolved or dissolved/dispersed in the polymeric NE matrix (186). Depending on the drug loading, the drug release was a combination of diffusion through the polymer and diffusion through pores or channels. The drug release increased with increasing drug loading and increasing amount of HPMC in the NE film. Zero-order drug release could be achieved by laminating a second drug-free latex film onto the first reservoir layer (187).

The mechanical properties of RS 30D films were tested in the dry and in the wet state by a puncture test (188). The water-soluble plasticizer triethyl citrate leached into the dissolution medium, while the water-insoluble plasticizer acetyltributyl citrate remained in the film. While films were quite flexible with both plasticizers in the dry state (the elongation values at normally used plasticizer concentrations were in excess of 100%), the elongation values of wet triethyl citrate–containing films were significantly lower than the elongation values of wet acetyltributyl citrate–containing films. The choice of the plasticizer therefore strongly affects the mechanical properties of the resulting films in the wet and therefore in the gastrointestinal media. NE films were highly flexible in both the dry and wet state.

Eudragit® NE 30D and RL and Eudragit® RS 30D have also been used in dermal and transdermal systems. They form clear and transparent films that are insoluble in water but hydrate. Films for transdermal therapeutic systems have been prepared from organic polymer solutions, aqueous polymer dispersions, and by a hot-melt extrusion technique (156,157). Matrix films can be prepared by incorporating the drug in the polymer phase followed by casting/drying or extrusion. Forty to sixty percent plasticizer are used for the hot-melt extrusion of RS and RL at 80–120°C. Films of Eudragit® NE 30D have shown good

skin tolerance; they are flexible and permeable to water vapor.

Matrix Tablets

Poly(meth)acrylate powders have also been used as retarding materials in matrix tablets (156,157). The polymer can be directly compressed or wet granulated. The necessary amount of polymer to obtain controlled release was in the range of 10 to 50% of the tablet weight. It is mainly affected by the solubility and dose of the drug. The polymer can also be incorporated by granulating the drug and excipients with the aqueous colloidal polymer dispersions. Eroding sustained-release tablets have been formulated by granulating Emcompress® and diprophylline with NE 40D. RS 100 and salicylic acid were directly compressed into tablet cores (189). The drug release was further retarded by a coating with aqueous RS–sucrose mixtures of varying ratios.

Microencapsulation

Micro- or nanoparticles based on the acrylic polymers as carriers have been prepared by various microencapsulation techniques including organic phase separation, solvent evaporation, and spray-drying techniques (see MICROENCAPSULATION).

Paracetamol was encapsulated with RS by an organic phase separation process. The nonsolvent, cyclohexane, was added to a chloroformic solution of the polymer. Polyisobutylene was used as an antiaggregating agent. The drug release increased with increasing proportion of the core material and with a reduced coating thickness (190). A gradation of the microcapsule wall porosity could be obtained by depositing polymer mixtures of RL and RS on drug particles by the organic phase separation process (191). The release rates increased with increasing polar group content (RL content). Salicylic acid has been encapsulated by a coacervation process whereby the nonsolvent, water, was added to an ethanolic solution of the drug and polymer. Both drug and polymer precipitated after the addition of water (192).

Various antiinflammatory agents were encapsulated within RS- and RL-microspheres by the solvent evaporation method, whereby an organic drug containing polymer solution was emulsified into an external aqueous phase (83). Nanoparticles in the colloidal size range were obtained after microfluidization of the oil-in-water (O/W) emulsion (86). Ketoprofen–RS microspheres were formed by a nonaqueous solvent evaporation method by emulsifying a drug–polymer solution in liquid paraffin (193). Aluminium tristearate was used as a stabilizing agent.

Multiple-unit hollow microspheres (microballoons) were prepared by an emulsion solvent-diffusion method (194). The drug and acrylic polymer were dissolved in an ethanol–methylene chloride mixture. This solution was poured into an aqueous PVA solution to form emulsion droplets followed by polymer precipitation. The volume of the internal cavity of the microballoons increased at higher polymer ratios. Floatable microballoons could be prepared. Ibuprofen–RS microspheres and microsponges with different intraparticle porosities were prepared by a similar method (195–197). The internal porosity of the microsponges could be controlled by changing the concentration of the drug and the polymer in the ethanolic emulsion droplet. The formation of the microspheres with ethanol, a water-miscible solvent, was possible because of the quaternary ammonium groups in polymer chain, which stabilized the emulsion.

Nanoparticles containing the water-insoluble drugs ibuprofen, indomethacin, or propranolol were formed spontaneously after the addition of solutions of the drugs and RS or RL 100 polymers in the water-miscible solvents acetone or ethanol to water without homogenization (198). The nanoparticle dispersion was stabilized by the quaternary ammonium groups of the polymer and did not require the addition of external stabilizers. Other water-insoluble polymers require the use of water-immiscible organic solvents (e.g., methylene chloride) and a homogenization step to form nanoparticles. The cationic acrylic polymers allowed the formation of nanoparticles without homogenization or toxic organic solvents. RS or RL nanoparticles could also be formed by the melt method. The drug containing acrylic nanoparticles could be transformed into films by including plasticizers. This could be useful for dermal applications of nanoparticle dispersions. The release from the resulting films could be controlled by the ratio of RS to RL or the inclusion of water-soluble polymers to the nanoparticle suspensions prior to casting.

Acetyl salicylic acid–RS microspheres were prepared by a falling-drop process (solvent-partition method) whereby a solution of the polymer in methylene chloride and acetone (9:1) was injected into a flowing mineral oil stream (199). The solvent was extracted, and drug–polymer microspheres were formed. This method is in principle very similar to a nonaqueous solvent evaporation method.

Microparticles containing diltiazem HCl were prepared by spray-drying RS and RL polymer solutions (200). The choice of the solvent affected the structure of the resulting microparticles; either microspheres or microcapsules could be obtained. When compared with other encapsulation methods, spray-drying has many attractive features. It is a rapid, single-operation procedure suitable for large-scale production. Most microencapsulation methods are based on two immiscible phases, and drug loss to the external phase resulting in low encapsulation efficiencies is often a problem. With spray-drying, the external phase is air, and drug loss is therefore not an issue. Alternatively to organic RS or RL solution, drug-containing aqueous polymer dispersions were used to form the microparticles by spray-drying (201–205). The drug was either dissolved (chlorpheniramine maleate) or suspended (ibuprofen, naproxen) in the aqueous phase of the polymeric dispersion (164). Under optimal spray-drying conditions, the colloidal polymer particles coalesced into microparticles within the atomized droplets. Spherical microparticles with drug loadings between 10 and 50% were obtained with an average particle size in the range of 5–20 μm. The yield decreased with increasing drug loading and plasticizer level because of sticking and agglomeration. Chlorpheniramine maleate and ibuprofen acted as plasticizers for the polymer. Although ibuprofen was suspended in the polymer disper-

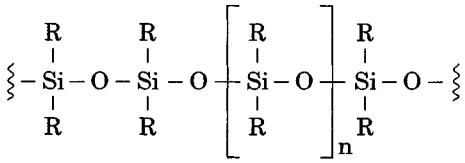

Figure 5. Structure of Si–O polymer chains; R is an organic substituent.

sion, it was dissolved in the microparticles, as indicated by X-ray diffraction studies.

Coprecipitates of ibuprofen and various acrylic polymers were prepared by adding a drug–polymer solution in acetone to water, followed by drying and milling of the precipitate (206). The coprecipitates had improved flow properties when compared with ibuprofen and are useful for the preparation of sustained-release tablets. Coevaporates of dipyridamole and the Eudragit® S, L, RL, or RS were prepared by dissolving the drug and polymer in an ethanol/methylene chloride (1:1) mixture, followed by removal of the solvent in a rotary evaporator and pulverization of the residue. Depending on the processing conditions, either a solid solution or dispersion was formed, as determined by X-ray and DSC. pH dependence and a variety of release profiles could be obtained by blending the different polymers (207).

SILICONES

Most silicones used in pharmaceutical applications consist of cross-linked Si–O polymer chains (shown in Fig. 5). R is an organic substituent, for example, CH_3 (in polydimethylsiloxane [PDMS]). There are several commonly used methods of synthesis, such as two-component condensation cures, one-component moisture cures, and two-component vinyl cures (208), resulting in different kinds of chemical cross-linking (Fig. 6a and b). Depending on the average chain length, type of substituent, and type and degree of cross-linking, the resulting polymers have significantly different properties (fluids, resins, elastomers). Generally, silicones are inert, poor conductors of electricity and hydrophobic.

The synthesis of drug-containing silicone systems is often very convenient. Before cross-linking, the adequate prepolymers are usually in a liquid state. The fluid components are mixed with the drug, and a cross-linking agent and/or a catalyst are/is added. This mixture is subsequently cast into a mold of the desired shape. After a few hours the formation of the polymer network (cross-linking reaction) hardens the device (209).

Owing to the ease of fabrication and high permeability for many drugs (e.g., steroids) silicones are often used for controlled drug delivery. The exceptionally high diffusion coefficients result from the high chain mobility of the Si–O backbones (210). The possibility of heat sterilization and remarkable biocompatibility make them favorable for parenteral systems.

As most silicones are physically weak, silica fillers are usually added to increase the mechanical stability of the resulting controlled-release system. The effective diffusion coefficient of the active agent is lowered by this addition of silica because the latter is usually not permeable for the drug and thus increases the diffusion pathways (211). Drug-release rates in these controlled-release systems are also significantly dependent on the amount and type of free polymer chains (that have not been cross-linked to the network during the synthesis of the device). Mazan et al. (211) used two different unreactive PDMS oils, $MD_{25}M$ and $MD_{75}M$, to produce well-defined systems (M represents a terminal block with three methyl groups; D is an SiO group with two methyl groups). Not only the diffusion coefficient of the drug but also the swelling extent of the system is a function of these components. The dependencies of the progesterone diffusion coefficient (D) and swelling extent (Q) of the silicone network on the amount and type of free polymer chains is illustrated in Figure 7 (nomenclature: relative amount of free chains F = [mass of cross-linked sample − mass of dry sample after elution in hexane]/mass of cross-linked sample). Moreau et al. (212) studied the effect of grafting an organic pendent segment along the PDMS chains. They evaluated the impact of this modification on the drug solubility, diffusivity, and elastomer properties. Thermal analysis and measurements of the swelling ratio have been used to characterize the influence of vulcanization conditions and chemical modifications on the network mesh size and subsequently on the diffusion of an active agent (213). An excellent review has been written by Baker

(214) concerning the role of silicones in controlled drug delivery systems.

Implantable Systems

Norplant® (Leiras) is a contraceptive subdermal implant system consisting of six hollow PDMS cylinders filled with levonorgestrel crystals (215–217). Figure 8 shows schematically the design of this device, which is implanted in the inner aspect of the woman's upper arm. The drug-release rate is controlled by the total surface area and thickness of the silicone cylinders. Because of the excess of drug at the inner surface, approximately constant release rates are achieved over a period of 5 years (216). Compared to oral contraceptives, implantable long-term systems have two main advantages: (*1*) owing to the elimination of the hepatic first-pass effect, the applied doses can be reduced significantly; and (*2*) avoiding daily application, the compliance and safety of the system are markedly increased.

The utility of controlled-release norgestomet/silicone implants in synchronizing estrus and diagnosing pregnancy in ewes has been investigated by Kesler and Favero (218). The overall estrus and lambing responses were 90 and 67%, respectively; the accuracy of the diagnosis of the pregnancy status was 100%. Refillable and implantable devices containing the anticancer drug 1,3-bis(2-chloroethyl)-1-nitrosourea (BCNU) were investigated by Ueno et al. (219). The release kinetics of various kinds of silicone and silicone–nylon-based systems were studied in dependence of the surface area and wall thickness of the device. Reversible chemical castration is one of the possible applications of RS-49947 ([D-Nal^6, aza-Gly^{10}]-luteinizing hormone-releasing hormone)–silicone elastomer implants, investigated by Burns et al. (220,229). In vitro and in vivo studies have been performed, investigating the effect of drug loading, γ-irradiation, and particle and implant size. The sustained behavioral recovery from unilateral nigrostriatal damage produced by the controlled release of dopamine from a silicone polymer pellet placed into the denervated striatum of rats was studied by Becker et al. (222). Studies of Hirsch et al. (223) deal with the synergistic inhibition of the calcification of glutaraldehyde-pretreated bovine pericardium by $FeCl_3$ and calcium ethanehydroxydiphosphonate (CaEHDP) containing silicone–rubber matrices. Calcification is a frequent cause of the clinical failure of bioprosthetic heart valves fabricated from glutaraldehyde-pretreated porcine aortic valves or glutaraldehyde-pretreated bovine pericardium (GPBP). Twenty-one-day subdermal implants in 3-week-old male rats showed 1% $FeCl_3$–20% CaEHDP silicone–rubber matrices to be most effective for inhibiting GPBP mineralization.

Intravaginal Systems

Silicone-based intravaginal devices (diaphragms and discs) have been developed by Lee et al. (224,225). They optimized the loading dose of the spermicide Nonoxynol-9 and studied the effect of an additional cosolvent (optimizing drug release) and of storage time.

Ocular Systems

Ocular drug delivery systems based on silicones were developed and tested in vitro and in vivo by Urtti et al. (226–228). Timolol inserts were compared to conventional eyedrops and were found to give similar decreases in intraocular pressure in open-angle glaucoma patients but to produce lower drug concentrations in the blood. Thus, the unwanted absorption of timolol into the systemic circulation could be reduced significantly. Dissolving or dispersing various prodrugs of 5-fluorouracil in silicone oil for ocular drug delivery has been studied by Steffansen et al. (209). The effect of γ-irradiation and exposure to heat on the physicochemical properties of novel silicone-based gentamicin sulfate ocular drug delivery systems has been presented by Bawa and Nandu (230). The mechanical properties were found to be unchanged, whereas the drug-release rates were affected by γ-irradiation as well as exposure to heat. In addition, a certain degradation of the active agent was caused by long-term heat treatment.

Miscellaneous

Li et al. published various articles concerning the preparation and testing of silicone-based matrix tablets (e.g., 231–234). They investigated, for example, the effect of additives like PEG or colloidal silica as well as different shapes and methods of fabrication. Planar dimethylsiloxane matrix systems containing 10 different substituted pyridines at their solubility limit were presented by Chen and Matheson (235) with respect to the drug–polymer interactions. Hydrogen bonding between the pyridines and the polymer matrix was found to be one of the factors governing the release rate. Numerous studies were performed by Sutinen et al. concerning silicone reservoir systems (of various shapes) with different additives to manipulate the release kinetics (236–238). Osmotic (e.g., sodium chloride) and buffering (e.g., Tris buffer) additives are excellent tools to achieve a desired release profile (239,240). Zero-order release kinetics during a considerable time interval were observed for cinnamyl alcohol from spherical PDMS beads in pentane by Lee and Lum (241). In water, however, the corresponding release was completely Fickian. Veterinary controlled-release systems have been developed by Brochart et al. (242). Reservoir devices of different composition were tested and constant release rates were achieved over a period of 22 days.

The use of aqueous silicone latex for the coating of tablets and pellets as well as the impact of heat treatment and the addition of the pore former PEG 8,000 on the mass transport in these systems were presented by Dahl and Sue (56,243). pH-sensitive hydrogels, releasing the drug at enteric pH but not at gastric pH, have been synthesized by γ-irradiation of solutions of *N*-isopropylacrylamide (NIPAAm), acrylic acid (AAc), and bis-vinyl-terminated polydimethylsiloxane (VTPDMS) and tested by Dong and Hoffman (244,245). This property is especially interesting for stomach-irritating active agents like indomethacin. An in vitro study has shown that only a negligible amount of indomethacin is released at pH 1.4 within 24 h, while at pH 7.4 more than 90% of the total drug in the gel is gradually released over 5 h. The effect of propranolol on the prevention of ventricular tachycardia/fibrillation due to acute coronary ischaemia using polyurethane–silicone copolymers was studied in dogs by Siden et al. (246). Loth and Euschen investigated liquid-crystalline side-chain silastomers (247). The type of polysiloxane main chain and the chain length of the PDMS cross-linker as well as the mesogenic group determine the structure and properties of the resulting silastomer. The relationship between the drug-release rate particle size, and swelling of PDMS matrices was studied by Golomb et al. (248). Controlled polymer cracking (osmotically induced) to promote macromolecular release (bovine serum albumin) was presented by Carelli et al. (249). Recent studies of Sheppard and coworkers (250) deal with a new class of controlled-release devices based on micromachined silicone structures. Processes developed for integrated circuit fabrication are used to produce three-dimensional networks that can be loaded with drugs. The advantage of this method is the possibility to gain well-defined pore structures instead of random pore size and shape distributions.

EVA

The general structure of the copolymer EVA is shown in Figure 9. EVA is chemically stable, nontoxic, and biocompatible. Owing to its thermoplasticity, it can be processed by extrusion and injection molding. Two other main advantages of this polymer are (*1*) its high flexibility (which allows avoiding plasticizers) and (*2*) its ability to be sterilized by radiation.

The physicochemical properties of EVA (and thus its permeability properties) are strongly dependent on the comonomer ratio. Not only the *Tg* but also the crystallinity of the resulting copolymer is determined by the relative vinyl acetate content. Generally, both the *Tg* as well as the crystallinity significantly influence the diffusion coefficient (*D*) of a drug (251). In crystalline regions, *D* is several orders of magnitude smaller than in amorphous regions (owing to the reduced chain mobility); in rubbery domains, *D* is higher than in glassy ones (for analogous reasons). Desired permeabilities can easily be achieved by varying the relative vinyl acetate content. Johnson and Nachtrab (252) investigated the influence of the vinyl acetate content on the crystallinity of the resulting copolymer. Pure polyethylene has a crystallinity of 70%. The addition of vinyl acetate into this structure destroys the regularity of the polymer chains, thus reducing crystallinity. Above 50 wt % vinyl acetate content, the copolymer is almost completely amorphous. On the other hand, the *Tg* of EVA varies sig-

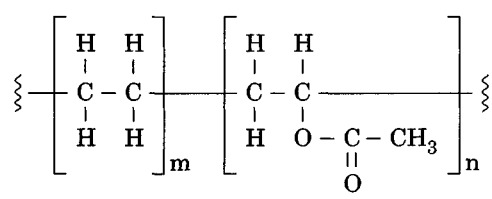

Figure 9. Chemical structure of the copolymer EVA [Poly(ethylene-vinyl acetate)].

nificantly with increasing vinyl acetate content (Fig. 10). This dependence is biphasic: The *Tg* remains constant (approximately −25°C) for 0 wt % up to 50 wt % vinyl acetate and then linearly rises up to 38°C at 100 wt % vinyl acetate (253,254). There are two contrary influences on the diffusion coefficient of a drug with increasing vinyl acetate content: (*1*) a rising *Tg* generally lowers *D*, whereas (*2*) the decreasing crystallinity increases *D*. The resulting permeability properties for the model drug camphor have been studied by Gale and Spitze (255,256). As a result of the two competitive processes, the limiting flux of camphor through EVA goes through a maximum.

Recently, Shin and Byun (257) investigated the permeation of ethinylestradiol through EVA membranes as a function of the drug concentration, vinyl acetate content, membrane thickness, and temperature. Benzocaine was chosen as a model drug by Chen and Lostritto (258) to study the effect of ethanol in EVA membranes. As ethanol leads to significant swelling of the copolymer, the permeability of the drug was markedly increased. The release mechanism from drug containing EVA films was elucidated by Miller et al. (259). Considerable pore collapse was observed during the release process.

Implantable Systems

In 1976 Langer and Folkman opened the door for the controlled release of proteins and other macromolecules from polymeric systems (260). They presented a simple method for incorporating large molecules into noninflammatory polymers (like EVA) and demonstrated sustained release of biologically active agents for periods exceeding 100 days. In that study, pellets were prepared by casting a mixture of an EVA solution and the macromolecular drug into glass molds. No inflammation was observed after implantation into the eyes of rabbits. The in vitro and in vivo release of soybean trypsin inhibitor and tumor angiogenesis factor was investigated. Langer and coworkers studied the use of EVA in various different controlled drug delivery systems. For example, they developed a new fabrication technique (261), leading to more uniform drug distributions in the EVA matrices and higher reproducibilities of the release kinetics. A mixture of powdered protein and polymer solution is cast at −80°C and dried at −20°C and subsequently 20°C. The effect of drug particle size, drug loading, and matrix coating has also been investigated. They observed three phases: (*1*) an initial burst, (*2*) a period of approximately $t^{1/2}$ release, and (*3*) a final period when release tapered off. The initial burst effect presumably is due to protein dissolution on the surface. As the macromolecules are too large to diffuse through a pure polymer film, it is possible that sustained release occurs via diffusion through channels in the matrix. The incorporation of the macromolecules during casting may introduce such channels through which the dissolved drug can diffuse. Thus, matrix characteristics (e.g., porosity and tortuosity) are very important for the resulting release rate. Figure 11 shows that the release rate increases with increasing drug particle size, probably due to the formation of larger channels or pores within the polymer matrix. Similarly, increased loadings may provide simple pathways (lower tortuosity) and greater porosity for diffusion, both of which facilitate the movement of water into and proteins out of the matrix (Fig. 12). The exposure to organic solvent can be avoided when mixing drug and EVA powders below the *Tg* of the polymer and compressing the mixture at a temperature above the glass-transition point (262). The mechanism of drug release (dissolution/diffusion) was studied in more detail 1989 by Saltzman and Langer (263). They developed predictive models using percolation concepts to describe pore topology and continuum models of diffusion/dissolution to describe protein movement at each single pore, and they measured pore size distributions. Up to 10-fold reversible increases in the release rate of incorporated molecules within EVA copolymers were observed when ap-

plying ultrasound, the increase being in proportion to the intensity of ultrasound (264). The treatment of Parkinson's disease is a potential application of a system releasing dopamine from EVA matrix discs for up to 65 days following stratial implantation. Drug release occurs through a single cavity present on one side of the disc, which is otherwise fully coated with an additional, impermeable layer of EVA (265). Langer and coworkers also embedded a drug and a small magnet into an EVA matrix and applied a magnetic field on this system (266). The presented drug release was increased up to 30 times above baseline levels. Using DSC and TMA, they studied the release of proteins from different types of EVA matrices over a wide range of temperatures. The observed effects could be related to the temperature-dependent diffusivity of the drug and elastic modulus of EVA (267). Another important system Langer et al. studied is an implantable, glucose-sensitive device releasing insulin. Feedback control is mediated by the glucose oxidase enzyme immobilized to Sepharose beads, which are incorporated along with insulin into an EVA matrix. When glucose in solution enters the device, gluconic acid is produced, causing a drop in the microenvironmental pH of the matrix. This fall in pH results in a rise in insulin solubility and consequently a rise in the insulin release rate from the matrix (268). Recently, they elucidated the role of the burst effect in an essentially zero-order controlled-release coated hemispherical EVA device (269). The macromolecular active agent bovine serum albumin (BSA) leaves the system through a single, small orifice.

The prevention of calcification of aortic walls using implants based on EVA and the calcium salt of ethanehydroxybisphosphonate (CaEHBP) and ferric chloride ($FeCl_3$) have been studied by Vyavahare et al. (270). They developed films releasing the drugs continuously over 60 days without any rapid burst phase. Calcification of the aortic walls was inhibited synergistically by the two active agents. Studies of Lesser et al. (271) investigate the in vitro and in vivo release of subcutaneous hydromorphone implants designed for the treatment of cancer pain. They developed and tested an implantable opioid delivery device capable of releasing the potent drug subcutaneously at a constant rate for 4 weeks. The treatment of Alzheimer's disease might be an application of the EVA discs prepared by Krewson et al. (272), releasing a protein (nerve growth factor [NGF]).

Intravaginal Systems

A very well known application of EVA in controlled-release devices is the intravaginal release of steroidal contraceptives, as in Progestasert® (marketed by ALZA Corporation). A liquid silicone oil serves as inert carrier medium for progesterone, surrounded by a controlling barrier of EVA (T-shaped reservoir device) (273–276). Barium sulfate is added to render the system radiopaque. Figure 13 shows a scheme of the device. The in utero release rate of the drug in humans remains approximately constant over a period of 400 days: 65 ± 10 μg/day (277). This is due to the constant progesterone concentration at the inner surface of the EVA copolymer membrane. Drug molecules leaving the reservoir are replaced due to the excess of progesterone in the silicone oil (initial concentration > solubility). Compared with conventional contraceptives, the decisive advantage of this system is the protection from pregnancy for more than 1 year without the need of daily self-medication or other regular patient action.

