Controlled-release technologies have been studied for a long time, and many preparations have been supplied on the market. The drug release-time is prolonged according to one of the following mechanisms (*1*) changing the physical properties such as solubility and stability of the drug molecules, (*2*) forming a complex of drug molecules with ion-exchanging resins, (*3*) incorporating drug molecules in slowly disintegrating or inert porous matrices, (*4*) coating drug molecules with pharmaceutical polymers that have a barrier function for the diffusion of drug molecules, and (*5*) osmotic pumps. In addition, new additives such as linear short-chain starches can be used to make sustained-release tablets (1). Delivery from this nonporous tablet is based on a swelling-controlled solvent-activated mechanism. In oral DDSs, this mechanism is used by itself or in combination with others (2).

Matrix-Type Tablets

Hydrophobic and Hydrophilic Matrices. To prepare a sustained-release tablet of water-soluble drugs, the drugs are mixed with hydrophobic matrices. With hydrophobic materials like fatty alcohols, acids, and esters, slow-release drug particles are prepared and are compressed into tablets. Voltaren SR is a commercial product of sodium diclofenac and is a hydrophobic matrix tablet consisting of a cetyl alcohol matrix. Ethylcellulose (EC), an inert and hydrophobic polymer that has been widely used in a number of dosage forms, was used as a matrix substance to prepare a sustained-release tablet of a water-soluble drug, pseudoephedrine HCl, by direct-compression technology (3). The lower-viscosity grades of EC are more compressible than the higher-viscosity grades, resulting in harder tablets and slower release rate. To prepare sustained-release tablets of a highly water-soluble drug, ABT-089, a cholinergic channel modulator for treatment of cognitive disorders, a hydrophobic matrix composed of carnauba wax and partially hydrogenated cottonseed oil were used as the rate-controlling materials (4).

Cellulose ether polymers such as hydroxypropylmethylcellulose (HPMC) in hydrophilic matrices are also used

to prepare oral controlled-release tablets (5). In particular, high-viscosity grade of HPMC (≈1,000–1,500 cps) is used to prepare matrix tablets by a dry-granulation method. The combination of high- and low-viscosity grades of HPMC was shown to be applicable as the matrix base to prepare diclofenac sodium (6) and zileuton (7) sustained-release tablets. A new ternary polymeric matrix system composed of pectin, HPMC, and highly water-soluble drugs such as diltiazem HCl was developed by direct-tablet compression (8). Further adjustments in the drug-release rate can be accomplished by two external layers (caps). This system, the Geomatrix trilayered tablet, was applied to develop a once-a-day formulation of diltiazem HCl (9). Diltiazem is contained in the hydrophilic polymer core, and two external layers serve to control the rate of hydration of the core, thereby restricting the surface area available for drug diffusion. Xanthan gum was also used as a hydrophilic matrix for sustained-release ibuprofen tablets (10). MSContin tablets, a controlled-release system for morphine, is a combination matrix consisting of a hydrophilic granular system inserted in a hydrophobic matrix. Theo-Dur is a controlled-release tablet of theophylline. As shown in Figure 1, it consists of 2 components: a matrix of compressed theophylline crystals and coated theophylline granules embedded in the matrix (11). One-third of the dose is in the matrix, and the remainder is in the pellets. In contact with fluid, the theophylline matrix disintegrates and dissolves. Next, theophylline diffuses slowly through the wall of the free granules. Finally, the granules dissolve completely. After oral administration of Theo-Dur 300-mg tablets to human subjects, serum theophylline concentrations over 1 mg/L were maintained over 24 h (12). A new melt-extrusion method for manufacturing matrix DDSs for theophylline was proposed (13). The powder mixture, drug, and polymerlike polyethylene and polycaprolactone were melted at 100–120°C for 30–45 s in a melt extruder. Thereafter, the mass was extruded into a disk mold (3 × 12 mm), and the polymer disk containing the drug was removed by cooling. Three-layer matrix tablets of diclofenac sodium have been reported in which poly(ethylene oxide) (PEO) and HPMC together with diclofenac sodium were directly compressed into a three-layer matrix system (14).

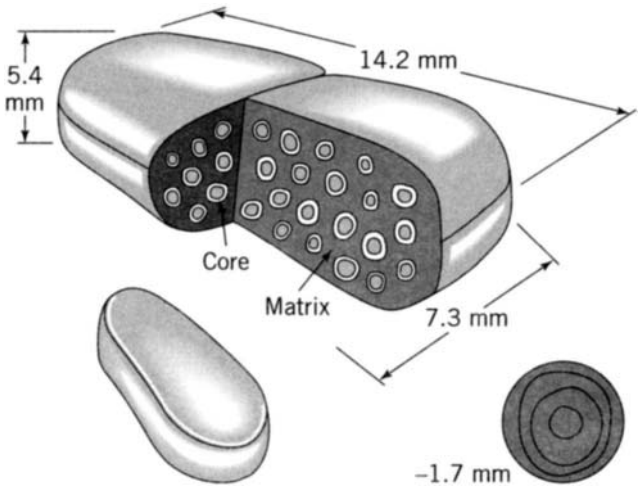

Figure 1. Structure of Theo-Dur.

Plastic Matrices. Sustained-release tablets can be also prepared by formulating an inert pharmaceutical polymer such as poly(vinyl chloride), poly(vinyl acetate), and methyl methacrylate. These polymers protect the tablet from disintegration due to the effects of peristalsis and turbulence and also reduce the dissolution rate of the drug inside the tablet. This technology was applied to theophylline (Theograd), sodium valproate, and iron. Theograd tablets consist of a matrix of a methylacrylate/methylmethacrylate copolymer that is mixed with theophylline and compressed into 250- and 350-mg tablets. In human studies, the extent of bioavailability increased about 1.4 times in fasting conditions (15,16). Therefore, it is recommended that Theograd sustained-release tablets be taken after a meal.

Owing to the shape of an average tablet (biconvex or disc), it is theoretically improbable for these tablets to release active drugs at a zero-order rate. Whether the matrix releases drug via swelling control or erosion (or both), it is almost impossible to attain a zero-order release. To solve this problem, core-in-cup tablets that release drug from a single, stable eroding surface of constant surface area were developed (17). As shown in Figure 2, the cup tablets were prepared by directly compressing the mixture of EC and carnauba wax, and the resultant cups were compressed with core tablets containing ibuprofen.

Ion-Exchange Resins. Drug molecules are formulated inside the tablets so as to be bound to ion-exchange resins and coated with a semipermeable water-insoluble polymer membrane made of EC or a similar substance. The merits of the ion-exchange resin–drug complex are (*1*) that sustained-release preparations can be made by formulating a gel-forming ion-exchange resin, (*2*) there is reduction of the degradation of drug molecules in the gastrointestinal tract by complexation, (*3*) the flavor is masked. Among the ion-exchange resins, divinylbenzenesulfonate is most commonly used because of its safety. This technology was applied to drugs with unpleasant flavors and strong effects on the stomach walls that, hence, need sustained-release characteristics. Phenylpropanolamine, codeine, dextromethorphan, acetaminophen, ephedrine, and chlorpheniramine are representative drugs to which cationic ion-exchange polymer matrices technology has been applied. For example, divinylbenzenesulfonate was used to prepare

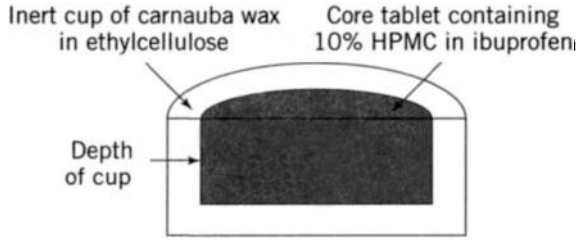

Figure 2. Schematic diagram of the core-in-cup tablet. *Source:* Ref. 17.

a sustained-release oral preparation of phenylpropanolamine by coating the tablet with EC (18). A problem associated with this approach is that drug release can be very rapid in the presence of an excess of ions, and dose dumping can occur. This can be prevented by impregnating the ion-exchange resin with an agent to impart plasticity and then coating it with a permeable membrane such as EC so that diffusion through the coating becomes the rate-limiting step (19).

Coprecipitates and Solid Dispersions. To modify the dissolution characteristics of drugs, coprecipitation involving the dissolution of ibuprofen and Eudragit S 100 in alcohol followed by the addition of cold water under agitation was developed (20). The release of oxazepam, a poorly water-soluble drug, was enhanced from tablets containing dispersions with a carrier, Gelita collagel (molecular weight 18,300), an enzymatically produced collagen hydrolysate, where the solid dispersion was prepared by a spray-drying method using the mixture of oxazepam, carrier, and lactose in 70% ethanolic solution (21). The bioavailability of cyclosporin A, a water-insoluble drug, was improved by solid dispersion with enteric coating polymer and surfactant (22).

Film-Coating Tablets

The dissolution rate of drug molecules from the tablet can be controlled by coating the tablet with a polymer membrane. For this purpose, EC and enteric-coating polymers such as Eudragit L and S (methacrylic acid copolymer) and hydroxypropylmethylcellulose phthalate (HPMCP) have been used.

Diffusion-Controlled Membranes. The dissolution rate of drug molecules can be modified by selecting the coating materials. Cellulose derivatives are generally used for this purpose. When a water-insoluble polymer such as EC is homogeneously used, the dissolution rate is dependent on the membrane thickness. However, when both water-insoluble and soluble polymers are used for the coating, the drug-release rate is accelerated. The addition of large amount of plasticizers such as triethyl citrate and tripropyl citrate to the coating polymer solution also increases the release rate of drug molecules. For example, drugs such as captopril, diltiazem, or ranitidine are blended with HPMCP, microcrystalline cellulose, poly(vinylpyrrolidone) (PVP), and magnesium stearate, wetted with anhydrous ethanol, and then compressed into tablets after drying. When these tablets were coated with a semipermeable membrane made from a mixture of microcrystalline cellulose acetate, PVP, and tripropyl citrate, satisfactory sustained-release tablets were obtained.

A gastrointestinal diffusion system (GDS) is a typical example of a DDS and consists of a soluble core including drug and tablet excipients. The porous membrane composed from arabic gum, dextrin 40,000, sodium chloride, sucrose, and cellulose acetate covering the core controls the diffusion rate of the drug (23). GDS was applied to metoprolol, diltiazem, lithium acetate, and disopyramide. As a new coating material, cross-linked amylose was developed and gave a sustained drug delivery (24).

Osmotic Pumps. The osmotic pump consists of a drug contained in a rigid, semipermeable membrane in which an orifice of approximately 300 μm has been created by a laser beam. This system is applicable to a drug having a suitable aqueous solubility, such as indomethacin and metoprolol (25). These drugs are formulated within the system with hydrogel polymers. After water is drawn into the capsule by osmosis, osmotic pressure increases within the capsule, and as a result the saturated drug solution is forced out through the orifice. The factors affecting the drug-release rate from the system are (*1*) quality and quantity of the hydrogel polymer and (*2*) permeability of the membrane. As semipermeable membrane substances, cellulose acetate ethylcarbamate, polyamide, and polyurethane are used. When drug molecules are dispersed within the tablet in a hydrogel, controlled release is obtained. Among the hydrogel polymers, ionic materials such as carboxymethyl cellulose (CMC) were useful because the ionizable groups provide most of the osmotic pressure required to draw water through the semipermeable membrane. These polymers can be compressed into tablets with conventional machinery when dry. There are three representative products: (*1*) The generic osmotic pump, supplied as OSMET, in which antipyrine or theophylline was contained. These pumps were applied to human subjects as rectal delivery systems for antipyline and theophylline (26). (*2*) The elementary osmotic pump, which is called OROS, was applied to metoprolol. The merit of OROS is the capability of obtaining a zero-order release rate, and the release rate is independent of the gastrointestinal pH and food intake. (*3*) The push–pull osmotic pump, which was developed to overcome the shortcomings of the osmotic pump system, namely, to produce small tablets in large quantities with high reliability and low cost for clinic application.

The technology has been applied to nifedipine, phenylpropanolamine, prazosin, and salbutamol. The GITS (gastrointestinal therapeutic system) tablet is a representative one (27). This tablet consists of a push layer and a pull layer. After oral administration, drug molecules are suspended within the water owing to the gastrointestinal fluid, and the polymer in the push layer swells. Because of this pressure, nifedipine molecules stream through the micropores on the surface of the tablet.

The first drug to which the osmotic pump was applied was indomethacin, which is a representative nonsteroidal antiinflammatory drug. However, severe gastric irritation occurred because of the concentrated indomethacin solution liberated from the small hole. To overcome this problem, bilayered osmotic tablets were applied to atenolol (28).

These osmotic tablet formulations are well suited for soluble drugs and core excipients with high osmotic pressures. However, osmotic delivery of moderate- to low-solubility drugs is limited because the dense coatings have relatively low permeabilities. To improve this problem, asymmetric-membrane tablet coating was developed (29).

Enteric Coating. To protect the drug molecules from the gastric degradation, as can occur with digoxin or erythromycin, and to reduce the side effects by protecting the gas-

tric mucosa from attack by drugs, such as can occur with indomethacin, enteric-coating tablets are used (30). The polymers used for enteric coating are acid-impermeable polymers. Commonly used enteric-coating materials and their threshold pH are as follows: cellulose acetate trimellitate (CAT), 4.8; HPMCP, 4.5–4.8; poly(vinyl acetate)phthalate (PVAP), 5.0; HPMCP 50, 5.2; HPMCP 55, 5.4; Eudragit L30D, 5.6; cellulose acetate phthalate (CAP), 6.0; Eudragit L, 6.0; and Eudragit S, 6.8. The use of CAP has been decreased because the phthalate ester group in CAP is known to be susceptible to hydrolysis during storage, with the gradual formation of phthalic acid and a reduction in acid resistance of the polymer film (30). Eudragit contains free carboxyl groups and is impermeable at low pH but disintegrates at a pH of about 7. According to the dissolution characteristics, several types of polymers are available. Eudragit S dissolves at pH 6.8, and two types of Eudragit L dissolve at pH 5.5 and 6.0 HPMCP dissolves at pH 5.5. These enteric-coating polymers were designed based on the assumption that the pH of the stomach is acidic, pH 1–3, while that of the intestine is neutral, pH 6–7. The reported ranges of the gastrointestinal pH values in healthy human subjects are 0.5–0.8 (stomach), 5.0–6.5 (jejunum), 6.0–7.5 (ileum), and 6.0–8.0 (colon). Although the normal gastric pH of human subjects is 1–3, the higher gastric pH was reported in the case of geriatric patients. Patients with achlorhydria also have higher gastric pH. In addition, the gastric acid is completely buffered by food in the case of postprandial administration. Therefore, considerable amounts of drug may be released into the stomach in these cases. The proximal jejunum usually lies within pH 5.0–6.5. The pH rises slowly along the length of the small intestine to reach only pH 6 to 7 in most subjects, although high values in the range 7 to 9 have occasionally been found. Therefore, the enteric coat should be soluble at a pH slightly lower than 7.

Enteric coating was applied to tablets using a solution of polymer dissolved with alcohol, acetone, methylene chloride, and similar substances. Usually, 6–8% of the tablets' weight is necessary to obtain acid resistance and impermeability. However, owing to environmental concerns, aqueous-based latex suspensions are used nowadays. In these cases, a much more precise coating technique is needed to eliminate the possibility of pinholes. Therefore, a higher quantity of coating material is required, approximately 10–12% of the tablet weight (30).

The evidence that enteric-coated drugs lessen or eliminate local side effects such as gastric irritation is conflicting. Enteric-coated aspirin is reported to be less likely to produce injury to the gastric or duodenal mucosa than plain or buffered aspirin. Enteric-coated potassium chloride tablets, however, are no longer used because of the risk of intestinal ulceration.

Erythromycin (EM) is rapidly degraded by gastric acid. Therefore, EM is administered as a stable ester prodrug or in enteric-coated tablets. However, the high pH (6.5–7.0) required for the dissolution of the enteric coating delayed the release of EM beyond its principle absorption site in the proximal small intestine. Therefore, choosing the right enteric-coating polymer is critical to produce efficacy. To obtain good reproducibility and less intersubject variation, enteric-coated tablets with diameters of less than 5 mm or so are preferable.

Floating Tablets. A floating dosage unit is useful for drugs acting locally in the proximal gastrointestinal tract. These systems are also useful for drugs that are poorly soluble or unstable in intestinal fluids. The floating properties of these systems help to retain these systems in the stomach for a long time. Various attempts have been made to develop floating systems, which float on the gastric contents and release drug molecules for the desired time period. After the release of a drug, the remnants of the system are emptied from the stomach. As a floating tablet, the hydrodynamically balanced system (HBS) is representative (31). This system is based on the principle that an object of less specific gravity than the gastric fluid will float on the gastric fluid in the stomach and thus keep the tablet in the stomach for a long period. Consequently, gastrointestinal residence time will increase. This system is applicable to drugs that suffer degradation in the intestine, have a higher pH than the stomach, and are poorly absorbed from the lower part of the small intestine. Diazepam, captopril, and morphine are suitable drugs for this system. These drugs are mixed with gel-forming hydrocolloids such as HPMC and fillers of low density in a tablet. Therefore, the hydrocolloids also retain drug molecules inside the tablet by decreasing the diffusion rate of drug molecules in the gel matrix.

The developing theory of gastric floating systems is based on the assumption that the subject is always upright. However, if the subject lies on his or her left side, this assumption breaks down. This point is the shortcoming of the floating system.

Intragastric floating diltiazem HCl tablets were prepared from chitosan and its HCl salt, polyvinyl alcohol (PVA) and PVP (32). Chitosan, a natural polysaccharide, has mucoadhesive properties. Therefore, the residence time of the chitosan-based tablets in the stomach was thought to be increased.

Swellable Tablets. It is possible to retain tablets in the stomach by increasing their size. The stomach discharges its contents through the pylorus into the small intestine. If the tablets are larger than the pylorus, they can stay in the stomach for a long time. For the sake of ease of swallowing, the tablets must swell in the stomach and attain a large size quickly. If not, the tablets are emptied through the pylorus. In addition, the swelled tablet should not block the pylorus. The physical characteristics of tablets such as size, shape, and flexibility also affect gastric emptying. The cloverleaf-, disk-, string-, and pellet-shaped tablets shown in Figure 3 were prepared from a silastic elastomer, and their gastric retain was studied (33). The tetrahedron made with low-density polyethylene remained in the stomach for longer periods than other shapes of similar size. Gastric retention of rigid rings was affected by their size. Disk and cloverleaf shapes showed poor gastric retention. The stomach eliminated strings and pellets fairly rapidly. As swellable gel-forming polymer retain drug molecules within the tablet, sustained-release tablets can be prepared. A tablet composed of a pH-independent

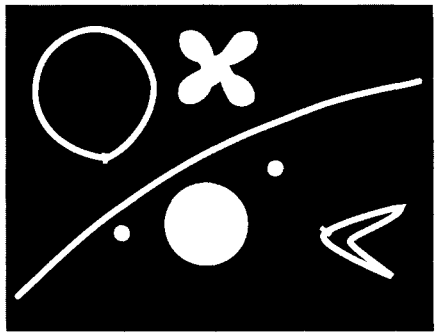

Figure 3. Shapes tested in the in vivo size/shape study. *Source:* Ref. 33.

hydrocolloidal gelling agent, a pH-dependent polymer such as sodium alginate, and a binder showed a sustained-release pattern of incorporated basic drugs.

The effect of fasted and fed conditions on gastric retention of balloon dosage forms were studied by comparing the gastric emptying time of the balloon dosage forms and the uncoated nondisintegrating tablets. The balloon tablet was 3–6 times larger than the plain tablet (34). The balloon type and nondisintegrating types of tablets were emptied from stomach under fasted conditions quite quickly. However, the balloon tablets remained in the stomach for a longer time than the plain tablets under fed conditions. The balloon tablets remained in the stomach for about 6 h more than the plain tablets. The balloon tablets floated more quickly in fasted condition than in fed condition. This could be due to the presence of high-viscosity gastric contents during fed condition.

Mucoadhesive Tablets. Oral cavities such as the buccal and sublingual sites have advantages for drug administration, for example, rapid onset of action, high blood levels, avoidance of the first-pass effect, and no exposure of the drug to the gastrointestinal tract. Drugs are also applied, localized, and removed easily. Several synthetic polymers including cellulose derivatives, plant gums, and polyacrylic acid are bioadhesive. For the treatment of aptha and oral *Candida* infections, bioadhesive tablets containing steroids or miconazole have been studied (35). Mucoadhesive, erodible buccal tablets containing clotrimazole have also been reported (36). Alternatively, mucoadhesive films composed of the highly water-soluble drug lidocaine HCl, EC, and HPC were reported as controlled-release preparations (37). To achieve high bioavailability and extended absorption time for nitroglycerin and isosorbide dinitrate, a slowly disintegrating plain tablet and a film-covered tablet in which disintegration was controlled by a hole in the film coating were developed (38).

Complexation ***Cyclodextrins.*** Hydrophobic drugs must be dissolved in the gastrointestinal tract to cross the membrane of the enterocytes. To accelerate the dissolution of water-insoluble drugs, traditional formulation systems involved a combination of organic solvents, surfactants, and extreme pH conditions. However, these systems often cause the irritation to the gastrointestinal tract. To solve this problem, cyclodextrins (CDs) have been included in tablets to improve the dissolution rate of drugs (39). CDs of pharmaceutical relevance are cyclic oligosaccharides composed of dextrose units joined through a $1 \rightarrow 4$ bond. CDs form complexes with hydrophobic drugs and increase the water solubility of drugs. Six types of CDs are now commercially available: α-, β-, and γ-CDs and three modified derivatives of β-CD-methyl, hydroxypropyl, and sulfobutylether (40). However, β-CD is the most popular pharmaceutical additive of these. The commercial pharmaceuticals with β-CD–based formulations are piroxicam as a plain tablet, prostaglandin (PG) F_2, and nitroglycerin as a sublingual tablet. CDs are capable of forming inclusion complexes with drugs. These noncovalent, inclusion complexes can have physical, chemical, and biological properties that are dramatically different from those of either the parent drug or CD. The safety evaluation of CDs have been reviewed (41). These complexes can be used to increase solubility (42,43) and dissolution rate, decrease volatility, alter release and dissolution rates, modify local irritation, and increase the stability of drugs. A complex formation of oxazepam and β-CD by the spray-drying method gave the most efficient dissolution characteristics (44). Solubility of ketoconazole was increased with β-CD complexation (45,46). In addition, sustained-release tablets were prepared by incorporating drug within the matrix in the form of a hydrophobic complex with β-CD. This technology was applied to diltiazem HCl using ethylated β-CD, and pH-dependent release of diltiazem was obtained. β-CD was also applied to salbutaine release preparations (47).

Pharmaceutical Additives. Polymeric complexes based on the interaction between Eudragit L and naltrexone HCl gave a significant reduction in the release rate of drug from the complex used as a naltrexone controlled-release system (48). New water-soluble polycations were synthesized and used as oral carriers (tablet) of diclofenac sodium and sulfathiazole sodium (49).

Multiple-Unit Tablets

The term *multiple-unit tablets* refers to tablets containing subunits that may be either the same (homogeneous) or different (heterogeneous). Multiple-unit tablets give much diversity in achieving dissolution profiles by combining various types of subunits in a tablet. Usually, by combining the immediate-release portion and controlled-release portion, sustained-release tablets are prepared. This system has been recently applied to nifedipine. The Adalat CR tablet is composed of two portions; the core is a immediate release, and the coat is a controlled release layer in which a gel-forming polymer is formulated with nifedipine. After oral administration, the coat tablet forms a gel by the permeation of gastrointestinal fluid. Thereafter, constant-rate drug release occurs according to the erosion of the matrix gel. In contrast to the finish of the drug release from the coat matrix gel, the core tablet releases drug at a comparatively fast rate. This nifedipine is a once-a-day tablet. After oral administration of an Adalat CR 40-mg tablet, plasma nifedipine concentration was maintained between 20 and 50 ng/mL for 24 h (50).

A sustained-release tablet formulation of naproxen (Naprelan) disintegrates to release discrete pellets that act as individual sustained-release units (51). A delayed-release tablet system that consists of a core containing diltiazem and an outer shell of CM-type hydroxyethylcellulose (HEC), a gel-forming polymer, has been designed. This system is useful for treating time-related symptoms that require time-controlled or site-specific delivery in the gastrointestinal tract (52).

CAPSULES

Hard Capsules

Gelatin capsules are the most popular hard capsules. Except for gelatin, which is a protein, carbohydrate and synthetic polymers are used as capsular materials. These are Capill capsules, HPMC (hydroxypropylmethylcellulose) capsules, poly(ethylene glycol) (PEG) capsules, and LSSM (liquid and semisolid matrix) capsules (53). The composition of HPMC capsules are HPMC/carrageenan/NaCl/water = 93.3:1.1:0.6:5.0 and have the following merits: (*1*) low water content, about one-third as much as gelatin capsules; and (*2*) applicability to drugs that are unstable with water. PEG capsules are produced by adding PEG 4,000 (5%) to gelatin; the resulting capsules have much tolerance to water loss. LSSM capsules can contain water-insoluble drugs that are dissolved with solvent. By using LSSM capsules, the bioavailability of water-insoluble drugs is improved. LSSM capsules were applied to oral sustained-release captopril, which was suspended in a semisolid oily base and filled inside LSSM capsules. After the gelatin layer dissolved, a sustained-release profile of captopril was obtained from the oily base matrix. Capill is made from potato starch and is an alternative to hard gelatin capsules. Capill capsules represent a robust dosage form with a reduced susceptibility to changes in storage conditions (54).

The solid-dispersion technique was applicable to prepare sustained-release gelatin capsules of dipyridamole and indomethacin, where enteric and insoluble acrylic polymers such as Eudragit S, RS, and RL were used (55). As compared with the conventional method of preparing solid dispersion by the melting-carrier method, the spray-drying method gives much better dissolution rates of low-solubility drugs (55). The bioavailability of a poorly water-soluble drug, a novel leukotriene B_4 antagonist, was further improved by the addition of a surfactant, Labrasol (a defined combination of mono-, di-, and triglyceride and mono- and difatty acid, C_8–C_{10}, esters) (56). Enteric solid dispersion was applied to nifedipine and enhanced release was reported (57). Solid dispersion of piroxicam in PVP K-30 was prepared to increase the solubility (58). The mixture of HPC and PEO was used to prepare solid dispersion of flurbiprofen (59).

However, in the field of sustained-release preparations, hard gelatin capsules have been generally used. As the contents composed of multiple units can elucidate the function of sustained-release preparation, hard gelatin capsules are used merely as a container. In these preparations, gelatin capsules are made of subunits such as granules or spheroids, beads, or beadlets and pellets. Hard gelatin capsules can be also filled with molten formulations of drug substances that solidify on cooling. The carriers are PEGs and macrogol esters such as Gelucires. However, recent study suggests that rapid cooling will leave material that is not fully solidified and is liable to change on storage (60). Modification of gelatin capsules with enteric coating is possible (61,62). Microporous EC capsules were prepared for the sustained release of cisplatin, an extremely hydrophilic and low-molecular-weight anticancer drug (63). To improve the bioavailability of peptide that undergoes degradation by proteolytic enzymes, capsules with fast gel-forming and fast drug-releasing properties were developed by formulating neutralized freeze-dried carbomer inside the capsule (64,65). The bioavailability of the water-insoluble drug KNI-272, a protease inhibitor for HIV, was improved by dissolving with propylene glycol and filling a gelatin capsule whose inside surface was coated with EC (66). Sustained-release of diclofenac sodium was achieved from several minimatrices enclosed in a hard gelatin capsule containing locust bean, xanthan, and karaya gums (67).

Soft Elastic Capsules

To solve many problems associated with tableting, including poor compaction, lack of content or weight uniformity, and other powder-flow or mixing problems, formulation of drugs into soft gelatin capsules has been performed. Soft elastic capsules are made of gelatin, glycerin, ethylparaben, propylparaben, and water. The representative composition of capsule film is gelatin/glycerin/*p*-hydroxybenzoate esters/tar color = 100:30:0.2:q.s. As a plasticizer, sorbitol is added to this formula to decrease the permeability of water vapor through the soft capsule. Usually drug liquid or paste is contained inside the capsule. However, the drug and the base must be inert to the gelatin layer. Both oily and aqueous bases are available in soft capsules. The formers are vegetable oil, medium-chain fatty-acid triglyceride, lecithin, paraffins, and higher alcohols. The later are PEG, propylene glycol, and polyhydric alcohols such as sorbitol, glycerin, and so on. Soft capsules are applicable to oily drugs and drugs whose clinical dose is extremely low, for example, prostaglandins. The drug content of these preparations is less than 1 mg. With the recent implementation of drug-development systems such as computer-aided drug design (CAD), extremely hydrophobic compounds are identified. However, these compounds suffer from low bioavailability because of their low solubility. To improve the dissolution rate of these compounds, soft capsules are used as delivery systems (68). Nifedipine is an example of this type. By formulating nifedipine into soft capsules after being dissolved with PEG, the bioavailability of nifedipine was improved. Ibuprofen soft capsules are another example. On the other hand, soft capsules also have several problems, namely, (*1*) hydrophilic base cannot be used; (*2*) drugs that need high clinical doses are not suitable, because the percentage of the formulated base is high compared with the amount of the drug; and (*3*) the stability of drug molecules must be considered because of the water remaining in the gelatin capsule film.