Ocular Systems

Another well-known system using EVA membranes is the Ocusert® (ALZA Corporation). It is placed in the conjunc-

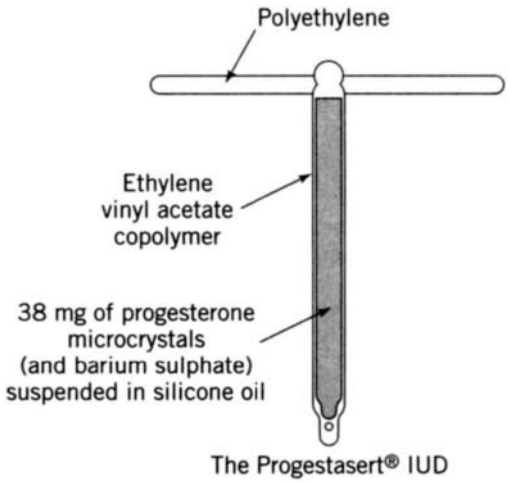

Figure 13. Scheme of Progestasert®, an intrauterine progesterone contraceptive system. *Source:* Reprinted from Sam (215) with permission from Elsevier Science Publishers B.V.

tival cul-de-sac to release pilocarpine during 1 week. The drug is dispersed in alginic acid and surrounded by two EVA membranes, controlling the release rate (278–281). As in Progestasert®, excess of drug (11.0 mg in Pilo-40, 5.0 mg in Pilo-20) leads to a constant drug concentration at the inner membrane surface of this reservoir system and subsequently to constant release rates, as shown in Table 5.

Miscellaneous

Miyazaki et al. (283) investigated the factors affecting the release patterns of 5-fluorouracil from EVA matrices. The influence of the surface area, temperature, pH, and an additional coating on the release characteristics of the devices has been studied. Blends of EVA and the bioerodable poly(D, L-lactic acid) (PLA) for controlled-release applications have been presented by Dollinger and Sawan (284). The PLA mass loss was evaluated as a function of blending technique employed, incubation media, and molecular weight of the polymer. Spherical devices composed of a core and a shell have been studied by David et al. (285). The core was made of a polymer able to absorb the agent to a large extent (more than 100%), while the shell exhibited both low diffusivity and low capacity. The release rate of an active agent was significantly influenced by the shell properties, such as thickness, nature of polymer, and capacity of absorption for the drug. A one-step preparation method of double-walled microspheres with layers made of PLA and EVA was described by Pekarek et al. (286). This technique takes advantage of the phenomenon of phase separation and can be used to produce spheres of diameters less than 20 μm and up to 1,000 μm. A completely different kind of release system containing EVA was developed by Amsden and Cheng (287). These devices consist of particles of intimately mixed sodium chloride and a protein dispersed in EVA. Protein and NaCl release results from osmotically induced membrane rupture subsequent to water inhibition.

POLY(ETHYLENE OXIDE)

PEG and poly(ethylene oxide) (PEO) are terms for materials containing a multiplicity of connected units of the structure [-CH_2CH_2-O-]. PEG is one subspecies of PEO that contains a hydroxyl group on each end of the chain: HO[-CH_2CH_2-O-]$_n$H.

The physicochemical properties of PEO have been described in detail by Graham (288). Depending on the molecular weight, PEO is a liquid, a waxy solid, or a solid. PEO has a very regular backbone structure, free of sidechains. In the absence of crystallinity, the amorphous material is a rubber with a low Tg, typically -60°C and exhibiting a maximum of Tg at molecular weights in the region of 4,000 Da. Having no chiral centers in the structure and no sidegroups, the polymer is normally highly crystalline, with melting points up to 65–68°C. The crystalline structure of linear PEO has been determined by X-ray diffraction as a 7_2 helix (289). This is a coil containing 3.5 -[CH_2CH_2-O]- groups per turn and a repeat unit of seven such groups. The non-cross-linked polymer swells in water and subsequently dissolves, but it can also be made insoluble by cross-linking.

One major advantage of PEG is its low toxicity: It is approved by the U.S. Food and Drug Administration (FDA) for use in foodstuffs and in pharmaceutical products via injection, topical, or oral routes.

Table 5. Average In Vitro Release Rates of Pilo-20 and Pilo-40

Time (h)	Release rate for Pilo-20 (μg/h)	Release rate for Pilo-40 (μg/h)
0–7	57.6 ± 2.2	108.0 ± 5.0
7–24	25.3 ± 0.6	54.4 ± 2.5
24–168	19.4 ± 0.3	40.4 ± 4.2

Matrix Systems

The drug-release mechanism from monolithic PEO devices depends strongly on the molecular weight (M_w) and the degree of cross-linking of the polymer. Low-M_w PEO dissolves fast, leading to an erosion (polymer dissolution) controlled process. On the contrary, high-M_w PEO swells owing to penetrant uptake and either dissolves (non-cross-linked polymer) or swells until an equilibrium state is reached. Depending on the diffusion characteristics of the incorporated drug, the entire release kinetics will be governed by diffusion, swelling, dissolution, or a combination of these. Apicella et al. (290) investigated the release of etofylline from compression-molded tablets of semicrystalline PEG with M_w of 600,000 and 4,000,000 Da, respectively. While the low-molecular-weight polymer dissolves at a constant rate (continuously delivering the practically immobilized drug), the release from the slowly dissolving high-molecular-weight polymer is exclusively driven by the drug diffusion. Similar results were found by Kim (291). He studied the release kinetics from compressed tablets manufactured with a powder mixture of PEO, a drug, and magnesium stearate. Several factors such as molecular weight, drug loading, drug solubility, the pH of the dissolution medium, and stirring rate were investigated. To provide a constant drug release over a long period of time (>20 h), Kim also produced tablets with a central hole (donut-shaped) (292). The release of theophylline was observed to be zero order for the first 80–90% of the drug. Semicrystalline, cross-linked PEG was used by McNeill and Graham (293) to prepare and study prostaglandin E_2 (PGE_2)–containing vaginal pessaries. To avoid drug degradation during the fabrication process of the device, the PEG hydrogel was swollen with a solution of PGE_2 in an organic solvent and not in water. Approximately zero-order release was achieved for the first 45% of drug from a dry slab in vitro. Laboratory pessaries have been stored at 4°C for more than a year with no significant change in the release profile or degradation of PGE_2.

Miscellaneous

Graham and McNeill (294) studied hydrogels based on PEG with a number average molecular weight of 3,000 to

8,000 Da. Drugs have been classified into five groups showing different release profiles. They also developed and tested morphine-loaded PEG suppositories, showing zero-order release. Urquhart and Theeuwes (ALZA Corporation) have a patent (295) on an orally administrable dispersing device for controlled delivery of drugs, comprising a matrix of nonhydrated PEO and a number of tiny pills dispersed through the polymer matrix. A cellulose–polymer coating controls the release rate. An oral capsule utilizing an aqueous polymer (like PEO) and an oil to control gastrointestinal transit time has been patented by Uemura et al. (Fujisawa Pharmaceutical Co.) (296). The capsule is filled with a substantially anhydrous mixture being in solid or semisolid form consisting of (*1*) a drug or a drug treated by a conventional manner, each of which is in solid form; and (*2*) a drug carrier that is a semisolid mixture comprising an aqueous polymer (e.g., PEO) and a liquid oil (e.g., arachis oil or medium-chain triglyceride). The ratio of the aqueous polymer to the liquid oil by weight is 2:1 to 1:40.

Bibliography

One of the immediate consequences of the late twentieth century revolution in molecular biology was the availability of biological macromolecules and their analogues as potential drug substances. The first of these were the recombinant and synthetic proteins and peptides, which can be used as agonists and antagonists of their natural homologues. Recently, polynucleotides have moved to center stage in a similar manner. Thus, the coding regions of entire genes can be used to produce proteins or peptides of therapeutic consequence in situ. Furthermore, shorter oligonucleotides and oligonucleotide analogues can be employed to alter gene expression and, consequently, the in vivo levels of specific proteins. The utility of all four of these macromolecules, proteins, peptides, large polynucleotides, and oligonucleotides, is severely limited by delivery problems that include instability as a consequence of enzymatic, chemical, and conformational processes, as well as targeting, passage across the cytoplasmic membrane, and intracellular processing and targeting. A general consensus seems to be that delivery is in many if not most cases the limiting step in the ultimate therapeutic efficacy of these agents. Not surprisingly, work on the delivery of small molecules as well as proteins, peptides, and DNA plasmids has had a major influence on early attempts to deliver oligonucleotides. In this regard, the reader is referred to the article POLYMERIC SYSTEMS FOR GENE DELIVERY, CHITOSAN AND PINC™ SYSTEMS, in which many of the same problems are addressed with a molecule of related physical properties but of much greater size.

A discussion of oligonucleotide delivery presents several problems due to the embryonic state of the field. For example, a wide variety of different types of oligonucleotide analogues have already been synthesized and examined, with varying degrees of characterization. Besides the prototypic phosphodiester type, forms that have been modified in their backbone, termini, sugar base, and stereochemistry have all been produced (1,2). Because of their increased nuclease resistance (and therefore potentially longer half-life), the backbone-modified analogues have been most intensively studied. These include thiolated forms and the methylphosphonates, as well as the peptide nucleic acids, in which the phosphodiester linker is replaced by an amide moiety (3). For simplicity, here we will primarily consider the phosphodiester and phosphorothiolate forms because up to this point they have received the most extensive examination from a delivery perspective. Both have the property of being polyanions, which is the physical characteristic that might be expected to dominate their chemical and biological properties. These molecules are usually 15–25 nucleosides in length, although both larger and smaller chains are sometimes encountered.

Although not the subject of this review, the potential mechanisms of action of oligonucleotides need to be understood to rationally prepare them as pharmaceuticals (4). In fact, multiple mechanisms of action are recognized, and knowledge of the one (or more) involved in a specific case will usually be helpful. The one most often postulated to be involved in the reduction of expression of specific genes involves complementary binding to mRNA molecules (5). Changes in translation of these hybrids can be due to simple steric effects or result from activation of the enzyme RNase H, which specifically degrades the mRNA component of the complex (potentially releasing the pharmaceutical oligonucleotide for further activity). Alternatively, the oligonucleotide can bind directly to nuclear double-stranded DNA, forming a triple-helical structure that blocks transcription (6). It is a matter of semantics whether we consider such triple-helix-forming oligonucleotides as true "antisense" agents, but from a delivery perspective this is relatively unimportant with the exception of potential nuclear-targeting issues. A third class of oligonucleotides is the RNA-based ribozymes, which themselves manifest enzymatic activity (7,8). These molecules have primarily been used to target mRNA, but they also have the potential to attack nonnucleic acid targets (e.g., proteins) with therapeutic effects. Finally, a fourth type of oligonucleotide with potential therapeutic utility has recently been developed, the so-called aptamers (9,10). These are single- or double-stranded oligonucleotides that bind to sites on proteins that perturb their activity. These molecules are usually selected through combinational approaches and may contain specific tertiary structure that is involved in their biological activity. Extensive discussion of the mechanism of action of oligonucleotides can be found in the references already cited. Although the specific delivery method employed for a particular oligonucleotide will be dependent on the unique situation in which each will be employed, the basic principles of delivery will probably

be similar among the various classes, at least in terms of organ and cellular targeting and entry.

It is convenient to begin our discussion of the oligonucleotide delivery process itself in the middle, at the cellular entry stage, and then consider earlier stages (e.g., pharmacokinetics and tissue targeting), followed by final elements of the delivery pathway (intracellular). It is perhaps somewhat surprising that highly negatively charged oligonucleotides are able to enter cells, but this is certainly the case. Without the assistance of transport facilitators this process is rather inefficient, but it is clear that incubation of cells in culture or administration to animals of phosphodiester or phosphorothiolate oligonucleotides at many sites will result in transport of these molecules into cells. It is fair to say, however, that the mechanism by which this is accomplished is currently unclear. Several non–mutually exclusive hypotheses can be advanced to explain such phenomena. Most postulate the existence of some type of receptor on the cell surface that can mediate entry. This is, of course, the mechanism used by viruses that are able to transfer very large oligonucleotides into cells with high efficiency. Attachment of oligonucleotides to such receptors could then facilitate entry by a number of well-recognized different processes including receptor-mediated endocytosis, pinocytosis, and phagocytosis. What is not known is the identity of the attachment size of oligonucleotides and oligonucleotide complexes on the outer surface of the plasma membrane (11).

Attractive candidates for this binding site are the cell surface proteoglycans. These molecules contain polyanionic polysaccharide side chains attached to proteins that are cycled into cells and back onto the cell surface at a rate commensurate with that seen for cellular entry of oligonucleotides (12). Thus, this can be viewed as one natural ingress pathway for polyanions. Oligonucleotide attachment to these similarly charged entities would presumably be mediated by a cross-linking mechanism through normally present cationic molecules (e.g., divalent metal cations, cationic peptides, proteins) or synthetically produced cationic sites on delivery vehicles (e.g., cationic lipids, polymers, peptides; see later). In support of this pathway, enzymatic removal of the heparan sulfate side chains of cell surface proteoglycans or inhibition of their sulfation produces a dramatic decrease in the passage of oligonucleotides into cells (13,14).

A second potential site of entry is the specialized structures known as caveolae, which have been implicated in transcytotic events. Studies of intramuscular delivery of polynucleotides have specifically identified these cell surface invaginations as potential sites of entry of "naked" polynucleotides (15). These membrane microdomains are enriched in cholesterol and various sphingolipids and are thus regions of positive charge concentration (16). It is therefore possible that they could be involved in direct electrostatic interactions with polynucleotides, although this has yet to be experimentally demonstrated. Certain proteins are also commonly found in these regions, including many involved in signal transduction events (17). These proteins could also provide potential polyanion binding sites and serve as vectors to "piggy-back" polynucleotides into cells. In this regard, it is still entirely possible that one or more unknown proteins located elsewhere in the plasma membrane play a role in cellular entry (e.g., see Ref. 18), but no strong evidence in support of this idea as a general mechanism has yet been presented. Obviously if such proteins exist, efforts could be made to directly target these molecules. Because cell surface proteins are generally recycled from the cell surface into the interior, these molecules potentially provide a facile point of entry. Thus, as will be discussed later, by construction of artificial targeting vehicles, it is possible to attempt to target any cell surface molecule that eventually reenters the cell.

Once inside a cell, an oligonucleotide must be transported to an appropriate site of action. In the case of antisense or catalytic activity, this could be either the cytoplasm or the nucleus. If the target is DNA itself, then nuclear transport will be required. Aptamers, on the other hand, would need to be present at the specific intra- or extracellular location of the target protein. Most evidence suggests that oligonucleotides will initially be found in endosomal compartments (14), although this has been disputed (e.g., see Ref. 19). Thus it may be necessary to provide some active mechanism to release oligonucleotides from these membrane-bound vesicles. In general, the transport of oligonucleotides into the nucleus does not present the problem encountered with DNA plasmids because they are small enough to passively diffuse through nuclear pores. Nevertheless, it is at least possible in principle to either increase the efficiency of this process or enhance nuclear retention. In general, attempts to stimulate endosomal release or nuclear entry have been peptide or lipid based and will be considered below in that light.

By what routes might oligonucleotide-based pharmaceuticals be initially delivered? The major approach has been intravenous infusion, although numerous other routes such as direct injection into specific sites or oral, nasal, or bronchial administration have been examined with some limited success (20,21). Most pharmacokinetic information has been obtained from the intravenous route. In general, it is found that negatively charged oligonucleotides are rapidly distributed throughout the body, with most accumulation in organs such as the kidneys, liver, and spleen, with extensive secretion in the urine over a 24-h period (22–24). Extensive degradation of phosphodiester oligonucleotides is seen, but phosphorothiolate analogues are much more stable at all sites examined (22,23). Equilibration is slower upon intraperitoneal injection and much slower with subcutaneous administration. It should be noted that in many cases oligonucleotides rapidly become protein bound with serum albumin and immunoglobulins, the major binding proteins so far identified (25). Conjugation of oligonucleotides to cholesterol appears to retarget them to low-density lipoproteins and extend their circulation time (26). The exact role of oligonucleotide–protein complexes in oligonucleotide delivery is poorly understood but will be critical to the ultimate design and use of these pharmaceutical agents.

Informative comparative studies of the delivery of oligonucleotides by noninvasive methods have been performed (25). Somewhat surprisingly, direct introduction of 5′-^{32}P-labeled phosphodiester oligonucleotides into the nose, vagina, or rectum or onto the skin of mice resulted

in significant levels of labeled compounds in the blood. Intranasal and oral administration resulted in serum levels 5–20% of those seen with intraperitoneal injection, and levels 5–10 times less than those seen with intravaginal and rectal application. The ocular route was also found to be about 10% as effective as i.p. administration. Interestingly, longer oligonucleotides seems to be more effective when introduced through the eye. The skin route was much less effective. The relative distribution of the oligonucleotide among the various organs examined was very similar.

Although oligonucleotides have some ability to pass through the circulation and enter cells, it is not clear that they will be able in most cases to do this with sufficient efficacy to be effective pharmaceuticals. Thus, efforts are actively underway to design vehicles that better target and more effectively enter and ultimately act at desired sites. Because the mechanisms by which oligonucleotides enter cells are still obscure, most efforts at designing novel vehicles have been semiempirical in nature. We therefore focus on a select number of approaches that currently appear most promising. In general, the design of oligonucleotide delivery vehicles is based on the following criteria. First, one wishes to protect the potentially labile oligonucleotide to the maximum extent possible from destructive processes; enzymatic digestion is probably the chief concern. Secondly, it is usually thought (although see earlier) that the polyanionic character of the oligonucleotide should be reduced or even eliminated. This is usually accomplished by some type of charge neutralization or shielding mechanism, although later-generation oligonucleotide analogues have this built directly into their intrinsic structure. Third, the surface characteristics of any resulting complex should be such that some degree of intrinsic targeting resides in the vehicle. Fourth, some type of endosomal release property might be incorporated. Fifth, nuclear targeting may or may not be included. In some cases, it is thought that creating a particle that could range from submicron to many microns in size might be advantageous. We consider here a number of examples in which one or, usually, more of these properties are included in oligonucleotide delivery vehicles. We discuss only representative examples in which more extensive citations to other examples are included, and the reader is referred to these for more extended considerations.

A potentially very powerful approach to the oligonucleotide delivery problem employs viral vectors. In this method, the nucleic acid sequence of interest is inserted into a viral genome where it can then be expressed as part of the normal viral infection and maturation process. This approach has the great advantage that it avails itself of the natural ability of certain viruses to infect specific cells with high efficiency. The virus particles may also possess intrinsic effective endosomal release mechanisms that further enhance their utility. The most common viruses usually considered for such use are the retro-, adeno-, and adeno-associated viruses. Unfortunately, this technology manifests several serious shortcomings. These include toxic effects often involving potential insertional mutagenesis, immunogenicity (especially upon repeat usage), and the complexity of the vehicle, which introduces major problems in analysis, reproducibility, and manufacturing. For these reasons, unlike the case in gene therapy, viral delivery systems are not generally pursued for oligonucleotide administration if a more classic chemical pharmacological approach seems possible.

By far, the area in which the most effort has been expended has involved the use of liposomes. Two somewhat different approaches have been undertaken. In the first, oligonucleotides are entrapped within anionic lipid vesicles of varied size, structure, and composition. In the second, the oligonucleotides are complexed to cationic lipids of various structural and assembly types. Most recently, the latter approach has received the most attention. We begin with the former.

Employing what is usually considered the "conventional" liposomal approach, several research groups have had some success in enhancing the uptake of oligonucleotides into cells. In an early report, Loke et al. (27) used phosphatidylserine-based liposomes to deliver oligonucleotides into cells in tissue culture. This required polyethylene glycol (PEG) to induce liposomal cell fusion, as well as calcium to enhance loading of the oligonucleotide. Using specially designed minimal volume entrapment approaches, Thierry et al. (28,29) have employed cardiolipin-based liposomes to enhance entry of oligonucleotides 10- to 20-fold into different types of cancer cells, resulting in measurable biological response. Biologically active ribozymes have been successfully delivered in a similar manner using a dipalmitoylphosphatidylglycerol-based system. Several important observations can be made from these and related studies. First, oligonucleotides are substantially protected by the anionic lipid barrier created. Secondly, uptake is enhanced, and activity is detectable. Thirdly, the oligonucleotides seem to be concentrated in the nucleus soon after administration. The efficiency of delivery, however, is not as high as desired for optimal therapeutic effects.

Although evidence exists that even unmodified anionic liposomes can enhance endosomal release to some extent, pH-sensitive liposomes have been designed with the intent of avoiding lysosomal destruction (30,31). The lipid most commonly used for the construction of pH-sensitive liposomes is dioleylphosphatidylethanolamine (DOPE). In bilayers, DOPE can be present in a lamellar form at neutral pH. Under certain conditions of temperature, salt concentration, and pH, however, an inverted hexagonal phase can be induced, which leads to fusogenic behavior. Most importantly from our perspective, low pH leads to protonation of DOPE headgroups, which removes their stabilizing repulsive interactions and induces hexagonal phases. Almost always, however, a second molecule (usually a fatty acid) is necessary to prevent premature formation of fusogenic hexagonal phases under physiological conditions. Examples of such agents include cholesterol hemisuccinate, palmitoylhomocysteine, and oleic acid. Alternatively, as described later, peptides or proteins that undergo pH-dependent conformational changes to structures that can insert into lipid bilayers or create pores can be employed; this latter approach more closely simulates the mechanism used by viruses to escape endosomal degradation, with actual viral proteins sometimes inserted

into a synthetic lipid-based delivery system to achieve this end.

It is clear that such systems work in protein-based systems, at least to a limited extent in that cytoplasmic localization is enhanced. For example, delivery of the diphtheria toxin A fragment by DOPE–oleic acid liposomes results in significant inhibition of protein synthesis, an effect normally prevented by endosomal encapsulation (32). Even more dramatic effects are seen when the diphtheria toxin A fragment is presented in DOPE–cholesterol hemisuccinate liposomes (33). Nevertheless, more than 90% of the protein is still undelivered to the cytoplasm.

Several studies have shown that oligonucleotides can also be delivered in a biologically active form by pH-sensitive liposomes. Inhibition of the replication of retroviruses by oligonucleotides complementary to envelope proteins has been demonstrated, with free polynucleotide unable to induce any effect (34). This area remains relatively undeveloped, however, with few reports of successful in vivo delivery. This seems to reflect, at least in part, the relative instability of pH-sensitive liposomes in a biological milieu including serum. Initial attempts at increasing stability by the inclusion of compounds such as cholesterol have been promising, but at some cost of release efficiency. This should remain an active area of investigation.

Attempts have also been made to deliver oligonucleotides by various types of anionic multilamellar vesicles, which are complexes that contain many lipid bilayers that may or may not be separated by an aqueous space. Cellular delivery can be significantly increased by such structures, and they can provide dramatic protection from nuclease digestion (reviewed in Ref. 35). The fusogenic properties of both unilamellar and multilamellar anionic vesicles has been enhanced by the inclusion of viral proteins into the bilayers. This should in principle permit direct introduction of oligonucleotides into the cytoplasm, bypassing the endosomal degradation route already discussed. Most effort has focused on the Sendai virus fusion proteins (e.g., protein F), although a wide variety of proteins is potentially available for such uses (36) (see later). This method does result in the increase in entry of polynucleotides, but problems of increased structural complexity and immunogenicity are apparent.

By far, the currently most promising liposome-based approach involves the use of cationic lipids (37–39). In this case, preformed cationic liposomes are induced to spontaneously form electrostatic complexes with polynucleotides. Recent structural studies suggest that oligonucleotides are adsorbed between cationic bilayers in these complexes (40,41). Although perhaps not true liposomes, the retention of the bilayer structure in cationic lipid–nucleic acid complexes has resulted in use of the liposome designation. It is clear that some fusion of the original liposomes occurs upon complex formulation (42). The effectiveness of cationic lipids as delivery agents appears to be a complex function of the nature of the lipid itself (headgroup, headgroup charge, fatty acid side chains), absolute concentration, and perhaps most importantly the charge ratio (lipid headgroup to oligonucleotide phosphate). Attempts to establish clear structure–function relationships, however, have so far been unsuccessful, and final formulations are normally based on empirical studies of the aforementioned variables. Several investigations suggest that (1) cationic lipid–nucleic complexes are readily taken up into cells by an ill-defined endocytotic pathway, (2) some enhancement of endosomal release is seen, and (3) nuclear entry and dissociation of complexes may be rate limiting steps in oligonucleotide (and plasmid) activity (43–47). A further accumulation of data will be necessary, however, for a consensus to be reached about the mechanism of transport and activity of these complexes.

Although most work with cationic lipid–nucleic acid complexes has focused on DNA plasmids for gene delivery, a variety of studies of oligonucleotide delivery have appeared. It is apparent that the uptake of cationic lipid–oligonucleotide complexes is usually markedly enhanced relative to both pure oligonucleotides and oligonucleotides encapsulated in conventional anionic lyposomes (37–39). Most work has focused on commercially available cationic lipids such as *N*-[1-(2,3-dioleoyloxy)propyl]-*N*,*N*,*N*-trimethylammonium chloride (DOTMA), dioctadecylamidoglycyl spermine (DOGS), 1,2-dioleoyl-3-trimethylammonium propane (DOTAP), and dimethyldioctadecylammonium bromide (DDAB) (which also often include a helper lipid such as dioleylphosphatidylethanolamine [DOPE] or cholesterol), but as second-generation cationic lipids become increasingly available, we can expect to see a reemphasis on these improved delivery vehicles. It is also clear that cationic lipid–oligonucleotide complexes provide some protection against nuclease digestion, although the relative contribution of this effect to their observed enhanced cellular delivery efficiency is unknown. Perhaps most importantly, cationic lipid–oligonucleotide complexes have demonstrated improved efficacy in some in vivo animal systems. For example, inhibition of tumor growth in nude mice by a phosphorothiolate oligonucleotide complimentary to an untranslated region of the 3′ end of human nucleolar antigen mRNA is significantly improved by complexation to DOTMA (48). Importantly, no toxicity was observed in these studies. In another instance, intracerebroventricular injection of antisense DNA complexed to DOTAP was able to inhibit expression of a potassium channel in mice, resulting in impaired memory (49). At least one situation has been described, however, in which cationic-lipid antisense-mediated inhibition of expression in cultured cells was not reflected in in vivo activity because the lipid was not required to produce the biological response in the animal (50). Thus, actual studies in animals are still necessary to ensure the utility of cationic-lipid-mediated delivery. In general, effects in cell culture of complexes composed of cationic lipids and oligonucleotides do not correlate well with in vivo results. This seems to be due to a combination of reasons including interaction of complexes with plasma components and variable bioavailability, especially involving uptake by the liver and reticuloendothelial system (51).

Both conventional liposomes and cationic lipids clearly have the potential to be used to enhance oligonucleotide delivery (36,52). Both can protect oligonucleotides as well as enhance cellular uptake, but differ significantly in their bioavailability and intrinsic localization properties in situ. Both can potentially be further targeted; this is discussed

later under the general approaches available to cellular targeting.

An alternative attractive approach from a pharmaceutical perspective involves the use of synthetic polymers to facilitate oligonucleotide delivery. Behr et al. have described the use of polyethyleneimine to markedly enhance the uptake of oligonucleotides into embryonic neurons (53). They postulate that this polymer can act as a "proton sponge," which can buffer lysosome interiors, thereby protecting DNA from nuclease digestion. A pH-sensitive polymer, poly(α-ethylacrylic acid), however, had only minor effects compared with fusogenic peptides, a pH-dependent surfactant, or dendrimers (54). The latter polymeric substances, of the cascade polyamidoamine type, have shown some promise in several laboratories. Transfection of antisense agents into several cell lines significantly inhibited luciferase expression (55), and increased uptake of oligonucleotide–dendrimer complexes as well as enhanced metabolic stability have been directly demonstrated (56). The effectiveness of dendrimer complexes is a function of the generation of the dendrimer as well as pH and ionic strength (57). Further studies of these well-defined cationic polymers are clearly warranted.

Peptides provide a second class of polycationic polymer that has been preliminarily examined. This work involves several different ideas including (*1*) the creation of neutralized oligonucleotide–peptide complexes, (*2*) the use of fusogenic sequences, and (*3*) nuclear translocation signals (58). In general, the simple use of nonspecific peptide–polynucleotide complexes has not been particularly promising and is not discussed further here. More promising is the use of sequences that possess pH-dependent activity that leads to membrane destabilization. Such peptides are usually based on the structure of natural sequences found in viral surface proteins. More than a hundred natural and synthetic peptide sequences have been described that possess fusogenic and/or lytic activity (59). These sequences can be complexed to oligonucleotides electrostatically, covalently, or as part of purified proteins or viral particles (59–62). In many cases, dramatically improved antisense activity is observed, presumably due to facilitated exit of oligonucleotides from endosomes (59,63,64). In several instances, enhanced uptake into cells of oligonucleotides as well as ribozymes has been obtained by combining liposomes and the hemagglutinating virus of Japan (65–68). In a somewhat analogous manner, nuclear entry has been facilitated by peptides containing nuclear localization sequences. The transport of nuclear proteins from the cytoplasm through the nuclear membrane pore complex is mediated by short, basic sequences. Preliminary studies suggest that the inclusion of such sequences can indeed facilitate the nuclear transport of oligonucleotides and even of plasmids (69), but their utility as components of oligonucleotide vectors has yet to be convincingly demonstrated. It is attractive to imagine peptide-based vectors that contain cellular entry, endosomal release, and nuclear entry facilitation sequences (58), but potential problems of immunogenicity, interference between activities, and overall complexity compared to naked oligonucleotides must currently temper enthusiasm for this approach.

Other combined approaches have been described. For example, well-defined poly(ethylene glycol)–poly(L-lysine) (70) and polyspermine–PEG (71) block copolymers have been created, with the latter manifesting antisense activity in cultured cells. Oligonucleotides have been complexed to leucine- and lysine-containing peptides and then entrapped in PEG–polylactic acid "stealth" liposomes (72). Although biological experiments have yet to be reported in this system, the physical properties of these particles make them interesting candidates for oligonucleotide delivery vehicles. Enhanced oligonucleotide cellular entry as well as improved polynucleotide stability have been obtained with synthetic 30-nm particles created from an internal core of cross-linked polysaccharide, a middle covalently attached fatty acid layer, and an external lipid bilayer (73). These complexes were passaged at least 10-fold more efficiency than free oligonucleotides. We can expect that increasing numbers of vectors containing multiple components will be constructed, but this approach is in its infancy.

The well-known method of encapsulation of drugs into bioerodable microparticles has also been attempted with oligonucleotides (74). Although there are many different polymers that have been employed to this end, initial studies with oligonucleotides have been primarily confined to the polylactide–coglycolide type. Both poly(L-lactic acid) (75,76) and lactic acid–glycolic acid matrices (77,78) have been tested and found to release oligonucleotides in a controllable, biphasic manner as well as protect them from degradation. A novel type of microsphere has recently been described that can bind to intestinal mucus and transverse both mucosal absorptive and follicle-associated epithelium (79). Polynucleotides have been successfully delivered to the circulation by this method, suggesting the potential for oral delivery. Compared to peptides and proteins, systems of this type have only been fleetingly examined for oligonucleotides, and their promise remains uncertain but provocative.

We conclude this discussion of delivery complexes by noting that small molecules can also be used to facilitate oligonucleotide delivery. For example, under certain conditions, a cell permeabilizer such as streptolysin O can be used to enhance uptake of RNA into living cells without cell death (80). Perhaps more promisingly, cyclodextrin analogues have been prepared than can stimulate oligonucleotide cellular entry (81,82). Interestingly, cyclodextrin analogues were able to specifically inhibit the immunostimulatory activity of a phosphorothiolate oligonucleotide in mice (83). Further exploration of small molecules in formulations of oligonucleotides seems in order. Finally, we mention that electroporation, ultra- and low-frequency sonic energy, and shock waves have been briefly explored as delivery facilitators, but it is too early to judge the potential utility of such external energy-based approaches. The reader is referred to the article POLYMERIC SYSTEMS FOR GENE DELIVERY, CHITOSAN AND PINC SYSTEMS for a discussion of the "gene-gun" approacn and related methods.

Lastly, we turn to the question of targeting; in this case the term indicates the localization of oligonucleotides to specific cell types after systemic administration. In some

ways this is the "holy grail" of oligonucleotide as well as gene delivery because many of the potential problems of oligonucleotide therapy could be overcome if we could limit the delivery of oligonucleotides to specific sites (84,85). It will probably often be the case that the inherent selectivity of oligonucleotides will not be sufficient from either a toxicity, bioavailability, or efficacy perspective for optimum pharmaceutical use. The availability of numerous specific receptors on the surface of all cells seems to offer such an opportunity. Ligands can be attached to oligonucleotide delivery vehicles in any number of ways. This includes covalent attachment to a component of the vehicle, including the oligonucleotide itself, electrostatically through ionic complexes with the polyanionic component or through apolar interactions, perhaps by insertion into lipid bilayers. The choice of ligand is really limited only by the presence of an appropriate receptor and its intracellular pathway, the latter generally seeming to permit at least some limited release into the cytoplasmic compartment without the use of further mechanisms to stimulate endosomal membrane breakdown. Ligands that have so far been successfully employed to deliver oligonucleotides into cells with some degree of selectivity include carbohydrates (to the asialoglycoprotein and mannose scavenger receptors) (86–89), monoclonal antibodies and associated antigen-binding fragments (85,90), folic acid (91–93), and growth factors (94). The reader is referred to the article on gene therapy in this encyclopedia as well as reviews for further discussion of this topic (84).

We conclude by what is perhaps a statement of the obvious. Oligonucleotides will not be successfully developed as therapeutic agents unless they can be delivered to their site of action in a stable form and gain entry into the proper regions of a cell where they can exert their biological effects. An understanding of the biology necessary to accomplish this is still primitive, and current efforts at delivery thus remain semiempirical at best. Because current clinical studies of pure oligonucleotides hint at some activity (95–97), more complex delivery systems will be required to demonstrate a significant improvement on these simpler, more convenient formulations. Although much of the work described here would seem to offer some leads in this regard, much more extensive work including radically novel developments will probably be necessary to produce pharmaceutically acceptable delivery methods for oligonucleotide drugs.

Oral administration has been the traditionally preferred route of administration for most therapeutic agents and is, in general, the first avenue investigated in the discovery and development of new drug candidates and formulations. Owing to patient acceptance, convenience of administration, cost-effective manufacturing that does not require sterile processing, and a generally long product shelf-life that is often dictated more by the stability of the active drug itself rather than the formulation components, a continued emphasis on development of oral formulations will persist. For many drugs and therapeutic indications, conventional immediate-release formulations provide effective therapy. The required balance of pharmacokinetic and pharmacodynamic profiles with an acceptable level of safety to the patient can be achieved, and the often costly and complex development of specially designed controlled-release formulations is neither necessary or justified.

Oral controlled-release formulations for the small intestine and colon have, however, received considerable attention in the past 20–25 years for a variety of reasons, including pharmaceutical superiority and clinical benefits derived from the drug-release pattern that are not achieved with traditional immediate- or sustained-release products (1). The necessity for frequently repeated administration to maintain therapeutically effective plasma drug levels can present problems for both patient compliance and fluctuating pharmacodynamic responses. Obviously, drugs that are susceptible to acid hydrolysis or enzymatic degradation in the stomach require a delayed-release mechanism, most often accomplished with stable coatings that prevent drug release in the stomach and thereby postpone release until the formulation is in the more favorable environment of the small intestine. This technology, commonly referred to as enteric coating, is rather routinely employed and will not be discussed in any detail in this section. Some examples of oral formulations employing coating technology to delay drug release until the formulation exits the gastric environment are given in Table 1. Another relatively common problem requiring development of controlled-release formulations is peak-associated side effects that have the potential to be reduced or minimized if a formulation can provide lower, but effective, constant plasma levels of the active drug. The ultimate goal has been to develop true zero-order-release formulations that provide a constant rate of drug release that is independent of remaining drug content in the formulation. Although this approach has certainly proved effective for some drugs and has been utilized to prolong drug absorption or achieve a more stable pharmacodynamic response, the varying absorption rates and drug stability in different regions of the gastrointestinal (GI) tract has meant that a zero-order release pattern will not necessarily achieve constant plasma drug levels. Controlled-release systems that achieve pseudo-zero-order or first-order release can also achieve effective pharmacokinetic and pharmacodynamic results. Another factor that occasionally justifies the development of controlled-release formulations for the small intestine and colon is the apparent presence of drug absorption "windows" that can dictate the regions of the GI tract from which a potential drug candidate can be effectively absorbed (3–5). When an absorption window exists for a drug candidate, a time- or location-directed formulation may be required to achieve the necessary driving force in the proper region of the GI tract to effect adequate drug absorption. In some cases, particularly for drugs that are susceptible to enzymatic degradation in the small intestine, such as peptides and proteins, designed formulations that release the drug in the lower small intestine or colon are thought to present potential advantages by minimizing enzymatic degradation and achieving higher local concentrations of the drug at the absorptive surface (6,7). The relatively more quiescent state of the lower small intestine and colon, as well as reduced fluid content, have also been cited as rationales for developing controlled-

Table 1. Examples of Enteric-Coated Oral Products

release formulations for the lower small intestine and colon. In addition to designing formulations to achieve specific release profiles, modifying the drug itself through complexes or conjugates, that is, prodrugs, can be utilized as a controlled-release technology to achieve specific delivery profiles. For the reasons previously cited as well as others specific to individual drug candidates, the interest in controlled-release formulations for the small intestine and colon remains high and is the target of major pharmaceutical research and development efforts.

By definition, oral controlled-release products refer to those formulations in which a "controlling technology or component" is incorporated that is critical to modulating the drug-release pattern in a predictable fashion or that controls the timing, and subsequently the location, of drug release within the GI tract. Also included in the category of controlled-release formulations are strategies that are conceived and design to improve the pharmacokinetic profile, often by improving the performance or stability of the oral formulation in the dynamic and often hostile environment of the GI tract, in other words, by utilizing bioadhesive technologies to localize the drug and formulation components in close spatial and temporal proximity at the epithelial barrier membrane of the GI tract and, hence, increase the driving force for drug absorption. Table 2 provides examples of some marketed products that have employed sustained- or controlled-release technologies to provide a product with therapeutic or marketing alternatives. To provide an organized discussion of various approaches to small intestine and colon controlled-release technology, the subject matter is divided into pharmaceutical approaches as indicated below:

- Small intestine
  1. Time specificity
  2. Bioadhesives
  3. pH sensitivity
  4. Prodrugs
- Colon
  1. Time specificity
  2. Enzymatic control

It is important to bear in mind that with the exception of the transition from the stomach to the duodenum, there are few, if any, dramatic changes in physiology. Rather, the changes that occur in the physiology of the GI tract are more truly characterized as a continuum or gradual change, with decreasing enzymatic activity, decreasing motility and fluid content, and increasing pH. The presence of specific bacterial populations in the colon and an apparent transient, small reversal in the otherwise increasing pH gradient (8) are exceptions that have been targets for pharmaceutical strategies. These gradually changing physiological parameters means that few "triggering" elements can be utilized to effect a sudden and dramatic change in the performance or release characteristics of an oral controlled-release formulation. As a result, many of the same principles have applied to developing technologies for the small intestine and colon, and in some cases, the duration or timing of the controlling factor has been modified to achieve the desired end result. As such, the performance of controlled-release formulations can often be precisely regulated only in an in vitro environment but becomes subject to the vagaries of GI physiology and its resultant impact on controlling elements in the formulation itself.

SMALL INTESTINE

Time Specificity

Time-specific controlled-release systems are engineered formulations that are designed to release the active drug(s) in a specific temporal pattern. The technology, which can be applied to both continuous and pulsatile release systems, is generally utilized to deliver the active drug to a specific region of the absorptive GI surface. In this section, a variety of time-specific controlled-release systems are reviewed to provide the reader an appreciation for the range of applications for which these technologies might be useful.

The performance of time-specific controlled-release systems for drug delivery to the small intestine can be dra-

matically affected by residence time in the stomach. In the fasted state, the physiologic mechanisms responsible for emptying nondigestible solids from the stomach will generally ensure that a dosage form will exit the stomach within 15–120 min of administration as a result of the "housekeeper" wave of contractile activity (9). Drugs that are susceptible to acid hydrolysis or enzymatic degradation in the stomach will potentially, therefore, exhibit lower-than-desired absorption during residence of the formulation in the stomach environment. This can be overcome by applying specific coating technologies (as represented in Table 1) that prevent activation of the controlling mechanism until the dosage form exits the stomach. As a result, however, initiation of drug absorption will be delayed by a factor proportional to gastric residence time and may not be appropriate for therapeutic indications where an immediate pharmacological effect is necessary. The same issue of gastric residence times applies to time-specific bolus-release systems, that is, controlled-release systems where the drug is released in a manner similar to an immediate-release formulation except that the initiation of drug release is delayed by the controlling mechanism of the delivery system. These factors must be evaluated in the development of any oral controlled-release formulation designed for delivery of the therapeutic agent to the small intestine.

Of the variety of approaches that have been employed to incorporate a time-specific element to oral controlled-release systems, perhaps the most widely used approach has been designing technologies based on generation of osmotic pressure as the driving force. The rationale for this approach is that the presence of water in the GI tract is relatively constant, at least in terms of the amount required for activating and controlling osmotically-based technologies, and provides a more constant regulating parameter than does enzyme activity, pH, bacterial activity, or any other physiological or biochemical parameter. Not surprisingly, a rather incredible number of patent applications have been submitted and approved based on osmotic technologies. In a review published in 1995 (10), Santus and Baker identified 240 U.S. patents that have been approved in the past 20 years covering various applications of osmotic technology. Obviously, it is not possible to review and discuss all of the various osmotic technologies that have been evaluated and, in some cases, developed into commercialized products. The discussion here will deal with the basic concept of osmotically based time-specific drug delivery technologies and a presentation of representative examples that are in various stages of research and development.

In general, osmotic systems incorporate a drug core that contains an osmotically active drug and a semipermeable membrane coating that serves to regulate the influx of water into the device in response to the osmotic core (Fig. 1). In some cases, the drug core also contains an osmotically active salt, for example, NaCl, to assist in establishing the necessary osmotic driving force. Pressure developed as a result of the influx of water serves as a driving force to control the rate of drug release, which can be in either solution or suspension form. A port for drug release is normally created in the device through an orifice engineered

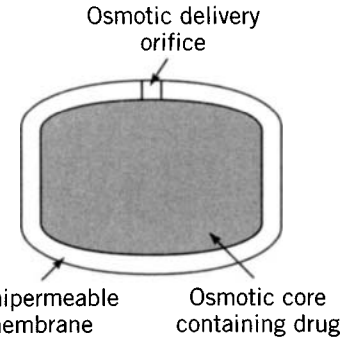

Figure 1. Osmotic pressure-controlled drug delivery system. *Source:* Reprinted from Ref. 11, with kind permission from Marcel Dekker, Inc., New York.

during manufacturing or created in the in situ environment of the GI tract. As long as the concentration of osmotically active agent(s) remains above saturation solubility, zero-order drug release can be achieved in which the rate of drug release $(Q/t)_z$ can be described as shown in the following equation (12):

$$(Q/t)_z = \frac{P_w A_m}{h_m(\Pi_s - \Pi_e)S_D} \quad (1)$$

where P_w, A_m, and h_m are water permeability, effective surface area, and thickness of the semipermeable membrane, respectively. S_D, Π_s, and Π_e are drug solubility, osmotic pressure of the saturated solution of osmotic drug and salt core, and osmotic pressure of the GI fluids, respectively. The mathematical description of the osmotically driven device permits calculation of a desired release rate based on such parameters as osmotic load (Fig. 2) and thickness of

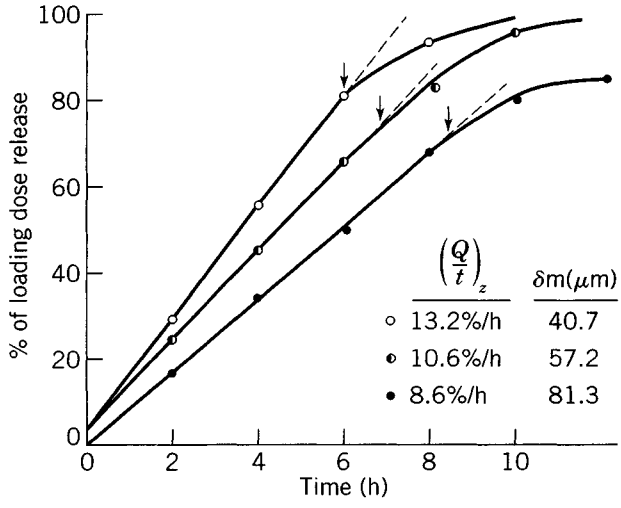

Figure 2. Effect of coating membrane thickness on the rate and duration of zero-order release of indomethacin from osmotic pressure-controlled gastrointestinal delivery system. *Source:* Reprinted from Ref. 11 with kind permission from Marcel Dekker, Inc., New York.

the rate-controlling membrane (Fig. 3) that modulates water influx (11). Several examples of employing osmotic technology to achieve time-controlled release of therapeutic agents are described in the following sections.

The absorption of metoprolol from conventional tablets, an osmotic OROS system (Ciba Geigy, lot No. L 001), and a multiple-unit coated pellet formulation (CR/ZOK) was evaluated in 18 healthy volunteers (13). The OROS design was a single-unit tablet coated with a semipermeable membrane according to principles of the elementary osmotic pump. The CR/ZOK formulation utilized metoprolol succinate as coated pellets in a disintegrating tablet. The CR formulations contained 95 mg metoprolol, while the conventional immediate-release formulation contained 100 mg. Both the OROS and CR/ZOK formulations afforded linear drug release for 2–3 h and continuous, nearly linear release for up to 6 h (Fig. 4). An analysis of the in vivo pharmacokinetics demonstrated that the CR and OROS formulations were essentially bioequivalent on the basis of C_{max} and AUC, and both resulted in a relatively constant maintenance of the plasma metoprolol profile (Fig. 5). The 24-h absorption profile for nifedipine was examined in 12 volunteers given a commercially available nifedipine GI therapeutic system (GITS, Adalat® XL, Miles Canada, Inc.) (14). The GITS system is a push–pull design that can be utilized for delivery of insoluble or poorly soluble drug suspensions and provides essentially zero-order release for 24 h following an initial 2-h hydration period, which is typical of these osmotically based systems (15,16). Measurable nifedipine levels were not observed in the first 2 h postadministration, which is expected based on the initial hydration period required for the GITS. Both 30-mg and 60-mg formulations were evaluated and showed that, as expected, the C_{max} and AUC were approximately doubled with the 60-mg dose compared with the 30-mg dose. The observed T_{max} value frequently occurred at 24 h in spite of the fact that a number of volunteers had total GI transit times considerably less than 24 h (6–32 h). The authors suggest that nifedipine chronopharmacokinetics might account for this observation based on previously reported data that suggest a lower absorption of nifedipine when dosed in the evening versus the morning (17). Regardless of the underlying cause for the specific pharmacokinetic profile with nifedipine, this study points out a common concern with controlled- or sustained-release oral dosage forms, particularly those with release profiles approaching 24 h, in that total GI transit may occur in a significantly shorter time frame than the time required for total drug release from the formulation (i.e., the formulation is eliminated from the body prior to complete absorption). An obvious outcome is that less than the total dose is absorbed, which may have therapeutic implications.