The most successful soft gelatin capsule is the new oral cyclosporin formulation Sandimmune Neoral. As cyclosporin is extremely hydrophobic and a poorly water soluble drug, it has low bioavailability, limited dose proportionality, and highly variable systemic plasma drug concentrations. Neoral is a microemulsion formulation of cyclosporin. Microemulsions are thermodynamically stable, isotopically clear dispersions of two immiscible liquids, oil and water, stabilized by an interfacial film of surfactant molecules (69). When the water is absent, mixtures of oil and nonionic surfactant form clear solutions that are known as self-emulsifying drug delivery systems (SEDDSs) (70,71). In Neoral, cyclosporin A, surfactant, a hydrophilic cosolvent, and a blend of lipophilic and hydrophilic solvent are contained in a soft gelatin capsule. Neoral showed reduced inter- and intrapatient variability in the bioavailability of cyclosporin A compared with the original preparation (72).

Solid-state water-in-oil-in-water (w/o/w) emulsion was applied to vancomycin. The primary emulsion (w/o) comprised sesame oil, monoglycerol stearate, and water (73.5:1.5:25). Vancomycin was contained in the aqueous phase, which was isotonized with NaCl. By using sucrose as a matrix material at a ratio of 3.5:1 sucrose/primary emulsion, w/o/w solid-state emulsion was obtained. Although vancomycin is not normally absorbed, it was significantly absorbed, and sustained-release characteristics were obtained after administration to rats in solid-state w/o/w emulsion (73). Enteric-coated soft gelatin capsules containing ibuprofen in either PEG 400 or Miglyol can also improve the bioavailability of hydrophobic drugs (74). Microemulsion is a useful delivery system for the improvement of bioavailability of RGD peptide, a fibrinogen-receptor antagonist of tetrapeptide, after oral administration in rats, where microemulsions were prepared by formulating Captex 200 (C_8/C_{10} diesters of propylene glycol), Capmul MCM (C_8/C_{10} mono-/diglycerides), and Cremophor EL (polyoxyl 35 castor oil) (75). Lipid-based vehicles for the oral delivery of poorly water soluble drugs have been reviewed recently (76). A list of natural and synthetic lipids and formulations using lipid-based vehicles is described in relation to the dissolution and digestion processes occurring in the intraluminal circumstance. Inversely, solubilization of hydrophilic drugs in oily formulations gives rise to new possibilities for peptide delivery via the intestine (77). For the oral delivery of calcitonin, Bridgelock formulation, a w/o emulsion system, was proposed (78). In an alternative approach to improve the bioavailability of a low-water-solubility drug, DMP 329, a protease inhibitor for HIV, an amphiphilic material such as Gelucire 44/14 (a mixture of glycerides and PEG esters) was shown to be useful (79).

Floating Capsules

A billeted floating capsule was developed for misoprostol. There were two layers in a capsule: a release layer and a floating layer. The floating layer consisted of Methocel K4M, lactose, Aerosil 200, and magnesium stearate. The release layer consisted of various combinations of Methocel K4M, K100, drug, HPMC, and Pharmacoat 606 and 603. Large quantities of high-viscosity polymer were incorporated to form a strong viscous layer. This helped in maintaining the integrity of the floating layer for a long time. The drug-release layer consisted of a gelling agent. This helped avoid disintegration and prevented delivery of large particles containing drug into the intestine, thus reducing side effects (30). HALO delivery capsules consists of a biphasic rapid- and sustained-release formulation contained a lipophilic drug such as propranolol dissolved in oleic acid. Initial rapid release of the drug–oleic acid solution is followed by the subsequent sustained release of those components from a solid erodible matrix containing a Gelucire of low hydrophilic lipophilic balance (HLB) and melting point above 37°C (80,81). A novel in vitro dissolution test method for a floating-dosage form with biphasic releasing characteristics was proposed (82).

MICROGRANULES/SPHEROIDS

Wet-granulating drugs or incorporating them into inert granules that are then coated to control the release pattern are two common approaches in preparing controlled-release oral preparations. The majority of published work on spheronization relates to idealized aqueous-based systems, which contain high concentrations of microcrystalline cellulose and lactose. With respect to the organic solvent-based systems, which have potential applications for many drugs that are moisture and/or heat sensitive, extruders and spheronizers fitted with flame-proof motors and specialized drying equipment are used (83). As pharmaceutical additives that regulate the release rate of drug molecules from the granules, cross-linked β-CD, crospovidone (a water-insoluble but swellable nonionic polymer), Eudragit RS (a slightly water-soluble polymer), Eudragit NE 30D, and EC are used. In addition, wax or waxlike pharmaceutical additives such as cetostearyl alcohol are used. These technologies were applied to diltiazem and hydrochlorothiazide.

BEADS

Small beads prepared from various polymers and other pharmaceutical additives are used as carriers to prepare oral sustained-release capsules of water-soluble drugs by filling gelatin capsules. Rapid- and slow-release beads were obtained by coating the central cores of beads with different amounts of Eudragit RS and RL. By adjusting the ratio of these two types of beads in a hard gelatin capsule, a once-a-day diltiazem preparation can be obtained. A sigmoidal drug-release pattern can be obtained by preparing the beads from Nonpareil (sugar spheres) layered with drug molecules and coated with a swellable polymer layer and a water-insoluble polymer layer. The most representative of these is the time-controlled explosion system (TES) (84). The most important point is that a swellable layer is formed between the drug layer and the water-insoluble layer. The sigmoidal drug-release pattern is obtained by the following processes: (*1*) permeation of fluid into the system through the water-insoluble polymer layer (membrane), (*2*) creation of pressure by expansion of swellable material, (*3*) pressure causing drug to break out of the

water-insoluble layer, and (3) drug release to the outside. By adjusting the thickness of the water-insoluble layer, beads having any release lag time can be prepared. By formulating several kinds of beads with different release lag times, sustained-release capsules have been prepared in which EC was used as a water-insoluble coating polymer. Granules were prepared by a centrifugal fluidizing (CF) granulator (83). As a variation of TES, a sigmoidal release system and pulsatile-release tablet were also designed (85,86). Flowable-bead cellulose (BC) coprecipitates consisting of spherical BC as carrier, the film former HPMC, the hydrophilic solubilizer PEG 6000, the plasticizers dimethyl phthalate and dioctyl phthalate, and the model drugs prednisolone and griseofulvin were prepared for controlled release (87). Chitosan was used to prepare controlled-release beads containing piroxicam by gelling the cationic polysaccharide with an anionic counterion, tripolyphosphate, solutions (88). Swellable porous hydrogel beads were loaded with diclofenac sodium, and sustained release was obtained (89).

PELLETS

Multiple-unit dosage forms are also known to have less variance in transit time through the gastrointestinal tract than single-unit dosage forms. Sustained-release diltiazem HCl pellets were prepared simply by coating inert diltiazem HCl pellets with soluble Eudragit L and S film-forming polymers (90). Alternatively, similar diltiazem pellets capable of controlling the drug release over 24 h were possible. Diltiazem HCl, fumeric acid, and talc were blended, mixed, and applied to Nonpareil using a coating solution of PVP to prepare the pellet core. The core was then coated by spraying solutions of Eudragit RS and Eudragit RL. The ratio of the two polymers could be optimized to get a controlled-release profile over 24 h. A comparative bioavailability study using two types of sustained-release oral isosorbide dinitrate (ISDN) showed that pellets had higher bioavailability than tablets (91). Two reasons are possible: One is the lower dissolution rate of ISDN from the tablet, as ISDN received high hepatic first-pass effect, and another is that ISDN was absorbed from the larger area of the gastrointestinal tract as pellets received wide distribution there. Moreover, to prevent the effect of gastric emptying or the change of the transit of the preparation through the gastrointestinal tract, pellets are preferred because the gastric emptying time for pellets is faster than that for tablets. For this purpose, sustained-release oral pellets of ISDN and propranolol have been developed. To prepare pellets, the mixture of drug, organic acid, and polymer was coated on the core substance. Organic acids like citric acid and tartaric acid have the role of accelerating the release rate of drug even in the high-pH environment of the gastrointestinal tract. As a polymer, HPMC, PVP, Eudragit RL and RS, methylcellulose, and EC are used. As a coating material that was used to control the release rate of drug molecules, EC, sometimes with a small amount of HPC, was used. In the case of sustained-release propranolol pellets, a mixture of 20% PVP in isopropanol/33% shellac in ethanol (19:1) was used as a polymer solution. Sustained release from pellets is conventionally achieved by polymeric coating. However, versatile matrix pellet formulation based on the combination of a hydrophobic material and a starch derivative using a melt pelletization technique is possible (92).

Another method for the production of enteric beads using a purely aqueous system composed of HPMCP and riboflavin has been developed (93). Pellets containing enteric coprecipitates of nifedipine formed by nonaqueous spheronization have also been reported (57). Calcium pectinate was used as a coating material to prepare sustained-release theophylline pellets (94).

On the other hard, prolonged gastric residence was obtained by increasing the density of pellets. The critical density to achieve prolonged gastric residence was reported to lie between 2.4 and 2.8 g/cm^3 (95). For the manufacture of sustained-release pellets for highly dosed, freely soluble drugs such as diltiazem HCl, the hot-melt extrusion method was shown to be suitable (96). Figure 4 shows the extruder used in this study. The volume and viscosity of coadministered fluid also affect the gastrointestinal distribution of small particles (97). Recently, an extrusion–spheronization method was developed to prepare sustained-release indomethacin pellets whose shape and size are shown in Figure 5 (98).

STABILIZATION OF DRUG

Examinations of drug stability using chemical kinetics gives us clues to how to stabilize the drug and helpful suggestions for its preservation requirements as well as a determination of its validation date.

Stability in Liquid Preparation

In liquid preparations of drugs, hydrolysis, oxidation, racemization, decarboxylation, or ring-opening reactions are usually observed; however, the majority of drugs in liquid phase are disintegrated according to hydrolysis or oxidation (99). The most popular order of reaction observed in liquid preparation is first order due to a large excess of medium compared with drug, which is called pseudo-first-order reaction.

Factors Affecting Drug Stability and Method of Stabilization

Temperature, pH, and other factors such as kind of medium, concentration, ionic strength, or permittivity are major factors that affect stabilities of drugs in liquid phase (99). To investigate the effect of temperature, which is one of the strongest factors affecting the rate of drug degradation, an analysis using the Arrhenius equation should be performed. When this Arrhenius plot is linear, the reaction rate of the drug at normal temperature can be estimated by the results under a higher temperature; this relation is applicable when activation energy is 10–30 kcal/mol unless chemicals are separated or melted (99). In general, Arrhenius plotting is done at several temperatures. The statistical evaluation of accelerated stability can be determined for a single temperature, and by this method it was reported that a reasonable prediction of the expected

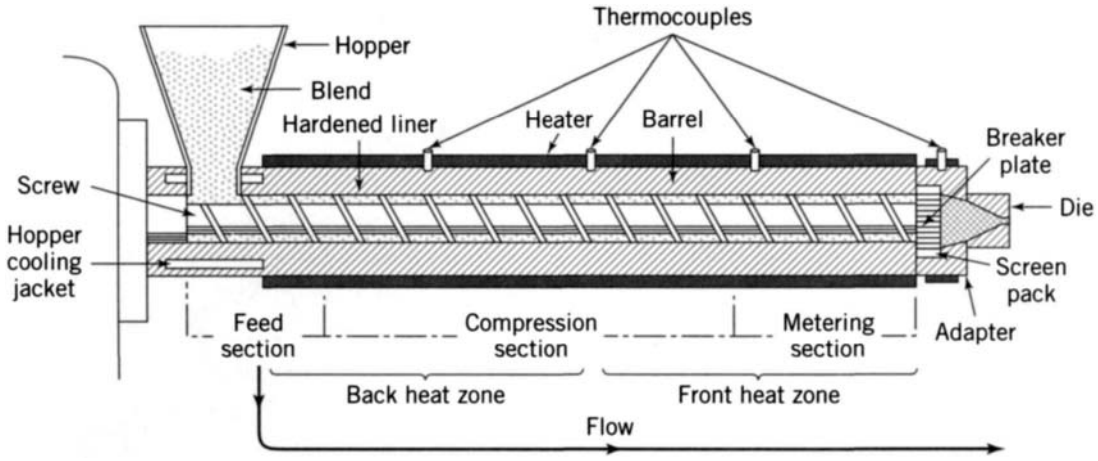

Figure 4. Cross-section of the single screw extruder. *Source:* Ref. 96.

shelf life as a function of activation energy may be possible (100). When we design a liquid preparation, the effect of pH on drug stability is also a frequently encountered problem. In pH analysis, the reaction rate of the pH profile can indicate the most stable pH range of the drug. There are three types of pH profiles: the so-called V type, the sigmoid type, and the bell type (101,102). Specific acid–base catalysis, an action of a single dissociation group, and that of two dissociation groups affecting reaction rate is a major cause of drug degradation according to the pH profile of the V type, sigmoid type, and bell type, respectively. From this information we can determine how to stabilize a drug in liquid preparation, that is, we can select a pH at which a drug is most stable, storage at lower temperature, blocking of oxygen in air, and preservation in a shaded container. In addition to these countermeasures, which sound like passive stabilization, various active stabilizations have also been attempted (Table 2). Stabilization of ampicillin in aqueous solution using a base formation with benzaldehyde and furfural has been reported (103). With an increase of added benzaldehyde and furfural, the degradation rate of ampicillin decreased, which is caused by binding of both chemicals to form a Schiff base, which is relatively insoluble in aqueous solution and thus leads to drugs being excluded from a degradation system. This stabilization by aldehyde is also observed in cephalexin, a β-lactam antibiotic that possesses an amino group at the α-

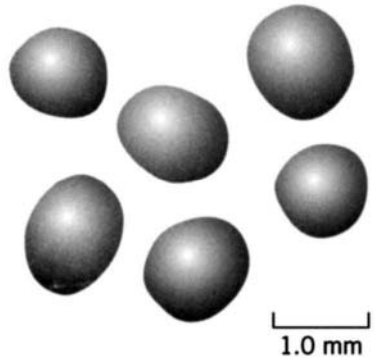

Figure 5. Shape and size of indomethacin pellets.

position (103). Inclusion compounds such as cyclodextrin can also stabilize drugs that are disintegrated by hydrolysis. In these attempts, bencyclane (104), prostacyclin (105), and a nonsteroidal antiinflammatory agent (106) were stabilized by an addition of cyclodextrin. In these chemicals' hydrolysis, sites are considered to be protected from reaction by means of cyclodextrin. Dissolved oxygen contributes to oxidative degradation that is accelerated by metal ions as catalists, and an attempt to protect isoniazid in aqueous solution from oxidative degradation has been

Table 2. Factors Affecting Drug Stability in Solution and Methods for Stabilization

Major ways of degradation	Factors affecting degradation	Methods for stabilization	
		Passive methods	Active methods
Hydrolysis	Temperature pH Ionic strength Permittivity Polarity	Storage under suitable conditions	Formation of complex or base Chemical modification Addition of solvent or surfactant
Oxidation	Oxygen Metal ions Light	Protection from air and light	Addition of chelating agents and antioxidants

made using chelating agents. In this report, chelating agents such as ethylenediaminetetraacetic acid or nitrilotriacetic acid, which trap metal ions in liquid preparation, stabilized high-isoniazid solutions (107). Whereas the components of containers for liquid preparations sometimes decrease drug stability owing to adsorption of drugs to the container wall or evaporation of medium through the wall, comparative stability was reported with cimetidine, furosemide, and theophylline in glass and polypropylene containers (108). After 30 days of storage, the residual rate of furosemide in glass containers was approximately 80%, but only 70% in polypropylene containers. With cimetidine and theophylline, a significant difference of stability was not observed between the containers. This study suggests that container materials should also be considered as a factor leading to degradation of drugs.

CONTROL OF THE ABSORPTION PROCESS

Enhancement of Absorption

Many important therapeutic agents, such as peptide drugs, are not absorbed sufficiently through gastrointestinal tissue barriers. In pharmaceutical research, efficient drug delivery of poorly absorbable medicines from the gastrointestinal tract has been of major interest. A series of compounds with very different structures has been proposed as effective absorption promoters for drugs after gastrointestinal administration in recent years (109). According to their ability of promotion and their adverse reaction with the mucosal membrane of the gastrointestinal tract, these promoting agents are classified into four groups (109). Middle-acyl-chain saturated fatty acids (110), long-chain unsaturated fatty acids (111,112), and Azone (1-dodecylazacycloheptan-2-one) (113) promote drug absorption with strong, fast reactivity and also with a rapid recovery of barrier function. The next group exerts a moderately fast reactivity at absorption enhancement and also has fast recovery. In this class, salicylates (114) and bile salts (115) are representative examples. Relatively effective at enhancing the absorption of chemicals but with a slow recovery rate is a third group of agents in which various chelating agents and powerful surfactants such as sodium lauryl sulfate (SLS) are categorized (116,117). Group four is a category of moderate reactivity as miscible solvents on absorption promotion: ethanol (118), dimethylsulfoxide (119), dimethylformamide (120), and so on. Structurally, in these enhancing agents the most promising have mutual peculiarities: (*1*) hydrophobic moieties such as C_{10}–C_{20} acyl chain or steroid skeleton and (*2*) hydrophilic groups such as hydroxy, carboxyl, glyceryl, or sulfate groups (109).

Chemical Modification. Attempts to modify preexisting drugs chemically and improve their physicochemical characteristics, thus gaining more valuable derivatives, have been systematized as a drug design strategy. These chemically modified drug derivatives are divided into two classes: prodrugs and analogs (121). A promoiety is added chemically to the parent drug, and when the new drug expresses its pharmacological effect after separation from the parent drug, the derivative is called a prodrug. On the other hand, if the derivative exerts a pharmacological activity without disintegration, it is called an analog. In absorption enhancement of drugs from the gastrointestinal tract, efforts using prodrugs for promotion have also been performed. Generally, gastrointestinal absorption of most drugs depends on simple diffusion, which is controlled by the lipid membrane of epithelial cells, and therefore increasing lipophilicity of drugs to raise their permeability across the biomembrane barrier is one of the most important purposes of prodrugs (121). Among attempts to improve gastrointestinal absorption of medicines, antibiotics have been target drugs for long time. Ampicillin is a typical drug for such targeting its absorption from the intestine is not good owing to a poor oil–water partition. As prodrugs for increasing lipophilicity of ampicillin, bacampicillin (122) or talampicillin (123) were synthesized. These are stable in aqueous solution at neutral pH; however, in the presence of a hydrolysis enzyme, an ester site is rapidly hydrolyzed and reverts to ampicillin. For both prodrugs, oral administration to humans indicated higher blood levels compared with ampicillin, which is sufficient for therapy. Also for cephalosporin, same esterification increased its lipophilicity and thereby improved its gastrointestinal absorption (124). Despite the importance of peptides and protein drugs for various therapies, their oral bioavailability is not good usually because of their poorly absorbabilities and enzymatic degradation in the gastrointestinal tract (125). Thus, in the absorption promotion of peptides and proteins, enhancement of absorption as well as protection from proteolysis should be addressed. For peptides and proteins, it has been pointed out that chemical modification may be a potential method for fulfilling these requirements in their gastrointestinal absorption (126). Consequently, the advantages of chemical modification of peptide drugs are (*1*) protection from degradation by peptidase or other enzymes in the lumen or the mucosae of gastrointestinal tract and (2) increasing their permeability through the membrane when lipophilic residues are added. Recently, derivatives of insulin (127,128), calcitonin (129), tetragastrin (130,131), and thyrotropin-releasing hormone (132,133) were synthesized in which acyl-chain residues of aliphatic fatty acids were added. In these, acylated insulins such as dicaproyl and lauryl insulin still possessed moderately high pharmacological activities (over 60% compared with that of native insulin), and their half-lives in the small-intestine mucosa in vitro increased 1.2- to 3.4-fold in monoacylated derivatives (128). However, the absorption of insulin after small-intestine administration could barely be improved. In contrast, its absorption after large-intestine administration was enhanced by increasing the number of caproic acid molecules attached to insulin (128). These in situ results indicated that the chemical modification of insulin with fatty acids was a beneficial approach for improving insulin absorption from the large intestine. Similar results have been obtained with other peptide drugs (129,131). Thus, these findings indicate that lipophilicity is an important factor for enhancing the permeation of peptides through the intestine; however, the small intestine is a more powerful degradation barrier in

vivo, probably because of potent enzymes, than the large intestine.

Classical Suspensions. Usually suspensions are chosen for administering drugs for the following reasons: insolubility or instability of drugs, difficulty of correction of taste, and adjustment of overly rapid absorption when dissolved in medium. A crystal polymorphism is a frequent problem in absorption using the suspension form. In spite of the same chemical composition, different crystal structures yield various physical differences, for example, the dissolution rate is sometimes greatly affected by polymorphism, which causes the absorption fluctuation (134).

Emulsions. Emulsion is a heterogeneous system that finely disperses a liquid into another one using a third material such as an emulsifying agent. This formula is suitable for liquid preparation of lipid-soluble drugs as well as water-soluble drugs; however, few products use emulsion for oral administration.

Classification of Emulsions. A dispersed phase, that is, an inner phase of emulsion, usually ranges from 0.1 to 1.0 μm in its diameter (135). When the diameters of emulsions are under 0.1 μm, they are called microemulsions, which appear translucent or transparent, and compared with conventional emulsions, microemulsions are thermodynamically stable (136). Emulsions consist of at least three components, the inner phase (dispersed phase), outer phase (dispersion medium), and emulsifying agent. Oil-in-water (o/w) emulsion includes a lipid in inner phase, and inversely, the same phase of water-in-oil (w/o) emulsion is an aqueous solution. In addition to these simple emulsions, there are so-called multiple-phase emulsions such as w/o/w type and o/w/o type.

Application of Emulsions to Gastrointestinal Absorption. Conventional emulsions are physically unstable heterogeneous mixture systems, which limits their broad application to medicine. However, many investigators have recently attempted to use emulsions as dosage forms in gastrointestinal absorption for the purpose of improving absorption and retaining drugs in the alimentary canal. Lipid-soluble drugs are the main target for improved absorption, especially immunosuppressive drugs such as cyclosporins, which are clinically administered as microemulsions, resulting in a more enhanced absorption of the drug compared with marketed oily formulations (137,138). A multiple emulsion (w/o/w type) has also been reported useful for promotion of drug absorption; it was reported that intestinal absorption of a poorly absorbable model fluorescein chemical by this emulsion using oleic acid as an oily phase was almost equal to that of solubilized mixed micelles (139).

Liposomes. Liposomes are vesicles that consist of a double-layer membrane of phospholipid. Liposomes have fundamentally the same structures as natural biomembranes, and thus they have been investigated as model membranes. The reasons why liposomes have been highlighted as drug carriers are their ability to encapsulating drugs inside themselves like microcapsules and their susceptibility to endocytosis or fusion with cell membranes. By devising the proper preparation methods, various kinds of liposome shapes and sizes are available, such as multiple liposomes or unilamellar liposomes (140). Additionally, incorporating basic lipids or acidic lipids into membranes can change the surface charge of liposomes. From these characteristics, we can expect to use them as controlled-release media, or to stabilize or target drugs in the body.

Employment of Liposomes in Gastrointestinal Absorption. On application of liposomes for gastrointestinal absorption, the oral administration of liposome-encapsulated insulin was reported to reduce the blood sugar level of rats with diabetes (141). Since this report, many others have been submitted on the improvement of gastrointestinal absorption of drugs such as glucose oxidase (142), cytarabine (143), gentamicin (144), erythropoietin (145), and amphotericin B (146). However, there are many problems regarding the application of liposomes to improve gastrointestinal absorption of drugs: (*1*) less reproducibility of absorption enhancement, (*2*) low rate of entrapment of water-soluble drugs, and (*3*) unclear mechanism of absorption enhancement. Regarding the mechanism of liposome's absorption enhancement, it has been argued that liposomes might reach through the cell membrane to circulation or that drugs are released from liposomes and then transfer to the blood or lymph. On this point, an experiment of permeability of liposome through rat everted sac using encapsulated macromolecular dextran as a marker revealed that a little bit of intact liposome was taken up into the epithelial cells (147,148). However, any clear mechanism on absorption enhancement by liposomes has been not submitted, and thus further investigations are necessary for clinical use of them in gastrointestinal absorption. Most drugs that are employed with liposomes are hydrophilic, but some investigators reported that the intestinal uptakes of lipophilic drugs such as vitamin K (149) and dolichol (150) are being considered to locate at the membrane of liposome were enhanced.

Micro- and Nanoparticles

Microparticles are polymeric particles ranging in size from 1 to 1,000 μm, and nanoparticles are similar, ranging in size from 1 to 1,000 nm (151). Both consist of natural or synthetic macromolecular materials in which drugs are encapsulated, entrapped, or dissolved or to which they are adsorbed (151).

Particulates for Gastrointestinal Delivery. In peroral administration, particulates have been employed for carriers to enhance the absorption of drugs (152). An enhanced oral absorption of vincamine was reported in rabbits using nanoparticles of adsorbed type (153). Using the same type of nanoparticles, the oral absorption of insulin was enhanced in diabetic rats (154). In this attempt, a reducing effect on blood sugar level was sustained for 20 h after administration. Additionally, the absorption of tomato lectin in rats has been shown to be enhanced by nanoparticles (155), whereas microparticles have been reported to also be useful for sustainment or enhancement of gastrointestinal absorption. Sustained release of zidovudine (AZT)

was shown in vivo using EC microspheres after oral administration in dogs (156). Encapsulated AZT showed significantly lower maximum concentration (C_{max}) values and longer times to C_{max} (t_{max}) values. And longer mean residence time (MRT) was also observed compared with AZT powder. In rats an oral delivery of γ-interferon was attempted in which it was encapsulated in polylacetate microspheres (157). In this report, a quite different distribution of interferon level was observed in vivo at 15 and 240 min after oral administration, in contrast to the control group, which received equivalent doses of unencapsulated interferon. These findings would suggest the tentative conclusion that microencapsulation of proteins markedly affects oral uptake and possibly postabsorption pharmacokinetic parameters as well. This experiment stands on the hypothesis that particulate material itself could be absorbed from the gastrointestinal tract.

Intestinal Uptake of Particulates. Despite many findings in the past 20 years of the uptake of micro- or nanoparticles through the intestine after peroral administration, there is much difference of opinion as to the site of absorption and its mechanism. In 1977, so-called persorption of large starch microspheres (5–150 μm) via the intestinal villae tips was reported in animals including humans (158). It was pointed out that this persorption was an infrequent occurrence and also a rather pathological phenomenon (159). Several investigators examined cytosis of particulates by the intestinal epithelial cells. In these examinations, phagocytic transport of 1-μm polystyrene microspheres in the intestines of rats and dogs was found (160). The uptake of polystyrene nanospheres up to 100 nm with the aid of endocytosis was also reported histologically (161). However, it was insisted that 2-μm microspheres of polystyrene could be taken up through the epithelial cells of the intestine (162). In addition to these convenient routes of intestinal absorption, recent studies have revealed a predominant contribution of M cells on uptake of particulates at the Peyer's patch. Peyer's patch localizes in duodenum, jejunum, and ileum spottily and originally constructs a gut-associated lymphoid tissue in which there are M cells being specially compared with normal absorption cells (163). These M cells possess a high activity of endocytosis that is performed by specific receptors at the surface of its cell membrane. Macromolecules or particulates absorbed by M cells are released into extracellular space, being included by lymphocytes or macrophages, and thus appear in the intestinal lymph nodes (163). The effect of particulate size on their uptake through M cells has been argued by many investigators. In their research, various upper-limit sizes of particulates for uptake into Peyer's patch were reported: 15 μm (164), 10 μm (165), and 3 μm (161). It was also found that although particulates under 5 μm were transferred into the lymphatics, larger particles of 5–10 μm remained in the Peyer's patch (165). Recently, the usefulness of biologically erodable and adhesive particulates (0.1–10 mm) composed of a copolymer of fumaric acid with sebacic acid or lactide-*co*-glycotide was reported for potential oral drug delivery systems (166). These particulates were recognized microscopically to traverse both the intestinal absorptive cells as well as Peyer's patches and to reach the spleen and liver tissues after lengthy contact with gastrointestinal mucosa. An enhanced exertion of pharmacological effects of three model chemicals (dicumarol, insulin, and plasmid DNA) with widely different molecular weights loaded in these particulates was observed inside the intestinal tissue, in the liver and in the blood. As just mentioned, despite the very limited area of Peyer's patch, microparticles or nanoparticles probably enable the absorption of loaded drugs through M cells. Thus, for drugs designed for lymphatic absorption, uptake through the Peyer's patch is surely significant; however, further examinations are necessary for drugs that require a transfer into systemic circulation. Additionally, the route as well as mechanism of particulate uptake in the intestine is not completely clear, and thus such examinations also should be continued for clinical usage of micro and nanoparticles.