Both OROS and GITS systems employ an engineered (i.e., laser-drilled) port for drug exit from the device. Other systems have been designed that do not require prefabrication of the exit port. Pore-forming agents can be employed in the coating process to effect in situ pore generation (18–20). Potassium chloride–core tablets were coated with a cellulose acetate–latex formulation containing a plasticizer (triacetin) and urea as a pore-forming agent (19). Coated tablets required high-temperature (60 or 80°C) curing to coalesce the latex beads into a film on the tablet surface. Urea content was found to be the most important variable in terms of the resultant release profile. Cure time did not affect performance. Excellent agreement was observed between in vitro release rates (14.6 ± 0.87%/h in U.S. Pharmacopeial Convention (USP) method 2) and in vivo release rates (12.04 ± 1.18%/h as determined after necropsy retrieval of devices from fasted dogs). The release profile, both in vitro and in vivo (Fig. 6), approximated linearity over 6–8 h. Controlled-porosity osmotic pumps (MODS) were also evaluated for their applicability to the sustained delivery of simvastatin, an HMG–CoA reductase inhibitor for controlling plasma cholesterol levels (20). Core tablets of 105 mg drug-free base, 25.4 mg tromethammonium II, 100 mg mannitol, 45 mg Dowex 50 × 8–100,

25 mg Povidone 29–32 K, and 0.06 mg BHA were formulated by aqueous granulation. Magnesium stearate (1.5 mg per core tablet) was used as the lubricant, and 3/8-in.-round standard concave tablets were compressed. The controlled-porosity coat was applied to the core tablets by fluidized-bed spray-coating techniques with a coating solution of CA-398-30, CA-320S, sorbitol, and poly(ethylene glycol) (PEG) 400 dissolved in a water/methanol/methylene chloride (1:10:15) solvent blend. Simvastatin systems (8-, 12-, and 14-h release profiles) were prepared and evaluated in dogs and humans. The in vitro release profile for the 12-h system (Fig. 7) exhibited approximately zero-order release kinetics over the initial 6 h (55% release), with 74% release in 12 h and 90% released in 24 h. The 8- and 14-h MODS systems provided 76% release in 8 h and 70% release in 14 h, respectively. Comparing the MODS12 system with conventional tablets in a single-dose dog study, 4-fold reduction in AUC and 13-fold reduction in C_{max} for MODS was observed compared with the conventional tablet. Similar results were observed in a phase I human study in which a 14-h 20-mg simvastatin MODS system afforded a 54% reduction in AUC and 73% reduction in C_{max} compared with conventional tablets. Given that the pharmacodynamic effects on cholesterol lowering were similar between MODS and conventional tablets in the dog study, the data indicate that the MODS controlled-porosity system could be utilized to afford lower but constant plasma simvastatin levels that provided the same therapeutic potential without wide fluctuations in plasma drug levels.

Other osmotically based systems have been reported that are designed to release drugs in a pulsed or bolus fashion rather than the continuous profile achieved by OROS or GITS. The PORT System (Fig. 8) comprises a gelatin capsule, a semipermeable membrane coating, an insoluble

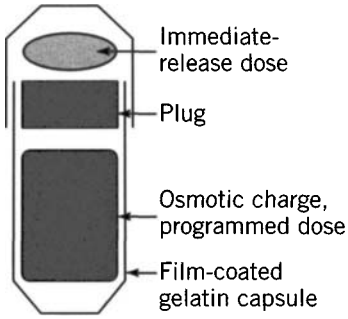

Figure 8. Design of PORT Systems. *Source:* Reprinted from Ref. 21, with kind permission of Elsevier Science–NL, Sara Burgerhartstraat 25, 1055 KV Amsterdam, The Netherlands.

plug, and an osmotic charge that can be balanced to achieve the desired drug-release time (21). A drug-osmotic core was placed in #-elongated hard gelatin capsules and overlayed with melted Gelucire 50/02 (Gattefosse). Following cooling, solidification of the Gelucire layer, and coating of the capsules with an acetone solution of 0.7% w/v triacetin and 2.1% w/v cellulose acetate, the release time was proportional to the number of coats applied. In vitro release times in simulated intestinal fluid (pH 7.5) of 0.23 ± 0.03 h, 1.68 ± 0.04 h, 2.96 ± 0.31 h, and 8.53 ± 0.28 h were observed for capsules with one, three, five, and seven coating layers. Combined with an understanding and estimate of GI transit times, one could envision utilizing these time-delayed systems to target relatively specific regions of the GI tract for drug release.

Not all controlled- or sustained-release technologies are based on underlying osmotic principles as the main driving force. A wide variety of other strategies have been employed and are being evaluated and developed with the goal of providing predictable, time-controlled oral drug delivery. The following sections, although not totally inclusive, describe a variety of technologies that may be appropriate for achieving time-controlled drug delivery.

TIME CLOCK, developed by Zambon Group SpA (Milano, Italy), is a pulsed-release system manufactured with conventional film-coating techniques and uses common pharmaceutical excipients (22). The principle behind TIME CLOCK involves applying a hydrophobic surfactant layer (as an aqueous dispersion) containing a water-soluble polymer onto a tablet or capsule core. The dried coating dispersion can then rehydrate and redisperse in an aqueous environment (e.g., GI tract fluids), and the time for rehydration/redispersion is proportional to the coating thickness (Fig. 9). A typical tablet core consisted of 74.5 mg lactose, 3 mg poly(vinylpyrrolidone), 13.5 mg corn starch, and 1 mg magnesium stearate. The compression mixture is prepared by granulating lactose with an aqueous solution of poly(vinylpyrrolidone), drying and sieving, and adding additional components by blending. The mixture was compressed to a theoretical weight of 100 mg with convex, 5.5-mm-diameter punches. The dispersion coating consisted of 3.5% carnauba wax, 1.5% beeswax, 0.5% poly(oxyethylene) sorbitan monooleate, 1.0% hydroxypropylmethyl cellulose (HPMC), and 93.5% deionized water and was applied with fluid-bed techniques with inlet air at 75°C. Tablet weight increases due to the coating process were in the range of 45% (B45 batch) to 60% (B60 batch). Mean lag times for in vivo disintegration in human volunteers after a light breakfast for the two batches were 204 ± 18 min and 345 ± 54 min, reflecting the impact of the coating thickness on disintegration times. Uncoated tablets showed complete disintegration in less than 20 min. Lag and disintegration times were unaffected by pH. Scintigraphic evaluation indicated that the in vivo behavior of TIME CLOCK did not influence the absorption of a model drug, salbutamol.

Dry-coated wax matrix tablets comprised of a table core with disintegrator and an outer layer compressed from pentoxifylline and behenic acid provided sigmoidal drug-release profiles with the high rate of drug release occurring during core tablet disintegration (23). The disintegration time decreases with increasing tablet core weight due to the concomitant reduced outer layer. A linear relationship was shown for time for 50% dissolution versus disintegration time for tablet cores ranging from 31 to 63% drug content, indicating that drug-release rate was controlled by tablet disintegration. Tablets composed of 70% amylodextrin and 30% paracetamol exhibited constant in vitro drug release in pH 6.8 buffer for approximately 8 h and relatively constant plasma paracetamol levels for 14 h in human volunteers (24). The amylodextrin tablets were apparently not hydrolyzed in vivo by α-amylase. Plasma levels on repeated dosing tended to decrease, apparently due to excretion of tablets prior to complete drug release and absorption. Wax microspheres of ibuprofen were examined, and it was shown that modifiers such as stearyl alcohol and glyceryl monostearate significantly increased the in vitro dissolution rate (20% w/w optimal) (25). Drug concentrations of 17% could be achieved in these microsphere formulations. Approximately 80–90% of the drug load was released within 12 h, indicating the potential application of wax microspheres for drug candidates with physicochemical properties similar to ibuprofen. Multiparticulate sustained-release theophylline formulations (26) comprised of spherical pellets (ethylcellulose–methylcellulose) coated with rate-controlling membranes of two different thicknesses (4.1 and 2.3% weight gain) afforded in

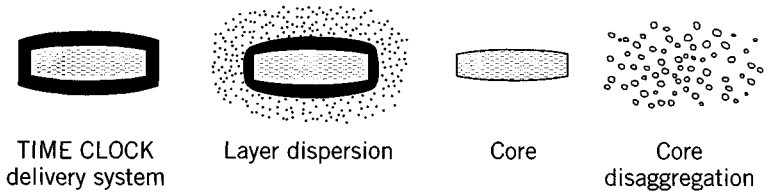

Figure 9. The working principle of the TIME CLOCK system. *Source:* Reprinted from Ref. 22, with kind permission of Elsevier Science–NL, Sara Burgerhartstraat 25, 1055 KV Amsterdam, The Netherlands.

vitro theophylline drug release that was independent of pH between pH 1 and pH 7. In vitro release was nearly complete within 5–8 h, while in vivo release was extended to 8–10 h. Although the rates of release varied with the two coating thickness, the extent of release was comparable and complete for both formulations, and the extent of theophylline absorption equated with that seen in solution dosing. Hydrophilic matrix tablets of felodipine, composed primarily of hydroxypropyl methylcellulose, were examined in human volunteers (27). In vitro disintegration and dissolution were linear over 8–10 h. In the human evaluation, felodipine absorption was related to tablet erosion as evinced by similarity between the in vivo erosion (as determined by γ-scintigraphy) and pharmacokinetic profiles.

Hydrophilic matrix tablets of zileuton, a 5-lipoxygenase inhibitor, were prepared by directly compressing hydroxypropyl methylcellulose and 50–60% zileuton (28). Wet granulations with water and low shear force were also used to compress tablets with magnesium stearate. In vitro release in USP I, II, and III methods was linear for 8 h. Sustained in vivo absorption in dogs was observed, which correlated with the in vitro release profiles although in vivo release was more rapid (release complete in approximately 4 h) than that noted in vitro. Prodan, a fluorescent marker, release from poly (D,L-lactic acid) (PLA) nanospheres coated with albumin or poly(vinyl alcohol) (PVA) was examined in vitro (29). In simulated gastric fluid where polymer degradation did not occur, release kinetics typified diffusion through the intact polymer matrix, with complete release within 120 min. In simulated intestinal fluid, release was dependent on the coating applied to the nanospheres. With PVA coating, the marker was released by diffusion through the PLA matrix, with only 44% released due to the marker's poor affinity for water. With an albumin coating, marker release was both matrix erosion and diffusion controlled with 100% release in 480 min.

A soluble oral controlled-release formulation regulated by both pulsatile and zero-order release kinetics has been described (30) that utilizes poly(ethylene oxide) and HPMC excipients with diclofenac in a three-layer matrix system (Fig. 10). In vitro dissolution studies suggested that both biphasic release and zero-order release kinetics up to 24 h could be achieved with this system. Dissolution and swelling/erosion are proposed to account for the linear portion of drug release, while disintegration and dissolution are mechanistically suggested for the burst phase. Hydroxyethylcellulose (HEC) has been utilized as a gel-forming matrix to prepare delayed release tablets of diltiazem hydrochloride (31). The tablets are cores of diltiazem surrounded by an outer shell of HEC of different viscosity grades. Diltiazem was rapidly released from all tablets after an initial lag phase, which was a function of the HEC coating. Lag time increased as the HEC viscosity increased. The lag time was not greatly affected by pH between pH 1.2 and pH 6.8. In a human volunteer study, T_{max} and mean residence time increased with increasing HEC viscosity with small intersubject variability. In vitro and in vivo lag times appear to exhibit a reasonable correlation. The diltiazem AUC did, however, decrease as the lag time increased. This approach for time delaying could represent a useful approach for drug candidates where an initial delay is appropriate.

Although it has clearly not been possible to elucidate and discuss the tremendous number of approaches that have been, and continue to be, developed for oral time-controlled drug delivery, the examples presented here should at least provide a sampling of the varied approaches that can be considered. Inherent in the selection of any time-controlled release technology has to be the physicochemical properties of the drug candidate, as this can determine or modify drug release from a given formulation, depending on the release mechanism. The intended therapeutic regimen is also critical in the selection process because the duration of drug release is obviously dependent on residence in the GI tract, and the absorption profile of a given drug may be different depending on the location within the GI tract.

Bioadhesives

The use of mucoadhesive polymers to improve oral drug absorption or the performance of oral controlled-release drug delivery systems has received considerable attention in the past 10–15 years and has been the subject of previous review articles (32,33). This interest has been generated with several goals in mind, including increasing local drug concentrations to improve absorption, retarding the transit of controlled-release dosage forms to take advantage of upper-GI absorption windows, or targeting drugs or dosage forms to specific regions of the GI tract for specific applications, such as antigen sampling by the M-cells of the Peyer's patches in the lower small intestine and colon. In every case, the successful application of bioadhesive technology is a balancing act between the creativity and expertise of the pharmaceutical scientist and the physiologic mechanisms of the GI tract that function to dilute, mix, and propel food substances in a proximal to distal direction in the GI tract.

In one potential application for bioadhesive polymers, the intrinsic permeability of the drug candidate is too low or the drug is susceptible to hydrolytic or enzymatic degradation in the lumen of the GI tract, either of which results in insufficient absorption of the drug candidate. In both instances, it has been felt that the ability to localize high concentrations of the drug candidate at the absorptive epithelial surface would increase the driving force and

thereby lead to increased levels of drug absorbed into the systemic circulation. The approach here has been attempting to link a mucoadhesive polymer to a drug candidate such that a selective attachment to the epithelial cells occurs and presents the drug candidate in high concentration and close proximity to the absorptive surface. To be therapeutically effective, the attached bioadhesive polymer must not interfere with the absorption or activity of the parent drug, or the linkage of the polymer to the active drug must be reversible such that the active parent drug is efficiently released, either at the epithelial surface or after absorption, and can exert its pharmacologic effect.

Another area of interest for bioadhesive polymers has been to retard the GI transit of controlled-release dosage forms for those drugs whose absorption is restricted to the upper regions of the GI tract, that is, absorption-window drug candidates. Some drugs have been clearly shown to be absorbed in specific regions of the upper GI tract, including chlorothiazide (33), riboflavin (34), and furosemide (35), and other drugs are likely to have specific preferred regions of absorption there. Additionally, for most drugs examined to date, it is generally felt that absorption in the colonic region is significantly lower than in the small intestine, probably because of differences in the lumenal contents of the colon that either impair the dissolution and diffusion of drugs from the lumen to the epithelial cell wall or impose additional degradative pathways, such as bacterial enzyme activity, that also decrease drug absorption. With this apparently common problem, controlled-release dosage forms whose release times exceed 5–6 h will likely exhibit a significant deviation in zero- or first-order kinetics owing to poor colonic absorption. To overcome this problem and extend the effective release time of controlled-release dosage forms, major interest has evolved in ways to prolong the upper GI residence time of controlled-release dosage forms such that a greater proportion of the drug load is released in an environment where reliable absorption can occur. Owing to the very high fluid content and mixing activity in the stomach, attempts to prolong gastric residence times via adhesive technologies have not been successful and will not be covered here. Rather, the focus will be on approaches that are being investigated to retard the small-intestine transit of small particulates where the balance of bioadhesion and physical forces in the GI tract offers some promise for success.

A final area of interest for bioadhesive technology has emerged from the advances in the biotechnology arena where biopharmaceuticals directed toward the gut-associated lymphoid tissues (M-cells in the Peyer's patches) are being developed for vaccination, immunization, and tolerance therapies. The M-cells are known as a preferred site for particulate uptake in the GI tract, and this mechanism has been proposed as a possible avenue for improving the absorption of particulate formulations, although it is not clear yet how effective this route will be for systemic delivery of drug candidates because the primary function of these cells is macromolecular sampling and degradation to feed the antigen-processing cells of the immune system. Regardless, bioadhesive polymers specific for M-cells, particularly lectins, have been evaluated as candidates for this approach.

A variety of bioadhesive molecules, particularly polymers, have been evaluated with varying results in terms of in vitro adhesive forces and in vivo efficacy. Polyanions with a high charge density, particularly those containing carboxylic acid groups, appear to exhibit the highest degree of bioadhesive properties. Mucoadhesive hydrogels have received the major share of attention and effort, from which polymers of poly(acrylic acid) derivatives (35), hyaluronic acid (36), and some chitosans (37) have demonstrated adhesive properties (Fig. 11). Linear cellulose polymers have not demonstrated effective in vivo bioadhesive properties, probably due to a lack of rigidity and structural integrity seen in hydrated, non-cross-linked polymers (38).

Akiyama and coauthors (39) reported on the preparation and evaluation of 177- to 500-μm-diameter polyglycerol ester fatty-acid microspheres composed of tetraglycerol pentastearate and tetraglycerol monostearate in which Carbopol 934P was either applied as a coating (CPC) or dispersed into the matrix of the microspheres (CPD). Carbopol 934P was chosen because of previously demonstrated bioadhesive properties (38,40). In an in vitro bioadhesion assay, more than 90% of the CPD microspheres adhered to gastric and small intestinal tissue, whereas only <10% of CPC and PGEF (similar composition without Carbopol 934P) microspheres showed adhesion. In an in vivo evaluation in conscious rats each receiving 100 PGEF and 100 CPD microspheres, the CPD microspheres showed significantly longer gastric retention time (T_s 50 = 1.8 h) and

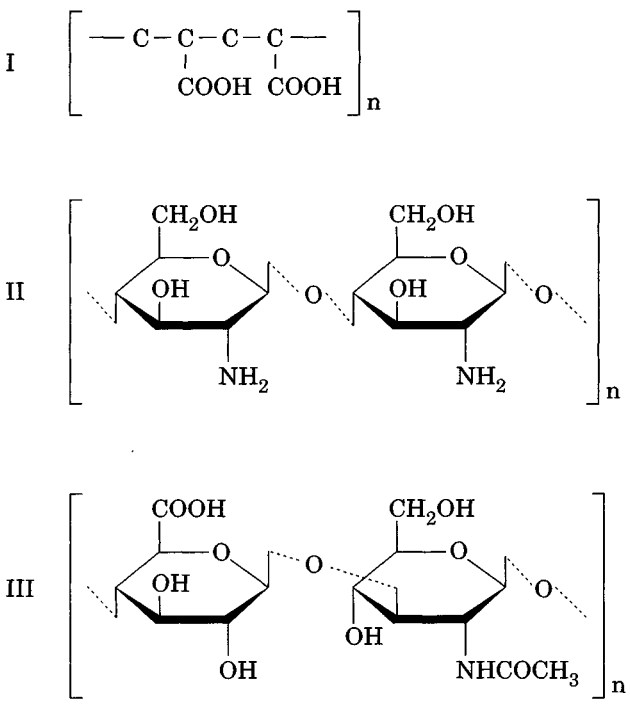

Figure 11. Polymers forming mucoadhesive hydrogels: I, poly(acrylic acid); II, chitosan (poly[D-glucosamine]); III, hyaluronic acid (poly[D-glucuronic acid-*N*-acetylglucosamine]). *Source:* Reprinted from Ref. 32, with kind permission of Begell House, Inc., New York.

a longer transit time to the colon ($T50$ = 7.3 h) than that observed with PGEF microspheres (T_s50 = 0.5 h and $T50$ = 4.9 h). The mean residence times of the CPD microspheres in the stomach and three sequential small-intestine regions were also significantly greater for CPD microspheres than for PGEF microspheres, although small-intestine transit was not delayed as significantly as gastric residence time. The potential mechanism proposed by the authors (Fig. 12) suggests that the bioadhesive properties of CPD microspheres (when compared with PGEF or CPC microspheres) are caused by the partial extrusion of gelled polymer from the matrix dispersion, which allows the bioadhesive properties of Carbopol 934P to "anchor" the microspheres to the mucosa. PGEF microspheres did not contain a bioadhesive polymer, and the coated CPC microspheres formed an overhydrated surface gel that separated from the microsphere and would not serve to anchor the microsphere to the mucosal surface. Regardless of the mechanism, the in vitro and in vivo characterizations of the dispersed Carbopol 934P polyglycerol ester fatty-acid microspheres suggest this approach may provide limited advantages in terms of increasing the residence time of a microsphere formulation in the upper small intestine.

Hosny (41) evaluated polycarbophil diclofenac sodium tablets and compared their in vitro and in vivo performance to a commercially available enteric-coated preparation (Voltaren). Directly compressed tablets were prepared from polycarbophil (0.2- to 0.3-mm or 0.5- to 0.8-mm particle size) and diclofenac sodium. Release testing was conducted with USP dissolution apparatus I. Voltaren tablets did not release measurable drug during 2 h at pH 1.2 owing to the enteric coating. The bioadhesive tablets released approximately 9–12% of the drug content under similar conditions. On increasing the pH of the dissolution media to 6.8, complete drug release was seen in approximately 1 h for Voltaren and 0.5 and 2.0 h for small- and large-particle-size bioadhesive tablet formulations, respectively. Comparing the in vivo performance of Voltaren tablets and the bioadhesive tablets in a fasted dog model (n = 6) indicated no significant differences between any of the formulations in terms of C_{max}, T_{max}, and AUC. The equivalent pharmacokinetic performance of the bioadhesive tablets to enteric-coated Voltaren shows that the bioadhesive tablets may be a reasonable alternative to the enteric-coating approach. Previous work (42,43) had shown that a similar formulation with indomethacin was less irritant to gastric and intestinal mucosa, presumably owing to cross-linking between the polycarbophil and the mucosal surface, which creates a protective environment on the underlying cell layers.

Eudragit RL-100 (ERL) has been shown to be able to affect the swelling property, mechanical properties, and bioadhesive nature of polycarbophil compressed tablets (44). All compositions of ERL and polycarbophil exhibited a lower degree of swelling in pH 5 buffer as compared to pH 7.4 buffer, but in all cases, increasing amounts of ERL significantly decreased swelling relative to pure polycarbophil films. As the amount of ERL increased relative to polycarbophil, the mechanical properties (torsion force and modulus of elasticity) also increased, indicating that it was possible to formulate ERL–polycarbophil mixtures with acceptable mechanical properties for withstanding the external forces present in the GI tract and provide sufficient physical integrity to tablets in vivo. By balancing the ratios of ERL and polycarbophil, it was possible to achieve linear and comparable in vitro release rates for sodium cefazolin (highly water soluble) and ibuprofen (poorly water soluble). Sodium cefazolin could be expected to possess a significant diffusive component to its release profile given its high water solubility, while the release of poorly soluble ibuprofen would necessitate an erosion process because little aqueous diffusion would be expected. The fact that the sodium cefazolin and ibuprofen releases were nearly identical (Fig. 13) demonstrated that balancing the ratios of ERL and polycarbophil could be achieved in such a manner that the release profiles were identical for two compounds of very different physicochemical properties. The bioadhesive properties of ERL–polycarbophil tablets were evaluated with an in vitro model utilizing intestinal tissue from various regions of the rat GI tract and indicated a preferential bioadhesion to tissue from the cecum (Fig. 14). The combination of ERL and polycarbophil evaluated in this study indicated that tablets could be obtained that allowed designed control of release rates for both water-soluble and water-insoluble compounds, had adequate mechanical properties, and exhibited a preferential bioadhesive potential for cecal tissue of the rat. The potential of this application, particularly the bioadhesive activity and specificity for cecal tissue, requires confirmation in large animal models or human clinical studies.

Lectins are proteins that possess an affinity for binding to specific sugars and therefore have been shown to bind to the mucous and epithelial cells layer of the GI tract (45,46). Irache and colleagues have covalently coupled various lectins to latex particles (826–956 nm diameter) and evaluated their mucoadhesive properties with an in

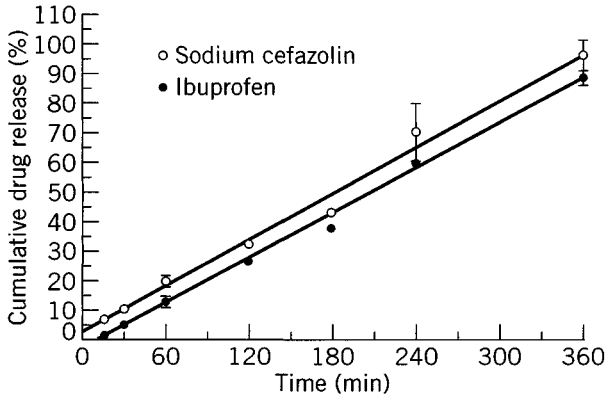

Figure 13. The release kinetics of sodium cefazolin and ibuprofen from CEF/IBU tablets, demonstrating similar release rates of the highly soluble (sodium cefazolin) and the sparingly soluble (ibuprofen) drug molecules from the erodible matrices. vitro intestinal tissue model (47). Control BSA–conjugated latex particles possessed only minimal bioadhesive properties. The results obtained with tomato lectin (TL), asparagus pea lectin (AL), and bacterial adhesin (ML) demonstrated tissue specific responses. Latexes prepared with TL showed greater affinity than AL or ML for the mucous glycoproteins of non–Peyer's patch tissue. In contrast, both AL– and ML–latex conjugates demonstrated higher affinity for the Peyer's patch region of the intestine than did TL–latex conjugates. This difference could form the basis for selection of lectin-targeted formulations to target different regions of the GI tract. With all latex conjugates, the mucoadhesive properties decreased with distal distance down the GI tract, probably reflecting decreasing amounts of mucous glycoproteins in the direction from duodenum to ileum. Additional studies with tomato lectins confirmed these observations by demonstrating a specificity of tomato lectin–conjugated nanoparticles for absorptive epithelial cells rather than cells of the gut-associated lymphoid tissue (48). Fluorescent 500-nm polystyrene nanoparticles were covalently coupled with tomato lectin through a carbodiimide reaction and administered to rats on a daily oral gavage regimen. The results of this study (Fig. 15) clearly demonstrate a significant increase in tomato lectin–nanoparticle uptake when compared to uptake of control nanoparticles.

A high degree of species and intestinal site specificity has been shown in the binding of lectins to tissues from mouse and rabbit intestine. M-cells from mouse Peyer's patches have been shown to have a binding affinity for α-L-fucose–specific lectins (49). This specific binding was not found in Peyer's patches from rabbit small intestine, although strong binding was seen in rabbit cecal lymphoid patches. Sugar specificities between mouse and rabbit tissue were also observed for peanut agglutinin, wheat germ agglutinin, and *Bandeiraea simplicifolia* agglutinin II. These observations, although not involving pharmaceutical preparations, indicate that a concern must be noted when extrapolating experimental results from one species to another and from one tissue type to another in the same species.

Mathiowitz and coworkers have prepared and evaluated a number of polymeric approaches to bioadhesive oral formulations. Initial evaluations included developing and utilizing a microbalance-based system to quantitate the bioadhesive forces of various polymeric microspheres (50,51). The results from these early in vitro evaluations indicated that (poly)fumaric-*co*-sebacic anhydride polymers, which rapidly degrade, afforded the strongest bioadhesive interactions with rat small intestinal tissue of the polymers tested. The proposed mechanism of adhesion is the generation of carboxylic acid groups during degradation, which increases the potential for hydrogen bonding to mucus and epithelial glycoproteins. Alginate microspheres were also shown to possess significant in vitro adhesive properties. Subsequent to the in vitro selection of

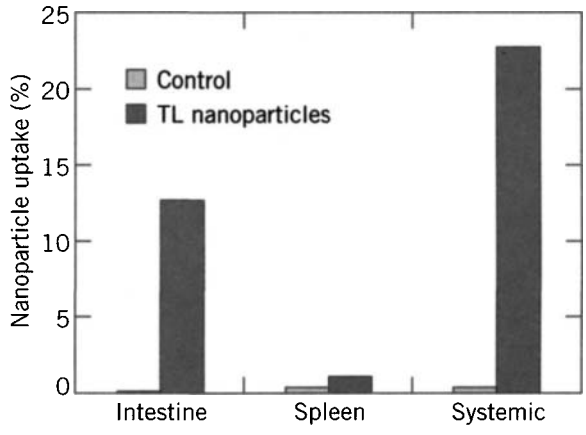

Figure 15. Oral uptake of tomato lectin–conjugated (TL) and blocked nanoparticles (500 nm) as a function of total dose administered and organ weight. *Source:* Reprinted from Ref. 48, with kind permission of Plenum Publishing Corporation, New York.

these two polymers, in vivo evaluations were carried out in a rat model to determine whether the in vitro adhesive properties translated into an advantage that could be exploited in vivo in the development of oral drug delivery systems (52). Alginate microspheres were prepared by blending dissolved alginate and dicumarol or radioopaque marker and pumping droplets into a calcium chloride bath. Microsphere size range from 600 to 850 μm for radioopaque-loaded microspheres and <212 μm for dicumarol-containing microspheres. A phase inversion microencapsulation technique was used to prepare polyanhydride microspheres. Briefly, polymer and dicumarol were dissolved in an appropriate solvent (methylene chloride), and the solution was poured into a strong nonsolvent (petroleum ether) that was miscible with the solvent. Microspheres were spontaneously formed whose size ranged from 0.5 μm to 5 μm. The phase inversion microencapsulation techniques avoided the need to utilize a hot-melt procedure (with temperatures around 100°C), which can have significant limitations in terms of drug stability. Compatibility with an organic solvent, for example, methylene chloride, still has to be taken into consideration. The polyanhydride microspheres were at a fumaric acid/sebacic acid ratio of 20:80, P(FA:SA)20:80. The GI transit of barium-loaded microspheres was evaluated in a rat model in which fasted rats received approximately 200 mg of barium-loaded microspheres by stomach gavage in 0.9% sodium chloride. Transit of particles was quantitated by X-ray techniques, and the results (Fig. 16) indicated the P(FA:SA)20:80 microspheres had a significantly slower GI transit than the alginate microspheres. Pharmacokinetic analysis of dicumarol (6.5 dicumarol in 40-mg microspheres) plasma levels also demonstrated that improved absorption of dicumarol was achieved with the P(FA:SA)20:80 microspheres relative to spray-dried dicumarol (Fig. 17). The plasma AUC for P(FA:SA)20:80 dicumarol microspheres was 363 ± 100.3 μg/h/mL compared to 232 ± 38.4 μg/h/mL and 211 ± 30.3 μg/h/mL for spray-dried dicumarol and alginate dicumarol microspheres, respectively. These data are highly encouraging with respect to potential utility for developing effective oral delivery technologies based on bioadhesive principles. However, it should be noted that the dose of microspheres employed in the GI transit studies, 200 mg per rat, is quite high and may or may not be reproducible in larger animal models or humans where the formulation mass relative to GI dimensional parameters may not favor such an intimate and highly concentrated contact of bioadhesive microspheres with the GI mucosal cell layer.

In addition to their potential utility in localizing drug or particulate formulations at the mucosal surface of the GI tract, several bioadhesive polymers have also been shown to possess activity with regard to inhibiting degradative enzyme activity and modifying the barrier function of the epithelial cell layer. This mixed function activity of the bioadhesive polymers offers an opportunity to coordinate both formulation localization and biological effects of a single formulation component.

Polycarbophil and carbomer have been shown to inhibit trypsin enzymatic activity in a calcium-dependent manner (53). Both poly(acrylic acid) derivatives are known to bind divalent cations in the undissociated state. Utilizing 0.35% (w/v) polycarbophil or 0.25% (w/v) carbomer in an in vitro incubation experiment, trypsin activity was inhibited approximately 93%, calcium was depleted to 10–15% of its original content, and free protein concentration was decreased approximately 30–40% (indicating the bioadhesive potential of polycarbophil and carbomer toward proteins).

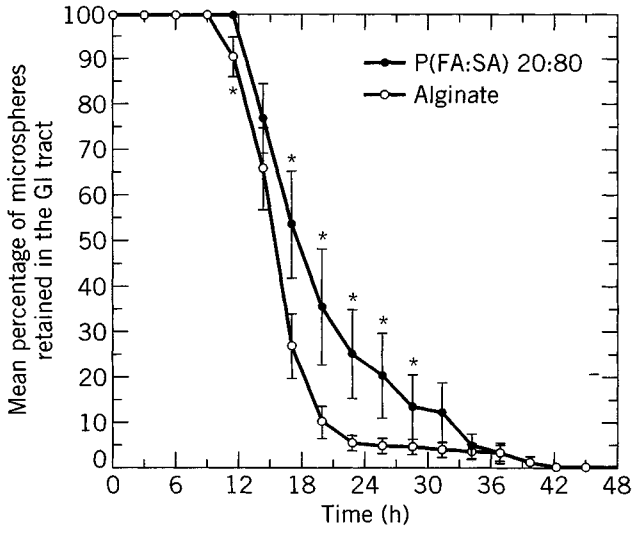

Figure 16. Percentage of microspheres retained over time. Paired, one-tailed *t*-tests were performed on the raw data, and those time points with percentages statistically different ($P \leq 0.05$) from each other are represented by asterisks (*). Carbomer, which has a higher binding affinity for calcium than polycarbophil, also was able to inhibit trypsin activity at lower concentration than polycarbophil, indicating a relationship between calcium-binding activity and enzyme inhibition. This is consistent, considering the important role of calcium in maintaining the thermodynamic stability of trypsin (54).

The enzyme inhibitory activity of polycarbophil and carbomer were also examined with a variety of peptide substrates (55). Employing brush-border membrane vesicles (BBMVs) obtained from the entire small intestine of rats, the capacity of polycarbophil (0.1–0.5%) and carbomer (0.1–0.5%) to inhibit the enzymatic degradation of buserelin, 8-arginine vasopressin (DGAVP), metkephamid, L-pyroglutamic acid *p*-nitroanilide (PGNA), hippuryl-L-arginine (Hipp-Arg), and insulin was determined. Because BBMVs were utilized as the biological system, only enzymes associated with brush-border membranes are evaluated by this method. Buserelin degradation was not affected by either carbomer or polycarbophil. Polycarbophil and carbomer were only weakly effective in inhibiting degradation of DGAVP and Hipp-Arg at the highest concentration (0.5%) tested. Insulin, which only exhibited an approximate 10% degradation by BBMV enzymes with 240 min, was slightly protected by 0.25% carbomer. Overall, the data indicate that carbomer and polycarbophil are only very weakly protective against brush-border enzyme activity isolated from rat GI tissue. Polymers with a stronger affinity for divalent cations could afford an advantage in terms of inhibiting BBMV enzyme activity.

In addition to the bioadhesive and enzyme inhibitory potential of some of the polymers utilized in the aforementioned studies, there are also data to indicate that these polymers may also be capable of modifying the barrier properties of epithelial cells in a manner that increases drug flux. Carbomer (0.5 and 1.5% w/v) and chitosan (0.5, 1.0, and 1.5% w/v) were evaluated for their effects on electrical resistance (TEER) and drug flux utilizing an in vitro Caco-2 cell monolayer derived from a human colon carcinoma cell line (56). TEER was significantly decreased to approximately 40–50% of the original resistance by both polymers but only at the highest concentration tested. If the polymer solutions were replaced with fresh buffer, TEER recovery was observed to occur (65% for carbomer and 88% for chitosan of original TEER), indicating that the change in resistance was not due to irreversible damage to the cell layer. Chitosan–glutamate at 1.5% did not increase mannitol flux over a 150-min incubation period, whereas 1.0% carbomer afforded a 2.7% flux of mannitol over a 120-min period. It should be noted that drug flux in this in vitro model is not directly proportional to what could be anticipated in vivo. In fact, an in vitro flux of 2.7% in 120 min would likely translate into a rather more significant in vivo absorption level. Carbomer was also found to significantly enhance the in vitro flux of FD-4 (FITC-dextran, M_W 4,000). Confocal fluorescence microscopy provided evidence that carbomer was loosening the tight junction structure of the epithelial cell layer and providing an aqueous pathway for molecule movement between cells of the monolayer. The affinity of carbomer for divalent calcium may account for its effect on tight junction structure because calcium depletion has been shown to open tight junctional pathways of epithelial cell monolayers.

Several polymers and polymer systems have been described that possess varying degrees of bioadhesive potential. Most of the data generated to date has involved in vitro evaluations and, in some instances, evaluation in small animal models, for example, rats. The practical utility of bioadhesive approaches for oral drug delivery will obviously depend on demonstrating a similar performance and efficacy in larger animal models and human clinical studies. The particular intriguing feature of some of the polymers employed, particularly the polyacrylate types as carbomer, is that they possess multiple functional capabilities, including a bioadhesive potential, enzyme inhibitory activity, and some membrane permeation–enhancing activity. These multiple effects may afford particular advantages to utilizing these systems for oral controlled drug delivery. Finally, the data and interpretations from several investigators would suggest that the potential for bioadhesive properties may be optimal in the lower GI tract where the epithelial mucus layer is thinner and there is at least a somewhat reduced state of fluid content and muscle contractility. It remains to be demonstrated that the mucoadhesive approaches evaluated here will have a practical utility in the upper GI tract.

pH Sensitivity

Controlled-release technologies based on pH-sensitive control mechanisms are designed to release acidic or basic drugs in the GI tract at a rate that is not dependent on the pH of the GI fluids, which can vary from pH 1.2–3.5 in the stomach to pH 6.0–7.5 in the lower small intestine. The general principle underlying this technology is the incorporation of an acidic (or basic) drug and appropriate buffering agents as a core granulation. These particles can then either be coated with a fluid-permeable membrane that allows influx of GI fluids, or the particles can be uniformly dispersed in a tablet core that serves a similar function. In either application, the influx of fluid from the GI tract dissolves the buffering agents and provides a microclimate pH within the formulation that regulates the rate of drug release. Ideally, the rate of drug release should be independent of the pH of the GI fluid being imbibed.

Sutinen et al. have reported on the development of pH-controlled silicone microspheres for controlled drug delivery (57). Silicone microspheres were prepared with an amine-resistant Dow Corning X7-3012 silicone elastomer. Monosodium phosphate, disodium phosphate, trisodium phosphate, and tris(hydroxymethylaminomethane) were used as potential buffering agents. Using timolol maleate as a model drug, spray-dried mixtures of timolol with and without varying compositions of buffering agents were prepared and mixed with the silicone elastomer. Spray-drying timolol and buffers together proved most effective, as opposed to mixing timolol and buffer that had been spray-dried separately, because the drug and buffer were localized in the same particle within the silicone elastomer microsphere. Spray-dried timolol particles were approximately 3 μm and incorporated into the silicone microspheres at a 30 wt % loading (loaded microsphere diame-

ter, 143–301 μm). Without added buffering agents, timolol release was relatively slow, showing less than 20% release in 11 h. When trisodium phosphate was incorporated in the microsphere preparation, the timolol release rate was increased 3.3–8.2 times greater than nonbuffered microspheres. Release of timolol from the silicone microspheres followed square-root-of-time kinetics, which is typical of a matrix-controlled dissolution process (58). The rate of timolol release was directly proportional to timolol loading (wt %), basic nature of the added buffer, and the loading level of the buffer (10–25%). This reflected a higher proportion of timolol in the unionized state, which could more readily partition through the silicone matrix and be released in the dissolution medium. As the strength of the buffering agent increased, not only did the timolol release rate increase but the release rate also became independent of the pH of the dissolution medium (Fig. 18). These studies indicated the potential utility of silicone-type elastomers as components for developing pH-sensitive oral controlled-release systems.

Methacrylic acid copolymers (Eudragit, Rohm GmbH) have been utilized as pH-sensitive polymers in oral drug delivery. A peptide analog inhibitor of HIV-1 protease (CGP 57813) has shown increased bioavailability in mice when administered as a pH-sensitive polymeric nanoparticle formulation (59). Similar results have been recently reported in a dog oral bioavailability study (60). Nanoparticles (245–264 nm) were prepared from poly(methacrylic acid-*co*-ethylacrylate) with a 1:1 molar monomer ratio (Eudragit L100-55) or poly(methacrylic acid-*co*-methylmethacrylate) with a 1:2 molar monomer ratio (Eudragit S100). The Eudragit L100 nanoparticles were soluble above pH 5, and the Eudragit S100 nanoparticles were soluble above pH 7. Aqueous suspensions of CGP 57813 in an amorphous form were used as controls for oral dosing studies in dogs and showed no detectable plasma levels of the drug. Significant increases in CGP 57813 bioavailability were observed in the dog oral dosing study (Fig. 19) that were both polymer and food dependent. With both polymers, bioavailability

was greater in the fed state than the fasted state, possibly reflecting a slowing of GI transit, allowing more efficient nanoparticle dissolution and drug absorption. S100 nanoparticles showed a greater effect on CGP 57813 bioavailability in dogs than did L100 nanoparticles, which is in contrast to results previously observed in mice. This discrepancy in results may be related to species-specific differences in GI pH and is a factor that requires further evaluation to predict the performance of these systems in a human clinical application. The results of this study do indicate, however, that pH-sensitive polymers that dissolve above pH 5.5 may be useful as controlled-release polymers for oral administration.

Narisawa et al. also employed Eudragit coatings in a pH-sensitive bead formulation to develop a sigmoidal release system (SRS) (61). Uncoated drug beads were prepared from a powder mixture of drug and sucrose or drug and succinic acid using a CF granulator. After applying the powder mixture to nonpareil seeds with continuous binder spray, the resultant beads were spray-coated with Eudragit RS 30D, talc, triethylcitrate, and water. The beads were approximately 1,100 μm in diameter, with a 90-μm coating film. Utilizing sucrose instead of succinic acid in the initial bead preparation led to beads from which the release of a model drug was dependent on the coating thickness and followed first-order (10% coating) or zero-order (15% or 20% coating) kinetics without a significant lag period. At 30% coating, there was little or no drug release. Conducting the dissolution studies in various organic acid media demonstrated that drug release was significantly increased in the presence of an acidic medium, with succinic acid providing the most dramatic increase in drug release. Incorporation of succinic acid into the bead formulation converted the release profiles to a sigmoid shape characterized by an initial lag phase that was followed by a rapid increase in drug release. The duration of the lag phase

could be controlled by the thickness of the applied coating, but the release phase at a fixed succinic acid level was extremely constant after the lag delay. An evaluation of this bead formulation with acetaminophen as a model drug was evaluated in an oral dosing study in dogs (Fig. 20) and indicated that the lag and release phases observed in vitro were confirmed in vivo.

Polymer beads that are pH sensitive and thermally responsive have also been studied. The strategy employed with these systems is based on the fact that the polymer blends will not solubilize at gastric pH levels and the incorporated drug will be protected during residence time in the stomach. Linear terpolymers of (poly[*N*-isopropylacrylamide-*co*-butylmethacrylate-*co*-acrylic acid]) were fabricated into beads loaded with human calcitonin, an enzymatic labile peptide (62). The polymer becomes soluble in the vicinity of neutral pH and can thus release drug once in the small intestine. Higher loading of calcitonin was attained with increasing content of acrylic acid (hydrophilic polymer). Polymer beads with 7 and 10% acrylic acid achieved approximately 50% calcitonin loading with 85% drug release in 4 h at pH 4.5 (compared with 15% calcitonin loading and 15% drug release under similar conditions). The released calcitonin was apparently not aggregated into fibrillar structures because it could be isolated from the dissolution media and used in a rat intramuscular injection study to show the expected changes in plasma calcium levels. The ability to achieve high loading capacity and rapid release in a pH-responsive manner could provide a useful basis for developing this system into an effective oral controlled-release system. A somewhat similar system has been reported using theophylline as a model drug with polymeric nanobeads prepared from poly(*N*-isopropylacrylamide-*co*-methacrylic acid) with *N,N'*-methylenebisacrylamide as the cross-linking agent (63). Particle size ranged from 114 to 413 nm depending on polymer composition and experimental temperature (decreasing size with increasing temperature at a fixed polymer composition). Volume-phase transitions of polymer lattices demonstrated clear dependence on polymer composition, temperature, and ionic strength. Regulation of volume changes and drug loading can be achieved by varying these parameters and can be envisioned to provide a rational basis for designing pH-sensitive controlled-release strategies for oral administration.

Gelling polymers have also been utilized with or without rate-controlling coatings to effect controlled release of active agents. Typically, water-soluble drugs are released by diffusion of dissolved drug across the gel layer, whereas poorly soluble drugs are primarily released via a surface erosion mechanism. Matrices incorporating alginate salt or a combination of salts have been utilized with several drugs (64–66). Sodium alginate is a high-molecular-weight linear random copolymer of D-mannuronic acid and L-guluronic acid residues. Below pH 3, alginic acid is insoluble but forms a swellable polymer. At or above neutral pH, sodium alginate is soluble and hydrates to form viscous solutions. Because of the pH dependence of alginate hydration and rheology, pH-dependent controlled-release formulations can be designed that afford varying release rates depending on the water solubility of the incorporated drug. Tablets prepared from 49% sodium alginate, 20% drug, 30% lactose, and 1% magnesium stearate can be manufactured by direct compression of the blend and have been shown to provide pH-dependent drug release (67). When chlorpheniramine maleate, a highly water-soluble drug, was prepared in this matrix, the release rate was significantly higher in simulated gastric fluid (pH 1.2) than in simulated intestinal fluid (pH 7.5). Incorporation of hydrochlorothiazide, a poorly soluble drug, afforded the opposite results, that is, release was faster at pH 7.5 than at pH 1.2. The differences in release rates for very soluble and poorly soluble drugs at different pH levels were attributed to differences in the internal microscopic structure of the

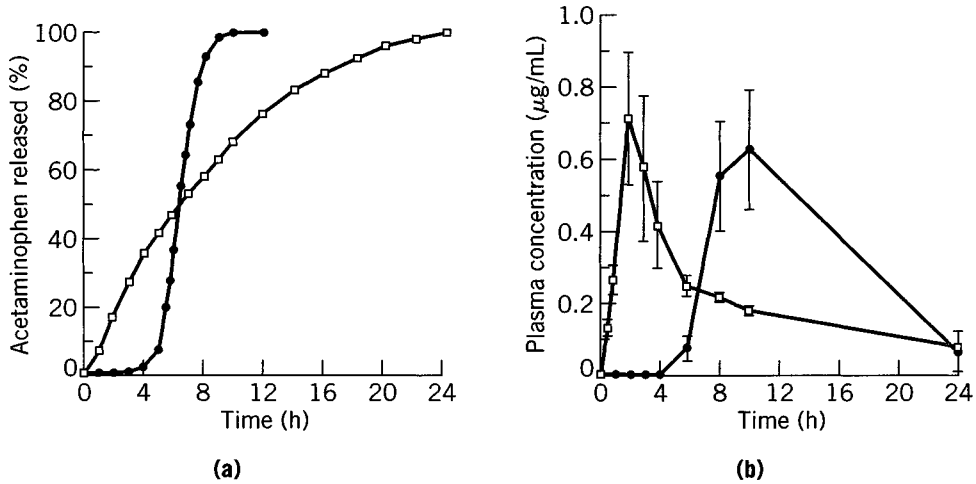

Figure 20. Release profiles in water (**a**) and plasma concentration-time profiles (**b**) of acetaminophen following oral administration to beagles of EC-coated beads or SRS with the same T_{50}. Preparations: (□) EC-coated beads (4% coating); (●) SRS (70% coating). *Source:* Reprinted from Ref. 61, with kind permission of Plenum Publishing Corporation, New York.

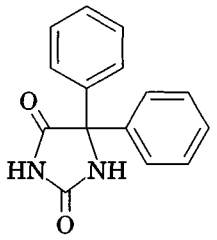
hydrated surface layer and the different hydration kinetics in the two pH conditions. At low pH, alginate matrices formed a particulate and porous gel medium, which could account for the very rapid release of highly water-soluble drugs through aqueous pathways. This same particulate hydrated layer observed at low pH, however, also exhibited strong mechanical properties that were much more resistant to surface erosion than the continuous gel that is formed at pH 7.5. The resistance to surface erosion at low pH can explain the slow release of poorly soluble drugs at low pH because the release of poorly water-soluble drugs from a hydrated gel matrix generally relies on surface erosion processes rather than diffusion.

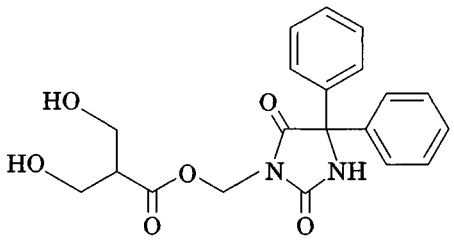
pH-responsive gelatin microspheres have also been prepared by coating glutaraldehyde–cross-linked gelatin and applying either alginate or chitosan coatings (68). Chitosan is deacylated chitin and a linear, cationic polymer of 2-amino-2-deoxy-β-D-glucan that is soluble in dilute acid. Alginate is a linear, anionic polymer that is soluble at higher pH values. Cross-linked methotrexate gelatin microspheres of various particle sizes were prepared and coated with either alginate or chitosan. Nearly zero-order methotrexate release could be obtained that was inversely proportional to particle size and coating thickness. Alginate-coated microspheres afforded slower release rates in simulated gastric fluid than in simulated intestinal fluid, whereas chitosan coated microspheres gave the opposite result. As such, alginates coatings could be utilized to prolong drug release in acidic environments (for example, the stomach), whereas chitosan coatings could provide the same control in neutral or basic environments (for example, the intestine). The results from these studies, however, were of questionable utility because the release profiles generally extended over a period of days rather than hours. Although microsphere coatings that exhibited pH selectivity could be selected, the eventual practicality of the approach requires developing particles and coatings that provide release rates more consistent with the gastric and intestinal residence times that oral formulations normally experience.

The examples provided in the preceding paragraphs indicate the potential utility of pH-sensitive controlled-release systems. As indicated, the performance of these systems is determined by the effects of GI pH changes on the components of the dosage form and the incorporated active drug. Further optimization and development of this approach is required to lead to effective oral controlled-release systems that can be manufactured to perform in a reliable fashion.