INTRODUCTION

Some General Considerations

Gregordiadis in 1978 (1) noted that the ideal dosage form in cancer chemotherapy was one that provided a sufficient amount of an antineoplastic drug or anticancer agent—not necessarily the same thing—to the tumor site in a sufficient amount for an adequate period of time without adverse interaction on normal, healthy tissue. This definition implies that the delivery system is capable of targeting the tumorous tissue, and it is easier to envisage small particles being able to specifically target tumors, tissues, or organs. However, the definition applies equally well to devices that are implanted or inserted in close proximity to the target tissue. These devices may consist of a drug dispersed in a slab or rod of suitable polymer that can be implanted into the tissue or a pump that infuses controlled amounts of drug into the vicinity of the target.

Nevertheless, as Illum and Davis (2) suggested, targeting of microparticulate drug carriers to extravascular tumors required particles in the submicrometer size range, by implication in the colloidal region. Colloidal drug carriers have been described by others (3,4). More recently colloidal microspheres as sustained release targeting agents for antitumor drugs have received a considerable amount of attention, reviewed by Donbrow (5) and Kreuter (6,7). Microparticulate vehicles prepared from albumin, gelatin, or polymers such as poly(lactic acid) (PLA) have been evaluated (8,9) and, in some cases, have become pharmaceutical products, although for the most part these have been diagnostic agents. Other colloidal systems such as liposomes and emulsion products are also now appearing in the pharmaceutical marketplace after extensive development and scientific exploration of their properties. One is always reminded, after reading about a new "development" or drug delivery system, that it took roughly 25 years for liposomes to be developed to marketable, realistic products. The initial excitement evident in the early research papers describing the possibility of using liposomes

as drug delivery systems makes for interesting reading today. These early pioneering authors were apparently unaware that there are huge differences between making an ill-defined suspension of liposomes on a 5 mL scale in the laboratory and to manufacturing a 5,000 liter (or more) batch of a well-defined and well-characterized material suitable for administration to patients with efficacy, safety, and reproducibility. Moreover, these pioneers did not seem to be aware that before patients could receive these complex systems, the systems themselves had to have other basic requirements. Thus, knowledge of the reproducibility of the state of dispersion—not only the mean particle diameter itself but also the way in which the distribution of size was spread around the mean—were essential requirements for any product specification. In addition, because many of these laboratory-scale products were going to be injected directly into the patient, they had to be sterile and apyrogenic, requirements that were evidently of low priority to many of these early workers. Indeed, one early review on parenteral products failed to even mention sterility (10). Eventually, when it became necessary to scale-up these laboratory-scale experiments to make sufficient of a product for sale, issues such as particle size changes associated with chemical degradation of components on autoclaving or thermal effects produced on dispersions became evident and proved to be difficult to resolve for several years. These requirements resulted in significant delays in the development of some liposomal products, in some cases having profound economic consequences on their developers.

These issues have now become evident on hindsight for liposomal products; in fact, they are applicable to any controlled release product intended for parenteral delivery. A general review of issues associated with scale-up has recently appeared and can be strongly recommended as an introduction to the topic (11).

Essential Requirements of Parenteral Products

All parenteral products are designed to bypass the body's natural defenses against microorganism invasion associated with skin and mucosal tissues. Irrespective of the physical nature of the product, be it a simple solution of the drug in water or a complex insertable pump, all parenteral products have some basic requirements to which must be added the general requirements associated with all pharmaceutical products:

1. Sterility
2. Apyrogenicity
3. Reproducibility in performance
4. Safety
5. Efficacy

Methods of achieving *sterility* are reviewed in a later section, but it makes sense not to introduce a pathogenic microorganism into a body that is most likely already debilitated by disease and therefore has lower resistance to bacterial invasion. *Apyrogenicity* is closely associated with the need for sterility because, under some conditions, bacteria or products associated with dead bacteria can produce febrile reactions that are rarely fatal but can be unpleasant for the patient. Moreover, pyrogens can be measured with some precision and accuracy, and low levels of pyrogen infer a low bioburden in the product being tested. *Reproducibility* of the product implies that there is uniformity of drug content, not only in each item produced in a batch but also from batch to batch. The same implication applies to the rates of drug release from the device or system so that ultimately there is a reproducible effect produced on the target tissues over a sufficient and reproducible length of time. *Safety* is also clearly necessary, and even the Hippocratic Oath required that doctors (and their associated medications) do no harm. *Efficacy* is also implied—there would be little point in administering the system otherwise.

Over the past two decades or more, many elegant and ingenious methods for obtaining the controlled release of a wide variety of drugs have been described in the literature; few products based on these methods have actually achieved commercial success. Obviously, one could argue that much of this ingenuity was expended in what were, for the most part, academic exercises designed to train, learn, and stimulate. However, it could also be argued that the intellectual effort expended in this area may have been substantially dissipated by a failure to realize that parenteral products must have these five essential requirements before proceeding to test the devices or systems in humans. Nevertheless, some groups of workers still persist in making impressive claims for potential applications based on experiments involving laboratory experiments on a scale of 5–10 mL or less. Naturally, beginnings have to be made somewhere but one might suggest that these initial claims could have been somewhat muted.

The Importance of Scale-up and Reproducibility

Most of the five essential requirements have been covered by textbooks that are readily available. However, scale-up and reproducibility are generally not covered and the following section provides some pointers.

Parenteral sustained release products are usually dispersions of one phase, often a solid, or a liquid in another liquid phase, usually water. Exceptions are the implanted solid products, which are themselves macroscopic and therefore relatively easy to produce with precision and accuracy. In the same way, characterization in terms of dimensions and performance prior to administration is also straightforward. This is less true for dispersed systems, which are generally much more difficult to make reproducible and characterize with precision and accuracy. Although it is not appropriate to go into this area in more detail, it should be noted that regulatory authorities such as the U.S. FDA rightly demand that production and characterization methods used for human-use products must be validated. The scientific challenge is to prove (and validate) claims made for the product. If the specification calls for a product containing particles 200 nm in diameter, the key question to be answered by the validation process is just how true is that statement? How do different batches of the product compare; are they always 200 nm in diam-

eter (as measured by an appropriate method itself validated as precise and accurate), and how does any batch-to-batch variation in the diameter, if detected, affect performance as measured by a suitable method, preferably in human patients? Scale-up and, to a large degree, reproducibility go hand in hand and should be considered together.

METHODS OF STERILIZATION OF PARENTERAL DRUG DELIVERY SYSTEMS

Introduction

Any material introduced into the body (human or animal) parenterally (that is, *para enteron* or "beyond the gut") should be sterile, because the body defenses have been bypassed. Philosophically, sterilization is quite absolute in concept and means (e.g., *The Concise Oxford Dictionary*) "rendered free of microorganisms"). Certainly it is important that any parenteral "should do no harm." The production of disease or even death by injection of contaminated product is not unknown, and it is certainly not acceptable. Even the production of abscesses following injection, which may ultimately heal, is not acceptable. Many patients receiving parenteral products are doing so because they have a disease or condition that impairs their natural defense mechanisms through the immune system. What would be easily dealt with by a healthy individual often cannot be tolerated by a sick person.

The absolute need for sterility is therefore easy to understand and one can appreciate why regulatory authorities insist on regarding sterility as an absolute concept. Nevertheless, there have been reasons to raise questions about this rigidity of definition because situations have arisen that ultimately lead to confusion. Sterility as such is easy to conceive but, in reality, microorganisms are ubiquitous in the environment and difficult to remove. In a closed system they can be killed by the application of heat or irradiation, but exposed to the environment once again, the product will become contaminated with more viable and therefore equally potentially dangerous microorganisms. The dictionary definition of sterilization, "rendering free of living microorganisms," can be carried out, but now we are becoming more aware of peripheral issues. For example, if we apply some environmental stress to a closed system containing living microorganisms (e.g., heat), how do we know just how much stress we need to apply to kill, or render nonviable, *all* of the microorganisms present? In practice a manufacturer uses a traditional overkill approach, such as autoclaving for 15 minutes at 121°C. These conditions are generally recognized as being sufficient to produce a "sterile" product. But what if the exposure time was only 14 minutes; does that mean the product is no longer sterile and therefore safe to use? How about only 10 minutes exposure to the stress or only 5 minutes?

The issue here is the rigidity of the thinking process and the attitude of regulatory authorities reviewing processing proposals. The absolute approach—15 minutes safe, 14 minutes unsafe—is safe from a regulatory standpoint but scientifically it is unlikely to be valid. A modern solution of a drug, filtered repeatedly through porous membranes down to 100 nm pore size, is "almost sterile," i.e., the bioburden is very low, before it is put into the autoclave, and a much lower heat insult is required to achieve "absolute sterility." To be fair, parametric release is now allowed by some regulatory authorities, and this process takes these considerations into account. There are additional issues if the drug itself is labile and is adversely affected by heat. In that situation it is likely that the solution would need to be "sterile filtered" and filled into a presterilized container in an "aseptic process." However, a filtration process is anything but absolute, and there are issues associated with running a truly satisfactory aseptic process. Here the absolute certainty associated with an overkill heating process is diminished considerably, and one has to start thinking in terms of an acceptable element of risk.

Some of the issues of this dilemma have recently been discussed by Gilbert and Allison (12) and their arguments expanded by Groves (13). The essential point of the argument is that a filtration process is certainly not an absolute process in the sense that, perhaps, a few microorganisms may not have been removed so the filtrate may not be truly sterile. Issues now arise, such as how can such small numbers of microorganisms per unit volume be measured or even detected. Gilbert and Allison pointed out that, in fact, not all microorganisms are pathogenic and are easily dealt with by the body's defense mechanisms or are simply not able to survive in a physiological environment. Moreover, even most pathogens require a sufficient number of organisms to produce some manifestation of disease. There are some interesting exceptions to this point but essentially their argument is that, if we remove most organisms from a product, that product can be regarded as aseptic and is therefore *safe* to use.

As already noted, in practice absolute sterility cannot be achieved in many situations because of the lability of the drug. In addition, because degrees of sterility of a product cannot be measured—it is either sterile or not—we have to start using statistical concepts to estimate the effectiveness of the sterilization process. Many of these concepts were proposed at the turn of the twentieth century with especial reference to foodstuffs, where levels of contamination were often very high and product lethality was a major concern. One must therefore question just how valid these earlier concepts are now when applied to modern pharmaceutical products that, by any standards, are exceptionally clean, so that the initial numbers/unit volume of contaminating microorganisms are very low. A real difficulty is that concepts or probabilities are not scientific *measurements* and many attempts to understand and explain modern ideas on the subject have simply become confused. Judgments are being made based on poor science, and one must suspect that nobody benefits, especially the patient who ultimately pays for all of this confusion.

It is also ironic that novel processes and ideas being used or explored in the food industry today are proving very difficult to translate into what is already a very conservative and economically driven pharmaceutical industry. It is also true that the death rate today due to microbiologically contaminated foodstuffs is finite although small, due to heavy regulation, the death rate in the pharmaceutical industry is infinitely small.

Many of these issues have been discussed in detail elsewhere by this author (13), and only a summary is necessary in this article.

The "Death" of Microorganisms

Because of the labile nature of so many of the new biotechnological drug entities such as proteins, genes, or DNA fragments, it has become necessary to explore sterilization procedures that lack the overkill approaches associated with older, more stable drugs. With heat or radiation it may be more feasible to apply a graded approach, using the minimum amount of energy sufficient to kill likely microbial contaminants without producing loss of product. The issue has now become about how to define bacterial "death." Dictionaries are of little help, because they just define *death* as a state of annihilation or ceasing to exist. For a bacterial cell, there is generally a clear relationship between form and function that is essential for "life" or conversely "death." Vegetative bacterial cells are relatively easy to kill by exposure to modest temperatures; the cell stops metabolizing and is unable to divide to form other bacterial cells. The metabolic processes by which the cell generates, uses, and stores energy in order to synthesize cellular components and allow replication of genetic material are complex but, individually, are dependent on a series of sequential reactions that can be blocked or broken when, perhaps, the conformation of just one essential protein is subtly changed. This process in itself is unlikely to require much external energy to accomplish. However, bacteria have developed survival mechanisms designed to resist environmental stresses, and generally, if one enzymatic pathway is disrupted, it is replaced by another. Damage to DNA sequences can be repaired over time, so it is possible that bacterial cells that shut down after the application of a mild heat stress would, over a period of time, recover their functionality. Bacterial death is therefore not very easy to define or to measure. Some bacteria have an interesting defense mechanism in that, when exposed to extreme environment changes such as desiccation, they form endospores that are nonfunctional cells in the usual sense but are quite capable of resisting applied environmental stress. When subsequentially exposed to a milder, favorable environment, the endospores rapidly revert to the usual metabolizing (vegetative) dividing cell forms. Endospores can be killed by exposure to extreme heat conditions such as those encountered in an autoclave or hot air oven, and it is for this reason that otherwise overkill conditions are employed. Part of the problem is judging the total amount of energy required to inactivate a mixed culture of different bacterial species in suspension. A typical but exaggerated situation in a nonsterile situation is that not only do the different individual species have inherently different susceptibilities to an applied stress but that individual organisms of the same species also have different sensitivities, mainly because they are inevitably at different points of their growth cycles. Some, for example, have just divided and others would be just on the point of dividing, with other cells at various stages in between. In order to inactivate (sterilize) such a broad cellular mixture, it would be necessary to apply enough stress to kill the least susceptible (or most resistant) organisms present, and it is usually assumed that in practice these are the endospores noted already. However, not all microorganisms produce endospores, and this is apparently also true for some of the extreme thermophilic organisms recently reported (14).

Historically, this type of rationalization has been derived from studies on foodstuffs where the bacterial burdens are usually much heavier than those of pharmaceutical solutions, quite apart from the fact that the latter are generally less hospitable and, therefore, less favorable for growth. Working on the survival of the spore-forming botulism organism *Clostridium botulinum* in canned foods, the highest concentration of endospores that could be harvested, cleaned, and suspended in phosphate buffer was approximately 10^{11} organisms/mL. It was therefore reasonable to apply enough heat to kill every organism in the system. Because one-tenth of the organisms could be killed in 0.21 minutes at 250°F (121°C), (D, the decimal reduction value) it is not difficult to calculate that $12 \times 0.21 = 2.52$ minutes, under the same conditions, would be sufficient to kill all the spores in the system and more (i.e., 10^{12}/mL). This is the basic logic that most of the pharmaceutical regulatory authorities are using to control sterilization processes. Enough energy is required to be applied in order to produce a reduction of 12 logs in the bacterial count to ensure that a pharmaceutical solution is sterile. In the case of a foodstuff consisting almost entirely of *Clostridium* spores, 2.52 minutes autoclaving would be sufficient heat exposure; any additional heating time would be an unnecessary overexposure and would most likely result in spoilage of the food due to a loss of quality or flavor. Applying the same logic to a pharmaceutical solution, likely to be less hospitable and certainly containing far fewer viable organisms or endospores in the first place, one can begin to realize why exposure to 12D values is an anachronism which could result in a deteriorated product. Unfortunately, regulatory authorities are going to need to be convinced that less heat (or energy trauma) is acceptable. The arguments of Gilbert and Allison (12) are very persuasive at this time but their gospel needs to be disseminated more widely and pondered on longer. Heat sterilization conditions may well destroy bacteria but, at the same time, the product is also destroyed. If the product could be manufactured with very few bacteria (per unit volume) it would mean that the applied stress could be much lower, and consequentially, there would be less resultant deterioration of the product.

Sterilization Methods

Killing or inactivation processes are limited to applied physical environmental stresses or the application of chemicals that irreversibly damage the bacterial cell functionality. In addition, filtration is used to physically remove all bacteria present, although this is an assumption that needs to be evaluated more closely.

Physical means of sterilization include:

- Dry heat
- Moist heat

- Ionizing radiation
- Intense light
- Filtration

Chemical means of sterilization include:

- Aldehydes
- Ethylene oxide
- β-propriolactone
- Peroxides
- Chlorine dioxide
- Iodine
- Ozone
- Alcohols/phenols
- Quaternary ammonium compounds
- Chlorine, chlorate

In its very helpful review of the current technicalities of sterilization in a General Information Chapter (⟨1211⟩ Sterilization and Sterility Assurance of Compendial Articles), the United States Pharmacopeia 23 (15), notes, as discussed earlier, that the absolute definition of sterility cannot realistically be demonstrated because of limitations in testing. In other words, every container in a lot would need to be tested in order to demonstrate that the lot had been made sterile. The emphasis of the USP 23 chapter then turns to the sterility of a product in probabilistic terms, the *chance* of a container being contaminated or not. Since probabilities cannot be *measured*, the importance of properly validated procedures and equipment becomes dominant. This requires, of course, total reliance on documented good manufacturing procedures (GMPs), which is outside the scope of this present review. Nevertheless, it serves to emphasize when working in a modern pharmaceutical plant just how important are properly validated and documented procedures. The USP 23 lists five methods for sterilization, which are briefly reviewed here, together with a more recent procedure currently under development.

The Effect of Heat

Heat sterilization processes are divided into moist heat and dry heat conditions. Because these conditions vary considerably both in the temperature and time of application required to achieve sterilization, it seems that there may be a fundamental difference in the mechanism by which loss of functionality is achieved.

As the environmental temperature around a microorganism is raised, enzymatic processes increase in tempo to a plateau temperature that may be at or only slightly above that of the normal environment of the organism. Indeed, some organisms are now known to be at their optimal activity at temperatures approaching that of boiling water (14), although most other vegetative bacteria are killed under those same conditions. The rate processes decline after plateauing until the main enzymes associated with cell functionality have effectively stopped. Initially, the slowing of the processes may be due to some enzymatic proteins changing conformation but, at higher temperatures, the hydrogen bonding affecting the overall protein structure becomes unable to hold it together, and it comes out of solution as more and more hydrophobic groups are exposed to the aqueous environment around the molecule. Ultimately, the protein becomes completely denatured, unable to function, and unable to recover functionality. This process affects all of the proteins within the cell as well as DNA and RNA, but some of these are more readily affected than others, thereby becoming key or limiting reactions. Applying heat to a mixed bacterial suspension does not affect all bacteria equally, and as noted earlier, some may be more resistant to the stress than others. In any mixed population it is the most heat-resistant organism that is the crucial element in determining the success of a heat sterilizing process. In a suspension of a single species or organism the key reaction is the enzymic process that is the most heat-sensitive, resulting in complete and irreversible damage. In the application of heat—moist or dry—the process is deliberately designed to produce an overkill, mainly in order to kill endospores that are very resistant to heat and may be presumed to be present in a system. The point of the previous discussion was to emphasize that it might be possible to design an effective sterilization process in which a minimal amount of heat could be applied for a sufficient time to achieve the same endpoint. This becomes more feasible if there are very small numbers of viable bacteria present in the system in the first place. The kinetics of this process are examined later in this article.

One essential difference between moist heat (e.g., 121°C for 15 minutes) and dry heat (e.g., 150°C for 60 minutes) sterilization conditions may simply lie in the efficiency with which heat is applied. Beyond desiccation, however, dry heat probably also destroys some, if not all, functionality by oxidation of proteins as well as inflicting irreversible structural damage to the cellular DNA.

Conditions for the Application of Heat

The conditions noted for sterilization (121°C moist heat for 15 minutes or 150°C dry heat for 1 hour) were applied in a time when sterilization was regarded as a cookery book exercise without necessarily taking into account the bacteriology involved. Today, any sterilization process is designed to kill the most resistant organism that could conceivably be present in a system, using it as a "marker" or test species. For example, *Bacillus stearothermophilus* and *B. subtilis* endospores are both used as markers for the moist heat and dry heat sterilization processes, respectively, by the United States Pharmacopeia, although it does not follow that these microorganisms are guaranteed or even likely to be present in any pharmaceutical system prior to sterilization. They simply represent species of heat-resistant spores that are considered to have an above average degree of resistance to the chosen heating process, a worst case situation, and are therefore markers to indicate the likelihood of success.

The interesting thing about this USP chapter is that it has moved away from the classical cookery book approach to sterilization and places emphasis on the design and validation of a particular system or set of circumstances. In

other words, if it works (i.e., if it can be validated to demonstrate effectiveness), that should be sufficient. The chapter actually states that with an article where extensive heat exposure may produce damage, the development of the sterilization process (Chapter ⟨1211⟩ uses the word *cycle*) depends heavily on the knowledge of the microbial burden over a suitable time period of a *substantial* number of lots of the presterilized product. The inference is there; the actuality is not. This means it is up to the manufacturer to present sufficient evidence to the regulatory authorities that any new process is satisfactory for its purpose.

Use (and Abuse) of the Sterility Assurance Level

The sterility assurance level (SAL) is defined (16) as the probability of the nonsterility of a unit from a batch of product in the final container. This author then goes on to explain that it is assumed throughout the parenterals industry and by regulatory authorities such as the FDA that where a process appears to have an SAL of 10^{-3}, approximately 1 vial per 1,000 could be contaminated with microbes.

There are two problems with this. The first is that SAL cannot be measured; it is a concept or probability. The second issue is that, as a concept, it applied to each and every vial in the batch—each vial, for example, has a *chance* of 1:1,000 of being contaminated. It is certainly not acceptable to produce a single contaminated vial in any batch of product, irrespective of the lot size. So where does this concept come from and how may it be used correctly?

It should be noted that D values for any microorganism are characteristics of the applied heat stress. A typically resistant endospore-forming organism such as *Bacillus stearothermophilus* has a D value of 1.5 minutes at 121°C, much longer at lower temperatures, and, typically, vegetative organisms have D values well below 1 minute at a temperature of 100°C. If we set the sterilization criteria at 6D and the actual, measured, D value is 4.5 minutes, and, if the initial solution contains 100 organisms mL, it will take $4.5 \times 6 = 27$ minutes at 121°C to reduce the count to one-millionth of the original count. The SAL is 100/1,000,000 or 10^{-4}. Under the same conditions, if the initial viable count in the product was 1 organism/mL, and, assuming a worst-case scenario, the SAL then drops to 1/1,000,000 or 10^{-6}. Sterility assurance is therefore a direct function of the number or organisms initially present in the product to be sterilized.

Again, SAL values cannot be measured directly, even in a heat sterilization process, and when talking about SALs for aseptic processes or other less dramatic sterilization processes, one is strictly speaking talking about a concept, not a precise entity. The concept has become abused, with "experts" speaking of the numbers of contaminated containers to be found in a production process. If there is a SAL of 10^{-6}, in principle one of the containers in a batch size of one million could be contaminated. Should the batch size be higher than a million, this implies that the lot has one or more contaminated units in it. The issue becomes more personal when considering that aseptically assembled products are required to have an SAL of 10^{-3} or better and are made in batch sizes that might suggest several containers could be contaminated. This concept has encouraged regulatory authorities to insist on media fills to "validate" a particular aseptic process. If more than one "contaminated" sample appears in a run of 3,000, the process is considered to be unsatisfactory. One could argue that any contaminated sample in any run, irrespective of the size, is unacceptable and the fact that these guidelines have been written at all is an indication of just how far away the technology is from the older overkill situation of terminal heat sterilization. Application of the same concept to totally different and dissimilar processes would appear to be poor science and is certainly not justified.

Nevertheless, what the SAL is effectively doing is to suggest that there is a *chance* that every single vial in the batch has a *possibility* of being contaminated; it does not mean that there are going to be x vials in the batch that are contaminated. Nevertheless, the principle of a complete, validated process designed to reduce the presterilization bioburden to its lowest feasible level, together with a worst-case scenario in terms of the thermal resistance of any possible microbial contaminant is quite scientifically reasonable, but there must be emphasis on validation. Although the discussion here has tended to be concerned with a heat-stress situation, the same broad concepts apply to any other sterilization process.

Sterilization Using Gases

An attractive alternative to the application of heat stress is the use of reactant gases that are able to permeate a product and sterilize *surfaces*. The commonest gaseous sterilant at present is ethylene oxide, which is extremely effective, albeit a little slow compared with heat stress. The gas itself is highly flammable and must be mixed with suitable inert carrier gases such as nitrogen. Moreover, the mode of action depends on the humidity, concentration of sterilant, and time of exposure. The gas is also harmful to humans because of its mutagenic properties. The process, usually carried out in a sealed pressurized chamber, essentially similar to an autoclave, is designed to ensure that the product is exposed to the ethylene oxide without at the same time exposing the operators to even small residues of gas. After the sterilization process has been carried out in the presence of the required level of humidity for the requisite amount of time, often for 16 hours overnight at ambient room temperature, the residual gas must be removed by pulling a vacuum and passing sterile nitrogen through the system, again for the necessary amount of time. Sterilized product is often allowed to stand under atmospheric conditions to ensure that the last traces of gas have been removed, because even small amounts can be toxic or irritant. This is especially true for surgical dressing materials.

Again, the USP 23 emphasizes the need for adequate validation of the designed process, placing emphasis on using appropriate biological indicators such as *Bacillus subtilis* spores. Other gases have been evaluated, including β-propriolactone, but toxicity to equipment operators was unacceptably high and better alternatives are being sought.

Again, gases are useful for sterilizing surfaces, although the gas may permeate into some polymeric materials. In

these cases this permeation through and below the surface only makes it even more difficult to remove gaseous residues.

Other Methods Used To Sterilize Surfaces

The surfaces of containers and the interior of barriers where sterilized components are aseptically assembled also need to be sterilized. Containers made of glass can be heat sterilized, often in hot air tunnels through which the containers pass on their way into the aseptic assembly area. Stoppers or seals, often made of natural rubber or suitable polymers, cannot be dry-heat sterilized but can be washed and autoclaved, often in smaller quantities enclosed in plastic bags to enable them to be more readily transported to the assembly area. An alternative is ethylene oxide gas, but this is more rarely used because of the associated difficulty of removing residual gas after exposure.

Barrier technology has been developed over the past decade for aseptic processes. It effectively places a barrier between the human operators, who are the main source of bacterial and particulate contamination, and the product being assembled by providing a blanket of sterile filtered air moving under laminar flow conditions. More and more computer-controlled robotic assembly processes are being employed inside the barrier but all of these surfaces need sterilization. Where robotic arms are moving this becomes more difficult because moving surfaces must have lubrication and the lubricants may react with some if not most of the chemically reactive materials used to sterilize the internal environment. Foremost amongst current sterilants are sprays or mists generated with steam of concentrated hydrogen peroxide, which is an extremely effective material but is equally a strong oxidizing agent. Surfaces under barriers are generally composed of stainless steel, poly(methyl methacrylate), or other transparent polymers. All materials used to construct barrier and isolates must be able to withstand hydrogen peroxide and, in the case of steam-generated mists, temperatures in excess of 100°C for at least the period required during the clean or sterilize in place cycle. Not only are moving surfaces of, for example, fans and pumps affected by the sterilants but sensors, and flexible materials such as rubber or latex gloves, may be affected. In addition, barrier systems require transfer ports. The evident complexity of an effective barrier system requires an integrative approach to its design and construction. Some of the issues involved are described by Melgaard and Haas (17), and this can be considered to be a rapidly developing subject.

Other sterilant gases are probably unsuitable for plastic and stainless steel constructions because chlorine and chlorides are known to attack stainless steel surfaces. Sprays of alcohols, phenols, and detergent bactericides, although less corrosive, are also less effective. The main advantage of steam or peroxide is that no residue is left, and the degradation products are environmentally acceptable water and oxygen.

Formaldehyde and glutaraldehyde are effective sterilants for surfaces but may leave residues. However, these materials are also used as cross-linking agents in the preparation of some particulate drug delivery systems such as those involving albumin, gelatin, or chitosan. It is tempting to suggest that bacterial bioburden during processing with these materials would most likely be reduced but this does not appear to have been demonstrated in practice.

The use and effectiveness of other chemical sterilant systems was recently reviewed by Olson (18).

Sterilization by Filtration

Because many drugs, especially those produced by the new biotechnology, are heat-labile, cold sterilization through appropriate filters has been widely employed. Many microorganisms can be physically removed from liquid products, and gases may also be filtered free of microorganisms. An assembly for filtration usually incorporates a porous matrix, sealed or clamped into a suitable nonporous holder, but the assembly needs to be considered as a whole. Groves (19) noted that the criteria for an ideal filter depends on the nature of the product to be filtered, but the following attributes are generally desirable:

1. A filter should be absolute in the sense that there should be a known limit to the size of the particles in the filtrate.
2. There should be an independent means of checking the efficiency of the filter.
3. The filtration process should not be materially affected by the pressure differential across it or pressure fluctuations produced by the pumping of fluids through it.
4. The filtration medium should not affect the product.
5. The filtration system as a whole should be capable of being sterilized by heat or gas.
6. It should be economical in use.

Unfortunately, there is no ideal filtration medium and, as described by Groves (19) and Olson (20), the whole area has been confused by overenthusiastic sales personnel for the various media, not by any means confined to one commercial source. The novice reader is therefore enjoined to use much caution when reviewing sales literature in this area.

Physically one can envision the passage of suspended particles through a porous matrix until the particles become trapped when the pore becomes smaller than the particle, a sieving mechanism. Although broadly true, some filters have a surface charge that also helps to trap particles carrying an opposite charge. Asbestos fiber filters, for example, carry a strong electropositive charge that helps to collect microorganisms, which often have an electronegative charge, depending to some degree on the pH of the continuum. Asbestos fiber filters are not used today because of concerns about possible toxicity, but the same type of charge–charge interaction may well help modern membrane filters to remove particles that are much smaller than the nominal size of the filter.

Membrane matrices are now available in a wide variety of materials, including cellulose derivatives and polymers, and have different porosities. Selection of a filter depends

on the requirements of the process and compatibility with the product. Some membranes are claimed to be "absolute" in the sense already discussed, but this term is probably best avoided because the underlying science remains, even today, somewhat uncertain. Even very carefully regulated and controlled production processes result in filtration matrices with a range of pore sizes, although the range in some cases may be narrow. So-called anisotropic membranes, with coarser pores on the face of the filter decreasing in size to very small pores at the exit, are useful in effectively behaving like a staked pair of filters, one coarse and the other fine, but *all* filters have a range of pore sizes. To talk of a membrane filter with a pore size of 200 nm is misleading in an absolute sense because, in reality, the pores probably range in size from 100 to 300 nm diameter. One absolute sense would be to demonstrate that there was no pore larger than 200 nm present in the membrane, but it is not likely that a filter manufacturer would make that claim today. Instead, manufacturers have taken to claiming, again absolutely, that the filtrate will not contain particles larger than the 200 nm diameter, or whatever size is being claimed. This now becomes a performance issue that, in the case of 200-nm membranes, can be validated by challenging the sterilized filter with a suspension of 60 or fewer cm^2 filter area *Pseudomonas diminuta* organisms. This microorganism, when grown in unstirred saline–lactose broth, grows to a diameter of around 250–300 nm and is, as noted earlier, a worst-case scenario. Nevertheless, as discussed by Olson (20), if the filter is challenged with more than 60 organisms/cm^2 of filter, passage usually occurs. The use of filtration as an absolute sterilization procedure is therefore affected by the conditions of use. As noted by Olson (20), passage of particulate through a porous medium can almost certainly be considered as a probalitistic process, the higher the challenge the more likely particles are going to pass through. The success or otherwise of a terminal sterilization process therefore depends on the degree of the challenge, and this means that the bioburden prior to sterilization must be reduced to very low levels before the sterilization process is applied. This is a situation that will be familiar when considering heat sterilization, and the analogy is probably reasonably close.

These issues apart, some microorganisms are very likely to pass through filtration matrices, especially viruses. Although it may be true that many are removed by adsorption onto the medium surface as they pass across the charged surface of the matrix, this cannot be quantitated or relied on. Filtration is therefore anything but an absolute process and needs to be carefully designed into any cold sterilization process.

The Concept of "Size" Applied to the Filtration Process

Most bacteria have sizes somewhat larger than 1 μm, but spherical forms, with an unique dimension (diameter) defining size with precision, are generally only found in endospores which have diameters varying from 400 nm to 1 μm. Viruses are considerably smaller, with diameters of 50–100 nm, and fungi are often larger than 20 μm. The range of size to be removed from the system being filtered is therefore at least three orders of magnitude, varying from, say, 50 nm to 50 μm. This immediately suggests that the solid phase separation needs to be carried in stages, removing first the large particles with coarse screens, followed sequentially by smaller and smaller screens. Conventional wisdom suggests that final screens with pore sizes of 0.2 μm (200 nm) or even better 100 nm are required to remove most, if not all, of the biological particulate matter. When sterilizing a solution by this method, this size must be regarded as being a *maximum* size as determined by some externally applied physical test such as measurement by a mercury intrusion test or gaseous or liquid flow method. This consideration is important because in any filter surface a range of pore sizes is present, some large and some small, and obviously, it is the largest pore diameter that determines which is the smallest size of particle that will be retained on or in the surface. Very few membranes have uniformally sized pores, which may also vary in size as one passes from the front of the membrane to the rear. An exception to this may be found in the Nuclepore™ membranes made by weakening the structure of a polycarbonate film by etching the track left by exposure to neutron particles to remove damaged polymer. Another exception are glass membranes made by stacking bundles of acid-resistant and acid-soluble glass rods together. The acid-soluble glass is dissolved out to leave parallel and uniform pores in the sheets. In practical terms, although the maximum pore sizes represent a limit to the performance of the filter, in fact there are other considerations that affect the performance, including environmental factors such as pH and electrolyte concentration. These factors influence the electrical charge on the surface of the membrane or on the bacteria themselves, and electrostatic adsorption, quite apart from physical screening, is a mechanism by which particles much smaller than the nominal opening or pore size can be retained by the membrane.

Practical use of these types of membranes is substantially limited by the support equipment. Large filter surfaces can be wound onto cartridge-type filters that are connected to other filters or to other equipment. Flat filters made of cellulose or plastics need to be carefully supported by metal perforated screens, and a single hole in the entire system is a source of contamination because bacterial particles pass onto the product filtrate or are drawn in from the surrounding atmosphere. For this reason, performance tests designed to detect unusually large holes in a complete filtration system (filtration surfaces and supports) have been designed. These include bubble testing, in which gas is forced under pressure through the system wetted with product, the pressure at which bubbles are first detected being a measure of the largest hole.

Some microorganisms are capable of growing through or insinuating themselves through the porous filtration medium. This is especially true of protoplasts, which lack the rigid walls of most bacteria. Currently, a recommended pore size of 200 nm for a sterilizing filter is being advocated because there are forms of *Pseudomonas diminuta* that grow under certain conditions to be around 250 nm in diameter, thereby providing a useful challenge for the system. Nevertheless, it is noticeable that newer filters of 100-nm nominal diameter are being employed for sterilization of biotechnological products, in part because virus

removal at this level becomes more efficient. However, an important requirement is to use stacked or sequential filters, passing the solution through the coarsest first back down to the finest. Nevertheless, there must always be doubts that filtration is an absolute sterilization process. The best that can be said is that the process is aseptic, following the argument put forward by Gilbert and Allison (12).

Sterilization by Ionizing Radiation

Although it was rapidly realized that ionizing radiation reduced bacterial counts, there was some uncertainty about the dose needed to achieve sterility. Two types of ionizing radiation are in use, γ irradiation from radioisotope decay and electron beam radiation. γ radiation is usually carried out by exposing the product to a source of ionizing radiation such as cobalt 60 (^{60}Co) or cesium 137 (^{137}Cs). Electron beam sources are usually Van de Graaff generators in some form, and X-rays may also be used. The same amount of energy is delivered slowly by a ^{60}Co source but very rapidly as an electron beam, and it is important to validate the product for a specific type of radiation to be used. Reed and Fairand (21) noted that when ^{60}Co radiation was first introduced there was general agreement that high absorbed doses of at least 25 kGy were necessary, but these became associated with color and viscosity changes, and in some cases undesirable chemical changes were also observed. As experience developed, it became evident that much smaller doses could achieve sterility without degradation. Taken with current advances in aseptic processing and the reduction of bioburden before sterilization, smaller radiation doses are likely to be required, but validation on a case-by-case basis is still required.

Radiation has a large number of advantages over other methods of sterilization. It is operated in the cold and radiation penetrates both product and container, so sealed containers and their bulk packages can be treated as one. The process does require investment in significant capital equipment, but it has a long and effective life, it is quiet and environmentally acceptable, and minimal maintenance is required, unlike that required for steam autoclaves. The process is now accepted as being cost-effective and experience gained in the treatment of foodstuffs and cosmetics has been successfully applied to pharmaceutical products.

Pulsed Light Sterilization

As part of a technology developed during the Star Wars initiative, the use of very short pulses of high-intensity, broad-spectrum white light is a technology that may become more widespread. The light has approximately the same spectrum width as sunlight but is actually richer in ultraviolet light since same ultraviolet light is usually filtered out by the earth's atmosphere. However, the intensity is 20,000 times brighter than sunlight but the pulse may only last a few milliseconds. Produced by condenser discharge through appropriate lamps, the light is a form of nonionizing radiation and appears to be very effective at rapidly sterilizing surfaces contaminated with vegetative and spore-forming organisms. One advantage of light is that the intensity may be increased by focusing with mirrors to a point or target of the application. This means that individual containers in a production line may be sterilized as they pass through an appropriately designed tunnel, which is readily incorporated into a production line. The cost of incorporation of this type of device would therefore be minimal.

If the container is translucent to the ultraviolet radiation, the technique can be used to sterilize the contents. For example, plastic ampoules are transparent, and the method is being applied to automated filling lines associated with blow, fill, and seal methods. However, it may not work with glass ampoules because the appropriate ultraviolet wavelengths are filtered out, but development work in this area is ongoing. The Pure Bright® technique was reviewed in more detail by Dunn (22) and may be a valuable technique for sterilization of some types of packaging materials on a continuous basis.

Aseptic Processing

Aseptic processing is the assembly of a product using components sterilized by different methods in a suitable aseptic environment designed to minimize or totally eliminate contamination of the product. There is no final sterilization of the sealed container; it is assumed that sterility has been designed into the product. Now very widely used in the pharmaceutical industry, Groves and Murty (23) suggested that as many as 87% of parenteral products were being aseptically assembled. The likelihood is that, as more and more thermolabile products enter the marketplace, this number will increase. Regulatory agencies went on record a decade ago, requiring terminal sterilization unless the product was demonstrated to be labile. This was not a particularly timely move although the FDA still does not allow a large volume parenteral (100 mL or more in volume) to be assembled aseptically.

An aseptic process usually consists of filling a thoroughly filtered solution of a drug, the final filtration being regarded as a sterilization process, into glass or plastic vials sterilized by dry heat or gas and sealing these containers with rubber plugs sterilized batchwise using moist heat. A series of steps are required to bring the components to the assembly area, put them together in an aseptic environment, and remove the final product to the open environment. The success of an aseptic filling operation critically depends on the successful operation of the individual steps but must be considered as a whole. The entire operation needs careful and consistent planning and operation, with constant monitoring. Final and ongoing validation represents an essential stage that is often extremely difficult to carry out satisfactorily. The complete operation is operator-dependent, which means that the operators not only have to be properly trained but also have to know how to apply methodologies thoroughly documented in standard operating procedures that are such a critical element in GMP. It can be seen that an aseptic process is where all of these regulatory requirements come together. Nevertheless, some agencies, including the FDA, require validation to be carried out using media fills in which sterile growth media instead of actual product is passed through the sys-

tem. In some ways it can be seen that this might be a proof of concept; to actually validate the process itself is an exercise in futility. First of all, the final product, with some exceptions, is unlikely to resemble a fluid culture medium. Secondly, the growth medium does not necessarily demonstrate a failure or breakdown in the system, because the level of contamination may be very low, and contaminating microorganisms may not grow rapidly enough to be visibly evident in the medium after only a few days incubation. Finally, it seems ludicrous to suggest that 1 contaminated vial in a media fill of 3,000 is satisfactory, because it indicates a SAL of less than 1 in 1,000. Surely *any* contamination is unsatisfactory, and SALs, being a statistical concept, are not measurable directly.

Improvements in system design, especially those involving the use of robotic and barrier technologies designed to eliminate human contact, have certainly increased confidence in the effectiveness of aseptic processing. Nevertheless, it is probably time to reexamine the concepts of Gilbert and Allison (12) and attempt to *measure* the risks involved in aseptic processing. Given the very low incidence of microbiological issues associated with the parenteral administration of millions of aseptically prepared products worldwide over 80 years or more, the issue may have become more remote.

STERILE IMPLANTS

Protein Compacts

One of the oldest drug delivery systems is the pellet or tablet produced by compaction or extrusion of powdered drug together with appropriate excipients. Tabletting technology is not confined to the pharmaceutical industry but the technology is exceptionally well developed and is both simple and inexpensive in its basic form. Generally applied to low molecular weight drugs for oral administration, tabletted proteins are also employed in a number of nonpharmaceutical industries. Compacted proteinaceous materials such as enzymes are used in dairying, fermentation, brewing, fruit processing, wine making, milling, baking, starch production, and detergent applications. All have been prepared as tablets as a convenient form for handling and ensuring accurate dosage as well as improved storage and transportation. With the advent of the newer highly biologically active proteinaceous drugs, this pharmaceutical presentation has assumed a major challenge. This is especially true for proteins or polypeptides for oral administration. For example, Saffran et al. (24,25) claimed that vasopressin or insulin in enteric-coated gelatin capsules were active orally, although these observations do not appear to have been confirmed. Nevertheless, compaction of dried proteins appears to allow them to retain much of their native conformation and, therefore, biological activity. They are readily protected from moisture when suitably packaged. Azain et al. (26) described prolonged release devices for parenteral administration of somatotropins and Oppenheim et al. (27) suggested that protein compacts could be used for subdermal administration. In both cases the final product must be sterilized using an appropriate procedure.

Effects Produced by Compaction of Proteins

During compaction the protein molecule is subjected to both pressure and shear (and possibly heat) that could result in reversible or irreversible denaturation. Most studies of denaturation have been carried out on protein solutions. Tirrel and Middleman (28), for example, showed that the jack bean urease-catalyzed urea hydrolysis reaction was both reversible and irreversible, depending entirely on the rate of shear and the presence or absence of additives such as glycerol or ethylene diamine tetra acetic acid. Similar results have been reported for lactic hydrogenase, peptidases, and rennet, and amongst the genetically engineered proteins, human growth hormone is known to be denatured by mild shearing conditions. These are all believed to be due to the hydrodynamic induction of conformational changes at the molecular level. There are relatively few published studies of dried protein compacts and the effects induced by the compaction process or the complex three-dimensional structure of a protein, especially as measured by the changes produced on subsequent biological activity. Graf and co-workers (29–31) studied the effect of compactional pressure on pancreatin and showed that a slight loss of activity occurred at 500 MPa, the minimum pressure needed to form a compact. However, this loss of activity was mitigated by incorporation of pharmaceutical adjuvants such as lubricants and diluents normally employed to make acceptable tablets. These observations would suggest, in retrospect, that solid-state shear caused loss of activity in an analogous fashion to that observed in the solution state. However, most authors agreed that compactional pressure produced some degree of adverse effects on biologically active proteins. Groves and Teng (32) reviewed earlier work and described their own investigations on the compaction of four enzymes with widely disparate molecular weights and functionalities. Working over a much wider range of compactional pressures, urease, lipase, α-amylase, and β-glucuronidase were all shown to be affected by pressure, although to different extents. More to the point, the mechanism of loss of biological activity was evidently different in each case. For example, α-amylase and β-glucuronidase both lost their α-helix structures, whereas the secondary structures of urease and lipase were unaffected. The molecular weight of urease showed an increase, suggesting effects on both tertiary and quaternary structures. The 30% loss of activity observed with lipase could not be correlated with any structural changes measured by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) or circular dichroism (CD) methods, indicating that, whatever structural changes had actually occurred were too subtle to be detected directly. In all cases limiting compactional densities were observed. This lead to the proposal that the mechanism of activity loss was due to a reduction of the space in between the molecules or particles, irrespective of the source of the protein. Compacting at different rates or holding pressures for different times had no measurable effect on activity loss, showing in these cases that thermal energy inactivation was not responsible for activity loss. Water adsorption onto dried proteins was also shown to be influential on the subsequent properties of compacts, es-

Next Page

pecially the rate of release of the active component into an aqueous environment.

As noted, the range of pressures tested were in excess of pressures normally required to make serviceable compacts, and the additional of appropriate pharmaceutical adjuvants was not evaluated. Activity losses ranged from 50% (urease) at 190 MPa to 15% (β-glucuronidase) at 290 MPa, pressures well inside the approximately 500 MPa required to form a compact. Nevertheless, one can be optimistic about the issue because if a loss of activity of a biologically active protein is detected it would appear that the effect can be minimized by judicious selection of diluents and lubricants making up the rest of the tablet composition. However, it should be noted that if a compressed protein was required for parenteral use, the usual pharmaceutical diluents and formulation adjuvants used for orally administered tablets would be unlikely to be suitable. This may apply to fatty acid derivates, such as magnesium stearate, and certainly applies to the talc when used as a lubricant. Alternative adjuvants and diluents are available but should be selected with care. Indeed, in some cases, they may not be needed.

If a protein was to be compressed and a loss of biological activity was demonstrated, it would be necessary to totally evaluate the mechanism of degradation, to find methods of minimizing the effect, and to carry out a complete investigation of the influence of the presence of resultant degradation products on the biological behavior of the compact. Appropriate analytical methodologies are certainly more widely available today, and this type of investigation would be a normal part of providing a complete characterization of what is likely to be a complex drug entity.

Sterilization of Protein Compacts

The safest way of producing a sterile protein drug implant would be to operate the entire process aseptically, starting with sterile filtration of a solution of the drug and aseptic lyophilization to provide a sterile solid. If a diluent were needed, this could be added to the solution of the drug prior to the sterile filtration process. Suitable diluents such as lactose or mannitol are unlikely to be available as bulk sterile products so it would be necessary to go through the same process, especially if the diluent was required to be added as a separate entity. The compaction equipment would need to have metal surfaces cleaned and sterilized, which could be achieved with a gaseous sterilant such as ethylene oxide. The use of halogen oxides or hydrogen peroxide as gas or mist is likely to be corrosive to most metal surfaces and therefore unsuitable for sterilization of the compaction surfaces. Aseptic manipulation using barrier technology has certainly become more widely accepted in recent years, and providing the equipment was dedicated to this function, it should be an acceptable procedure. Shangraw (33) suggested that a dedicated single punch tablet machine was likely to be used but, more recently, extrusion of the material has been preferred, using poly(ethylene glycol) 6,000 as an external lubricant. Direct sterilization of the compact by heat is unlikely to be effective or acceptable but γ-radiation is a possibility, providing the drug itself is not damaged or the vehicle affected in terms of its performance such as release/time pattern.

Polymeric Implants

Polymeric implants are commonly prepared from hydrogels, silicone rubbers, or other biocompatible materials. Hydrogels generally have an advantage in that they are able to swell in an aqueous medium without necessarily dissolving. This capacity for water is useful in that it promotes or improves compatibility with body tissues but it has been suggested that incorporated low molecular weight drug substances are able to diffuse out of the device without necessarily being rate-controlled.

Implants are usually introduced subcutaneously using a surgical procedure. The need for surgery is an obvious disadvantage but, conversely, the device can also be removed when required or when exhausted of drug, which is an advantage. Numerous shapes have been explored, from plates, long rods, and short rods to spheres, and newer bioerodable matrixes are coming into use. For example, poly(lactide-co-glycolide) (PLGA) was originally developed as an absorbable suture so that it has obvious advantages as an implant containing a drug. The Norplant device has been introduced in which silicon rubber rods containing levonorsgestrel have been implanted under the skin with the aid of a local anesthetic. For additional information see the chapter FERTILITY CONTROL.

Subdermal injection of small rods or cylinders or even spheres through a cannula has some advantages, and these devices have also been evaluated clinically.

Sterilization of Polymeric Implants

Polymeric implants are readily made by extrusion of powdered components but application of heat would melt the polymer and affect the release properties of the device, assuming that the drug itself was stable enough for the purpose. γ-irradiation is effective and commonly used for this purpose because of the great deal of experience in the sterilization, for example, of PLGA suture threads. Oxidizing gases such as peroxides are not suitable for sterilization of surfaces because, with a bioerodable implant, there is a need to sterilize throughout the structure of the implant, not just its surface. Moreover, there is a real danger that these reactive chemicals produce chemical changes at the interface of both the biopolymer and its incorporated drug. One group has suggested that a volatile sterilant such as chlorbutanol be incorporated in the matrix, which is then removed by exposing the final product to a temperature of 80°C, preferably for a long time and under vacuum (34).

Implants, being introduced under the skin and exposed to a biological environment, must not irritate the tissues surrounding them or produce an infected or sterile abscess. Sometimes this may be due to the polymer alone. For example, PLGA hydrolyzes to lactic and glycolic acids, which in the high concentration immediately adjacent to the surface of the dissolving implant, may become irritating. However, one possibility here would be to insert the implant into muscle where the tissue environment is normally acidic due to lactic acid production.

PRODUCTION OF MACRO-, MICRO- AND NANOPARTICULATE SYSTEMS

Introduction and Definitions

It has to be realized that sterile drug delivery systems have to be produced by close attention to the preparation process, with appropriate modifications being made to achieve sterility. Particulate systems have been used as drug delivery vehicles, probably since at least ancient Egyptian times, but more recently they have become of interest to the pharmaceutical sciences in a rather more sophisticated form. Defined by size rather than constitution, macroparticles can be considered to be larger than 100 μm, microparticles are 1–100 μm, and nanoparticles are less than 1 μm in diameter. Approximately rounded in shape, these systems can be employed according to their size, macroparticles being too large to pass down an hypodermic needle but being suitable for controlled release implants or, in some cases, as artificial cells or organs. Micro- and nanoparticulate solids, on the other hand, can pass through hypodermic needles and be employed for targeted drug delivery. An example here would be passive targeting of the lung, which can be achieved by intravenous administration of particles around 7–10 μm diameter or larger. In a similar manner, nanoparticles of 100 nm or less can escape through the fenestrations (or holes) of the lining of the blood vessels and reach hepatocytes in the liver. These small particles also accumulate in the mononuclear phagocytic system (MPS). As pointed out by Wright and Illum (35), particle size is a major factor in determining the sites of lodgment but also, to a lesser degree, so are the particle surface characteristics in terms of identity, hydrophilicity, and especially electrical charge. Foreign particles in the bloodstream are removed through phagocytosis by MPS components, especially macrophages. This process is initiated by recognition of opsonins. These are proteins that precipitate onto the particle surface, which are then recognized by specific receptors on the macrophage surface. It is possible to interfere with this process by adsorbing or incorporating competitive high molecular weight surfactants or polymers such as poly(ethylene glycol) onto the particle surface, and this is the principle underlying the new generation of surface or sterically modified liposomes (Stealth™ liposomes) (36).

It is a matter of semantics as to whether or not one should define surface-modified microparticles as microcapsules (that is, particles that are encapsulated or covered in a material that differs from the core). Chemically core materials reported for macro- and microparticulate systems vary widely from starches and celluloses to polymers such as PLA and polymethacrylates. One essential requirement is that the core material should be metabolizable or biodegradable. This is obviously likely to be true for albumin and gelatin particles, and PLA dissolves slowly by hydrolysis of the polymer.

Release of incorporated material—a drug or guest molecule—has been discussed by Jalšenjak (37) in theoretical terms. Although he regarded microcapsules as a general case, strictly speaking, they are core materials surrounded by another medium. He did, however, admit that the rate-controlling solution stage could be affected by the presence of a stagnant aqueous layer at the microcapsular surface. Other than this, three stages were identified in the release process:

1. Solvent penetration to the core
2. Solution of the core material(s)
3. Solute removal by a diffusional process into the bulk aqueous phase

Jalšenjak (37) then explored the case of release from microspheres where the drug was not concentrated in a core but rather distributed throughout the particular matrix. There is no reason, a priori, to assume that the particles are indeed spherical although this is a convenient approximation that is adequate for most purposes. The constitution, preparation, and properties of injectable nanoparticles and microparticles are reviewed in several texts, including Donbrow (38). However, rarely if ever in these texts is the sterilization of the intended product discussed, although this remains a prime requirement for any parenteral product. Accordingly, methods of production are reviewed here to allow interpolation of points in the process where sterilization can be introduced or where the process could be improved to ensure sterility.

Production Methods for Solid Particles

For the most part, it will be presumed that macroparticles and particles with a mean diameter $\approx$50–100 μm would not be suitable for parenteral administration for the simple reason that a suspension of these particles would be less likely to pass smoothly through, say, a 20-gauge hypodermic needle, depending on the concentration of the particles, their shape, and the presence of larger particles in the system (39). Nevertheless, although the administration system is different, large rods or granules have been used as sustained drug delivery systems for subcutaneous or even intramuscular implantation.

This limitation on the size of the particulate, although not absolute, limits the application of some technologies involving growth of primary systems such as granulation, spray-drying, or spray-chilling, because the resultant products tend to be too large in size to be suitable for the purpose. For the most part, this may also be true for many of the microencapsulation processes that have been described in the literature. Methods suitable for the preparation of micrometer and submicrometer (nano-) particulate systems are:

1. Grinding
2. Phase changes (solvent precipitation)
3. Emulsification process, with or without solvent removal
4. Spontaneous liposome and emulsion processes
5. Polymer emulsification

Grinding. Until recently grinding solids was associated with manufacturing processes involving ores and rocks, and relatively few grinding processes have survived into

current pharmaceutical production processes. However, in recent years this perception has changed with development of a grinding process originally developed by Kodak for production of submicrometer pigments used in photographic processes. An offshoot of this process has been adapted for pharmaceutical use by Nano Systems, Inc. Details of the processing are proprietary but involve ball-milling insoluble drugs in the presence of stabilizing agents in water. In this process a solid dispersion is ground by rolling in a closed pot with steel or ceramic balls. One must assume that the stabilizing agents are viscous materials with surfactant properties. As crystalline and bonding forces are exposed during the grinding process, fundamental properties of the particulate change as the nanoparticles are generated, including solubility. Some impressive claims have been made for this process and a number of major pharmaceutical companies are exploring the potential application of the technology. Ball-milling is certainly not a new process and traditionally has had some well-recognized problems, including the time taken to grind to a specific size, the generation of heat, and the presence of significant quantities of fragments of the grinding balls and container walls that inevitably contaminate the product.

Preparation of Sterile Product. Although ball-milling is carried out in a closed vessel, this vessel has to be opened and closed during the process, and even if sterile components were added to the mill it would be difficult to maintain sterility. Terminal heat sterilization of the final product is likely to be counterproductive, because solubility would be increased at higher temperatures and the particle size therefore increased on cooling. However, with modern heat-resistant ceramic materials, this may be one option in the final process stage, with additional grinding and handling the mill and its contents under aseptic conditions thereafter. Regulatory authorities traditionally have had problems with aseptic processes operated without adequate controls, but, although not impossible, production of a sterile product with this process has considerable difficulties.

Phase Changes. The formation of small particles can sometimes be achieved by mixing a solution of the drug in one solvent with another miscible solvent, thereby precipitating out the drug. An example would be the precipitation of gelatin particles by cold alcohol in the process described by Öner and Groves (40) (Fig. 1). Gelatin is readily soluble in water but is insoluble in ethanol. Many systems described in the literature involve precipitating a component out of an aqueous solution with water-miscible solvents such as acetone, ethanol, or dimethylsulfoxide. Careful control of the relative amounts of the two solvents, temperature, rates of stirring, and rate of addition of one component to another help to control the resulting size of the precipitate. In some cases the addition of the wetting agents may help to stabilize the size of the precipitated particles, and for most purposes this is an essential requirement.

Preparation of Sterile Product. Because the process involves adding two liquids together, it should be feasible to sterile-filter both components separately and carry out the processing and collection of product under aseptic conditions.

Emulsions

Introduction: Essential Requirements. Emulsions, defined as dispersions of one immiscible liquid in another liquid, are intrinsically thermodynamically unstable and therefore require interfacial stabilizing agents. Because of the physical complexity of emulsion systems, they have received relatively little attention as parenteral drug vehicles with one exception, the vehicle and system originally marketed as Intralipid® (Pharmacia-Upjohn and, more recently, Fresenius-Kabi), which appeared in Sweden in the 1960s after a great deal of original research by Wretlind (41) and Håkansson (42). Earlier attempts to develop injectable emulsions as nutritional supplements were rather less than successful due to toxicological issues associated with raw materials and degradation products, as well as long-term stability concerns. Some principles were established early on, because it became quite clear that only oil-in-water emulsions, which had to mix quickly with blood, were suitable for intravenous administration. On the other hand, it should be noted that water-in-oil emulsions would form depot drug delivery systems, suitable for subcutaneous or intramuscular administration, and these have been used since the turn of the twentieth century.

Wretlind (41) demonstrated that, ideally, particles in intravenous lipid emulsions should mimic the small triglyceride emulsion droplets—chylomicra—that carry lipids throughout the body after a fatty meal. These chylomicra vary in diameter from 200 to 3,000 nm and consist of a

lipid core surrounded by phospholipids, together with adsorbed protein. He envisaged an artificial chylomicron made of natural triglycerides, obtained from soybean oil, as an example, emulsified and stabilized with phospholipids purified from avian egg yolks. Wretlind went to a great deal of trouble to obtain and specific highly purified materials, and it was even rumored that he specified eggs from one particular source collected at the same time of the year to ensure that the natural and therefore variable constitution of the separated egg phospholipids were reproducible. The importance of storage conditions for the system was established and it was shown that these homogenized emulsions, with mean droplet diameters of 200–400 nm, were stable enough to be sterilized by autoclaving without the catastrophic destabilization that is characteristic of most other emulsions when heated. Indeed, it was later shown that the particle size of a heat-sterilized emulsion actually decreased, suggesting that structural changes were occurring in the emulsion or at the oil–water interface as a result of the application of heat (43). These considerations resulted in the realization that injectable emulsions can be terminally heat-sterilized, and this observation has contributed to confidence in their clinical application.

Phospholipid-stabilized emulsions have been used clinically for almost 40 years as nutritional supplements, for the most part without serious clinical problems. Their clinical usage is clearly understood, and limitations in their application are well recognized. Moreover, other manufacturers have marketed similar systems with artificial short-chain triglycerides, safflower or olive oils, and phospholipids obtained from soybean. The potential for the use of these emulsions as drug delivery systems is considerable, and a number of emulsion-based products are now in the marketplace.