Prodrugs

Many potential therapeutic candidates do not possess satisfactory physicochemical properties to be viable candidates for oral drug delivery, either as immediate-release formulations or through controlled-release technology. The limitations can be related to solubility, stability, aggregation tendency, and intrinsic membrane permeability. These factors, either alone or in combination for some drug candidates, can render the candidate ineffective as an orally administered drug. The general strategy of prodrug technology, which has been known and practiced for decades, is to synthesize a chemically modified version of the parent drug that overcomes the inherent problem in the ability of the drug to be adequately absorbed. For instance, a drug may be too hydrophilic to partition into biologic membranes. If a prodrug can be synthesized that modifies the parent drug partitioning behavior appropriately, then flux across a biologic membrane can be achieved. Inherent in this whole approach is the aspect that the prodrug must be readily reversible to the parent drug, either by hydrolytic or enzymatic mechanisms, and that the regenerated parent drug must retain its intrinsic pharmacologic activity. An additional item that has to receive careful attention is the potential pharmacologic or toxicological activity of the prodrug moiety. Because the prodrug moiety will be released in the in vivo setting after cleavage of the prodrug to the parent drug and prodrug moiety, the potential exists for either unwanted pharmacologic effects or undesired adverse effects due to the prodrug moiety itself. If the prodrug moiety is a chemical entity that has not been proven to be safe, then regulatory issues concerning additional required safety studies also become a factor. The prodrug itself, given that it will likely have to exist in the prodrug form for a discreet amount of time after administration, will also be subject to both pharmacologic and toxicological scrutiny in the development and regulatory cycles. Prodrug strategies have been frequently attempted to improve the absorption of poorly absorbed drug candidates. In some cases, such as sulindac sulfide, poor water solubility has limited absorption from oral formulations. Sulindac, which is a prodrug of sulindac sulfide with improved water solubility compared to sulindac sulfide, was developed to reduce GI toxic reactions but also demonstrated improved bioavailability (69,70). Improving aqueous solubility does not, however, ensure improved bioavailability of drug candidates. Absorption across biological membranes requires a certain degree of lipophilicity and the creation of very aqueous soluble prodrugs can, in fact, reduce membrane transport if a proper hydrophile/lipophile balance is not attained. In many cases, in fact, lipophilic prodrugs have been created to improve absorption of polar drug candidates including clindamycin (71), erythromycin (72), cefotiam (73), and ampicillin (74). The ester prodrugs of ampicillin, namely bacampicillin, pivampicillin, and talampicillin, show improved bioavailability compared to ampicillin and rapid reconversion via ester hydrolysis. Within the scope of this text, it is not practical to review all of the prodrug approaches that have been evaluated for a rather long list of potential drug candidates to which they have been applied. What will be attempted is a review of several approaches to provide a background for what may be achievable with prodrug approaches to oral controlled-release technology.



Phenytoin is an anticonvulsant with poor bioavailability that is most often attributed to poor water solubility. A number of investigators have evaluated various prodrugs of phenytoin, including fosphenytoin, which increased water solubility nearly 5,000-fold (75). A glyceride-derived prodrug of phenytoin has also been synthesized (76) and evaluated both in vitro (77) and in vivo (78) for its applicability as a phenytoin prodrug that can overcome the in-

herent poor oral bioavailability of phenytoin itself. Direct esterification of 3-hydroxy-2-hydroxymethylproprionic acid (bis-hydroxyisobutyric acid) with 3-hydroxymethylphenytoin yielded the test prodrug, phenytoin-bis-hydroxyisobutyrate as shown in Figure 21. The pharmacokinetic profile and pharmacologic activity of phenytoin-bis-hydroxyisobutyrate were evaluated in rat models. Both phenytoin and the phenytoin prodrug were orally administered to rats as oral suspensions in 0.5% methyl cellulose. Pharmacokinetic analysis based on plasma phenytoin levels indicated that the prodrug afforded an earlier T_{max} (0.74 ± 0.1 h versus 1.25 ± 0.5 h), a higher C_{max} (5.25 ± 0.99 μg/mL versus 1.90 ± 0.11 μg/mL), and a larger AUC (28.5 ± 4.2 μg.h/mL versus 10.0 ± 1.1 μg/h/mL) than that observed following administration of the parent drug, phenytoin. The plasma half-life of phenytoin was not significantly altered. Measurable quantities of the prodrug were not identified in the plasma samples. Phenytoin-bis-hydroxybutyrate was found to be equipotent with phenytoin following ip administration but more active than phenytoin following oral dosing in rats (based on the maximal electroshock test). Toxicity was not observed for the prodrug. The temporal profile of the anticonvulsant activity of phenytoin-bis-hydroxybutyrate was consistent with its pharmacokinetic profile, suggesting that the improved pharmacologic activity of the prodrug is due to its improved bioavailability relative to phenytoin itself.

Morpholinoalkyl esters (HCl) salts of naproxen and indomethacin (Fig. 22) were synthesized and evaluated with both in vitro and in vivo models (79). Both parent compounds are poorly water soluble ($<5.9 \times 10^{-5}$ M/L in simulated gastric fluid and $<6.7 \times 10^{-3}$ M/L in pH 7.4 phosphate buffer) and are known to present issues with regard to a tendency to cause local tissue irritation. Aqueous solubility of prodrugs of both naproxen and indomethacin increased over 2,000-fold in both simulated gastric fluid and phosphate buffer. The pK_a values increased from a range of 4.2–4.5 for the parent drugs to 6.9–8.6 for the prodrugs. The prodrugs were more lipophilic at pH 7.4 but less lipophilic at pH 1.3 when compared with the parent drugs. As the carbon chain length was extended between the ester function and the morpholino function, stability in pH 7.4 buffer increased, while stability in pH 1.3 buffer decreased. The prodrugs of naproxen and indomethacin had half-lives in rat plasma of 1.1–4.1 min and 20.4–31.5 min, respectively. Based on an analysis of in vitro properties, naproxen and indomethacin prodrugs with a 4-carbon spacer were evaluated in a rat model for absorption kinetics and tissue irritation. When dosed to rats as an equimolar gavage solution, prodrugs of naproxen and indomethacin were 33.73 ± 8.4% and 34.3 ± 3.4% more bioavailable, respectively, than the corresponding parent drug. Using a ranked recording scale for tissue irritation or damage, both prodrugs were found to be less damaging than the parent drugs on both acute and chronic dosing regimens. These data indicated that the morpholino prodrugs of naproxen and indomethacin showed improved stability in gastric fluid, improved solubility at small-intestine pH, rapid in vivo conversion to the parent drug, and were more bioavailable and less irritating than the parent compounds. As such, this prodrug approach may be applicable to compounds similar to naproxen and indomethacin for oral delivery systems.

Another prodrug approach to indomethacin has utilized a triethylene glycol indomethacin ester (TIE) (80,81). The plasma half-life of TIE was 11.55 min in rat plasma with complete reversion to the parent drug, but it should be pointed out that this is significantly shorter than the half-life observed in human plasma, which was 3.8 h. Pharmacokinetic analysis of TIE prodrug indicated that in contrast to that observed with the morpholino ester prodrug (79), the relative bioavailability and time to C_{max} for TIE was less than that observed with indomethacin alone. The plasma profile was, however, significantly extended over that seen with indomethacin itself, which could indicate slower and more prolonged absorption or a partitioning into and slow release from a tissue compartment. Although the plasma profile of indomethacin was lower and more prolonged than indomethacin itself, the prodrug did not show an ulcerogenic potential, which could make this approach useful in spite of a lack of improvement in systemic bioavailability.

Phosphomonoester products of primary alcohols and unhindered phenols have shown good chemical stability and rapid enzymatic hydrolysis in vivo but exhibit a slow rate of conversion with sterically hindered secondary and tertiary alcohols (82,83). In an attempt to overcome this problem, an oxymethyloxycarbonyl spacer group has been utilized as a less sterically hindered spacer group between the hydroxyl group and phosphate functionality (84). Phosphoryloxymethyloxycarbonyl derivatives should be converted by phosphatase-mediated hydrolysis to an intermediate with subsequent rapid decomposition to the parent drug. The reconversion reaction scheme for these prodrugs is shown in Figure 23. Prodrugs of alcohols

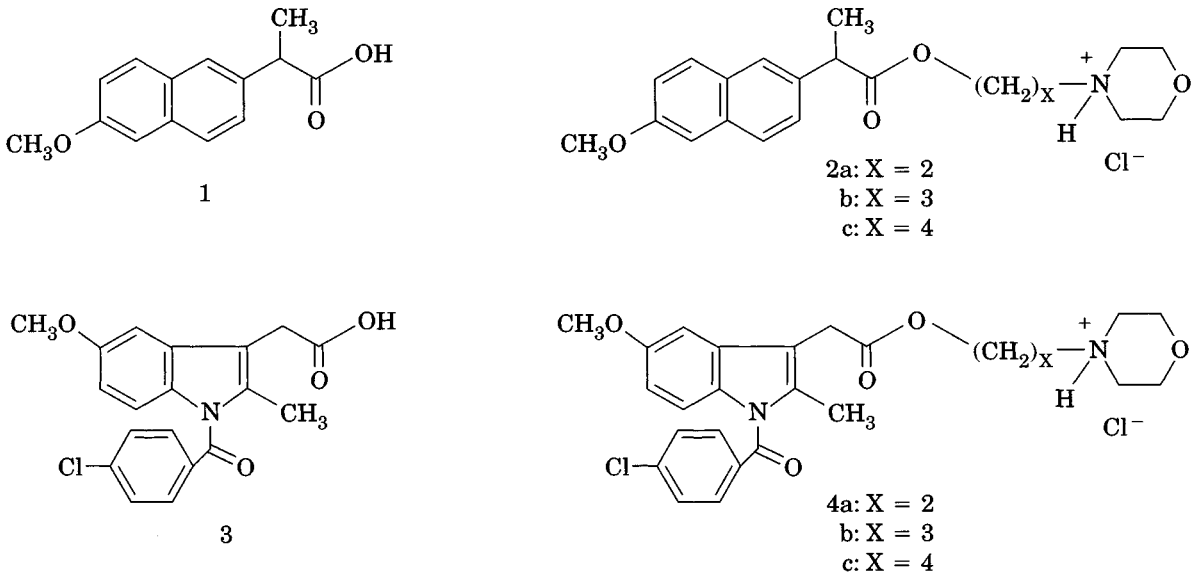

Figure 22. Chemical structures of naproxen 1, indomethacin 3, and their hydroxyalkylmorpholine (HCl) ester prodrugs. *Source:* Reprinted from Ref. 79, with kind permission of Plenum Publishing Corporation, New York.

(2-indanol), aliphatic amines (β-[3,4-dimethoxyphenyl]ethylamine), and aromatic amines (benzocaine) were synthesized but all exhibited unacceptable chemical stability, at least with regard to potential for utility in formulation processes. Even though the chemical stability of the prodrugs was not as great as needed, the phosphoryloxymethyloxycarbonyl prodrug of benzocaine was shown to have an approximately 10-fold greater catalytic constant for dephosphorylation by isolated human placental alkaline phosphatase at 25 C and pH 10.4 when compared with the constants for *p*-nitrophenyl phosphate. The other two prodrugs were not evaluated for enzymatic reactivity owing to either their very poor chemical stability (2-indanol) or low interest in water-soluble prodrugs (β-(3,4-dimethoxyphenyl)ethylamine. Therefore, even though chemical stability is not fully adequate with the current prodrug forms and requires further evaluation of alternate spacer groups, the basis for rapid enzymatic reconversion of the prodrug appears to be present, at least for the one benzocaine prodrug that was evaluated.

PMEA (9-[2-phosphonylmethoxyethyl]adenine) is an acyclic nucleoside phosphonate analog with antiviral activity that exhibits relatively poor permeation of biological membranes due to ionization of the phosphonate group at physiologic pH (pK_{a1} = 2.0 and pK_{a2} = 6.3). Measured oral bioavailability ranges from less than 1% in rhesus monkeys (85) to 7.8% in rats (86). A bis(pivaloyloxymethyl)-ester prodrug of PMEA (bis[POM]PMEA) was synthesized and evaluated in an in vitro cell culture model (Caco-2) to determine its transport, uptake, and metabolism (87). The bis(POM)PMEA prodrug was rapidly hydrolyzed by purified carboxylesterase with K_m = 87 μM and V_{max} = 9.5 μM/min values. Incubation of bis(POM)PMEA with homogenates of Caco-2 cells produced a similar profile. Transport studies in the human colon adenocarcinoma cell line, Caco-2, showed that 8.8% of the prodrug was transport in 3 h versus 0.1% of PMEA itself, which is consistent with the octanol–water partition coefficients (log P) of −4.11 and 2.48 for PMEA and bis(POM)PMEA. Because mono(POM)PMEA showed negligible transport across Caco-2 cells (<0.1% in 3 h), the increased flux seen with bis(POM)PMEA could not be attributed to the monoester. The ester was rapidly hydrolyzed with 23% appearing in the receiver compartment as intact bis(POM)PMEA, 33% as free PMEA, and 44% as mono(POM)PMEA. No intact bis(POM)PMEA was found intracellularly after a 3-h incubation, indicating rapid hydrolysis within the epithelial cells themselves. High levels of PMEA were found in the intracellular compartment, however, probably reflecting entrapment of the negatively charged PMEA.

The charge-related entrapment of PMEA intracellularly could account for slow release to the basolateral side of the cell monolayer. These results demonstrate an important point with regard to prodrug strategies for oral drug absorption. Unlike simplified lipid bilayer models that treat the GI mucosal as a single-lipid barrier membrane, the pathway for drug flux actually involves traversing two lipid bilayers (apical and basolateral) separated by a largely aqueous compartment (cytosol). For prodrugs that are absorbed via transcellular pathways and rapidly hydrolyzed in the aqueous intracellular compartment, the rate-controlling element in total drug flux can be the rate of release of the reconverted parent drug from the aqueous cytosol across the basolateral barrier membrane rather than the apparent transport of the prodrug across the apical membrane. The kinetics of prodrug absorption must also take into account the pathway of absorption as well as the hydrolytic or enzymatic lability of the prodrug in various cellular compartments to explain, or predict, the observed pharmacokinetic profile.

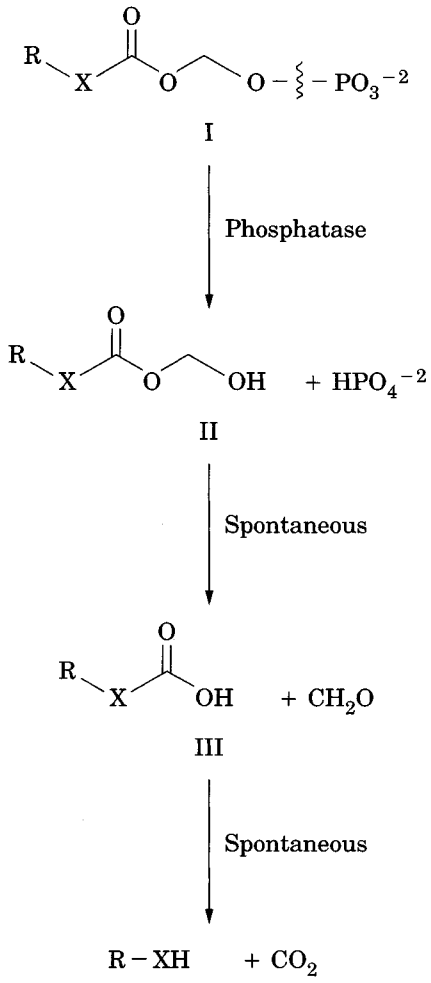

Figure 23. Enzymatic and nonenzymatic catalyzed steps involved in the generation of the parent drug from the phosphoryloxymethyloxycarbonyl prodrug system. *Source:* Reprinted from Ref. 84, with kind permission of Plenum Publishing Corporation, New York.

The potential utility of the bis(POM)PMEA prodrug was further evaluated in a nonhuman primate oral bioavailability study (88). The prodrug was orally administered to *Cynomolgus* monkeys as a solution in one of three formulations: hydroxypropyl-β-cyclodextrin complex, PEG-based cosolvent solution, and an aqueous suspension. The resulting plasma PMEA profiles are shown in Figure 24. Although PMEA itself showed only 4 ± 1% oral bioavailability, the three formulations tested in this study afforded bioavailabilities in the range of 22.2–24.7%. These data confirmed and extended the earlier in vitro data and demonstrated the potential utility of this prodrug approach.

Didanosine (2′,3′-dideoxyinosine, ddI) is an approved antiviral for HIV infection that exhibits relatively low and variable oral absorption that appears to be membrane permeability-limited (89). Adenosine deaminase (ADA)-activated 6-halo-dideoxypurine prodrugs (90,91) showed improved CNS penetration and were evaluated for oral bioavailability (92). Utilizing a conscious, chronically cannulated rat model, it was shown that the prodrug 6-Cl-ddP

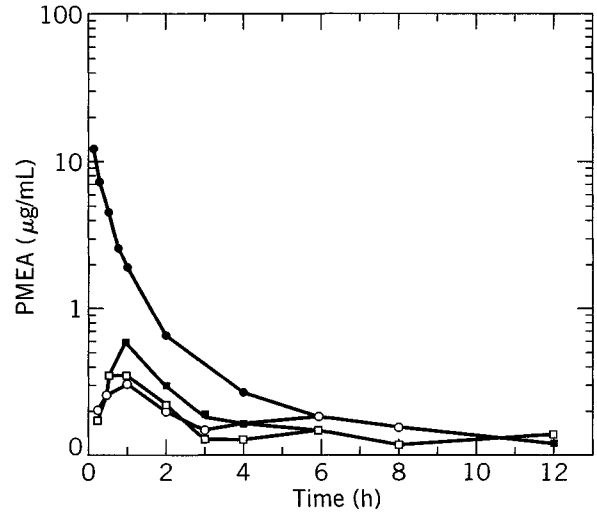

Figure 24. Mean PMEA concentrations in plasma following administration of intravenous ^{3}H-PMEA and three oral formulations of ^{3}H-bis(POM)-PMEA to *Cynomolgus* monkeys (n = 4). (6-Cl-2′,3′-dideoxypurine) had poor oral bioavailability (7 ± 3%) but high bioavailability (97 ± 11%) after portal administration, indicating that hepatic metabolism was not limiting. Greater than 50% of an oral dose of 6-Cl-ddp appeared in the systemic circulation as parent drug (ddI), indicating that the prodrug significantly improved the systemic availability of ddI and that prodrug absorption was not rate limiting. The data additionally demonstrated that the prodrug was extensively converted to the parent compound via ADA activity in the gut mucosa. These data suggest that lipophilic adenosine deaminase–activated prodrugs may have utility for improving the oral bioavailability of highly polar dideoxynucleosides such as ddI or related compounds.

Not all prodrug approaches for small molecules are directed toward improving bioavailability of the parent compound. An example is utilizing a glucuronide prodrug of menthol to provide stability in the small intestine with release of the parent drug upon arrival at the cecum or colon (93). Menthol-β-D-glucuronide stability was evaluated in contents isolated from various regions of the rat intestinal tract. The data (Fig. 25) demonstrated that the prodrug was stable in the stomach and small intestine but exhibited a fairly rapid hydrolytic rate in contents from the cecum and colon. Additionally, the change in octanol/water partition coefficient (log K = −1.61 and 3.07 for menthol-β-D-glucuronide and menthol, respectively) should minimize the absorption potential of the prodrug from the GI tract. This prodrug approach with menthol indicated, at least under in vitro conditions, how a strategy could be developed to synthesize a prodrug that is stable in the small intestine, has a log K value that should minimize absorption in the colon to effect local delivery of a therapeutic agent, and hydrolyzes to release the parent drug in the cecum or colon milieu.

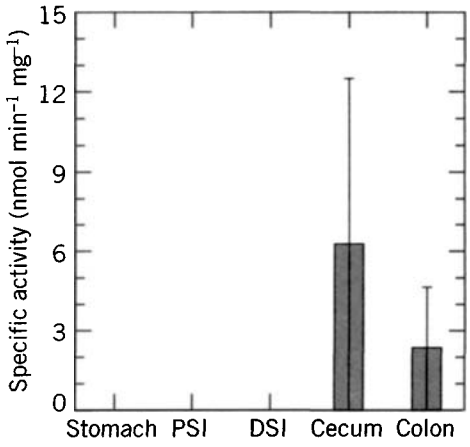

Figure 25. Hydrolysis of the prodrug menthol-β-D-glucuronide (nmoles of substrate hydrolyzed per min per mg of luminal contents) measured from various locations in the rat gastrointestinal tract. There was no menthol detected over the 1-h experiment in the luminal contents of the stomach, PSI, or DSI. Error bars are mean ±SD (n = 6). *Source:* Reprinted from Ref. 93, with kind permission of Plenum Publishing Corporation, New York.

Although most of the early prodrug efforts were directed toward traditional, organic drug candidates, the emergence of peptide and peptidelike drug candidates has spurred an interest in developing peptide prodrug strategies to improve their oral delivery. Unlike prodrug strategies for nonpeptidic drug candidates, where the goal is often to either modify solubility in the GI environment or alter the permeation properties of the parent drug in a favorable direction, prodrug strategies for peptides most often focus on providing increased protection against proteolytic enzymes in the GI tract because enzymatic degradation is generally a major barrier to effective oral formulation efforts. Several examples are provided to illustrate this approach.

A tripeptide prodrug of L-dopa was synthesized in an effort to develop a prodrug that overcame the decarboxylation of L-dopa in the gut wall and afforded acceptable oral bioavailability. Many prodrugs of L-dopa have been generated and evaluated, including esters, with varying degrees of success. In this study, the pGlu-L-Dopa-Pro prodrug was synthesized, and the proposed enzymatic pathway for reconversion to the parent drug in vivo is shown in Figure 26 (94). The prodrug structure effectively prevents L-dopa decarboxylation, which is the major intestinal degradative pathway for L-dopa. The conversion to parent drug involves two enzyme catalyzed steps, pyroglutamyl aminopeptidase I and prolidase. Evaluations with in vitro Ussing chambers with rat jejunal tissue and with an in situ single-pass intestinal perfusion model demonstrated that the prodrug was readily absorbed via an intestinal peptide transport that could be inhibited by captopril and various dipeptide competitors. The tripeptide was readily converted, both in vitro and in vivo, to the parent drug L-dopa, thereby demonstrating the potential utility of this approach.

Desmopressin (dDAVP), a synthetic analog of antidiuretic hormone, is normally administered nasally or orally, although the oral availability is quite low (<1%). The poor oral bioavailability is generally attributed to low lipophilicity, but susceptibility to enzymatic degradation, particularly by α-chymotrypsin, probably also plays a role (95). In an attempt to address these issues with the oral bioavailability of dDAVP, a series of ester prodrugs were synthesized at the tyrosine phenolic group of dDAVP (96). Several aliphatic carboxylic acid esters and a carbonate ester were made as shown in Figure 27. The octanol/aqueous buffer pH 7.4 log P of dDAVP is < -3.5. The log P values for the various prodrugs ranges from < -3 for proprionyl to 0.41 for octanoyl. All prodrugs were essentially stable in pH 7.4 buffer (half-lives ranged from 66 to 4,460 h) but exhibited half-lives from <1 min (hexanoyl and octanoyl) to 40 min (pivaloyl) in the presence of α-chymotrypsin. In 80% human plasma, the prodrug half-lives were basically similar except for pivaloyl (5.9 h) and 2-ethylhexanoyl (14.1 h). Utilizing the Caco-2 cell culture model, all the prodrugs except isobutyloxycarbonyl showed increased permeability relative to the parent dDAVP. There was, however, no correlation between permeability and lipophilicity. Regardless, the data indicated that this prodrug approach led to ester prodrugs of dDAVP that were stable in a buffer environment but readily converted to the parent drug in the presence of enzyme or plasma and generally afforded improved permeability characteristics.