For successful clinical application as a nutritional product or drug delivery system, an emulsion must be:

1. Miscible with blood and body tissues
2. Compatible with both blood and body tissues
3. Sterile
4. Nonpyrogenic
5. Prepared with droplets small enough not to pose a potential for forming embolisms
6. Fully metabolizable
7. Isotonic
8. Stable, both physically and chemically

For the most part, the aqueous phase does not provide a problem if it is Water for Injection (USP) or, more accurately, Water for Injections (BP). The tonicity is provided by adding a small amount of glycerol, and the initial pH is adjusted to around 8.0 with sodium hydroxide.

The oil phase, coming as it does from a natural source such as soybean oil, can vary in composition, and the Swedish workers associated with Wretlind (41) found that soybean oil could be fractionated and purified by cooling and filtration to remove the waxes, unsaponifiable matter, and higher-molecular weight entities usually found in the expressed oil. Oils with aliphatic unsaturated centers are prone to air oxidization so precautions have to be taken to avoid degradation. Natural oils usually contain antioxidants such as tocopherols, and either these are allowed to remain or are added after purification (44). Triglycerides are readily metabolizable and the differences between commercial products tend to lie on the distribution and degree of unsaturation of the various fatty acids. In Table 1, the Intralipid soy oil and Liposyn safflower and soy oil formulae are compared; the linolenic acid, deficient in the Liposyn II brand, was later determined to be an essential fatty acid. As noted, emulsions are intrinsically unstable, and a stabilizer, surfactant, or emulsifier is required to stabilize the dispersion. Most surfactants commercially available are unsuitable for parenteral administration because they have a potential to cause hemolysis and other direct manifestations of toxicity. Moreover, most stabilized emulsions break when heated, often due to significant movement of the interfacial material into one phase or another as the solubility characteristics change with temperature. Phospholipid stabilizers, on the other hand, are unusual in that the interface between the oil and water phases becomes more stable after heating. This effect was investigated by Groves and Herman (45,46). When freshly prepared, an emulsion system stabilized with an egg phospholipid containing phosphatidylcholine (PC), phosphatidylethanolamine (PE), and their respective lysoderivatives had the phosphatides roughly equally distributed in the aqueous bulk phase and at the oil interface. On heating there was an irreversible movement of the PE and PC toward the oil phase and from the aqueous compartment. It was suggested that this could have been due to the heat-induced formation of an interfacial cubic liquid crystalline phase. There is some parallel evidence for this type of reaction in isolated systems although, in a true emulsion, this has proven difficult to investigate. Cubic phase material, forming a mesophase at the oil–water interface, would then revert to a semiviscous mesophase lamellar liquid crystal, and indeed the two may coexist as an equilibrium mesophasic composition. This organization of interfacial material was held to account for the unexpected enhanced stability of sterilized phospholipid stabilized emulsions during sterilization. When investigating the stability of freshly prepared emulsions to lysine, a known water structure-modifier, stability was markedly enhanced when the emulsion was heated even under relatively mild conditions for a sufficiently long period (47,48).

Emulsification. Direct emulsification involves application of shear energy to two separate immiscible liquids (for

Table 1. Distribution of Fatty Acids From the Triglycerides of Intralipid and Liposyn Intravenous Emulsions

Fatty acid	Intralipid (g/100 g)	Liposyn (g/100 g)
Linoleic acid (C18:2)	54	77
Oleic	26	13
Palmitic (C16)	9	7
Linoleic acid (C18:3)	8	—
Stearic (C18)	3	2.5

example, oil and water) in order to produce small droplets of one phase dispersed in the continuous phase. Inevitably a stabilizing agent is required to prevent (or at least minimize) coalescence of the dispersed drops back to their preferred condition for minimal energy (i.e., as a completely separated layer, one floating on top of the other). Properties of the stabilizing agents employed as systems used for parenteral administration vary widely although for the most part purified egg or soy phospholipids are considered suitable. Because phospholipids are not truly soluble in either oil or water, forming dispersions in both phases, they are often to be found at the oil–water interface. This interface is structurally complex, and these properties are essential for the stability of the dispersion, although at present knowledge and understanding of this arena is less than perfect. Application of shear forces to dispersed droplets often has the effect of decreasing the droplet size, probably down to the limiting surface coverage of the emulsifier. Below this monolayer (or even multilayer) coverage, the droplets are not stable and quickly coalesce to the minimum size of particle under the conditions of manufacture. Other factors are involved, in particular the interface surface tension between the disperse and continuous phases. In addition, relative viscosity of the two phases is most probably involved, as is the relative density.

Shear forces can be applied by a number of methods, including simple stirring, high speed stirring, and pumping through small orifices.

One factor that needs to be mentioned is the phase behavior of the dispersed droplets. Usually these are assumed to be liquids, capable of demonstrating internal fluidity or movement. In point of fact, as droplets get smaller internal circulation becomes limited, and the droplets start to behave as if they were solid. This behavior is facilitated by the properties of the external mesophasic stabilizing layers, which are often viscous to the point of being semisolid, and these properties also inhibit internal circulation inside the liquid droplet. For all practical purposes, therefore, dispersed droplets, especially in the submicrometer region, behave like solid spheres or particles. This has not prevented some authors from claiming special properties for systems made of waxes or high melting point oils. From a manufacturing perspective, at elevated temperatures these systems consist of molten waxes or liquid oil droplets dispersed in water, and these liquid droplets cool to solid particles at room temperature after dispersion. Known and widely used in the cosmetic industry for many years, these systems undoubtably have potential as drug delivery systems. A recent paper (44) has demonstrated that high melting point trilaurin nanoparticles formulated with phospholipids were effectively similar in composition to phospholipid-stabilized emulsions with phospholipid bilayers wrapped around the central lipid core. Like the liquid lipid emulsions, these solid lipid systems have the potential to trap hydrophobic guest molecules in the phospholipid bilayers, with hydrophilic materials being held in the aqueous spaces.

Surface-Modified Emulsions. The physiological compatibility, together with their optimal chemical and physical stability profiles, make phospholipid-stabilized emulsions valuable parenteral drug delivery systems (49). It is inevitable that these systems should be compared with liposomes, and indeed the analogy is close when considered from the external surface view of the two systems. However, the interior structure differs, and it is the liquid triglyceride droplet that is the characteristic feature of the more stable emulsions systems. Some authors have claimed that solid lipid dispersions differ from liquid–liquid emulsions (44). This is not likely from a physical perspective because, as noted earlier, small liquid droplets behave physically as solid particles in the same size range. In addition, since the interfacial mesophase of phospholipid-stabilized systems is almost certainly very viscous if not solid in nature, the underlying liquid droplets would effectively behave like solid particles, and the similarities become quite evident.

Surface-modified systems have become available as modified liposomes or emulsions. One characteristic of both phospholipid-stabilized systems is the rapidity with which they are coated with apoproteins after coming in contact with blood as part of the opsonization process. Recently, liposomes surface-modified with poly(ethylene glycol) have appeared, sometimes referred to as Stealth® liposomes (36). These surface modifications, likened to disguising the surface with bound water, have effects on protein binding and, therefore, on physiological behavior and clearance. The net effect of surface modifications has been to extend the effects observed in the body produced by injected liposomes and, incidentally, to enhance the stability and commercial viability of these drug products (49).

Preparation of Sterile Product. Depending on the properties of the stabilizing entity used in the formulation, usually to be found at the interface of the dispersed droplets, it might be feasible to sterile-filter each of the components before processing under aseptic conditions. However, as noted earlier, most surfactants are too toxic to be employed as parenteral stabilizers and for the most part suitably purified egg or soy phospholipids are used. These have some curious properties in that phospholipid-stabilized emulsion systems can be terminally heat sterilized, thereby avoiding many of the issues associated with handling product under aseptic conditions. This, of course, presupposes that the drug entity itself is stable enough to be heat sterilized. If it is not, then presterilized emulsion would be aseptically manipulated to allow subsequent incorporation of the drug prior to packing. Nevertheless, it is extremely unlikely that any regulatory authority would approve an aseptically assembled large volume (>100 mL) parenteral and would insist on terminal sterilization of the product.

The Chemical Stability of Phospholipids. Phospholipids are heat-labile and hydrolyze in aqueous dispersion. Strictly speaking phospholipids are not truly soluble in water but readily form dispersions that could be recognized as liposomes. Groves et al. (50) reported the presence of liposomal-like material in phospholipid-stabilized emulsions, so aggregates of phospholipids readily form but a true solution of these materials, consisting of single molecular entities, does not.

Dispersions of pure PC or PE in water when heated, for example, in a sterilization process, hydrolyze to their cor-

responding monoacyl derivatives, called lyso-lecithins (51,52). These materials are also found in some snake venoms and have lytic properties on red blood cells (53). In principle, these might appear to be undesirable degradation products in an intravenous system, and this may also be true for the free fatty acids that are produced by hydrolysis of both the phospholipids and the triglycerides present in the starting material. However, no toxicity has ever been noted since the intact emulsions were first introduced into clinical practice over 30 years ago. It has been suggested that this may be a direct result of complexation within the intact emulsion so that the degradation products are not available in the free state. The general schema of degradation is shown in Figure 2. Degradation rates of phospholipids in liposomes have been measured (54). Similarly, Herman and Groves (45,46) determined degradation rates of these stabilizers in emulsions. Generally speaking, both groups found broadly similar results and consideration of the kinetics demonstrated that relatively small amounts of lyso-compounds are actually produced under the conditions necessary for heat sterilization. In the case of emulsions, it is likely that any small amounts of lyso-compound produced in the reaction would be held within the droplet mesophase, as noted earlier.

This cannot be entirely true for the free fatty acids produced by autoclaving because the pH does drop during sterilization (46). However, the amount of free fatty acid as determined by titration with potassium hydroxide or measurement of pH did not correlate well. It was therefore suggested that residual oxygen dissolved in the triglyceride oil phase was capable of reacting with some of the acyl unsaturated centers. There was evidence that the involvement of oxygen in the heat-induced lowering of the pH and emulsions made with saturated phospholipids did not show the same disparity.

Emulsification With Solvent Removal. It has been recognized for many years that dispersive emulsification processes often generate submicrometer droplets. A method widely employed to make polymer microparticles is to dissolve the polymer such as PLGA, in chloroform or methylene chloride, emulsify this solution in aqueous poly(vinyl alcohol) (PVA) or carboxymethycellulose in order to produce small droplets. The solvent is then effectively removed by adding the concentrated emulsion to an excess of water, allowing the microspheres to be collected by centrifugation or over a filter and dried under vacuum to remove both the water and the residual solvent. Drugs for controlled release purposes can be incorporated into the polymer system as an aqueous solution before making the polymer/water dispersion, effectively making a water/polymer/water double emulsion, analogous to an w/o/w double emulsion system. Thus, these are encapsulation procedures in some senses, using polymers to encapsulate an aqueous dispersion, and this is described as such in a recent patent (55). One major advantage of this process is that it is readily scaled-up using a static mixer fitted with continuous flow through.

An emulsification process has also been used to prepare micro- and nanoparticulate forms of albumin, a protein that is readily denatured by heat. This process has to be handled in different ways according to whether or not the incorporated drug is labile or not. If the drug is heat-stable, it can be incorporated in an aqueous solution of an appro-

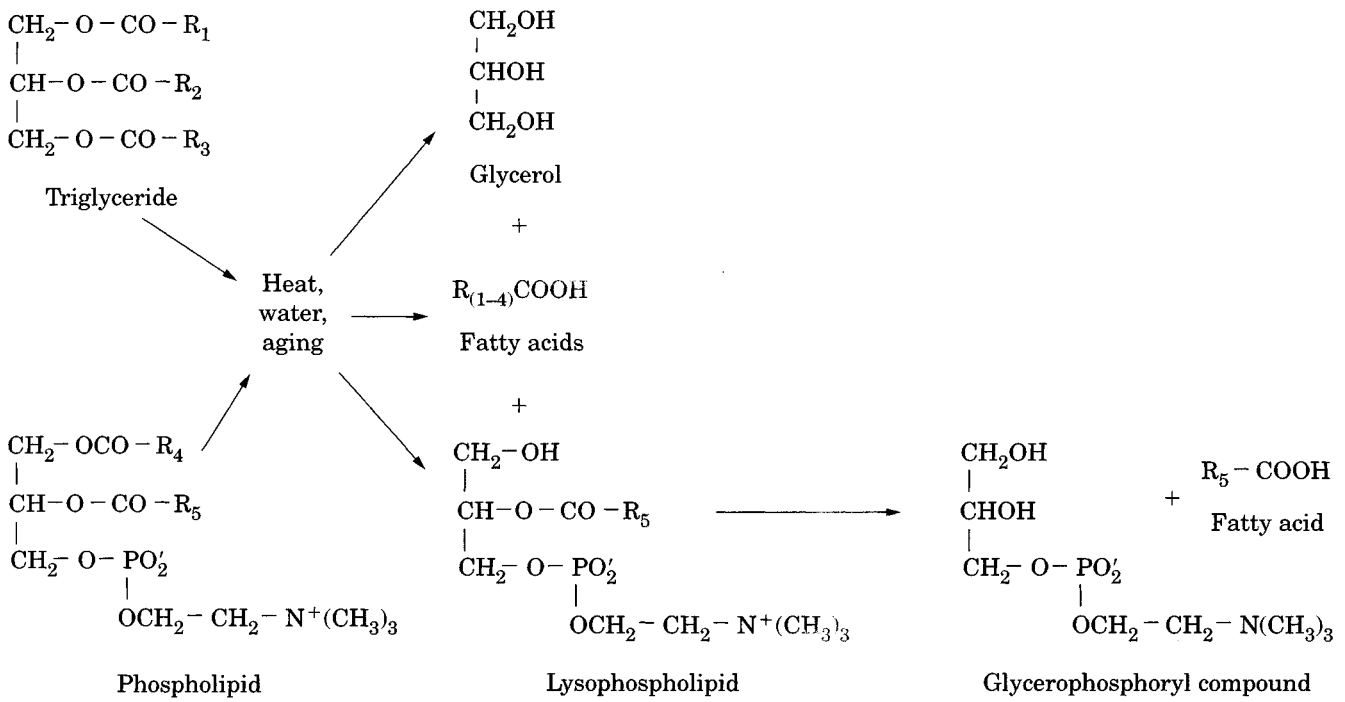

Figure 2. Degradation pathways for phospholipids and triglycerides in phospholipid-stabilized emulsions.

priate albumin (human is preferred for human administration), which is then emulsified in a suitable oil such as arachis or even mineral oil. A water-in-oil emulsion is prepared, usually requiring a suitable emulsifier such as Span®, and the system is heated up to 120°C or higher whilst stirring when adding the initial emulsion into an excess of hot oil. The albumin solution solidifies as the protein is denatured and comes out of solution. By maintaining the heat above 100°C the water is evaporated, leaving the albumin particles suspended in the oil. The dried particles are then collected and the residual oil removed with a solvent, often petroleum ether or diethyl ether. Both of these solvents are highly flammable, and this process is basically unsuitable for industrial application, although this consideration has not inhibited claims being made for the resulting product based on small-scale laboratory processes. Denaturation of a dispersed protein aqueous solution can be achieved by other methods, including addition of cross-linking agents such as glutaraldehyde or even formaldehyde. The issue of oil removal remains, especially as available solvents for this purpose are flammable and are often not acceptable from a toxicity standpoint. Once prepared, however, these microparticles can be loaded with a drug, and it does not matter if the drug is labile or not. Loading may have to be achieved by adding a solution of the drug in an acceptable solvent such as alcohol to the dried proteinaceous particles and stirring under reduced pressure until the solvent has evaporated. Unfortunately, alcohol and water from constant composition boiling point mixtures and the process may have to be modified accordingly, perhaps by using an alternative solvent.

Polymers such as PLGA, PLA, or poly(acrylamide) are acceptable physiologically and are generally soluble in organic (or water-immiscible) solvents. Ciftci et al. (56) described a simple process in which a PLAGA copolymeric system (containing drug) in methylene chloride was stirred in an aqueous PVA solution until the methylene chloride had evaporated. No evidence of the residual levels of methylene chloride was provided and, clearly, on a large scale this would be an essential element of information required for subsequent regulatory approval. However, the process is undoubtably simple and should be readily scaled up. Without the use of added surfactant the particles had mean sizes between 2 and 5 μm in diameter; with surfactant it might be anticipated that the resultant size would be in the nanometer region.

An earlier process described for the preparation of gelatin nanoparticles involved emulsifying gelatin aqueous solutions containing the drug in a vegetable oil such as sesame and cooling below the gelation point using an ice bath (57). Because the oil is soluble in acetone, the cold droplets were passed through a filter and cross-linked with formaldehyde in acetone before final collection, acetone washing, and air-drying. The particles were claimed to be between 100 and 600 nm in diameter, and apart from the use of a flammable solvent, the basic process is obviously more acceptable. As Kreuter (6) commented, it is a bit surprising that the nascent emulsion passed through a 50-nm pore size membrane filter, but once the acetone was removed the resulting particles had an average size of 280 nm. This suggested the small droplets of the initial emulsion were sufficiently fluid to change their shape and pass through the 50 nm filter. Nevertheless, based on a developing knowledge of the properties and structure of gelatin, it should be possible to produce gelatin microparticles by careful attention to the type of gelatin, pH, temperature, and concentration of the solution. Marty et al. (58) claimed that addition of ethanol or sodium sulfate to gelatin solutions enabled nanoparticles to be precipitated. This work has proved difficult to replicate with materials now available 20 years later, and the formation of microparticulates from gelatin solutions may depend on factors not yet completely evaluated (see later discussion). In both Kreuter's 1992 chapter and his more recent book (6,7) the subject of nanoparticle formation is dealt with in considerable detail with appropriate references, but the methodologies remain basically the same. The core materials, on the other hand, vary widely.

Preparation of Sterile Product. The very complexity of these processes does not prevent the need for sterility of the end-product. However, some processes may lend themselves to sterility being achieved inadvertently. For example, where a hot oil at temperatures up to 180°C is used to precipitate a proteinaceous vehicle such as albumin or to dry a gelatin system, it is evident that the product, under carefully controlled conditions, has effectively been heat sterilized. In processes in which glutaraldehyde or formaldehyde are used, these are sterilizing agents in their own right, and again, the process could be designed to ensure that the final product was sterile. Additional design changes would be needed to ensure that the sterility was maintained, if necessary operating under aseptic conditions for the final stages of production.

Spontaneous Liposome and Emulsion Processes. One well-recognized characteristic of liposome formation is the spontaneous formation of these vesicles when a thin lipid/phospholipid layer is placed in contact with an excess of water. This is due to the marked ability of phospholipids to form curved surfaces. The resulting vesicles may not have the desired properties in terms of size or the required lamellar structure, which can be designed into the process by application of additional shear (extrusion through small orifices) or heat. What is perhaps less well recognized is the fact that anhydrous oil systems containing appropriate oil-soluble surfactants, when added to water, or, preferably, aqueous solutions of other surfactants, also spontaneously and rapidly form oil-in-water emulsions. These emulsions are usually submicrometer in dispersion and are remarkably stable. Familiar examples are seen in domestic products such as insecticidal sprays or antiseptic solutions where a "concentrate" is added to water, forming an immediate emulsion. Spontaneous systems have been explored for pharmaceutical application although the number of suitable (i.e., nontoxic surfactants) suitable for this purpose are somewhat limited (59). The speed of the emulsification process is a function of the temperature and oil viscosity as well as the properties of the surfactants employed. The advantage of an anhydrous system is that it can be stored as an oily paste in gelatin capsules which, when administered orally, spontaneously forms small droplets in the stomach and upper gastrointestinal tract

once the capsule wall is broken. For injection, the system would be packed as an oil to which water or electrolytes would be added immediately prior to injection. Pouton (59) has found that 30% Tagat OT(poly(oxyethylene-(25)glyceryltrioleate) with 70% medium chain triglycerides (Miglyol 812) was a suitable system for oral administration but there appear to be no reports of similar systems being suitable for parenteral use.

Preparation of Sterile Product. Because both systems are effectively made by adding one liquid to another, it should be feasible to sterile-filter both components and operate under aseptic conditions for the rest of the process. Heat sterilization of liposomes has been attempted but this may cause considerable changes in the state of dispersion and generally redistribution of guest drug molecules (60). γ-irradiation has also been investigated for the sterilization of liposomes (60), but was found to be limited in application because of phospholipid degradation. Frozen liposomes in the presence of effective antioxidants may be an alternative application for sterilization by γ-irradiation, but this possibility requires further evaluation.

Polymer Emulsification. The production of polymer emulsions, especially nanoparticulate systems, is carried out by an emulsification process that is physically different from those processes used for the usual pharmaceutical processes. Polymers are usually derived from monomeric systems by providing an appropriate stimulus or catalyst. Some reaction initiators are heat or high-energy radiation and catalysts are often heavy metal salts or, in the case of methyl methacrylate, potassium peroxidisulfate. However, greater control over the polymerization process is exerted if the liquid monomer is emulsified in water and the catalysts added to the system. The polymerization process itself does not occur in the oily or dispersed droplets but rather to the monomer molecules that have dissolved in the aqueous continuous phase from the disperse phase. The polymerization or chain-growth process is maintained by more monomer molecules diffusing out of the dispersed phase. Because the polymerization process is always slower than the monomer diffusion process, polymerization continues in the continuous aqueous phase until the droplet reservoir is exhausted. The monomer droplets can be reasonably coarse by comparison with the dispersed polymer particles and, as noted by Kreuter (6), some systems do not require an interfacial stabilizer, although addition of casein (e.g., to a methyl methacrylate suspension) results in a finer, more monodispersed, polymer particles.

Preparation of Sterile Product. Although many of the monomeric compounds used are unfavorable for bacterial growth, this cannot be relied upon to sterilize the system prior to or during the polymerization process. In addition, the effect of a terminal heat-sterilization process on the polymer would be to change equilibrium conditions and, therefore, properties of the final product. Because the reactants are liquids, in a liquid medium, this would suggest that a process could be designed as an aseptic process in which components and reactants are sterile-filtered together into a sterile reaction vessel, and aseptic precautions maintained throughout.

Mixed Micelles

Mixed micelles, consisting of mixtures of phospholipids, especially PC, and bile salts have recently been advocated as solubilization systems for sparingly soluble drugs such as teniposide and paclitaxel (Taxol®) (61,62). Phospholipids are insoluble in both oil and water, forming swollen suspensions in both. In water these dispersions are better known as liposomes because they form spherical molecular aggregates with aqueous centers. Bile salts, on the other hand, are water-soluble and readily form micellar aggregates. When added together, bile salts and phospholipids form complex structures, most likely rod-like aggregates that have a significantly higher capacity for guest molecules (63). These structures are readily formed as transparent aqueous dispersions, and this transparency is maintained as the system is diluted (although the actual structure changes from rods to spheres, in other words to liposome-like structures). Both components are amphiphilic in nature and both can be used to solubilize water-insoluble (i.e., with aqueous solubilities of below 0.01%) drugs. Individually these materials can be employed to solubilize drugs although handling phospholipids on their own is not easy (see "Emulsions") and bile salts can manifest toxicities on administration principally due to their detergent properties. However, when mixed, the new structures vastly increased the solubilization capacity of the individual systems, and the incorporated "guest" molecules were not precipitated on further aqueous dilution. This was because the bile salt molecules were effectively disaggregated by dilution, but the phospholipids form curved bilayer structure-liposomes that retained the associated hydrophobic guest molecules.

These mixed micellar solutions therefore have a number of advantages:

1. Precipitation is eliminated when injected or diluted for injection.
2. The vehicle is aqueous throughout and can be adjusted for pH and osmolarity.
3. The solutions are clear, isotropic, and have low viscosities, which make them ideal for injection.
4. Mixed micelles form spontaneously by the internal energy of the system, which effectively means that they are thermodynamically stable and reproducible at defined compositions and temperature.
5. Technically these systems are readily made by solution in a mutual solvent such as isopropanol, which can then be removed.
6. These solutions can be easily sterilized by filtration. Terminal heat sterilization, often demanded by regulatory authorities, has not been evaluated but under carefully controlled conditions, may not represent a serious problem, depending critically on the properties of the incorporated drug.
7. Unlike liposomal formulations there is no problem with vesicle leakage and mixed micellar systems are readily lyophilized, spontaneously recovering their original properties on reconstitution with water.

8. In some cases pain on injection has been shown to be reduced.
9. The chemical stability of some labile molecules has been shown to be improved, hydrolysis being reduced or prevented altogether when the drug is incorporated into mixed micelles.

A number of other drugs have been explored in mixed micellar systems, including diazepam and steroids (63). A systematic evaluation of steroidal structures on solubilization by simple and mixed micelles has recently been published by Cai et al. (64) although here the emphasis was on oral absorption of these drugs. Ayd (65) demonstrated that linear increases in solubilized drug concentration with increased total lipid concentration were often observed. A critical lipid concentration was defined as a specific mixed micelle composition that existed over a limited range, showing a linear relationship between the phospholipid: bile salt molar ratio. Measurement of the particle size suggested that a molar ratio of $\approx$ 1.0 was optimal. Beyond this range the systems appear to react more until they restructured to form a gel-like state consisting of associated rods. Ayd (65) concluded that mixed micellar solubilization was a multifactorial event, with different types of aggregated structures contributing to the entire solubilization process.

Yet to be used in a commercial product, this approach to an old issue associated with poorly soluble drug substances would appear to be exceptionally promising and may well be investigated further.

Preparation of Sterile Product. The effect of terminal heat sterilization conditions on the final mixed micellar product remains to be explored. The use of filtration to sterilize components in an aseptic process may be necessary but the point of application may need careful selection because, often, the component solutions have high viscosities that renders any filtration process difficult to carry out.

Spraying Processes

Kwok et al. (66,67) were able to demonstrate that 5–15-μm diameter particles of alginate-poly(lysine) particles suitable for encapsulating microorganisms such as bacillus Calmette-Guérin (BCG) vaccine could be made by spraying solutions of the polymer system through a suitable atomizer. Later, this system was adapted to preparing gelatin or albumin microparticles (40). The process consisted of atomizing aqueous 1% gelatin or [human albumin] solutions through a Turbotak atomizer, Turbotak Ltd., Waterloo, Ontario, Canada) with a 1 mm orifice. Two sets of apparatus were used (Figs. 1 and 3). The gas inlet to a Turbotak was connected to a compressed carbon dioxide tank at an inlet pressure of 20 psi. The inlet solutions were sprayed into anhydrous ethanol (95% ethanol, 5% isopropanol) held at a temperature of -15°C. The droplets were then hardened by the addition of glutaraldehyde for 24 hours, followed by sodium metabisulfite to stop the crosslinking reaction. The particles were collected and washed before lyophilization in the presence of mannitol as a diluent. The process was improved by adding a second stage

vessel designed to trap the larger droplets also produced by the Turbotak. This proved to be somewhat less effective and gave a much lower yield, most probably because it had already been shown that direct mixing of the aqueous gelatin and anhydrous ethanol was effective in producing gelatin particles (68). Nevertheless, the spraying technique did produce significantly smaller particles with an average size of 0.86 μm as opposed to an average of 1.18 μm made by the direct mixing process. Although relatively large volumes of flammable alcohol are required, one advantage of using the inexpensive carbon dioxide gas is that it is a flame retardant, suggesting that the process might have some potential for scale-up to an industrial process.

Preparation of Sterile Product. Refreshingly, Burgess and her co-workers (66,67,69) have continued work on sterile or axenic product (i.e., containing only one, predetermined microbiological species), and this has recently culminated in a detailed description of how sterile microparticles of alginate/poly(L-lysine) could be made (70). The process was described in detail, producing sterile particles from 3 to 16 μm diameter (volume weighted mean) according to the spraying conditions. The method involves using a Turbotak atomizer operating inside a bioreactor chamber and was shown to be robust enough for major changes in operating conditions to have insignificant effects on the product properties. Attention needs to be drawn to this important pioneering contribution to the subject of sterile microcapsules; it is likely that other processes could be designed in a similar fashion.

Preparation of Poly(L-lactide) Particles by Carbon Dioxide Precipitation Solutions. Müller and his colleagues (71) have recently described an aerosol solvent extraction system for

preparing microparticles by spraying solutions of polymers in organic solvents, usually methylene chloride, into liquid carbon dioxide under supercritical conditions. The apparatus is described in Figure 4, and poly(L-lactide) microparticles were prepared in order to determine solvent residues in the final particles. Varying the conditions of particle production produced little change in the mean/particle size (~2.0 μm diameter), although residual solvent levels were affected. This suggested that microparticle production was by a precipitation process rather then one associated with spray-drying. More to the point, it indicates that this product is also robust enough not to be significantly affected by slight changes in the process.

Preparation of Sterile Product. Ruchatz et al. (71) also referred to their particles as being "sterile." No evidence for this was provided, and an adequate validation of this supposition would be required, although the supposition would appear to be not unreasonable. However, the lack of viability or otherwise of microbacterial spores and other viable contaminants in liquid carbon dioxide has not been established and would certainly make an interesting study.

Homogenization. Calvör and Müller (9) have recently demonstrated that polymers such as PLA can be heated above their glass-transition temperatures and dispersed to nanoparticle sizes by high-pressure homogenization without the need for organic solvents. This process may be potentially important since it is readily scaled up.