A final example of prodrug strategy for developing oral formulations for peptide drug candidates involves recent efforts to develop intramolecular cyclic prodrugs to provide prodrug candidates with improved absorption characteristics as well as reduced susceptibility to metabolic degradation via intestinal enzymes (97,98). A phenylproprionic acid prodrug of a model hexapeptide (H-Trp-Ala-Gly-Gly-Asp-Ala-OH) was prepared and evaluated. Previous work (99) had demonstrated that a cyclic acyloxyalkoxycarbamate prodrug of the same model hexapeptide gave enhanced membrane-permeation properties and increased stability to metabolic enzymes. The proposed scheme for metabolic breakdown of the phenylproprionic prodrug is shown in Figure 28 and involves a relative slow esterase-catalyzed step followed by a rapid chemical hydrolysis to regenerate the linear hexapeptide plus lactone. The permeability of the prodrug (P_{app} = 1.21 ± 0.12 × 10^{-7} cm/s) across Caco-2 cell monolayers was approximately 70 times greater than that for the parent hexapeptide (P_{app} = 0.17 × 10^{-8} cm/s) and showed greater stability for the prodrug than the parent peptide. Enzymatic cleavage and hydrolysis of the prodrug to the parent compound was significantly faster in 90% human plasma, rat intestinal homogenate, or Caco-2 cell homogenate than in pH 7.4 aqueous buffer. The intramolecular cyclization prodrug strategy for peptides offers another novel approach to developing peptide drugs as oral formulation candidates that possess improved stability to enzymatic degradation (of the parent peptide) and improved absorption characteristics across epithelial cell layers.

In the scope of the text here, it has obviously not been possible to cover all the diverse prodrug strategies that have been evaluated in attempts to develop oral formulations for both traditional, organic drug candidates and peptide or peptidelike drug candidates. Hopefully, the exam-

ples given exemplify the varied approaches that can be considered and provide a basis for development and utilization of prodrug strategies toward drugs that would otherwise be unsuitable candidates for oral drug delivery systems.

COLON

Although it is generally felt that the small intestine is the primary site of drug absorption and therefore the preferred area of the GI tract to target with various controlled-release technologies, a major interest has developed in directing drugs and dosage forms to effect primary drug release in the colon region (100–102). The reasons for this interest are varied, but include (*1*) reduced proteolytic activity in the colon region, which may be helpful in effecting reasonable absorption of certain drugs that are enzymatically labile in the small intestine, particularly peptides and proteins; (*2*) reduced fluid and motility in the colon when compared with the small intestine, which could afford advantages in terms of incorporating multiple components in a formulation, such as permeation enhancers, that must reach the epithelial absorptive layer in a high concentration and in close spatial proximity to the each other; and (*3*) treatment of local pathologies of the colon such as carcinomas and inflammatory bowel disease.

Regardless of the therapeutic strategy justifying efforts to develop systems for drug release in the colon, some basic elements will apply from a therapeutic standpoint regarding drugs that are reasonable candidates for this approach. Because the arrival time of a drug or dosage form in the colon is subject to the vagaries of gastric emptying and small-intestine transit, drugs that require an immediate onset of action or a very specific time of onset after oral administration are not reasonable candidates. As an extension of this—and the fact that under normal conditions a patient is on a daily meal regimen—it can be assumed that the transit time to the colon will likely exceed 6–8 h on average. Therefore, twice-a-day dosing is the maximum frequency that can be expected from colon controlled-release systems, and, more likely, controlled-release systems for the colon will most commonly have to be once-a-day dosing therapies. This is particularly true if the controlled-release system is a sustained-release formulation where a drug release profile of 6–8 h is superimposed on an average transit time of 6–8 h to the colonic region. In this case, the overall time from administration to completion of drug release will probably approach 12–16 h, thereby restricting applications to those where once-a-day dosing without a specific time of onset is an acceptable therapeutic regimen.

There have been three basic approaches to designing drugs or dosage forms for delivery of therapeutic agents specifically to the colon: (*1*) utilizing pH changes that occur in the upper colon (103); (*2*) timed-release capsules with sufficient delay to allow transit to the colon before activating significant drug release (104); and (*3*) polymeric carriers that are degraded by bacterial enzyme activity specific to the colon region (105). With all of these approaches, effectiveness will be limited by the capability of the dosage form to resist the hydrodynamic and enzymatic forces present during transit from the stomach to the colon and to protect the active drug from premature release or degradation prior to arriving in the colon. Another general concern, which will not be directly addressed here, is the viscous contents of the colon region. As food stuffs are digested and absorbed, nonabsorbed materials pass from the small intestine to the colon where water is gradually reabsorbed and the intestinal contents become more viscous, eventually reaching a semisolid state. The presence of this material in the colon can present significant problems to the effective performance of drugs or dosage forms in the colon. The viscosity of the contents can present a formidable barrier to release and diffusion of drugs from a controlling dosage form to the wall of the colon where absorption occurs. Additionally, a potential for significant nonspecific adsorption to colonic contents can reduce the effective amount of drug available for absorption. A third potential problem is that although bacterial contents can be utilized to effect drug release in the colon, these same bacteria may present a degradative pathway for the drug itself, again reducing the amount of drug available for absorption. This potential interference in drug release and absorption will not be evaluated here in any quantitative sense, but it is critical that the research and developer of colon controlled-release technologies be aware of this po-

tential and factor these parameters into any analysis of the effectiveness of a given drug or dosage form.

Time Specificity

Attempting to predict the time required for a dosage form to transit from the stomach to the colon has been tenuous at best. Some reasonably reproducible data have been generated indicating that, in humans, the small intestinal transit time generally falls in the range of 2–4 h (106). These data seem to be reasonably consistent, at least in the fasted dog model, regardless of the size or density of the formulation or the fed/fasted state of the volunteer (107). With multiparticulate dosage forms, data in dogs indicated that there is little spreading of multiparticulates after exit from the stomach, (108) whereas in the fed state, considerable spreading and dilution of multiparticulate dosage forms might be expected due to mixing with food contents and variable gastric emptying (106). Although this 3- to 4-h time window of small intestinal transit can be argued as to its validity and reproducibility in humans, it is well accepted that the major variable in overall intestinal transit is residence time in the stomach and that this plays the predominant role in determining the average time it would take a dosage form of any size or geometry to traverse the stomach and small intestine en route to the colon. In humans with normal GI physiology, dosage forms exceeding approximately 2 mm in diameter are not readily emptied from the stomach during the fed state. Rather, these dosage forms are most typically emptied during the interdigestive phase, which is generally initiated somewhere in the range of 3–4 h after meal consumption, depending on the mass, volume, and caloric content of the meal. The interdigestive contractile activity, which is physiologically divided into several phases, has a repeating cycle of motility with each overall cycle lasting approximately 3–4 h. Therefore, it can be expected that a dosage form >2 mm in size might reasonably be expected to exit the stomach somewhere in the range of 4–8 h after ingestion with a meal. Obviously, the normal physiologic motility patterns of the stomach and small intestine can be affected by an individual's health, presence of GI pathologies, and any concomitant medications being taken. The net result of all these factors is that transit time from mouth to colon is very difficult to estimate in humans with any great deal of reliability. For the sake of discussion, it can be assumed that the overall transit time to the colon will be approximately 3–5 h in the fasted state and 6–10 h in the fed state. Given these rather wide ranges of overall transit times, it is apparent that predicting arrival of dosage forms in the colon, and targeting drug release to be dependent on a timing mechanism, is complicated at best. In spite of these normal variabilities that must be factored into any design of an oral controlled-release dosage form for delivery of drug to the colon, significant efforts have been directed toward achieving such goal.

The most well-studied and well-published time-based delivery system for targeting drug delivery to the colon has been the Pulsincap capsule of R.P. Scherer (109–111). The Pulsincap capsule consists of a water-insoluble body and a water-soluble cap. The drug formulation is contained and protected within the capsule body and separated, inside the water soluble cap, by a hydrogel polymer plug. After a predetermined lag due to dissolution of the cap, the hydrogel swelling rate controls the time of release. After reaching a critical swelling stage, the hydrogel plug is ejected, and the drug formulation is released. In theory, by designing the hydrogel plug with specific swelling and ejection times, the Pulsincap capsule can be made to deliver its contents to any site along the GI tract, including the colon. The additional apparent advantage is that the formulation itself is relatively protected from the GI environment prior to release, thereby affording advantages in terms of drug stability. Toxicologic evaluation of the polymeric hydrogel plug and components indicated no safety issues (R.P. Scherer data on file). The maximum size of the Pulsincap

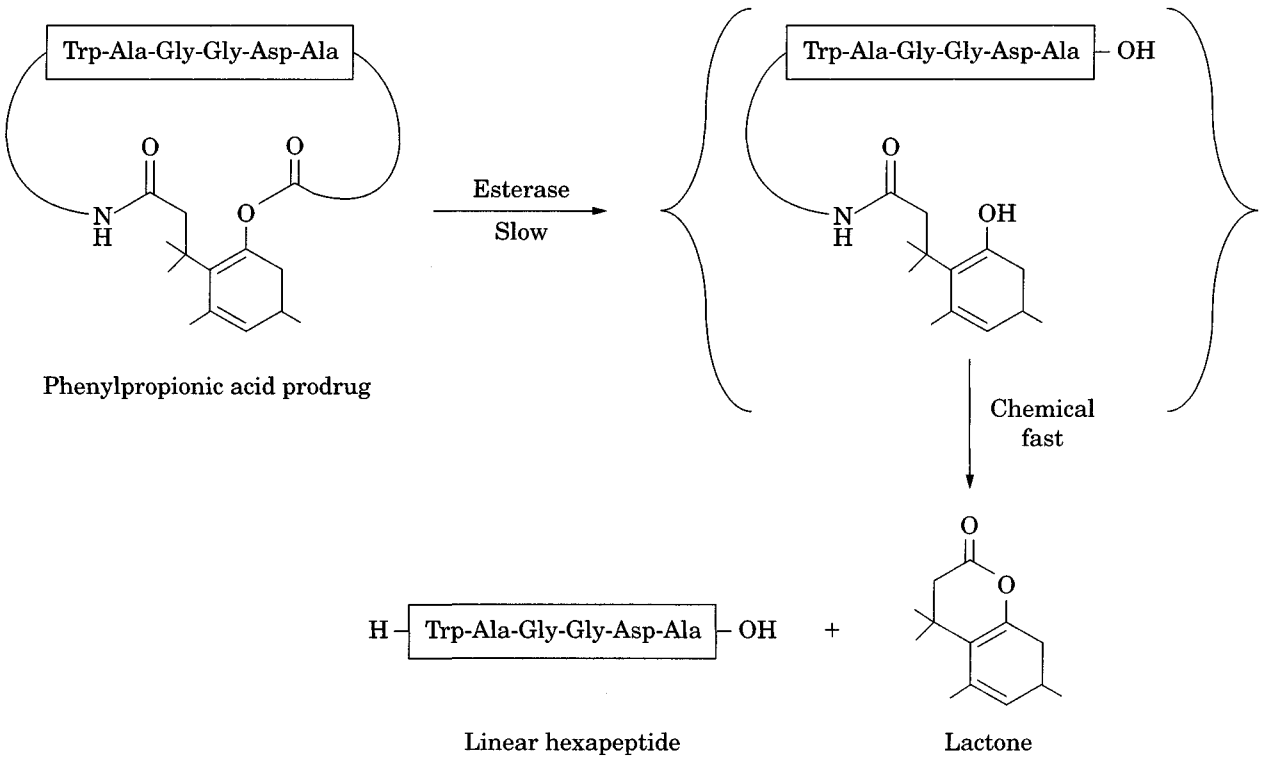

Figure 28. Proposed mechanism for the release of the linear hexapeptide from the cyclic phenylpropionic acid prodrug. *Source:* Reprinted from Ref. 98, with kind permission of Plenum Publishing Corporation, New York.

capsule approximates a size #0 standard gelatin capsule. In vitro studies indicated that the system maintained its integrity in pH 1.2 conditions for 5 h (simulating residence in the stomach) and exhibited a mean pulse-release time of 195 min after switching to pH 6.8 conditions. The mean 195-min lag time would represent the time interval over which the capsule must transit the small intestine to deliver formulation components to the colon. In an in vivo scintigraphic imaging confirmation study in humans (109), the Pulsincap capsule demonstrated integrity maintenance for 197–414 min in the stomach of fed volunteers with evidence of water-soluble cap dissolution within 29–70 min after exiting the stomach and entering the small intestine. A second phase of this study in fasted volunteers showed that the Pulsincap capsule hydrogel plug ejected at a mean time of 230 min postadministration, with a range from 208 to 275 mins. At the time of hydrogel plug ejection, all devices were shown to reside in the ascending colon. These data confirmed that, at least in the fasted state where gastric residence is not overly prolonged, the Pulsincap capsules successfully reached the colon prior to formulation release. The Pulsincap capsules were also evaluated in a double-blind placebo-controlled parallel group study evaluating the tolerability of a 28-day regimen of twice-daily dosing (no active drug agent). The incidence of reported adverse events was comparable between Pulsincap and placebo, with no indication of their being causally related to the formulation. This tolerability study indicated that this designed formulation for time-delayed drug release to the colon holds promise as a technology that can be effective without significant tolerability issues.

Limited information has been presented on a somewhat similar time-delayed drug delivery system named Chronset from ALZA Corporation (112). This device contains the drug formulation within an impermeable capsule configuration in which the driving force is an osmotic engine contained in the base of the capsule. By controlling the rate of water imbibition with the osmotic load and a semipermeable membrane coating, a swelling polymer is utilized to expand the capsule over a preengineered time frame resulting in the release of active components at either 2 or 6 h. In the fasted state where residence time in the stomach could be expected to be less than 2 h, the 6-h systems hold promise for delivery of therapeutic agents specifically to the ascending colon region. Pharmacokinetic data, with acetaminophen as a model compound, demonstrated that the formulation was released in a bolus fashion (simulating an immediate-release profile) after the predetermined lag time designed into the system.

Niwa and coworkers have reported on the development and evaluation of a novel ethylcellulose (EC) capsule that releases drug in a time-controlled fashion (113). The capsule, shown in Figure 29, has four-components comprising a drug container, swellable polymer, capsule body, and cap. The cap, body, and drug container were made of EC. The capsule body was a #00 gelatin capsule coated internally with EC, with the gelatin capsule subsequently dissolved to yield an EC capsule body. Four micropores, each ap-

proximately 400 μm in diameter, were mechanically drilled in the bottom of the body capsule. The drug container was made from an EC film. When assembled, the drug container is separated and placed above a swellable polymer (i.e., a low-substituted hydroxypropylcellulose) in the capsule body and sealed with the cap. The proposed mechanism controlling the timing of drug release is a balance between the swelling pressure of the polymeric material and the strength of the capsule cap. Utilizing the same swelling-polymer composition, it was shown that the time of in vitro drug release (or rupture of the EC cap) was dependent on the thickness of the cap. The mean times at which 50% of a model compound, fluorescein, was released were 2.4 ± 0.15 h, 3.39 ± 0.09 h, and 6.21 ± 0.15 h for caps with thickness of 44.1 μm, 65.7 μm, and 76.7 μm, respectively. In vivo, these same capsule designs performed comparably in fasted beagle dogs, with respective T_{max} values at 2.0 h, 4.0 h, and 7.0 h (Fig. 30). These data suggest the potential utility of this design, although lag times in excess of 7 h will most likely be required to ensure effective delivery to the colon, particularly in the fed condition. Additional studies examining the effects of food on these time-release capsules were conducted and suggested that in the postprandial study leg, the capsules actually disintegrated in the stomach rather than the colon (114). The mean residence time (MRT) of fluorescein in these capsules was not statistically different in the postprandial state (6.43 h) and fasted state (4.76 h). Simple enteric coating of capsules with either hydroxypropylmethylcellulose phthalate or Eudragit S afforded MRTs of 11.30 h and 12.83 h, respectively, in the fed state. These data suggested that the time-controlled capsule, which did not have an enteric coating, probably dissolved in the stomach. To effectively delivery a drug formulation to the colon with these time-controlled systems, an enteric coating is necessary to delay the initiation of the timing cycle until the capsule exits the stomach. Not only does this eliminate the variability due to gastric residence times but it also increases the likelihood that a 6- to 8-h time delay will be sufficient to deliver the formulation to the colon region prior to drug release.

In addition to the bolus or delayed-release systems just described for targeting drug delivery to the colon, more traditional or conventional sustained-release technology can also be considered as a means to provide continuous drug release in the colonic environment. Essentially any of the systems described in the section on time-controlled drug release for the small intestine could be extended to colonic applications. If a sustained- or continuous-release dosage form was enteric coated, then initiation of the release profile would not commence until the device empties from the stomach and the enteric coating dissolves. Given this circumstance and under normal GI physiological conditions, any sustained drug release beyond approximately 3 to 4 h will most likely occur in the colon. Therefore, an enteric-coated 12-h sustained-release system could be expected to release drug for approximately 8 h in the colon. Technical strategies for designing time-controlled, sustained-release formulations will not be repeated here (see "Time Specificity"). Obviously this approach is simply an attempt to utilize a general sustained-release delivery profile and time the release such that a significant portion of the dose is released after the formulation traverses the small intestine and enters the colon.

Enzymatic Control

A major share of the effort in designing and developing controlled-release technology for colon delivery has attempted to utilize the presence of colonic bacteria as a triggering element to initiate or control drug release on arrival of the drug or dosage form in the ascending colon. Although there is a significant population of bacteria in the lower small intestine (10^5–10^7 cfu/mL), there is a rather abrupt and dramatic increase in bacterial density (10^{11}–10^{12} cfu/mL) immediately distal to the ileocecal junction. The en-

zymes produced by these bacteria are the targets of controlled-release technology efforts. As with any other physiologic parameter, the specific strains and densities of bacteria resident in the ascending colon can be affected by numerous factors, including age, diet, pathological states, concomitant drug administration, general health, and normal interindividual variability. Although there is certainly variability in bacterial content, all individuals have very high resident populations of bacteria in the ascending colon, and this ubiquitous presence can justify efforts to target these bacterial enzymes as potential triggers for controlled-release technology. Additionally, the successful use of sulphasalazine and olsalazine, which depend on bacterial azoreductases for activity, strongly indicate that the bacterial enzymes of the colon are capable of providing the desired effect.

The vast majority of work in this field has been directed toward developing drugs or dosage-form technologies as substrates for bacterial enzymes and evaluating these approaches in either simulated in vitro environments or in small-animal studies. Simulated in vitro models are difficult to establish and validate, particularly because the colonic bacteria are primarily anaerobic, but they represent the first method of choice for comparing different substrates and strategies. Studies in small animals, while useful for verifying results observed in vitro, must be interpreted with a certain degree of caution because there may be considerable species-to-species variability in bacterial enzymes between selected animal models and humans. Enzymes produced by colonic bacteria can hydrolyze a wide variety of substrates, including glycosides, sulphates, nitrates, esters, amides, and sulphonates. They have also been shown to reduce double bonds, nitro groups, azo groups, aldehydes, sulphoxides, ketones, alcohols, *N*-oxides, and arsonic acids. Other metabolic processes affected by colonic bacterial enzymes include dealkylation, deamination, decarboxylation, ring fission, nitrosamine formation, acetylation, and esterification. Although obviously a very large number of metabolic process could be chosen as potential controlling elements in controlled-release drugs or dosage forms for colon delivery, the focus has been on azoreductases, which reduce azo bonds, and polysaccharides, which are represented by glycosidic enzymes.

Significant efforts have been directed toward utilizing the azoreductase capacity of colonic bacterial enzymes. Saffran and coworkers (115,116) synthesized various polymers that were cross-linked with aromatic azoaromatic groups. The polymer films developed in these studies were resistant to degradation or dissolution in the upper GI tract and could be utilized as tablet or capsule coatings that were substrates for bacterial azoreductase activity in the colon. Vasopressin and insulin were effectively delivered to the colon in animal studies utilizing this approach.

Van den Mooter et al. (117) investigated the release of a model compound, ibuprofen, from capsules coated with azopolymers. Gelatin capsules containing 20 mg of ibuprofen were dip coated in an ethanolic solution of azopolymers (20% w/w). PEG 400 (20% w/w) was utilized as a coating plasticizer, and the coating level on the capsules was 9.7% (w/w). The azopolymers employed in this study were copolymers of 2-hydroxyethyl methacrylate (HEMA) and methyl methacrylate (MMA) and terpolymers of HEMA, MMA, and methacrylic acid (MA). *N,N'*-bis-(methacryloyloxyethyloxycarbonylamino)azobenzene (B-[MOEOCA]AB) was used as the azoreductase substrate in the polymers. An in vitro dissolution medium was prepared from isolated rat cecal contents to which cofactors were added to create an electron-generating system capable of significant reducing activity that simulated the environment of the colonic milieu. Because ibuprofen has low water solubility, diffusion through the polymer coating prior to enzymatic degradation of the azopolymer coating is minimal. Copolymers of HEMA/MMA at ratios of 4:1 or 5:1 did not demonstrate in vitro drug release rates that were statistically different in buffer or reducing medium, indicating that the release most likely reflected diffusion of the drug through the polymer coating over extended time periods (34 h). Although a HEMA/MMA coating at a 6:1 ratio did demonstrate statistically faster drug release in the reducing medium compared to buffer, the lag phase exceeded 24 h, which is not practical for in vivo applications given the estimated residence time of dosage forms in the colon. The effectiveness of azopolymer coatings is based on a balance between the hydrophilic HEMA, which ensures good hydration and availability of azo bonds for enzymatic attack, and the hydrophobic MMA, which retards polymer swelling and prevents early drug release in the stomach and small intestine. Because neither of these components contains an ionizable group, swelling is pH independent. Incorporation of a small amount of methacrylic acid as a terpolymer with HEMA and MMA increases the degree of swelling when going from acidic to neutral or alkaline conditions owing to neutralization of the carboxylic acid group of MA while still retaining the generally water-insoluble nature of the polymer. As shown in Figure 31, a terpolymer of HEMA/MMA/MA 9:2:0.1 provided a coating that exhibited significant ibuprofen release beginning as early as 8–10 h after initiation of incubation

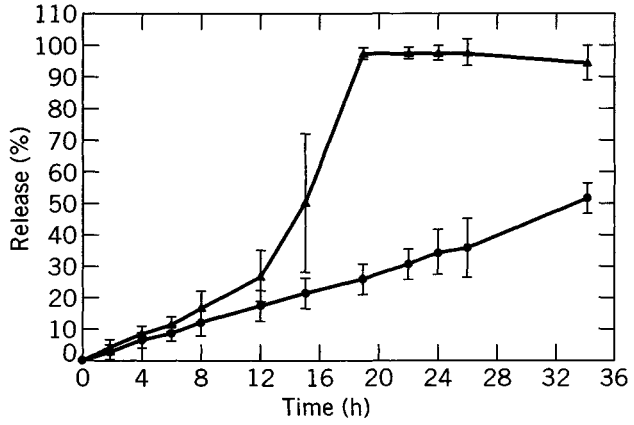

Figure 31. Release of ibuprofen from capsules coated with azopolymer P12 in RCCRM (▲) and phosphate buffer (●). $n = 6$; error bars indicate the standard deviation. *Source:* Reprinted from Ref. 117, with kind permission of Plenum Publishing Corporation, New York.

in simulated rat cecal content–releasing medium. Total release was achieved by 18 h, indicating the effectiveness of this coating composition.

Van den Mooter and colleagues (118) extended their in vitro characterization of azopolymer-coated capsules for colonic delivery by examining their performance in vivo. Theophylline was used as a model compound for measuring plasma concentrations and gelatin minicapsules were coated with azopolymers as described previously (117). Given the small size of the rat model, the minicapsules were surgically placed in either the upper small intestine or cecum. With the three polymer compositions evaluated, none showed significant theophylline absorption when administered to the small intestine of rats, indicating that drug release and subsequent absorption were primarily controlled by diffusion through the polymer coating rather than dissolution or degradation of the coating. Placement of the capsules in the cecum demonstrated the apparent effectiveness of the azopolymer coatings in initiating drug release in the colonic environment (Fig. 32). Significant plasma levels of theophylline were measurable as early as 6–8 h with the terpolymers containing HEMA/MMA/MA. The copolymer of HEMA and MMA also showed a significant increase in the absorption rate of theophylline, although the onset was significantly later (16–20 h postadministration) than that seen with the more rapidly swelling terpolymers. The data obtained in vivo are in general agreement with the previously reported in vitro release data, although less discrimination was seen in vivo with the terpolymers. The results obtained in the two studies by Van den Mooter et al. (117,118) were encouraging, but as currently formulated, the azopolymer coatings are unlikely to be effective in a normal, human dosing application. A residence time in the reductive environment of at least 10–12 h was required to initiate polymer degradation, and complete degradation and drug release were not achieved for nearly 24 h. With a transit time to the colon of approximately 6–8 h, one could not expect full absorption prior to 24 h, which would severely limit the applicability at this stage. In addition, the capsules would not be static in the ascending colon as they were in the cecal administration model evaluated in these studies but rather continue to transit through the colon, where enzymatic activity may be lower. This would most likely even further prolong drug release and absorption. This technology, therefore, requires further evaluation and optimization before it can be considered a viable approach for controlled release of therapeutic agents to the colon, where systemic absorption is the primary target.