Antigens and Adjuvants

Vaccination is by far the most efficient and cost-effective means for preventing a wide variety of infectious diseases. The effective use of what we can now recognize as a vaccine was known to the ancient Chinese as a means of preventing the spread of smallpox, a disease that has been eliminated from the world within living memory. Vaccines have been used to minimize polio, measles, diphtheria, tetanus, and pertussis in most areas of the world, and a tuberculosis vaccine, BCG, has been available since the 1920s. More recently, subunit vaccines against hepatitis A, B, and C have been developed, and vaccines against malaria and HIV have been explored and are currently on trial.

The use of vaccines, although originally empirically derived, follows from the way in which the immunological system of the body responds to the invasion of a foreign microorganism such as a virus or bacterium. Small amounts of foreign protein can stimulate a protective immune response, producing two types of immunity to subsequent infections. The first, called humoral immunity, develops after the invading pathogenic organisms have been destroyed by the immune system. The damaged bacterial cells are ingested by macrophages, which then present some of the foreign proteins to antibody-secreting cells called B lymphocytes. These cells then produce proteinaceous antibodies that recognize and bind strongly to the foreign protein. If these antigenic proteins are encountered again, the B lymphocytes carrying the appropriate antibodies are able to neutralize them or mark them down for destruction by other elements of the immune system. The second type of response, cellular immunity, occurs when invading cells penetrate cells in the body and make them produce more of the pathogen. The infected cells then display fragments of the pathogen proteins at the surface. This time the immune system responds by producing specific activated T lymphocytes that can recognize these fragments and bind directly to the infected cell surface. Antibodies are not produced by the T cells; they bind to the infected cells and destroy them, often by making the cell wall porous so that the cellular contents are lost.

For the most part, antigens are proteinaceous in nature. However, from the central dogma of biology, in which it is held that protein production in the cell is controlled and coded by DNA sequences through matching RNA fragments, it has now become clear that specific proteins antigens can be produced by administering so-called naked plasmid DNA sequences. Naked DNA has been used to generate antibodies to HIV proteins, and a naked-DNA influenza vaccine is currently in human clinical trial. Some workers have felt that liposomal-encapsulated DNA se-

Figure 4. quences may offer better prospects for cellular delivery than naked DNA (72).

For the most part, earlier vaccines consisted of heat-inactivated or attenuated viral or bacterial cultures. These systems contained numbers of unwanted proteins or portions of proteins, epitopes, that interacted not only with the antibodies for the disease but also with other receptors throughout the body. It should not, therefore, be surprising that unwanted side effects were often experienced on administration of a whole organism. The mildest of these side effects might vary from a mild to severe fever or, as in smallpox, a low-caliber manifestation of the disease. The attenuated tuberculosis vaccine, BCG, is a living organism, *Mycobacterium bovis*, which has to be administered orally or intradermally. Given intravenously, either deliberately or inadvertently during clinical treatment of superficial bladder cancer, it becomes disseminated throughout the body, producing a tuberculosis-like reaction that may require intensive isoniazid treatment for six months. There is little information about the oral administration of BCG, although it was by this route that the early vaccine was administered. Today, the preferred route is by superficial intradermal administration where it has become evident that the living organism is effectively behaving like a controlled release system, delivering on a continuous basis small amounts of cell wall proteins as antigens and stimulating production of the appropriate antibodies after administration, in some cases for several years (73).

Use of monoclonal antibodies, with very specific epitopes that react with exquisite specificity to other proteins, have demonstrated that the target site may be moveable. An excellent example of this is HIV, which is capable of changing its surface proteins, making the development of an epitopic vaccine exceptionally difficult. Although epitopic vaccines are attractive from a manufacturer's point of view because they are chemically well defined, generally free of the side effects associated with older vaccines, and relatively straightforward to manufacture, they are exquisite in the sensitivity and specificity of their antibody reactions. Thus, if the antibody shifts its epitopic identification center slightly the reaction may not take place at all. There are, therefore, advantages to using the older types of vaccine because they contain a much broader range of required epitopic sites even though, for the same reason, they are also capable of producing toxicity. A compromise may therefore be necessary.

Another disadvantage with these subunit antigens is that they are almost, without exception, poorly immunogenic. In order to induce an effective protective immunity, these vaccines require boosting with agents called adjuvants. The most effective adjuvant is probably Freund's complete adjuvant, consisting of BCG cells dispersed in a oily matrix, but the reaction produced on injection is so severe that it is not acceptable in human practice, and ideally should not be used in animal testing either.

The only adjuvants approved by the FDA for human use are aluminum hydroxide and aluminum phosphate in the form of alum. More effective adjuvants are currently being evaluated, including liposomal phospholipids, Lipid A, muramyl dipeptide (MDP), and various forms of quillaia saponins, including a purified form in a construct with cholesterol and phospholipids termed ISCOMS. Part of the issue associated with adjuvant use is how they work. Recent investigations have indicated that the immune system is controlled and coordinated by local excretion of cytokines such as interleukins, tumor necrosis factors, and interferons. An alternative strategy to the use of adjuvants might be to use controlled and targeted delivery of cytokines to specific sites of action. These materials are now available in significant quantities through the application of genetic engineering, although when administered in bulk, almost inevitably these compounds produce additional and unacceptable side effects.

In a recent review Zhao and Leong (74) suggested that advances in controlled release technology could improve immune responses by altering the spatial and temporal presentation of both antigens and adjuvants. The rate of delivery and the duration could be manipulated to generate an optimal immune response. Other evident advantages would be to protect the vaccine from degradation until it was released, and by combining slow release and depot effects, the amounts of antigens and the required adjuvants could be reduced, thereby reducing toxicity. It was suggested that by providing a continuous supply of antigen, progressive maturation of the neutralizing antibodies may be promoted. Unfortunately, as these authors admit, the exact mechanism by which an adjuvant is effective is poorly understood at present. The use of single epitopic vaccines may not be the best approach to vaccination in all cases but at least controlled release matrices do allow the possibility of encapsulating multiple antigenic epitopes as well as a number of adjuvants in a single carrier. At present in an exploratory phase, this approach might be feasible when a great deal more information is available about the mode of action of adjuvants, the number of subunit epitopes that are required, and the optimal quantities and type of cytokines. Nevertheless, the future development of prophylactic vaccines in the future is almost certain to involve controlled release formulations for both humoral and cellular responses. Selkirk (75) suggested that what was needed was the development of vectors that enabled both the target antigen and regulatory cytokines to be secreted simultaneously, taking care to minimize toxicity. He noted that delivery systems were needed that would target specific tissues and antigen-presenting cells. Some ideas and approaches will undoubtably disappear into the mists of history but, from the present perspective, many appear to be very promising.

Current Vaccine Delivery Systems. Although systems now used for antigen and adjuvant delivery have been discussed elsewhere, it might be helpful to summarize some of the more useful systems.

Liposomes. Liposomes and their recent derivatives, lipoplexes, have advantages in that they are hollow spherical constructs formed by phospholipids when dispersed in water. The constructs consist of one or more lipid bilayers that have aqueous spaces between them, thus allowing entrapment of either hydrophilic or hydrophobic moieties. By the addition of cholesterol the fluid lipid bilayers can be rendered rigid at ambient room temperature, and by changing the phospholipid constitution, the liposomes can

have an electropositive surface charge instead of the natural negative charge. Liposomes act as potent nontoxic immunological adjuvants and can be made to incorporate many antigens expressed at the surface. The versatility of the liposome as a drug delivery system is well recognized (76).

Adjuvants such as MDP and its analogues have been added to liposomes containing an antigen, and interleukin-2 has also been incorporated, confirming the versatility of the delivery system. Liposomes have another advantage in that the phospholipid bilayer is capable of fusing to cell walls. For this reason, they tend to get incorporated into elements of the reticuloendothelial system quite rapidly after administration. The recent introduction of surface-modified liposomes (sometimes called sterically stabilized or Stealth® liposomes) has produced a new generation of liposomes that are physiologically more stable. This has been achieved by covalently bonding poly(ethylene glycol) to the PE found in the lipid layer, producing a strongly hydrophilic surface that is not opsonized by proteins (36). This development appears to be exceptionally promising and may make the clinical application of liposomal products more realistic in the immediate future. Moreover, by attaching appropriate antibodies to the terminus of the liposome-attached poly(ethylene glycol) (77,78), the targeting of liposomes has been vastly improved.

Solid Particulate Systems. Biodegradable polymers, in particular PLGA, previously used as a surgical implant and suture material, have proved popular as particulate drug delivery systems. The polymer can be tailored to a specific purpose and has been explored as a matrix antigen delivery system. The polymer degrades by an aqueous hydrolytic process, producing acids and therefore low pH conditions close to the surface, which may be detrimental to any incorporated protein. In addition, as noted by Davis recently (79), storage of PLGA immunological systems can result in loss of immunogenicity, and "conventional" sterilization systems can cause damage, suggesting the need for aseptic processing. Davis also noted that scale-up of PLGA systems was proving to be difficult. According to Zhao and Leong (74), there have been vast differences between various workers in terms of vaccine preparation, immunization, and challenge protocols, as well as the assay methods. However, some general conclusions may be drawn. For example, the antigens need to be encapsulated in microspheres to elicit an enhanced antibody production and humoral protective immunity. The effect of particle size was evident, especially if the antigen dose was low. Because of the larger surface-to-mass ratio, release was faster from small particles compared with larger ones, and it seems that small ($<10\ \mu m$) microspheres are capable of facilitating extracellular delivery of antigens to the phagocytic accessors cells that infiltrate the administration site, leading to enhanced antigen processing and processing.

Indeed, larger particles could not be phagocytosed by the macrophages until they had disintegrated into smaller debris. In principle it was suggested that a combination of large and small particles might produce a pulsatile pattern of antigen release, mimicking an immunization process that involved a primary dose followed by booster shots. Other particulate systems can be made from cross-linked albumin or gelatin, as noted earlier. Interestingly, empty gelatin microparticles produce only a mild inflammatory response at the injection site, suggesting that gelatin itself has only a minimal immunogenic activity.

However, gelatin on its own does have adjuvant activity and this probably arises from the ability of macrophages to phagocytose the microparticles. Poly(phosphazenes) are a class of polymers with a simple -P=N- backbone with physicochemical properties strongly influenced by side chain attachments to the phosphorus atom. Some can be rendered water-soluble, allowing the antigen to be encapsulated in the aqueous state at low temperature. Addition of ionic cross-linking agents such as calcium can then render the system insoluble, allowing sustained release from the precipitated solid. Further control is obtained by coating the solid surface with the cationic polymer, poly(lysine), and this approach has been used to control the release of antibacterial drugs in a controlled-release string made from calcium alginate, which was designed for impaction into dental periodontal cavities (80).

Other Current Formulation Issues

Pain on Injection. Injectable products are administered by various routes according to the physiological requirements of the product. The main routes are

1. *Intravenous* directly into the intravenous blood supply
2. *Subcutaneous* into the soft tissues just underneath the skin
3. *Intramuscular* directly into the muscles of the arm or gluteal region

Other routes include the *intrathecal* (subarachnoid space), *intraarticular* (directly into joints), *intracardial* (directly into the heart), *intraperitoneal* (used for kidney dialysis), and *intracutaneous* (just under the stratum corneum of the epidermis). However, all routes of parenteral administration require professional medical skills for successful delivery of the drug, and this can sometimes be stressful for the patient, contributing to pain. Nevertheless, although it is basically true that no parenteral administration is without pain, some drugs or their vehicles themselves produce pain. It is generally recognized that painful injections should be administered by intramuscular injection because there are few nervous receptors in these tissues. Nevertheless, this site is not always feasible and pain experienced by administration of a pain-causing drug can be difficult by the subcutaneous route or, due to drug residues along the needle-track, by the intravenous route. Some factors producing pain on injection, reviewed by Fransson and Espander-Jansson (81) include:

- Injection volume (the subcutaneous route should not exceed 1.0 mL and the intramuscular 2.0 mL)
- Speed of injection
- Injection site
- Size and quality of the hypodermic used (is it sharp or blunted?)

- Temperature of injection
- Presence of irritating substances (e.g., citrates)
- pH
- Osmolality

Fransson and Espander-Jansson (81) were concerned about severe pain experienced by patients receiving subcutaneous injections of human insulin-like growth factor. This protein is most stable at a pH of 6.0, which although not physiological, should have been acceptable. Morphine sulfate injections have a pH of 3.0, although these are administered into muscles where the ambient pH is often lower. These authors were able to demonstrate that the pain was not due to the drug itself but was caused by the concentration of the phosphate buffer used. Although lower concentrations of phosphate (10 mM compared with 50 mM) had lower buffer capacity, this was judged to be acceptable in view of the reduced pain experienced. In addition, it is probable that dilution to physiological pH occurred more rapidly around the administration site.

Pain is a subjective sensation and therefore difficult to measure. However, there are statistically valid methods of measuring it, and other sensations such as muscle damage, redness, paleness, and edema at the injection site can also be used to supplement the measurements (82,83).

Needleless or Jet Injectors. Alexander Wood invented the graduated glass syringe fitted with a hollow reed in Edinburgh around 1853, although syringes as such were widely employed in early Tudor times, to judge by artifacts found on the warship Mary Rose, which sank off Portsmouth in the early 1500s. After over a century of needle injections, the technology is well understood, although some issues have become evident, such as the associated dangers of needle sticks to health care personnel and cross-contamination during administration. A needleless injector, the Porton injector, was developed in the 1930s and used for routine mass inoculations in both military and veterinary applications. The principle was straightforward: a high-pressure liquid flow from a pressurized container penetrated the skin and deposited material in the dermis and subdermal layers. The equipment was heavy and required a compressor, which made it unsuitable for routine individual use. Various attempts to improve the technology have appeared in recent years and at least one of these, the Intraject® system, Weston Medical (United Kingdom), is one of several recently developed systems that have considerable promise as a technology for the immediate future. The Weston device uses a preloaded gas or coil spring-activated piston to force the liquid through an orifice that does not come into direct contact with the skin. The drug can be supplied in the type of filled cartridges already in wide use for dental syringes. The two are coupled together, and when activated, the spring-powered ram accelerates and strikes a piston with viscoelastic properties. This causes the formation of a liquid pulse in what is described as a "liquid nail," and this has sufficient energy to penetrate the skin, depositing a predetermined volume of fluid. The volume of liquid that can be deposited is limited to 0.2 to 1.0 mL, optimally 0.5 mL, but analysis of the hydrodynamics of the administration process has demonstrated that viscosity of the solution is relatively unimportant. In addition, if the orifice is very short, shear forces are minimized. This is relevant because many proteinaceous injections such as antigens are readily denatured by shearing. The advantages of the Intraject system is that it is light, readily portable, and allows individual patients to administer their own intradermal or subcutaneous injections. Intramuscular injections may also be possible, depending on the obesity of the patient. These may be more painful because of the speed with which liquid is introduced into the muscles, the individual fibers having insufficient time to displace and allow the injected fluid to penetrate into the tissues. In addition, because of the way the liquid pulse splays out on administration, some of the drug may be deposited into adipose tissue, potentially altering the pharmacokinetics. However, individual patients would be likely to adjust dosage according to their requirements, and this has been observed with diabetics using the system. The injector is automatically fired when the device is pressed lightly on the skin. This means that the amount of skill required for administration is minimal, and medical personnel are not required, thereby significantly reducing the associated costs. The device itself is also claimed to be inexpensive, below 20 cents (U.S.) in 1997 money. Obvious advantages of this system is the small size, speed of administration, and insignificant pain levels experienced on intradermal injection. It is therefore entirely possible that this type of device and others being commercially developed will provide a valuable means of administering sterile nanoparticulate systems subdermally for controlled drug delivery.

Albumin

Albumins are a group of proteins widely found in nearly all living body tissues. They are characterized by solubility in dilute salt solutions and precipitation at relatively low temperatures, heating at 55–65°C being sufficient to denature most albumins. Commercially they are obtained from egg white, bovine serum, and human serum, although significant quantities are also available from soybeans, milk, and some grains. Egg white albumins, for example, are usually called *albumins*, and the Latin for egg white is *albumen*. Pharmaceutical materials are generally from bovine or human serum and the remainder of the nonpharmaceutical albumins are widely used for baking although, as noted by Teng and colleagues (84), soy albumins are potentially valuable tablet excipients. Human serum albumin separated from whole human blood is employed as a plasma volume expander, and iodinated (^{131}I) albumin is used as a diagnostic in the measurement of blood volume. This protein has a relatively low molecular weight (~69 kDa) and comprises about 60% of the plasma proteins. Although it denatures and comes out of solution at temperatures below 65°C, the protein is carbohydrate-free and is stable at higher temperatures. The denaturation process in this case is reversible, and commercially available dried albumin, as an example, goes back into solution at lower temperatures, forming as much as a 40% solution at pH 7.4. Ovalbumin, on the other hand, is denatured at

61°C and, when dried, swells initially before it returns back into solution. Both bovine and human albumins could be potentially contaminated in vivo, the bovine with bovine spongiform encalphalopathy (BSE) organism and the human with the AIDS virus. Both contaminants are of concern to regulatory bodies, suggesting care be taken in sourcing the starting material.

Particulate Forms of Albumin. Because albumins readily come out of solution under mild heating conditions, they are suitable for preparing spherical nanoparticles or microparticles. Nanoparticles were first prepared by Zolle et al. (85) as vehicles for nuclear medicines, with the process effectively being repeated by others as general pharmaceutical formulations. The process involved dissolving albumin in water, together with the drug dissolved or suspended in water, and then emulsifying this mixture in oil to produce a water-in-oil emulsion. The size of the droplets was decreased using an homogenizer or by applying ultrasonics, and this system was slowly added to a bulk preheated oil phase and held at elevated temperatures (from 100° to 180°C) for 10 minutes. This was more than sufficient to denature and harden the albumin in the submicrometer water droplets. The overall system was then cooled, filtered, or centrifuged to collect the droplets, and the excess oil was removed with diethyl ether. Because of the hazard of this solvent, the process was not suitable for industrial scale-up, but has since been widely employed in the laboratory. Gallo et al. (86) evaluated factors that influenced the particle size, finding that nanoparticles between 400 and 800 nm in diameter were produced with relatively little effect being seen when manufacturing parameters were changed. Kreuter (6,7) commented in his review that a critical preparation parameter was the rate at which the primary emulsion was added to the bulk heated oil. Others have also demonstrated the inverse relationship between the subsequent release rate and the denaturation temperatures (7).

An alternative process, readily applicable to albumins, is desolvation of the dissolved protein followed by cross-linking. Desolvation can be carried out with ethanol or acetone as shown by Öner and Groves (40) or by using sodium or ammonium sulfates, the latter being preferred because an appreciably higher saturation concentration can be obtained. Wetting agents such as polysorbate 20 appear to help the process, perhaps by inducing interfacial changes in the protein configuration or by acting as a stabilizer (6). Cross-linking reagents such as formaldehyde or glutaraldehyde are then added and allowed sufficient time to react before being removed or neutralized with sodium metabisulfite.

In terms of the sterility of the final product, the heating process and certainly the presence of cross-linking reagents must have a major influence because they are potent chemical sterilants in their own right. Handled under aseptic conditions, it would appear very likely that particles treated with aldehydic cross-linking reagents would be "sterile" at the end of the process. However, this supposition does not appear to have been tested experimentally.

Although it is relatively easy to prepare submicrometer albumin particles by emulsification methods and low micrometer-range particles by desolvation procedures, the release properties of the resultant core matrix systems (i.e., where there is no outer skin or shell) appear to depend on the cross-linking conditions such as concentration of reagent and time of exposure. Anhydrous particles added to water appear to swell first as water is imbibed, hydrating the proteins, and this phase is followed by a slower solution or erosion process. In vivo the process would most likely be accelerated by the presence of proteases, which are ubiquitous throughout the body. In vitro the release of drugs from albumin microspheres is considerably slower than that from other materials, occurring in two fairly separate phases, an initial rapid phase being followed by a slow phase (37). Each phase was characterized as a first-order reaction, with the actual release rate being proportional to the remaining drug concentration in the particles. Jalšenjak (37) suggested a simple biexponential function to describe the release profile:

$$Q = \text{amount remaining in the microspheres at time } t = A \exp(-\alpha t) + B \exp(-\beta t) \quad (1)$$

where A and B are constants and α and β the rate constants. There is no physical explanation for the faster initial process unless it is analogous to the burst phase observed with other types of controlled release products in which the incorporated drug is present as superficial crystals or some other form that is readily available to the penetrating solvent. As noted, the release mechanism in vivo is likely to be activated by enzymes and should therefore be somewhat different both in the form of the release curve and the actual release rate. This does not appear to have been evaluated experimentally.

Preparation of Albumin Microparticles by Atomization. Although albumin microparticles are readily prepared by the application of heat (>55°C) to suspensions or emulsions containing aqueous solutions of the protein, these methods all require removal of oils and emulsifying agents from the precipitated protein. Many authors have employed solvents such as diethyl ether, chloroform, or methylene chloride to remove oils from the product, which for the most part are considered to be environmentally and toxicologically undesirable. Moreover, removal of solvent residues is by no means complete, and the net effect is that albumin microparticles in the final product are often less than ideal.

These considerations led to the exploration of alternative processes involving chilled dehydrating solvents such as anhydrous ethanol or acetone. Öner and Groves (40) described a relatively simple process in which aqueous solutions of albumin or gelatin were mixed into anhydrous ethanol at −15°C. The microparticles produced were hardened for collection by exposure to glutaraldehyde for a prolonged period before collection by filtration and extensive washing. Particles of albumin in the range of 2 to 5 μm in diameter were readily prepared, the size being controlled to some extent by the time of exposure and concentration of glutaraldehyde (40). Later, the process was refined by

Next Page

atomization of albumin solutions through a Turbotak atomizer and allowing the droplets to impinge into the chilled ethanol. This process reduced the mean size of microparticles produced by the mixing process from 3 to 1.8 μm by the atomization process, although the overall yield was obviously lower (85% vs. 67%). The use of carbon dioxide as a propellant was considered to be an advantage because the gas behaves as a flame retardant (87). The equipment used for this purpose is shown in Figures 1 and 3.

Properties of Albumin Microparticles. There have been relatively few studies of the properties of albumin microparticles, although they may be presumed to be porous assemblies of insoluble proteinaceous molecules formed by either heat or aldehyde cross-linking. Factors involved in the formation of albumin beads by the emulsification process have been evaluated. However, studies of factors involved in the in vitro disintegration of albumin microparticles are relatively limited. One advantage of insoluble microparticles made of proteins such as albumin is that the surfaces can be eroded by digestion with a nonspecific proteolytic enzyme such as trypsin. This was the method used to evaluate albumin microparticles (68). These authors found that both the size and the rate of in vitro disintegration of albumin microparticles (made by the chilled desolvation technique) were affected by both the concentration of the cross-linking agent (glutaraldehyde) and the time of exposure (Fig. 5). This strongly suggested that the cross-linking process itself was essentially a dynamic process, with particles becoming larger with both time and exposure and concentration of the cross-linking agent (Fig. 6). This observation was very different from that observed by the same authors for the formation of gelatin microparticles where, once formed, the particle remained constant

in size (40). This was considered to be due to the higher molecular weight of the globular albumin molecules and subsequent greater sensitivity to structural changes induced by the cross-linking agent. In the case of the linear gelatin molecules, unless particles had been hardened for a sufficient length of time they simply swelled and dissolved on exposure to water. On the other hand, microparticles formed very rapidly at low concentrations of reagent, and the size increased as reagent concentration and exposure time were increased.

Enzymic disintegration of hardened microparticles and, presumably, release of any incorporation drug was affected by a number of associated factors, especially particle size. Because the molecular size of the digesting enzyme is sufficiently large to inhibit diffusion into the particle interior, the attack and subsequent solution of the matrix would be anticipated to occur at the surface of the particles. The disintegration of the microparticle could be treated as a square root of time relationship commonly observed with Fickian transport phenomena. The release (disintegration) surface diagram (Fig. 5) is substantially but not completely the reverse of the formation surface (Fig. 6). However, the relationship between initial size of the microparticles and time for the solution process to go to completion was clearly more complex than a simple root time function would suggest, as is readily seen by comparing the two surface diagrams, and by the fact that the relationship between particle size and complete disintegration time was not linear. This may indicate that the process is going faster than might be anticipated because enzyme is capable of penetrating to the interior surfaces of the microparticles, thereby increasing the rate of the disintegration process. Involvement of particle interior surfaces was also suggested when investigating loading of thiotepa or low and high molecular weight sugars onto preformed gelatin microparticles (87,88).

Collagen

Collagen is widely used, especially in Europe, as a base material for a wide variety of drug carrier systems. In general, it is considered to be biocompatible and biodegradable, allowing, for example, its exploitation as lenses for ophthalmic delivery. Collagen sponges impregnated with antibiotics have been employed in surgery to improve wound healing and prevent diseases such as osteomyelitis (89). For the most part, parenteral collagen systems have been developed as matrices and are claimed to offer better alternatives to synthetic polyester of polyanhydride devices. However, most of the systems described to date are monomolecular collagen (atelocollagen) in which the nonhelical telopeptides are removed enzymatically (see "Gelatin and Gelatin Vehicles" for a discussion of the structure of collagen and its degradation products). This soluble product requires chemical cross-linking to prevent or delay the devices from dissolving at body temperature, 37°C. Using glutaraldehyde increases the danger of side reactions that can occur on incorporated sensitive drugs, such as proteins, and reduces the biocompatibility. Friess and colleagues (90) suggested that an alternative method was to use the higher molecular weight soluble collagens as a drug carrier. This insoluble material comes about from the natural tendency of the collagen triple helix structure to aggregate, eventually forming fibers and bundles of fibers that were stabilized by inter- and intramolecular cross-links. Commercially, the insoluble collagen is available as a slurry after milling, purification, and enzyme treatment designed to remove the noncollagenous materials. Friess and Lee (89) lyophilized this slurry for storage but could rehydrate it by swelling in water followed by homogenization. Devices were easily prepared by casting films of hydrated suspensions and punching out discs after air-drying. Properties were modified by adding glutaraldehyde to induce cross-linking.

Differential scanning calorimetry demonstrated that denaturation occurred at relatively high temperatures, 80–103°C, higher than the 43°C recorded for aqueous solutions of the same material. Cross-linking caused some controlled slow release from the devices but, correspondingly, increasing amounts of drug were entrapped in the matrix. This entrapped material was shown to be released by enzymatic digestion (90). This observation suggests that implanted devices would release incorporated drugs, especially those of high molecular weight, under the influence of locally available enzymes such as collagenases.

Because chemical cross-linking is required to obtain controlled release, it was found to be important to load the devices after preparation and initial lyophilization by soaking and swelling in a solution of the drug, followed by a second lyophilization. Proteins were readily loaded by this method (90) as were polysaccharidic glycans (91). In this latter case the drug, PS1, as a known immunostimulant, stimulated the in vivo degradation of the devices, apparently by macrophage attack. The mechanism involved here was not clearly defined but any unexpected in vivo effect similar to that observed here would obviously negate the purpose of using this type of controlled release system.

Gelatin and Gelatin Vehicles

Constitution of Gelatin. Gelatin is a biopolymer obtained commercially by the controlled hydrolysis of collagens from a number of animal sources. Native collagen consists of rods formed from triple helices that are held together by covalent bonds. During the denaturation process, which usually consists of heating in the presence of acid or alkali, the covalent bonds are destroyed and the helical structure disrupted. Above 37°C solutions of gelatin in water are liquids, and the molecules behave effectively as random polymeric coils. However, when cooled to ambient room temperature in excess of 1% concentrations by weight, gelatin solutions change to gels and the random chains partially revert back to triple helix structures. The bulk of the gelatin chain is made up of glycine, proline, and hydroxyproline (≅58%), which are weakly hydrophobic. Their periodicity along the chain, combined with the structural flexibility of the glycine molecule, provides a vehicle for the formation of helical structures (92).

At around neutral pH the gelatin chain is amphoteric and groups such as lysine and arginine (≅7.5% of residues) are positively charged, and others such as glutamic and aspartic acids (≅11.8%) are negatively charged. These entities provide centers for electrostatic binding. Light, small angle neutron and x-ray scattering all provided evidence of the persistent length and stiffness of the chain as approximately 20 nm, with a radius of gyration R_G of ≃35 nm. As the concentration was increased, two regions became evident by quasielastic light scattering. The fast mode was evidently due to cooperative movements of the entangled network of chains, and this appeared to persist over a range of concentrations and temperatures. The second mode was associated with the diffusion coefficient being inversely proportioned to the bulk Newtonian viscosity of the solution. This has been interpreted as being due to the self-diffusion of clusters of chains that have a constant hydrodynamic radius $R_C \cong 75$ nm. Contrary to the properties of the chains themselves, the clusters are affected by the molecular weight of the individual chains, the temperature and the presence of salts or surfactants such as sodium dodecyl sulfate. Herning et al. (93) concluded that clusters were stabilized by hydrophobic interactions between apolar lateral groups of the protein. Gelatin as such is not a single entity but behaves like a model protein. The bulk material is deficient in some amino acids, having only 18 constituent units, of which the principal constituents are glycine (32–35%), proline (11–13%), alanine (10–11%), hydroxyproline (9–19%), glutamic acid (7–8%), aspartic acid (4–5%), and arginine (5%). The parent collagen, for the most part, consists of three subunits of approximately equal molecular weight (95 kDa). When denatured to form gelatin, the collagen is broken down to a single chain α-fragment (M_w 95 kDa) and β-fragments (M_w 190 kDa), together with branched γ-chains of M_w 285 kDa which actually consist of three α-chains joined near the center point. As might be anticipated, there are also low molecular weight oligomeric degradation products (Table 2).

Using high-performance liquid chromatography and gel electrophoresis, Zavlin et al. (95) have examined the constitutional difference of gelatins from various sources al-

Table 2. Oligomers of Gelatin Showing the Relationship of the Basic α-chain to Other Components

Molecular weight class	Molecular weight range (kDa)	Possible composition (α-chains)	Approximate % w/w in B225 gelatin
Subalpha	<80	Low molecular weight fragments	20
Alpha (α)	80–125	1-α	14
Beta (β)	125–225	2-α	18
Gamma (γ)	225–340	3-α	8
Epsilon (ε)	340–700	6-α (or 2γ)	15
Zeta (ζ)	700–1,000	9-α (or 3γ)	5
Delta (δ)	1,000–1,800	12-α (or 4γ)	9
Microgel	>1,800	high molecular weight aggregates >12-α	11

though with photographic film processing in mind. Skin or bone gelatins were basically similar one to another, β-chains being substantially missing from skin gelatins. Differences between acid and alkaline processed gelatin were noted, the former apparently containing more degradation products. The authors suggested that desired properties for any particular gelatin could be obtained by blending various samples to give the desired low molecular (α) or high molecular (γ) fractions according to the end product usage. What is certainly missing at the present point in time is evidence that the gelatin-producing industry is prepared to carry out this blending process for the pharmaceutical industry, in part because pharmaceuticals represent a relatively small section of the total economic requirement and in part because there have been relatively few pharmaceutical studies that have helped to define the essential requirements for pharmaceutical gelatins.

Phase Relationships. Although gelatin is proteinaceous, comprising linear assemblies of covalently bonded amino acids, in many ways it has atypical behavior because it shows no tertiary structure and is not denatured by heating up to temperatures of 100°C. Albumin, for example, is denatured at 55–60°C and is readily precipitated out of aqueous solution by the addition of ethanol or sodium or ammonium sulfate. Gelatin, on the other hand, is slowly precipitated by the addition of either of these desolvating components, resulting in a complex phase diagram that is influenced by the temperature of the system. Gelatin is a mildly hydrophobic protein, and the addition of solutes results in two-phase liquid systems, today called coacervates, and it is the creation of coacervate structures that is the key step in the production of many encapsulated gelatin products. Although this has been known for many years, it is only recently that attempts have been made to systematically, experimentally determine the effect of temperature and solutes on the transition between various constituent phases of what is an exceptionally complex system (96). Ternary phase diagrams are often used to depict the effect of a third component on the phase behavior of a particular compound in aqueous solution. More commonly used for inorganic systems, the ternary diagrams have proved to be invaluable for defining the phase behavior of surfactants and spontaneous emulsions. Effectively, defining points or boundaries between incompatible systems or components, interpretation of ternary phase diagrams requires care and are rarely precise or exact. The first studies of the effects of salts on gelatin go back to the 1930s (97) but recently a systematic study of the effects of ammonium sulfate or ethanol on the solubility or constitution of Gelatin B (Bloom 225) has been published (96). These authors found after the inspection of several hundred gelatin–water combinations that a total of seven morphologies could be distinguished visually (Table 3) although only six were seen with the ethanolic systems. It must be assumed that the states described by these authors are stable and that the equilibrium phase boundaries are also stable, although these assumptions are not always justified. At least 33% water is needed to break apart and hydrate the gelatin in order to form a solution (Fig. 7). Interestingly, the addition of ethanol did not appear to change this situation, suggesting that the compact gelatin powder showed little preference for either water or ethanol and, as noted earlier, can therefore be defined as being relatively hydrophobic. It should be noticed that water-structure promoters such as sodium chloride destabilize gelatin structure, and almost 50% water is required to form a solution in the presence of 5% sodium chloride. This can be interpreted as indicating that both the gelatin and the salt compete for water of hydration. However, the question not answered by these authors is the nature of the structure of the opaque sols and gels described. It was pointed out that below 40°C, gelatin molecules began to interact with each other to form linkages stabilized by hydrogen bonds, which accounted for ethanol encouraging gel formation, as shown in morphology I, Figure 7. Herning et

Table 3. Gelatin Morphologies on Addition of Ethanol or Ammonium Sulfate

Morphology	Description
I	Transparent clear colorless liquid
II	Opaque liquid (small aggregates)
III	Coacervate region
IV	Transparent or opaque lower gel, upper liquid
V	Homogeneous transparent gel
VI	Powdery aggregates

al. (93) suggested that stable clusters of gelatin chains formed with hydrodynamic radii of 75 nm at concentrations in excess of 1% w/w, the radii being even smaller at around 60 nm for lower molecular weight samples. Electron microscopy of gelatin nanoparticles and microparticles (94) suggest that these consist of aggregates of small spherical primary particles of around 100–200 nm diameter, quite consistent with the clusters of molecular chains with diameters of ~150 nm postulated by Herning et al. (93).

The nature of the process involved with gel characteristic of gelatins remains unclear in details but must involve chains of the amino acids forming the primary structure to develop associations, most probably involving triple helix structures. Native collagen consists of triple helixes covalently bound to form a solid structure. These are broken by hydrolysis to allow triple helices that reform in the gelatin solution when favored by the presence of large numbers of glycine and proline molecules along the length of the chain. These helices can form along different segments of adjacent chains, thus producing a linked three-dimensional structure as a gel. Dimensions of these systems have been measured by various methods. Chains are approximately 16–20 nm long and a 5% gel has a three-dimensional structure, with "mesh" sizes of approximately 5 nm, the size of which are affected by the presence of salts or surfactants (92).

These parameters may be considered to be fundamental to the structure of the gels, being only determined by the nature and constitution of the primary gelatin molecules. Other parameters involving the gel structure are conditioned by environmental factors, especially temperature and constitution of the medium. Coacervates that form, such as morphology states II, III, or IV (see Table 3), are actually diphasic and consist of separated particles and a liquid. The real questions are, what is the size of these precipitated particles and how can they be made and preserved for use as drug delivery systems?

The Preparation of Gelatin "Nanoparticles". In what has proved to be an influential paper, Marty and her colleagues (58) pointed out that colloidal drug delivery systems lend themselves to parenteral administration and may have uses as sustained release products. It was noted that the ideal colloidal delivery system would transport the bound drug to its desired site of action and release it at an appropriate rate. The carrier itself was required to be nontoxic and to degrade in vivo so it did not accumulate indefinitely in the tissues. Somewhat optimistically, these authors also suggested that the colloidal product should have pharmaceutical stability and ease of administration, such as the ability to pass through an hypodermic syringe and needle. The preparations for parenteral use were also required to be sterilized although, as noted, this may not always be necessary if the production process is adequately designed. The systems, called "nanoparticles" by Speiser, were considered to be the closest approach to being ideal because particles with diameters 200–500 nm in diameter were prepared from materials such as gelatin, human serum albumin, ethylcellulose, or casein. Marty et al. described a process for preparing gelatin microparticles because gelatin was readily available, had low antigenicity, and had previously been used in parenteral formulations. However, although this paper has often been cited, the actual process described by these authors has proved exceptionally difficult to replicate (94) and clearly materials available 20 years later as well as the actual methods themselves are not precisely reproducible.

Gelatin Precipitation. The process described by Marty et al. (58) involved adding ethanol slowly with stirring to a 1–3% w/v solution of gelatin in water containing surfactant (e.g., polysorbate 20) and buffering salts at 37°C until a permanent turbidity was visible. A small amount of ethanol (or isopropanol) was then added until the turbidity was lost and aqueous glutaraldehyde added to cross-link (harden) the gelatin particles. Excess glutaraldehyde was then removed with sodium sulfite or sodium metabisulfite and the entire system lyophilized to remove both the water and the ethanol. The particles were claimed to be spherical, fairly uniformally sized at approximately 200 nm diameter, and a column chromatographic process was employed to separate out the salts and smaller molecular weight components. In fact, looking more closely at the electron photomicrographs these authors published, it may be that they were being somewhat optimistic in their estimates of size. Hydrated particles shrink considerably when exposed to the hard vacuum required for scanning electron microscopy, and associations between particles were evident in their published electron photomicrographs.

Over the years various groups have reevaluated this pioneering work and developed the concept further. Öner

and Groves (40) demonstrated that it was possible to produce micrometer-range sized particles by effectively reversing the process described by Marty et al. (58), in that warm 1% gelatin solutions were added to stirred dehydrating solvents such as anhydrous ethanol (95% ethanol plus 5% isopropanol) at −15°C obtained by surrounding the mixing vessel with solid carbon dioxide (see Fig. 1). In this case the generated particles are likely to be in the Morphology Region I (see Table 3) described by Elysée-Collen and Lencki (96), moving rapidly to Region II as the local concentration of ethanol is increased at the surface of the precipitated and frozen water (aqueous solution of gelatin) droplet. At this stage the solidified water would be removed by the excess of ethanol, leaving the gelatin solid behind. These authors found that considerably longer periods of glutaraldehyde contact than have been previously reported in the literature were necessary to effectively cross-link the gelatin particles. The particle size was found to be significantly affected by the pH, volume, and the concentration of the initial solution as well as the type of gelatin and temperature used (Figs. 8 and 9). The described process involved extensive washing to remove extraneous electrolytes, which meant that the microparticles, 2–5 μm in diameter, could not be preloaded with drug. However, later work by Lou and Groves (88) showed that highly water-soluble sugars and polysaccharides could be loaded by adsorption onto the surface of preformed gelatin microparticle using a lyophilization process, desorption (release) occurring by a reverse of this process. In addition, these authors demonstrated the sensitivity of the process to the temperature at which the dehydrating solvent was maintained. Here scanning electron micrographs suggested that the cross-linked microparticles were aggregates of small primary particles of ≈200 nm diameter, inviting comparison with size estimates of particles reported by Marty et al. (58) and the measurements of stable gelatin

chain clusters by Herning et al. (93). Lou and Groves (88) showed that the resultant size of particles was only modestly affected by the origin of the gelatin but was significantly affected by the pH of the system (Fig. 9). Moreover, systems prepared at high pH were shown to have bimodal size distributions, the small size (~2.5 μm) at low pH (≤6.0) being conserved. A second population developed with a diameter of ~5.0 μm as the pH was increased. The response surface demonstrated environmental influences for systems made at −15°C (Fig. 10).

The Toxicity of Gelatin. Although widely perceived as being innocuous, intravenous gelatin solutions adminis-

tered as blood expanders proved to have unexpected toxicities. Accordingly, gelatin microparticles, although perhaps less likely to suffer from the same effects, should not be viewed as being entirely without potential harm. As discussed in the following section, gelatin (and collagen) bind to fibronectin with a high affinity (98–102). By specifically binding to fibronectin, gelatin could interfere with the cell binding interactions that are characteristic of cancers but are also required in the healthy body. Infusion of gelatin-based plasma substitutes produced severe side effects due to depletion of plasma fibronectin, and this obviously limits the widespread use of gelatin solutions. Nevertheless, side effects due to the injection of gelatin microparticles, for example, would not be anticipated to be so severe or widespread. However, in human use the investigator should at least be aware of the previously observed manifestations of toxicity and anticipate possible side effects associated with the therapy. Two other more problematic issues also need to be raised here. One is the slow release of aldehydic cross-linking agents, as the cross-linked polymer disassociates in vivo. Although obviously at low levels and probably over a prolonged time, the long-term effects of local administration of glutaraldehyde have not been evaluated. The second issues of contamination of bovine sources gelatins with BSE or mad cow disease, which appears to have originated in the United Kingdom and is therefore of more immediate concern to European regulators. Although some politicians have attempted to ban all products derived from cows, including leather, gelatin products have also been somewhat irrationally targeted. Although it is true that much needs to be learned about prions, the causative agents of BSE, it is difficult to imagine anything surviving the processes used to produce pharmaceutical gelatin. Other nonbovine sources of gelatin are available, although porcine sources are not acceptable in some cultures. Moreover, at the time of writing no pharmaceutical gelatin products have been found to contain prions, so the issue is obviously a remote one that can probably be ignored.

Sterilization of Gelatin Products. Gelatin as such does not have a precise chemical structure, and solutions of gelatin are readily heat sterilized. Obvious heat damage to the general structure occurs, in particular a loss of viscosity induced by hydrolytic destruction of covalent and hydrogen beads. But, as noted earlier, gelatin has a tendency to attempt to revert to its original collagen-type structure. The structures effectively heals or reforms, and the properties for which gelatin is so widely used can be restored. However, irreversible damage undoubtably occurs, suggesting that aseptic filtration is probably required for most, if not all, injectable gelatins.

Tissue Targeting With Gelatin Microparticles. As noted in the previous section, gelatin binds avidly to fibronectin and by analogy to fibronectin-enriched surfaces. This interaction has been studied extensively starting with Engvall and Ruoslahti in 1977 (103). Fibronectin is an ubiquitous asymmetric glycoprotein or, more accurately, a family of at least 100 glycoproteins with structural homology (104). They have two similar but not identical polypeptide chains joined near their c-termini that are held together with disulfide bridges. The protein has a high molecular weight (~440 kDa) and is a normal constituent of blood plasma besides being widely deposited in connective tissues, blood vessel walls, and basement membranes. Excreted on the surface of a cell, fibronectin functions as a cell-to-cell or cell-to-basement membrane adhesive (Fig. 11). The free plasma fibronectin is considered to be the main opsonic protein modulating the functional capacity of the reticuloendothelial system. However, it is as a factor involved in the propensity of tumor cells to spread or metastasize from their site of origin to other body sites that fibronectin is of interest in the present context. As is well known, the high rate of death following diagnosis of cancer is due principally to the biological consequences of tumor cells disseminating from their original site. About half of all diagnosed cancer patients survive at least five years when treated by conventional means, involving surgery, chemotherapy, or radiotherapy alone or in combination. The failures are almost always due to metastases that removal of the primary tumor site has failed to eradicate.

The dissemination of malignant cells from a primary to a secondary site involves a complex sequence of biological events that are linked in both time and space, and although basically a very inefficient process in that thousands of cells may be detached from the tumor but only a few survive, malignancies can occur at sites well removed from the original tumor. The invasive process is assisted by the expression or recognition of a group of proteins called adhesins in the endothelial or subendothelial extracellular matrix; fibronectin is considered to have a key role in the metastatic process as an adhesion.

Because of the complexity of its function in a biological system, fibronectin has been shown to have areas or domains along its molecule that can be identified to specific binding functions. For example, as indicated in Figure 11, there are at lease two domains with direct cellular binding activity, another binds to DNA, and yet others to fibrin and to heparin. However, one domain has been specifically identified as being responsible for the binding to collagen or, in its degraded form, to gelatin.

A clear distinction need to be made between altered adhesive behavior that may come about because of a direct or indirect consequence of the neoplastic process and the exploitation by abnormal cells of the normal adhesion process. Tumor cells may need to adhere in order to proliferate or migrate through tissues but to do so may not necessarily require alternations to their normal adhesive machinery. Humphries (100) recognized this process and found that a simple peptide sequence, RGD (arginine-glycine-aspartic acid), actually in the form of a pentapeptide GRGDS, could interfere with the adhesion process. Although this peptide proved to be only effective with frequent administrations of high doses, because it had an exceptionally short half-life and it was not pharmaceutically stable, the work on RGD analogues and derivatives is still being developed a decade later. Nevertheless, the concept itself was of interest and has resulted in the development of the type of targeted drug delivery system implied in Gregordiadis's (1) definition.

Fibronectin-Targeted Gelatin Particles. In the treatment of human superficial bladder cancer with cellular suspen-

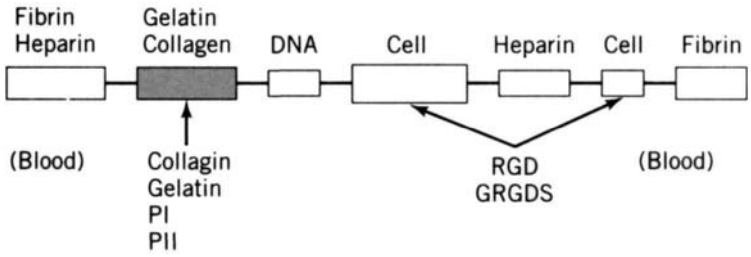

Figure 11. Schematic model of binding domains of the fibronectin molecule. *Source:* After Refs. 104–106.

sions of BCG vaccine, an attenuated living *Mycobacterium bovis*, it has become evident that the bacterial cells actually target and adhere to the tumor cells (99,100,102, 103,107). The mechanism of adhesion involves fibronection at or on the tumor cell surface and a specific fibronectin receptor on the bacterial wall thought to be cell wall proteins of the Antigen 85 homologous complex and other similar proteins of higher molecular weight. Because fibronectin has an affinity for collagen, Lou and her colleagues (99) hypothesized that gelatin would have much the same activity and measured the avidities of gelatin and gelatin microparticles for fibronectin-bearing surfaces as well as murine S180 sarcoma cells. This supposition was confirmed, and it was suggested that it might be feasible to load gelatin particles with suitable antineoplastics and substitute them for the viable microorganisms in the treatment of bladder cancer. It should be pointed out that although BCG treatment is clinically effective and the treatment of choice, most side effects associated with this treatment are due to the fact that a living organism is used and occasionally produces a form of septicemia and mild fever-like reactions as side effects. Lou later demonstrated that high molecular weight, highly water-soluble antineoplastics and thiotepa could be loaded onto gelatin microparticles and were effective in vivo (88). However, the clinical potential of this idea has not been evaluated.

Targeting of Macrophages Using Gelatin Microspheres. In a recent review by Tabata and Ikada (108) attention was drawn to the possibility of activating macrophages (Mφ) against neoplasms by incorporating biological response modifiers (BRMs). They suggested that the Mφ phagocytosed the biodegradable microspheres, in this case gelatin, digested them, and released any incorporated drug. In the case of BRMs these would be presented at the Mφ surface. These authors demonstrated that micrometer-range gelatin microparticles (mean ~1–5 μm) could be made by the water-in-oil method described for albumin. The drug, recombinant human α interferon (α-IFN), was incorporated in the initial aqueous gelatin solution so the subsequent glutaraldehyde treatment must have affected the α-IFN as well as the gelatin. Of interest was a figure in their paper showing spherical particles from approximately 200 nm to 2.0 μm diameter, suggesting a wide size distribution. The authors demonstrated the effect of glutaraldehyde on the solubility of the gelatin in the presence of collagenase. Using ^{125}I-labelled IFN demonstrated that the label was released slowly with time, although it is by no means clear if unmodified IFN was released at the same time, because it could be argued that this would be made available as the gelatin was digested by the environmental collagenase. Later, in vivo experiments involving injection into the peritoneal cavity of mice demonstrated Mφ activation by gelatin microspheres containing IFN. The authors noted that IFN-loaded gelatin particles were not always effective in preventing or suppressing tumor growth in the mouse peritoneal cavity. One must therefore ask if the IFN incorporated into the cross-linked gelatin microparticles was also affected by the glutaraldehyde treatment. No evidence was offered either way but in vitro data based on a radiolabeled release in vivo data on antineoplastic activity are not necessarily the same thing. Indeed, these authors then went on to produce a covalently bonded IFN–gelatin conjugate that was water-soluble and superior in in vivo performance to the particulate forms of the drug. It would have been interesting to determine what would have happened if the α-IFN had been loaded into preformed gelatin microparticles, thus avoiding the likely glutaraldehyde-induced structural modification of the drug.

Chitosan

The availability of chitosan, its biocompatibility, and its unique chemical and biological properties make it an attractive biomaterial for a variety of pharmaceutical applications, especially in the areas of wound dressing and drug delivery. It has been used or tested in different forms, such as tablets, matrix, and microparticles for the purpose of sustained release, controlled drug delivery, mucosal formulations and, more recently, drug absorption enhancement protein and peptide drug delivery and vaccine development (109).

Chitosan is a biocompatible and biodegradable natural biopolymer consisting of β-1→4 linked 2-amino-2-deoxy-glucopyranose (Fig. 12). It is currently manufactured commercially on the large scale by alkaline *N*-deacetylation of chitin, an abundant biopolymer isolated from the outer shells of crustaceans such as crabs and shrimps. Commercial chitosans have average molecular weights between 3.8 and 2,000 kDa and are from 66% up to 95% deacetylated (110). Chitosan has rather specific solution properties. It is only soluble at acidic pH when the free amino group ($-NH_2$) becomes protonated to form cationic amine group ($-NH_3^+$). At these pHs, chitosan has been identified as a linear polycation with an intrinsic pKa value of 6.5, independent of the degree of acetylation (111). The polycationic chitosan molecules have been found to readily adhere to negatively charged surfaces, such as skin, mucus, and proteins (112,113). Recent studies indicate that the binding of chitosan onto epithelial membranes resulted in cellular

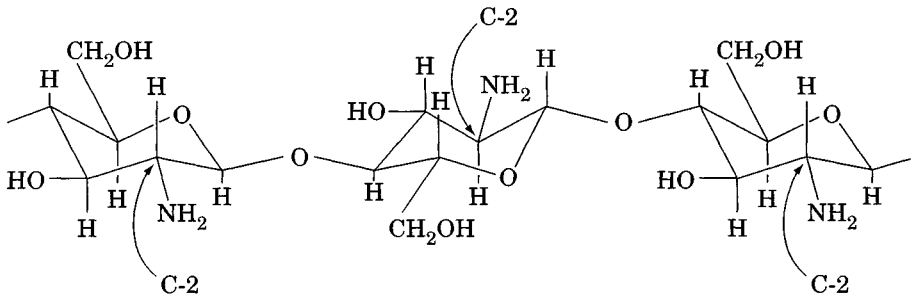

Figure 12. The repeating structural unit of chitosan.

F-actin depolymerization and disbandment of the tight junction protein ZO-1. This property is currently considered to be the major mechanism by which chitosan enhances drug adsorption (114). In vivo, chitosan is degraded by several glycosidases, primarily lysozyme and *N*-acetylglucosaminidase (115). Chitosan also has stimulatory effects on macrophages and this activity was suggested as being mainly attributable to the remaining *N*-acetylglucosamine groups (116). Activated macrophages were found to be able to accelerate the in vivo degradation of chitosan (116).

Preparation of Chitosan Micro-and Nanoparticles. High molecular weight chitosans have a low solubility at normal physiological pH, and until recently this factor may have inhibited pharmaceutical application of this otherwise attractive natural polymer. Conversion of the polymer to small particles is, however, readily achieved. Surprisingly, some authors (117,118) have described emulsification methods that, as noted earlier, require organic solvents and strong mechanical shearing forces. Apart from environmental concerns these factors are likely to be detrimental to any incorporated biological molecules and would not appear to be promising for future application. Fortunately, the solution to this problem is much simpler.

Recent studies demonstrated that chitosan nanoparticles could be formed spontaneously through ionic interaction between the positively charged amino group and negatively charged multivalent counterions, such as tripolyphosphate and sulfate groups. Novel precipitation methods based on this unique chitosan property have been developed and proved efficient in preparing chitosan nanoparticles (110,113). The attractive features of these techniques include: (*1*) the chitosan nanoparticles could be formed spontaneously through a relatively mild process, (*2*) the resultant particle size was homogenous and adjustable, and (*3*) there was no need for any organic solvents (113). Tian (119) has recently demonstrated that nanoparticles of low molecular weight chitosan are readily prepared by sonicating and stirring a solution of chitosan in aqueous acetic acid containing Tween 80 as a wetting agent while a 20% aqueous solution of sodium sulfate was added dropwise. Tian discovered that the resulting nanoparticles (diameter ~700 nm) could be stabilized for washing by cross-linking with glutaraldehyde, excess reagent being neutralized with sodium metabisulfite (Fig. 13). The lyophilized product was suitable for loading with drug by soaking the dried chitosan nanoparticles in an aqueous solution of the drug, followed by a second lyophilization process. He demonstrated the utility of the process by loading with bovine serum albumin. A adsorption/desorption process was demonstrated and information learned applied to the formulation and delivery of chitosan nanoparticles containing a bacterially derived immunostimulant, PS4. From this admittedly limited evaluation, chitosan nanoparticles appear to be an exceptionally interesting drug delivery system, with considerable potential for further application.

Sterilization of Chitosan Nanoparticles. Although effectively chitosan is a high molecular weight polymer, dilute solutions of this material can be sterilized by passing through a 200-nm filter (X.X. Tian, private communication). This would require operation of an aseptic process, with all its attendant complications and precautions. It would be unwise to attempt to heat-sterilize drug-loaded nanoparticles, especially if the drug is labile, but it is just possible that unloaded nanoparticles could be. Tian also used ethylene oxide to sterilize his nanoparticles, apparently without damage.

CONCLUSIONS

In a recent summary of the current and future status of controlled release technologies, Guy and his colleagues (120) pointed out that significant advances have been made over the past 25 years. One could not argue with this statement. However, they listed topics on current status and future possibilities without necessarily discussing the need for the technical advances needed to take the subject out of the laboratory and into the patient on a large or commercial scale. Powell (72) discussed the issues in greater depth, but the emphasis would appear to be the more immediate problem of getting vaccines (and related systems) to work on the small scale. The need to optimize sterilization procedures is, indeed, mentioned but there is no further consideration. It is true that one must run before walking. However, consideration of this essential requirement at any early stage of development may influence the design of initial experiments because, if the production process is evidently not realistic, it will be necessary to reconsider and redesign the approach being taken. Too many really innovative and impressive ideas may have died on the vine because, ultimately, production on a realistic scale as a "product" was simply impossible. Fortunately this issue is beginning to gain attention and progress is undoubtably being made. The subject is being

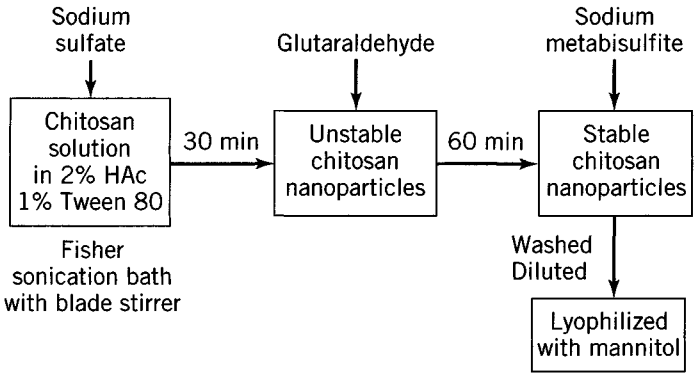

Figure 13. Preparation of chitosan nanoparticles. *Source:* From Ref. 119.

brought out into the light for deeper discussion. However, the discussion must be broad-ranged because not only is the technology of parenteral controlled release products changing and developing so also is understanding of the meaning of the word *sterility* and how it may be achieved and interpreted. The future will always be interesting!

Advancements in drug delivery technology often are achieved only through substantial investment of industrial, academic, and governmental resources. Patenting of these technological advancements is frequently employed to recoup that investment, to create profits that are used in part to develop new or improved products, and to enhance a competitive commercial edge. Other forms of intellectual property protection, such as trade secrets, copyrights, and trademarks, may also be used to further protect and exploit drug delivery processes, products, and services.

One of the most frequently asked questions is, why do we need to go to the trouble and expense of patenting a composition or method? The most common reason is that protecting a new composition or method of manufacture or use provides a means for obtaining the revenue required to develop a new drug or medical treatment. With the cost of developing and obtaining regulatory approval for a new drug approaching $200 million dollars in the United States, patent rights are essential to recovering expenses. For small companies that spend more time raising money then selling products, patents and patent applications represent the only tangible assets that they can show to potential investors. For universities and other nonprofit research institutions, patents and associated know-how and, in some limited cases, trade secrets, can be used to obtain royalties from license agreements, sponsored research funding in many cases, and equity in new companies started for the purpose of exploiting the technology.

Patents and other intellectual property are valued in many different ways. For example, a process for manufacture would typically be licensed for 2–3% of the gross selling price of a product of the process. This price would be decreased if multiple licenses had to be obtained to use the process. Patents claiming compositions tend to have a greater market value, for example, between 5 and 10% of the gross selling price, owing to the perception that these patents are easier to enforce than process patents.

Enforcement, however, is a risky business. A good patent strategy is to obtain patents that claim a product, methods of manufacture, and methods of use, broadly and specifically, so that a patentee is able to assert multiple patents against an alleged infringer. Patents with broad claims will generally be easier to invalidate than more specific patents. Faced with the prospect of fighting several patents, most parties will opt for settlement. The alternative, litigation, is extraordinarily expensive for both parties and can result in the patents being invalidated or the infringer being liable not only for damages for infringement but also attorney's fees and punitive damages.

Advancements in drug delivery technology often are achieved only through substantial investment of industrial, academic, and governmental resources. Patenting of these technological advancements is frequently employed to recoup that investment, to create profits that are used in part to develop new or improved products, and to enhance a competitive commercial edge. Other forms of intellectual property protection, such as trade secrets, copyrights, and trademarks, may also be used to further protect and exploit drug delivery processes, products, and services.