A different variation on the azopolymer composition theme was investigated by incorporating poly(ether-ester)s (119). Azopolymers were synthesized from 4-(2-(2-(2-hydroxyethoxy)ethoxy)ethoxy)benzoic acid (HEEEBA) and 4-(2-(2-(2-hydroxyethoxy)ethoxy)ethoxy)phenylazobenzoic acid (HEEEPABA) with either 12-hydroxydodecanoic (C-12) or 16-hydroxyhexadecanoic (C-16) acid. The degradation of the various azopolymers was determined in a cell-free extract prepared from the cecal content of male rats (118). Various compositions of HEEEBA, HEEEPABA, and the C-12 or C-16 acids were evaluated and indicated that HEEEBA concentration from 20 to 33% did not modify degradation rates, and there was no difference in utilizing the C-12 or C-16 acid in the formulation. All polymers without HEEEBA, however, showed slower degradation rates, indicating the importance of the hydrophilic properties of HEEBA in promoting accessibility of the polymer bonds to the azoreductase in the dissolution medium. The addition of small amounts of polysorbate 80 further accelerated the degradation rate, probably by a similar mechanism of increasing the wettability of the polymer matrix and hence the access of azoreductase to the polymer bonds. The measured reduction in azo bonds, however, was still only approximately 50% in 48 h of incubation, so the practical use of these systems also remains in contention given the normal in vivo residences times in the cecum or colon.

Shantha et al. have prepared and evaluated azo groups containing polymeric hydrogels for targeting to the colon (120). Methacryloyloxy azobenzene (MAB) was copolymerized with hydroxy thylmethacrylate (HEMA) as hydrogels containing 5-fluorouracil (5-FU) as a model drug. When drug release was determined in simulated gastric fluid or simulated intestinal fluid, releases were in the range of 20–30% in 3 h, with approximately 50% released in 12 h. The release rate decreased as the concentration of the azopolymer increased, possibly reflecting a higher crosslinking density in the copolymer hydrogel. When the same compositions were tested for in vitro 5-FU release in a dissolution medium made from a culture of intestinal flora obtained from human fecal samples under anaerobic conditions, the release rate was nearly zero-order over 4 h, with approximately 80% of the drug released over the interval. Complete release was achieved by 6 h, with the rate of release slower from 4 to 6 h than the zero-order release seen in the first 4 h of the in vitro incubation. Although a significant amount of drug (20–30%) would be expected to be released during transit through the stomach and small intestine on the basis of the results discussed in this article, a significant increase in release rate would appear likely in the colonic region, probably due to the higher pH and azoreductase activity. This polymer composition could

appear promising for colonic controlled release, although the very slow drug release in the small-intestine environment observed with some of the other azopolymer compositions is not likely to be obtained with this system.

Azo compounds have also been utilized to deliver active agents as prodrugs to the colon with the goal of releasing the active agent as a result of bacterial azoreductase activity. Various low-molecular-weight and macromolecular prodrugs of 5-aminosalicylic acid (5-ASA) have been prepared for colonic delivery (105,121). Schacht et al. (122) have prepared azo-linked polymeric prodrugs of 5-ASA wherein the drug is linked to a polymeric carrier via an azo-containing spacer. Drug carriers evaluated included dextran, poly(*N*-[2-hydroxyethyl]-D,L-aspartamide), and poly(1-vinyl-2-pyrrolidone-*co*-maleic anhydride). A continuous simulated human intestinal microbial ecosystem (SHIME) reactor was utilized to assess the degradation of various 5-ASA azo prodrugs in simulated sections of the human GI tract. Evaluation of the azo-linked prodrugs indicated that the major degradation occurred in the reactors simulating proximal colon medium (approximately 60% in 6 h). Little or no parent drug was released in reactors simulating the duodenum and jejunum (approximately 15% in 6 h). The amount of drug released with the most favorable macromolecular prodrugs approached that seen with low-molecular-weight prodrugs. The disadvantage of this prodrug approach is that specific chemistry needs to be developed and applied for each individual drug candidate and therefore lacks the potential general applicability that could potentially be achieved with the use of azopolymer controlled-release formulations that could be applicable to a variety of drug candidates.

Although azopolymers have received a significant share of the research and development effort targeting bacterial enzyme substrate–based delivery technologies, they are certainly not the only technologies that have been evaluated. In fact, given the unknown safety and toxicity issues that may become a factor with some of the substrates for azoreductase activity, the use of more commonly occurring substrates, particularly polysaccharides, may offer important development advantages. Table 3 lists polysaccharides that are known to be degraded by colonic bacteria (123–133). It is obvious from the list that a large number of polysaccharide-based substrates could be utilized for delivering drugs and dosage forms to the colon. Many of the compounds, however, are too soluble in water to survive transit through the stomach and small intestine, and the films created from these polymers often do not have the necessary physical properties. In spite of these limitations, a number of groups have successfully demonstrated the potential utility of these polysaccharides as substrates for colon bacterial enzyme activity.

A double-coated system has been tested in which the outer coat is a traditional enteric coat and the inner coat is an insoluble microcrystalline cellulose polymer subject to colonic degradation (134). X-ray evaluation of the performance of these systems in human volunteers indicated that the dual-coating system afforded protection in the small intestine, with apparent disintegration in the colon. A similar dual-coating system comprised of chitosan as the inner coat and chitosan/Eudragit L as the outer coat disintegrated in the large intestine of beagle dogs (135).

Table 3. Polysaccharides Degraded by Colon Bacteria

Polysaccharide	Reference
Alginate	11
Amylose	11
Arabinogalactan	11–13
Arabic gum	13
Arabinoxylan	14
Cellulose	15–17
Condroitin sulphate	13,14
Dextran	11
Guar gum	13,14,18,19
Heparin	13
Laminarin	14
Locust bean gum	14,19
Mucin	13
Pectin	11
Polygalacturonic acid	11–14
Starch	13,20
Tragacanth gum	11,14,19
Xylan	12–14,19

One polysaccharide that has received some considerable attention as a potential substrate for colonic bacterial enzymes in a controlled-release formulation is pectin (polygalacturonic acid). Some early studies with pectin have suggested its possible usefulness (136), although certain limitations also were apparent. Pectin itself is very water soluble and unlikely to serve as a resistive coating or barrier during transit through the stomach and small intestine. Rubinstein et al. have attempted to address the problems associated with pectin solubility by utilizing a less water-soluble salt, calcium pectinate (137). Pectin and calcium pectinate tablets were prepared with indomethacin, a water-insoluble drug. Sieved pectin or calcium pectinate was mixed with indomethacin at 1% or 10% (w/w), respectively, and compressed into tablets at 7 kP. Each tablet weighed 200 mg and contained either 2 mg indomethacin (pectin tablets) or 20 mg indomethacin (calcium pectinate tablets). Pectin tablets showed complete indomethacin release in 2 h when incubated with a pectinolytic enzyme preparation at pH 3.5 but essentially no release over 8 h if the degradative enzymes were not present. Reducing the concentration of pectin-degrading enzymes by 10-fold significantly reduced indomethacin release (100% release in about 7 h), but the release profile now approximated linearity. When the studies were conducted at pH 6.2 in the presence of the anaerobic bacterium *B. ovatus*, cumulative indomethacin release ranged from 5 to 20% over 4 h, with an initial burst phase that can likely be explained by diffusion from the tablet surface. Calcium pectinate tablets exhibited a somewhat similar profile of indomethacin release with little or no release in the absence of pectinolytic enzymes and a fairly rapid zero-order release when incubated in the presence of these enzymes (~100% release in 6 h). As with the pectin tablets, incubation of calcium pectinate tablets in the presence of rat cecal contents at pH 7.0 exhibited greater indomethacin release when com-

pared to incubation without rat cecal contents (Fig. 33). These results indicated that calcium pectinate, as well as pectin itself, can be degraded by bacterial enzyme activity. In addition, because indomethacin has very poor water solubility, it is unlikely that diffusion of indomethacin from the tablet could account for the observed release; more likely, an erosion process initiated by bacterial enzymes is responsible for initiating and controlling drug release.

The initial in vitro work with pectin and calcium pectinate tablets was subsequently confirmed in human clinical studies utilizing α-scintigraphy to visualize the performance of tablets in volunteers (138). Either CaP/P tablets (calcium pectinate and pectin) or CaP/GG tablets (calcium pectinate and guar gum) were evaluated in 10 fasted, healthy volunteers. Both tablet formulations were enteric coated with Eudragit L. Guar gum was added to CaP/GG tablets to slow the disintegration. External imaging of the physical state of the CaP/P and CaP/GG tablets indicated only slight disintegration of either formulation in the small intestine, with tablets reaching the cecum in a relatively intact condition. Both formulations reached the cecum in approximately the same time frame (CaP/P: 272 ± 48 min; CaP/GG: 223 ± 47 min). With the CaP/P tablets, complete disintegration was observed in the ascending colon for 7 of 10 tablets and in more distal colonic regions for 2 of 10; 1 did not totally disintegrate during colonic transit. With CaP/GG tablets, total disintegration was seen for 3 of 10 in the ascending colon and 3 of 10 in more distal colonic regions; 4 of 10 did not fully disintegrate during transit of the colon. The data from this human volunteer study indicate that CaP/GG tablets appear to disintegrate more slowly, as predicted, than CaP/P tablets, but that both may be potential candidates for controlled delivery of therapeutic agents to the colonic region.

Although compressed tablets as reported by Rubinstein et al. (137) indicated a potential utility for pectin and calcium pectinate to direct drug delivery to the colon, this approach may not be suitable for all applications. As with the azopolymers, the ability to develop a film-coating process that would protect the components of the formulation prior to arrival in the colon and then degrade to release the active drug in the colonic environment could be a significant advantage. Due to its high water solubility, pectin alone is not a good candidate for a film-coating process. Wakerly et al. investigated the potential utility of combining pectin with EC in a film coat intended for colon-specific drug delivery (139). Paracetamol tablets were compressed with a hardness of 8 KP and disintegration times of less than 15 min. The paracetamol tablets were film coated in a fluid-bed spray granulator with a coating solution of 2% w/v pectin in water blended with distilled water and Surelease S (EC). Three different film coats were prepared and evaluated: 60S:40P, 50S:50P, and 40S:60P. The amount of paracetamol release was significantly higher in pH 7.4 buffer than 0.1 N HCl for both compositions with the lower concentrations of EC (40S and 50S). Increasing levels of EC reduced drug release at both pH levels, and only marginal paracetamol release (≤5% in 6 h) was observed with the 60S coating under both pH conditions. The 50S:50P coating was tested in a system utilizing pectinolytic enzymes and shown to release paracetamol at a higher rate in the presence of enzymes than in the absence of enzymes. The difference (37% versus 23% in 400 min) was, however, not particularly dramatic, and the release curves did not begin to separate until after approximately 170 min of incubation in the presence of the pectinolytic enzymes. These data appear to suggest that although the pectin/EC coatings do provide some degree of control based on bacterial enzyme activity, the effect may not be rapid enough or the effect large enough to utilize in a practical sense. However, these studies do show a potential utility of pectin in film-coating processes if the solubility can be reduced by coformulation with other less soluble components. Additionally, it is not really possible to predict how these coatings would perform in an in vivo environment, particularly that encountered in the human colon.

Pectin-based multiparticulates have also been evaluated as potential formulations for specific delivery to the colon (140). Control of release from a multiparticulate systems requires tighter regulation because the large surface-to-volume ratio of beads relative to tablets increases the probability that a gel or swelling system will become diffusion controlled, particularly for very water-soluble compounds, rather than degradation controlled by enzymatic activity in the colon. Amidated pectin/indomethacin and amidated pectin/sulphamethoxazole beads (2 mm) were prepared either with or without a chitosan coating. Drug levels were 20, 33, and 50% w/w based on theoretical loadings of dry beads. Swelling increased as a function of increasing pH, and chitosan reduced the degree of drug release. In the presence of pectinolytic enzymes, complete bead degradation was observed with 135 min. Although significant drug release occurred in enzyme-free media, especially with the more water-soluble sulphamethoxazole, the presence of calcium and/or chitosan did reduce this release aspect. The results indicated that a particulate formulation for delivery to the colon may be feasible. The particularly attractive feature of the multiparticulate

approach is that total degradation can occur in a much shorter time frame (i.e., 135 min) because of the large surface-to-volume ratio of multiparticulates compared to the much longer time (typically 15–24 h) required for total degradation of tablet formulations. If the early drug-release phase during transit through the stomach and small intestine can be adequately controlled with a particulate formulation, this approach offers promise for a delivery system that can effect more rapid and hopefully more complete drug release shortly after arrival of the dosage form in the colonic region.

Amylose is a linear α-D-glucan polymer composed of α(1→4)-linked D-glycosyl units and is comprised of approximately 20% starch. Films of amylose have been prepared that are resistant to pancreatic α-amylase (141) but are degraded by colonic bacterial enzymes (142,143). If used alone, amylose swelling in aqueous media is too rapid to be effective as a controlling coating because water-soluble drugs can diffuse through the coating membrane and would be released during transit through the stomach and small intestine. Milojevic et al. (144) have combined amylose with pharmaceutical polymers to decrease the swelling properties of amylose alone and provided a significant change in the resultant drug-release profile. Pellets (1.4–1.7 mm) containing 60% 5-ASA were prepared and coated in a fluidized bed coater with either a single coat comprised of mixed dispersions of amylose with acrylate polymer or with EC or as multiple coats with an inner amylose coat and an outer layer of either EC or acrylic polymer. During in vitro dissolution testing, uncoated pellets exhibited complete drug release in 2–3 h, while pellets coated with amylose alone showed complete release in 6 h. EC-coated pellets did not release drug over a 24-h period. Coatings comprised of amylose and EC showed a release rate that was dependent on the ratio of the two components. With low ratios of amylose to EC (e.g., 1:2.5 w/w), release was rapid and accompanied by cracking of the coating. An amylose/EC ratio of 1:4 appeared optimal for retarding drug release in simulated intestine fluid and was employed to further show a direct dependence of release rate on coating thickness. While release from the amylose/EC-coated pellets was significantly retarded in simulated intestinal fluid, dissolution studies conducted in a fermenter simulating bacterial flora (Fig. 34) showed a dramatic increase in 5-ASA release after approximately 2–5 h of incubation. A variety of other coating mixtures were evaluated, including Eudragit RS/RL30D and Aquacoat ECD30 in both mixed coatings and multilayer coatings. With Aquacoat ECD30, release was too rapid regardless of plasticizer or coating thickness. Eudragit RS/RL 30D was also ineffective in retarding amylose swelling and drug release, presumably because of pores formed by the dissolution of the soluble PEG plasticizer present in the coating formulation. The overall conclusion from this in vitro study was that an amylose/EC coating at a ratio of 1:4 provided the most promising formulation for coating tablets whose release rate could be initiated and controlled by colonic bacterial enzyme activity.

The potential utility of the amylose/EC coating technology was evaluated further in a human clinical setting (145). Pellets (1.4–1.7 mm) were prepared that contained

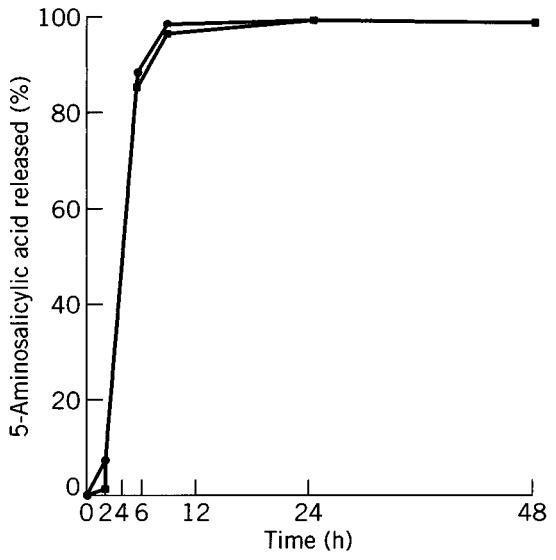

Figure 34. Release profile of 5-aminosalicylic acid in fermenter (simulated colon) system from pellets coated with (■) amylose-Ethocel (ratio 1:4 w/w) TWG 4.8% and (●) amylose TWG 4.8%. *Source:* Reprinted from Ref. 144, with kind permission of Elsevier Science–NL, Sara Burgerhartstraat 25, 1055 KV Amsterdam, The Netherlands.

50% [^{13}C]-glucose and coated with a 1:4 ratio of amylose:EC. Nine fasted subjects received a capsule containing 300 mg of the formulation and exhalation of $^{13}CO_2$ was monitored as a measure of pellet disintegration and release. A coadministered capsule of identical size and density containing a ^{99m}Tc marker was used to monitor GI transit and location by external scintigraphy techniques. The data obtained in this study (Fig. 35) indicated that less than 1% of the dose was recovered in the initial 6 h, followed by a steady increase in $^{13}CO_2$ recovery through 15 h, indicating degradation of the amylose/EC pellets over this time frame. The percent of dose recovered decreased from 15 to 24 h. External imaging of the second marker indicated that the pellets resided in the ascending, transverse, and descending colon during the rapid phase of $^{13}CO_2$ recover. These results in a human study confirmed the potential of the amylose/EC coatings as a colon-targeting technology that was previously demonstrated in the in vitro incubation studies.

A final approach to utilizing colon-specific bacteria as "triggering elements" for colon drug delivery involves the potential application of dextran-based hydrogels (146). Dextran-based prodrugs of naproxen have previously been shown to be specifically degraded in the presence of colon bacterial enzymes. In applying dextran to hydrogel technology, hydrogels were prepared that varied in dextran molecular weight (40,000 to 2,000,000), length of cross-linking agent (HDI: 1,6-hexamethylenediisocyanate; DDI: 1,12-dodecamethylenediisocyanate), cross-linking density from 2.9 to 17.5 mol %, and amount of DMSO (80–90% v/v) in the reaction mixture. The degree of hydrogel swelling in vitro was inversely related to dextran molecular weight and cross-linking density and directly related to the level

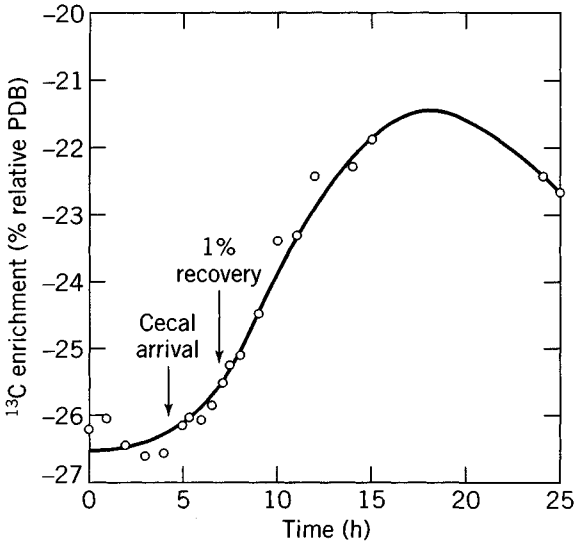

Figure 35. The time course of ^{13}C enrichment of breath CO_2 following the ingestion of pelleted ^{13}C-labeled glucose. The time at which >5% of the total observable activity was first recorded in the cecum and the time at which 1% of the dose given had been recovered in the breath are shown. *Source:* Reprinted from Ref. 145, with kind permission of Elsevier Science–NL, Sara Burgerhartstraat 25, 1055 KV Amsterdam, The Netherlands.

of DMSO in the reaction mixture. In general, both dextran molecular weight and cross-linking density were felt to increase the level of entanglement of dextran strands, thereby decreasing swelling. At the highest dextran molecular weight (2,000,000), however, hydrogel swelling actually increased, which may be related to interference with the cross-linking reaction. In vitro hydrocortisone release was determined with hydrogel discs (Dex-70, 85% DMSO, 11.6% cross-linking with HDI) in the absence and presence of dextranase. The observed release was approximately 32 and 100% in 120 min in the absence and presence, respectively, of dextranase. The in vitro performance of cross-linked dextran-based hydrogels appear promising as a potential technology for colon delivery of active agents.

Clearly, a variety of approaches have been evaluated with regard to identifying and optimizing a colon drug delivery system utilizing the endogenous bacterial enzyme activity as a site-specific triggering mechanism for drug release. Although considerable progress has been made at a research level, these approaches have not yet been commercialized. The primary advantage of utilizing colonic bacterial enzyme activity is that the relatively unique bacterial activity in the colon (both strain and density) represents a noncontinuous event that could serve as a mechanism relatively specific to the colon that has the potential of being independent of GI transit time. This potential benefit could be a major factor in practical utility because GI transit, which has to include the highly variable gastric residence time component, can be quite variable both between individuals and within the same individual depending on a variety of factors such as age, diet, pathology, and concomitant medications. The major drawback to the use of bacterial enzyme activity would appear to be the kinetics of the degradation process. In general, degradation of polymer coatings or tablet matrices by pectinolytics, dextranases, amylases, and the like is relatively slow, generally necessitating 12–24 h for complete degradation. As such, this approach is unlikely to be useful in attempts to deliver therapeutic agents to the colon in a bolus or pulsed fashion. For similar reasons, the slow release of active agents in the colon over prolonged time periods may be less than optimal in effecting adequate systemic drug absorption. Attempts to increase the rate of degradation by utilizing thinner coats or particulates will have to balance changes in degradation rate with stability of the formulation in the upper GI tract. The most apparent application of these types of colon delivery formulations may be for local application of therapeutic agents to treat pathologies of the colon itself. In this case, a prolonged, slower release over a number of hours while the dosage form is traversing toward the distal colon may be an effective means to spread the therapeutic agent over the maximal colon surface area. Obviously, a great deal of additional work is needed to develop formulations based on these strategies, but the early data offer a hope for success and warrant further investigation.

Microparticles
Nanoparticles
Pellets
Spheroids
Stabilization of drugs
Tablets

OUTLINE

Tablets
- Matrix-Type Tablets
- Film-Coating Tablets
- Multiple-Unit Tablets

Capsules
- Hard Capsules
- Soft Elastic Capsules
- Floating Capsules

Microgranules/Spheroids

Beads

Pellets

Stabilization of Drug
- Stability in Liquid Preparation
- Factors Affecting Drug Stability and Method of Stabilization

Control of the Absorption Process
- Enhancement of Absorption
- Micro- and Nanoparticles

Bibliography

Before the advance of drug delivery systems (DDSs), tablets and capsules were the principal oral preparations for drugs. However, with the development of drug delivery technology, many novel oral DDSs have been invented in the last two decades. Although these oral DDSs are prepared in traditional dosage forms as tablets, capsules, suspensions, emulsions, and solutions, they are superior to the conventional oral preparations. Oral DDSs are divided into two categories: controlled-release preparations and targeting preparations. Targeting preparations such as colon delivery systems are described in the next section; oral DDSs having controlled-release characteristics as shown in Table 1 are described in this section.

Table 1. Traditional Oral DDS

1. Tablets
   - 1.1 Matrix type
     - Hydrophobic and hydrophilic matrices
     - Plastic matrices
     - Ion-exchange resins
     - Coprecipitates and solid dispersions
   - 1.2 Film-coating tablets
     - Diffusion-controlled membranes
     - Osmotic pumps
     - Enteric coating
     - Floating tablets
     - Swellable tablets
     - Mucoadhesive tablets
     - Complexation
       - Cyclodextrins
       - Pharmaceutical additives
   - 1.3 Multiple-unit tablets
2. Capsules
   - 2.1 Hard capsules
   - 2.2 Soft elastic capsules
   - 2.3 Floating capsules
3. Microgranules/spheroids
4. Beads
5. Pellets
6. Stabilization of drug
   - 6.1 Stabilization in liquid preparation
   - 6.2 Factors affecting drug stability and method of stabilization
7. Control of absorption process
   - 7.1 Enhancement of absorption
     - Absorption promoters
     - Chemical modification
     - Classical suspensions
     - Emulsions
       - Classification of emulsions
       - Application of emulsions to gastrointestinal absorption
     - Liposomes
     - Employment of liposomes in gastrointestinal absorption
   - 7.2 Micro- and nanoparticles
     - Particulates for gastrointestinal delivery
     - Intestinal uptake of particulates