One of the most frequently asked questions is, why do we need to go to the trouble and expense of patenting a composition or method? The most common reason is that protecting a new composition or method of manufacture or use provides a means for obtaining the revenue required to develop a new drug or medical treatment. With the cost of developing and obtaining regulatory approval for a new drug approaching $200 million dollars in the United States, patent rights are essential to recovering expenses. For small companies that spend more time raising money then selling products, patents and patent applications represent the only tangible assets that they can show to potential investors. For universities and other nonprofit research institutions, patents and associated know-how and, in some limited cases, trade secrets, can be used to obtain royalties from license agreements, sponsored research funding in many cases, and equity in new companies started for the purpose of exploiting the technology.

Patents and other intellectual property are valued in many different ways. For example, a process for manufacture would typically be licensed for 2–3% of the gross selling price of a product of the process. This price would be decreased if multiple licenses had to be obtained to use the process. Patents claiming compositions tend to have a greater market value, for example, between 5 and 10% of the gross selling price, owing to the perception that these patents are easier to enforce than process patents.

Enforcement, however, is a risky business. A good patent strategy is to obtain patents that claim a product, methods of manufacture, and methods of use, broadly and specifically, so that a patentee is able to assert multiple patents against an alleged infringer. Patents with broad claims will generally be easier to invalidate than more specific patents. Faced with the prospect of fighting several patents, most parties will opt for settlement. The alternative, litigation, is extraordinarily expensive for both parties and can result in the patents being invalidated or the infringer being liable not only for damages for infringement but also attorney's fees and punitive damages.

PATENTS

Patents are used to exclude competition, not to "protect" a product. A patent is a limited monopoly granted by a government entity to an inventor in exchange for public disclosure of the invention. The limited monopoly permits the inventor to exclude others from making, using, selling, or importing into a geographical area (such as the United States) the invention, which may be a composition, method of manufacture, or method of use, defined by the claims in the patent, in exchange for teaching the public how to make and use what is claimed. The patent system is based on the public policy objective of fostering the collective advancement of technology and science through the sharing of individual achievements. The limited monopoly conferred by a patent provides the incentive for the inventor to publicly reveal his technological development.

Patentability Requirements

Patents have basically the same requirements throughout the world. In the United States, the requirements for obtaining and asserting a patent are defined by chapter 35 of the United States Code (U.S.C.). Patents are governed exclusively by federal law.

In the late 1990s, this law in the United States has been subject to a considerable number of changes. When the United States entered into the General Agreement on Trade and Tariffs (GATT) in December 1994, major changes in effective U.S. patent term resulted. Ongoing efforts to change the U.S. Patent and Trademark Office from a prominent agency to a governmental corporation, primarily to avoid further diversion of patent office fees to other government agencies, may result in even more changes to the U.S. patent law.

Further changes to the requirements for obtaining a patent, and in the enforceability of method of medical treatment claims, have resulted from reactionary changes in the laws following unpopular court decisions. Especially in the biotechnology area, the late 1990s are becoming known for the swift and drastic decisions by the U.S. Court of Appeals for the Federal Circuit, invalidating patents on the grounds that the claims are not enabled by the specifications.

Patentable Subject Matter. In general, patentable subject matter includes compositions, methods of manufacture, and methods of use (1). Compositions may include, for example, biodegradable polymeric microparticles containing a therapeutic agent or a bioadhesive compound useful for targeted drug delivery within the body. Methods of manufacture may be directed to, for example, a process for creating a unique drug delivery device. Methods of use may entail methods for administration of therapeutic compositions or surgical implantation of, for example, a synthetic tissue matrix containing implanted isolated cells that secrete insulin.

Although the law provides for patenting of compositions, methods of manufacture, and methods of use, biotechnology can present a problem under U.S. patent law when the subject matter moves away from the realm of the artificial or "things engineered by the hand of man" to a blend or chimera of "artificial" and "natural" (2). An example is when one blends cells and a matrix to form a cell matrix structure that is then implanted in a patient. Then the matrix degrades to leave only implanted cells and/or the patient's own tissue grows into an implanted matrix structure, which then degrades. At what point do these materials become the patient and cease to be patentable subject matter? Ethical issues may arise due to overlap between patient material and traditional subject matter, particularly in those cases involving dissociated isolated cells, biodegradable matrices for implantation, and polymeric materials for altering cell/cell interaction (such as adhesion or restenosis) as well as materials for implantation that are designed to remain in the body, such as stainless steel hip replacements or cryopreserved pig valves.

Outside of the United States, methods of treatment of humans or other animals is generally not patentable subject matter. For example, although surgical instruments, drugs, or devices used in surgery are patentable, surgical treatments are not patentable subject matter. Therefore, one cannot obtain a patent on a method for surgically treating a patient. Typically, while this subject matter is not patentable, the compositions and methods of manufacture for use in treating patients are patentable subject matter. Claims may be obtained to the composition per se that is to be implanted. In Europe, claims can be obtained to a first, or even a second, use of the material when the material itself is known. However, the patentability is quite limited in individual countries and in the European Patent Office for policy and ethical reasons. Generally, patent offices in Asian countries are far less flexible than the European Patent Office in this matter. As a result, patent attorneys have adopted a number of strategic approaches to obtain protection equivalent to that which is available in the United States. For example, one may draft claims directed to methods of manufacture of such materials as well as to methods of use that are defined by the composition rather than the method of use steps.

Novelty. The second requirement for patentability is novelty (3). Novelty, in its simplest terms, means that no one, including the applicant for the patent, has publicly used or described that which is being claimed prior to filing an application for patent. In the United States, there is an exception when the publication is made less than 1 year prior to filing of the patent application. The publication can be "removed" as prior art if the applicants are able to demonstrate that prior to the publication, they conceived and diligently reduced to practice what they are claiming.

What constitutes a publication? Generally, a publication is any oral, written, or physical description that conveys to the public that which applicant would like to claim. It may be a talk at the proceedings of a society (including any slides presented), an article in a scientific journal, a grant application that is awarded, a thesis, or even an offer for sale or a press release. A critical requirement is that the publication must be enabling, that is, it must convey to one of ordinary skill in the art how to make and use that which is being claimed. Public use means more than using the composition or method in one's laboratory. However, it

can include even a one-patient study that is reported during clinical rounds or at a presentation at which a drug company or surgical supply representative is present. The courts, in many cases, have had to interpret what it means to be publicly available. A frequent question is when is a student's thesis available as prior art. Courts have now held that once the thesis is cataloged, it is publicly available, because it has been entered into a computer database that one searching the database will be able to access (4). Accordingly, the publication date of a thesis is the date on which the thesis is cataloged, not the date on which it is defended or signed by the thesis committee. Slides that are not distributed but that are shown at an oral presentation are considered to be publications, particularly if the meeting is attended by those skilled in the art who would be able to understand and use the information in the slides.

Disclosures to another party under the terms of a confidentiality agreement are not publications. Uses that are strictly experimental may not be public disclosures, if, among other aspects, they are designed to determine if that which is to be claimed will work and if any other parties who are involved are clearly informed that the studies are experimental in nature. If something is an announcement that does not enable one of ordinary skill in the art to use or make that which is claimed, then the disclosure is not a publication. For example, an announcement could be a statement made to the press that researchers X and Y have discovered a cure for cancer. Because the announcement does not tell one of ordinary skill in the art how to cure cancer, it is not enabling. However, enablement can be difficult to prove, and standards may change over time. A recent court case in which the question of whether a publication was enabling related to the development of a transdermal patch for delivery of nicotine (5). The court found that a prior publication referring to transdermal patches for drug delivery mentioned that the drug in the transdermal patch for treatment of heart disease could be replaced with nicotine for assisting patients in quitting smoking. The court held that the article disclosed or made obvious the transdermal patch for delivery of nicotine claimed by the applicant because the applicant merely took the transdermal patch described in the article, put nicotine in it, and demonstrated that the nicotine was delivered and would work exactly as predicted based on delivery of the drug for treatment of heart disease. Even though there was no information relating to the exact dosage or schedule or how the drug was to be incorporated into the transdermal patch, the publication was enabling because those of ordinary skill in the art would have been able to determine the dosage and how to put the nicotine in the transdermal patch without undue experimentation.

Nonobviousness or Inventive Step. The third requirement for patentability is that the claimed method or composition must be nonobvious to those of ordinary skill in the art from what is publicly known (6). This is usefully referred to outside of the United States as a requirement for an inventive step. In the 1960s, the U.S. Supreme Court carefully analyzed nonobviousness and those factors that are to be considered in determining whether that which is claimed is obvious from the prior art (7). This analysis is a fact-based determination, involving not only the elements that are claimed but also the level of skill in the art and the expectation or predictability that the claimed method or composition would perform as predicted, actual success in the marketplace, long-felt need, and whether there are unexpected results. If one has no better than a 50–50 chance that a particular method may work and the method works, it is arguably not obvious, although it may be obvious to try. If one tries something and the results are vastly different from what was expected, then the results are not obvious. For example, if one administered two drugs each in the dosage known to yield a particular effect and the combination results in a substantially greater effect than the sum of the individual effects of the two drugs, resulting in the ability to use a much lower dosage of each drug than expected, then one would have unexpected results, or synergy. If the prior art teaches away from what the applicant has done, this result would support a finding of nonobviousness. For example, if the prior art states that one cannot administer drugs transdermally using ultrasound except at a very high frequency, then it may be nonobvious if the applicant for a patent finds that the same or better results are obtained using a very low frequency. Many other considerations factor into whether a claimed composition or method is obvious in view of the prior art.

Enablement and Best Mode. The fourth requirement for patentability is enablement and, in the United States only, disclosure of the best mode for practicing the invention (8). A written description is also required, but enablement and the written description requirement usually are considered together. To obtain a patent, the applicant must describe that which is claimed in sufficient detail and with appropriate methods and sources of reagents or other materials or equipment to enable one of ordinary skill in the art to make and use that which is claimed. This sounds far simpler than it actually is in practice. In many cases, particularly when coming out of a university study or a start-up company, the invention that applicants would like to claim is that which the applicant intends to develop over the next several years, based on a limited amount of data available at the time of filing. Particularly in the case of universities, where the applicant must publish or has submitted grant applications (which in and of themselves constitute prior art once they are awarded), the difficulty is in describing that which has not yet been done. The application must not only describe a specific limited example but must also describe the various ways in which one intends to practice that which is claimed.

The purpose of a patent is to exclude the competition from making and using that which is claimed, not to "protect" a product—a frequent misconception of patents. To exclude competition, one must describe and claim not only that which one intends to practice but also that which another party could practice in competition with the patentee. What does this mean in real terms? It means that the applicant for a patent must describe her preferred method, which is known as of the date of filing, the preferred embodiments that she or her company intends to market, and any embodiments that a competitor could make and use in competition with the applicant's product.

Invention usually consists of two steps: conception and reduction to practice. There are two kinds of reduction to practice: actual and constructive. Constructive practice means that the applicant has described in the application for patent *how* to make and use that which is claimed but has not actually made and used what is claimed. This may be as simple as stating that although a biodegradable polymer such as poly(lactic acid-*co*-glycolic acid) is preferred for making a matrix for drug delivery, other biodegradable polymers such as poly(orthoesters)s or poly(anhydride)s could also be used. It may be less obvious that other drugs may be used when only one example showing reduction to practice of a type of drug is available. The rule of thumb in this case is the level of predictability. Therefore, in stating what kind of drugs one could deliver using the claimed technology, one might list a wide variety of drugs based on the data available with one type of drug. However, delivery of a peptide or a very hydrophobic compound, which usually are viewed as difficult to deliver, may or may not be possible to list based on data obtained with a drug that is relatively easy to delivery, such as a sugar or low-molecular-weight dye. Being too predictive (i.e., engaging in extensive constructive reduction to practice), which includes "nonenabling" or non-enabled technology, may in some cases be a detriment during prosecution of subsequently filed applications because the examiner may cite the earlier work as making obvious the applicant's subsequent work. Patent attorneys frequently must play a balancing game in determining how far to go with constructive reduction to practice to exclude competitors while not eliminating the applicant's own ability to obtain additional, subsequent patent protection.

In the United States, there is a requirement to disclose the best mode for practicing that which is claimed at the time of filing the application. No similar requirement exists outside of the United States. Because most applicants file the same application in the United States as outside of the United States, U.S. applicants frequently disclose their best mode in foreign-filed applications. Furthermore, U.S. applications are not published until they are issued as a patent, whereas applications filed in other countries are published 18 months after their earliest priority date. Thus, it may be desirable in some cases to omit the preferred embodiment as of the date of the foreign filing to prevent one's competitors from knowing the best mode for practicing the invention until the U.S. patent is issued, which may be many years after publication of the corresponding foreign application. However, this strategy may create a problem, as patent laws vary from country to country. In particular, Japan has, in the past, required one to provide examples of that which one intends to claim, thus limiting available protection.

Patent Term and Provisional Applications

A patent is awarded by individual government entities for a defined period of time. In most cases that period of time will run 20 years from the initial date of filing an application for patent. In some cases, the term can be shortened, for example, by disclaimers of patent term in view of earlier issued patents, or lengthened, owing to delays relating to appeals or regulatory approval. Provisional applications are useful for delaying the filing of a utility patent application while simultaneously serving to establish priority over subject matter disclosed within the provisional application.

Patent Term. Under the revised U.S. patent law that was enacted as a result of implementation of GATT, the term of a patent is 20 years from the original date of filing or the filing date of the earlier application to which priority is claimed. Applicants therefore have more incentive to prosecute all claims in a single application to minimize costs for prosecuting and maintaining the patent. Under the law in effect prior to June 8, 1995, the patent term was 17 years from the date of issue in the United States. Divisional applications were a commonly used method to extent patent protection to encompass different aspects of the technology over a period of time much greater than 17 years. For example, an application would be filed in 1990, and a single inventive concept (e.g., the composition) would be prosecuted in the first application. Three years later, when those claims were allowable and a patent was to issue, a divisional application would be filed with another set of the claims that had been restricted out of the original application. This divisional application would be prosecuted for another 2 to 3 years, the claims would be determined to be allowable, the second patent would issue with a 17-year term, and a third divisional application would be filed. The result is that patents on related technology would issue sequentially over several years, increasing the effective term of patent protection beyond 20 years. Under the new law, this mechanism to extend patent protection is not possible.

GATT was signed into law in the United States on December 7, 1994, and the initial provisions affecting U.S. patent practice were implemented June 8, 1995. The most significant changes arising from enactment of that agreement, now called the Uruguay Round Act, were changes in the patent term in the United States, the implementation of provisional patent applications, and the broadening of what constitutes infringement in the United States. The change in patent term has already been discussed. For those applications filed before June 8, 1995, the term of any issuing patent is 17 years from the date of issue or 20 years from the filing date, whichever is longer. The term of any patent issued on an application filed June 8, 1995 or later is 20 years from the earliest claimed priority date. Extensions of terms are available upon delays in issuance arising from appeals or interferences. Additional extensions of terms are available for delays in obtaining regulatory approval by the U.S. Food & Drug Administration (FDA) for a device or a drug. Legislation is currently pending that would further revise patent terms in the United States.

Because biotechnology is a complex field, especially in the areas of patentable subject matter and enablement, many of the general observations relating to patents may not be as directly applicable to more conventional patentable subject matter. For example, the U.S. Patent Office has consistently maintained that the change from a 17-year term from the date of issue to a 20-year term from

the earliest priority date will not result in a significant loss of patent right. However, because the Patent Office applies such a stringent examination proceeding under §112 (enablement) in the biotechnology area, its assertion is likely untrue. Issue time in these cases typically has been considerably longer, not uncommonly taking as many as 5 to 7 years from the original priority date. The result is that these complex biotechnology patents will have a substantially shortened term as compared with many other types of patents. Because a patent extension can still be obtained for delays due to regulatory issues involving the FDA, as well as for appeals to the Board of Patent Appeals and Interferences, those in the United States who believe that their patent rights will be limited in term due to delays in prosecution should avail themselves of the Patent Extension Act if at all possible. One must bear in mind, however, that an extension for regulatory delays can only be obtained on *one* patent for any particular product or process; thus, the inventor or licensee with multiple, related patents clearly should choose the most important patent or the patent subject to the greatest increase in patent term when facing such a situation. The patent that is to be extended must be brought to the attention of the FDA. Following FDA approval of the claimed product or process, the extension must be applied for in a timely fashion.

Provisional Patent Applications. Provisional patent applications, while new to the United States, have been utilized for many years in other countries, such as the United Kingdom and Australia. These applications are a mechanism for obtaining a filing date at minimal cost and with fewer requirements for completeness of the application and determination of the inventive entity for a period of 1 year. The provisional application ceases to exist 12 months after the date of filing. If an application is filed as a provisional application, it can be converted to a standard utility application at any time during the 12-month period after filing. Alternatively, it can serve as a basis for a claim to priority in a subsequently filed utility application if the utility application is filed prior to the expiration of the 1-year life of the provisional application.

Although touted as a great benefit to the small entity or individual applicant, provisional applications have the same requirements for disclosure as a standard utility application. Failure in the provisional application to completely disclose and enable that which is subsequently claimed in an utility application can result in a loss of the claim to priority to the provisional application if that which is claimed is not enabled. Merely filing an article that will be published or presented to avoid loss of foreign rights usually will not comply with the enablement requirements and therefore will not serve as an adequate basis for priority. It is essential that applicants who file provisional applications based on an article amplify the description to encompass other embodiments and to provide the basis by which one of ordinary skill in the art can practice that which is claimed. Application sections that are not required for enablement but that are typically included in a utility application include the background of the invention, the problems that the claimed invention addresses, and the claims. These sections can be omitted from the provisional application, thus saving time and money in preparing the application. In many cases, fairly standard language can be used to expand or broaden the description in an article to meet the enablement requirements, providing a means for those with limited amounts of time or money to protect that which they are disclosing with minimum risk and expenditure.

The World Intellectual Property Organization (WIPO), which implements the provisions of the Patent Cooperative Treaty (PCT) and the European Patent Office, has confirmed that U.S. provisional applications serve as an adequate basis for a claim to priority in corresponding foreign file applications. However, under the Patent Convention, all foreign applications that claim priority from a previously filed application must still be filed within 1 year of the U.S. filing date or the filing date of the country in which the first application is originally filed.

Patent Procedure and its Implications to Inventors

An elaborate, detailed body of law and regulations has evolved to govern the granting of patents. These laws and regulations define, among other things, (*1*) the procedural steps that the Patent Office and applicant may undergo, (*2*) which individuals actually are the inventors of a particular claimed invention, and (*3*) the number of inventions or embodiments of an invention that properly can be claimed in a single patent. These laws and regulations also suggest certain beneficial habits, such as record keeping, that research scientists and other would-be inventors should undertake to facilitate issuance and enforcement of their patents.

Application Procedure. When a patent application is filed in the United States, it will be assigned to an examiner for review of the relevant prior art and for prosecution. The examiner may restrict the claims into more than one group, if, in his view, the claims are directed to patentably distinct inventions (see "Restriction Practice/Unity of Invention"). The nonelected claims can then be filed in divisional applications, which have the same effective filing date but issue as separate patents. The examiner likely will issue one or more office actions, objecting to the specification or rejecting the claims as lacking novelty, being obvious, not enabling the breadth of the claims, being indefinite, or a combination thereof. The applicant can amend the claims and present arguments and supporting data to overcome the rejections. The specification, or description, cannot be amended to add new matter once the application is filed. In many cases, an agreement will be reached as to what claims are allowable, and a patent will issue. In the event that the examiner finally rejects the claim and the applicant has exhausted her opportunities to respond to the rejections, an appeal to the Board of Patent Appeals and Interferences can be filed. A decision by the Board, which can be based not only on argument and data submitted during the prosecution of the application but also an oral hearing, typically will require 3 to 6 years. The applicant's only recourse following a negative decision by the Board is to file an appeal in the U.S. Court of Appeals for the Federal Circuit.

In the United States, patent applications are typically examined by a single examiner. In the European Patent Office, examination may be conducted by an examiner other than the one who conducted the initial search and issuance of a search report. If the applicant in the European Patent Office requests oral proceedings, at which oral arguments may be presented, the oral proceedings are held before a panel of three examiners, not just the original examiner. In contrast, the U.S. proceedings are between the applicant and the examiner, although the examiner's supervisor or a quality control specialist may be asked to attend if an in-person interview is held. In all cases, there are appeal procedures if an examiner maintains his rejection of the claims, asserting that the claims lack novelty, are obvious, or are insufficiently enabled.

Inventorship. The U.S. Constitution provides that inventors have the exclusive right to their discoveries (9). An application for patent must be made by the inventor, or under certain circumstances (such as when the inventor is dead) by persons on behalf of the inventor (10). When more than one person made the invention, the inventors are required to file jointly "even though they did not physically work together or at the same time, each did not make the same type or amount of contribution, or each did not make a contribution to the subject matter of every claim of the patent" (11). A patent may be invalidated if it names one who is not an inventor or if it fails to name an inventor, however, these errors may be corrected if they were not committed with an intention to deceive (12).

In a nutshell, an inventor is one who conceives and/or reduces to practice the claimed invention on his own and not at the direction of another. University settings are somewhat unique when it comes to determining what is prior art and what is the invention of another because it is often difficult to determine who is the inventor. When one attempts to remove prior art by demonstrating that one has conceived and reduced practice prior to the publication, one must first determine who the inventors are and whether the publication is in fact a publication by another entity. If the publication is the inventors' own, then it is easier to swear behind because they must have conceived and reduced to practice prior to that publication. Merely because a publication is coauthored by one of the inventors does not mean that the publication is the inventors' own work. There must be complete identity between the named authors and the inventors for the publication to be the inventors' own work. Publications typically will include coauthors who do not meet the legal definition of an inventor.

To determine who the inventors are, one must first ascertain that which is claimed. Second, one must determine what is already in the prior art; one is not an inventor if the claimed matter is already in the prior art. For example, if one is claiming a polymeric drug delivery device and the claim defines the matrix structure as formed from biodegradable polymer, then this particular element is probably already in the prior art, and that element alone would not be the invention of any named inventor upon the application for patent. However, if the polymeric matrix were defined as having a particular structure or shape or composition that has not previously been defined, then the individual (or individuals) who determines that shape or structure or composition would be an inventor. In methods for manufacture, the person who is in the laboratory using the method may or may not be an inventor. If this person has been told by another to go and make composition X using steps A, B, and C, then the person who performs the method is not an inventor—even if there is some optimization of the concentration or selection of reagents or conditions under which they are combined. If, however, that person determines that it is essential to use a concentration 10 times greater than what she has been told to make it work, then she may be an inventor of the method of use. A patent may name multiple parties as inventors. They do not all have to be inventors of each and every claim that defines the invention. One person may be an inventor of composition claims, another the method of manufacture claims, and yet another the method of use claims. Inventorship may need to be corrected following a restriction requirement or after cancellation or amendment of the claims.

The definition of *inventor* elicits questions about the definitions of *conception* and *reduction to practice*. In a university research laboratory, has a graduate student participated in the conception of his professor's invention if he conducted the experiments under her direction that resulted in the reduction to practice, that is, the synthesis of the claimed protein? Did the professor conceive the invention if she thought of the general idea and desired result but left it to the graduate student to figure out how to synthesize the protein? Is the professor's conception of a protein and the detailed steps of producing it an invention if she has not yet actually reduced her idea to practice by synthesizing the protein? And in a different laboratory, is a technician an inventor if he added bearings to the design that the supervising engineer told him to build? In each case, who, if anyone, is an inventor?

Conception is "the formation in the mind of the inventor of a definite and permanent idea of the complete and operative invention as it is thereafter to be applied in practice," such that a person of ordinary skill in the art would be enabled to convert the idea to tangible form without extensive research or experimentation (13). Usually, one who conceives the inventive idea, or part of it, is an inventor, while those who perform the ordinary interim experimentation under the direction of the inventor in reducing the inventive concept to practice are not defined as inventors. Conception followed by reduction to practice is a common sequence during invention, but invention may result from other sequences of events. For example, conception and reduction to practice may occur together, or unexpected discovery coupled with recognition of the discovery as something new and useful may occur without previous conception. For invention to be complete, the inventor's conception must include a clear idea of how the new product, process, or machine can be reduced to practice, or put into a tangible form. Reduction to practice may be done by persons other than the inventor if they work under his or her direction. In both university and commercial laboratories, an invention may occur through discovery without any previous conception. This type of invention is not formulated by conception of the inventive idea followed by

reduction to practice, as described earlier. Rather, the invention occurs through discovery coupled with recognition that the product, process, machine, or combination is new and useful. Experimentation involved in reduction to practice may also be part of conception.

Although coauthors may choose not to be named on a paper, the law requires that every person who contributes any part of what is claimed in a patent application must be named. If, in the course of prosecution of the patent application, all claims that reflect the contribution of one inventor are cancelled or rejected, that inventor's name must also be removed. There is an implicit lack of equality in coauthorship. Generally, the first or last listed author is considered to be the primary originator of the new ideas and data in the paper, and the others are assumed to be secondary collaborators. Joint inventors, however, are equal in the rights of patent that accrue to them, having a joint and undivided interest, unless they agree otherwise (14). Even though they did not conceive exactly the same idea together or each created a different part of the whole invention or the contribution of one was only a small but essential part of the invention, all are joint inventors and share an equal right to exclude others from making, using, or selling the claimed invention. In practice, university policy usually dictates that joint inventors assign ownership of the patent to the university, while the royalties that may accrue if the patent is licensed and the invention is marketed are allocated between the university and the inventors. The inventors' share of the royalties is distributed equally among them, unless they have contracted otherwise.

Ownership of the technology claimed in a patent is contractual. Unlike inventorship, ownership can be transferred by one or all of the inventors to one or more other entities merely by executing an agreement. Rights to use the technology can be granted by licensing of the patent to an entity by the owner of the technology. Once ownership is transferred from the inventors, they no longer have the right to allow a third party to make, use, sell, offer to sell, or impart that which is claimed. In fact, if a patent is exclusively licensed, or assigned, to another party, then the inventor and/or the assignee transferring the rights away will no longer be able to use the technology. In many cases, it may be important to retain the right to use the technology for noncommercial purposes (i.e., further research and development).

Provisional applications differ from standard utility applications in that there is no requirement to name all, or even the correct, inventors; neither do the inventors have to file a disclaimer of inventorship stating they believe they are the correct inventors of the claimed technology. This is in keeping with the absence of a requirement for having claims defining what applicants think constitutes their invention.

Outside of the United States, patent applications frequently are filed by the assignee rather than by the inventors. Inventorship is not usually a basis for challenging a foreign patent, and declarations of inventorship are not always required. A patent applicant may not even need an assignment to file and prosecute the foreign patent application.

Restriction Practice/Unity of Invention. A patent must have claims directed solely to a single invention (15). Guidelines for determining what constitutes a single invention in the United States are published in the *Manual of Patent Examining Procedures* (MPEP). For example, if the applicant has claims to a composition, a method of making that composition, and the method for using the composition, an examiner in the U.S. Patent Office may determine that multiple inventions are defined by the claims in the application as filed, and the examiner will require cancellation of the claims to all but the method of manufacture or use or composition from the application. The applicant would then be allowed to prosecute the elected claims in that application and file what are referred to as divisional applications with the nonelected claims, which may ultimately issue as a second or third patent. The effective priority date would still be the original filing date.

The standards for "unity of invention" are highly variable even within the United States, and U.S. standards are at wide variance with the standards of most foreign patent offices. One advantage of prosecuting PCT applications (discussed later) in the European Patent Office is the lower cost owing to far fewer restrictions being made.

Duty of Disclosure. Another unique requirement of the U.S. patent law is the duty of disclosure, described by Chapter 37 of the Code of Federal Regulations (C.F.R.), § 1.56. Applicants are required to submit to the examiner in the U.S. Patent Office copies of all publications or other materials that may be determined by an examiner to be material to examination of the claimed subject matter (16). Foreign publications must be accompanied by an English translation if they are not in English, although in some cases this may be limited to an abstract. Failure to cite relevant prior art to the Patent Office can result in a subsequent finding by an appropriate court of jurisdiction that the patent is invalid for fraud and violation of the duty of disclosure. Under the current standard, the applicant is not required to describe the relevance of the cited publication but may merely cite the publication and provide a copy to the examiner for the examiner's review. When many publications are being cited to the Patent Office, it may facilitate review to group the publications or even distinguish those that the applicant believes are most relevant. As discussed earlier, prior art includes oral or written publications made prior to applicant's filing date by applicant or any other entity. Relevance of material is more difficult to define. This requirement is in the process of again being revised and may soon change.

Record Keeping. It is extremely important in the intellectual property area that proper records be maintained. Laboratory notebooks should be completed and maintained in chronological order. Notebook pages should be consecutively numbered, entries should be recorded in ink, and each page should be signed and dated by the party making the entry. Furthermore, it is preferred that each page be witnessed at a time contemporaneous to the date the entries are made by one who is qualified to understand what is being entered on the page. The party does not have

to completely understand every aspect of the entry; he or she merely must be qualified to say, with some degree of certainty, what the entries on that page were.

Laboratory notebooks are used to show the origin of an invention. This may be important if there is a dispute as to ownership, if there is a dispute as to inventorship, or to prove priority of inventorship where, in the United States, patent rights are awarded to the first party to invent as opposed to the first party to file a patent application. Proceedings conducted by the U.S. Patent Office to determine priority of inventorship are referred to as *interferences*. The laws and regulations governing interferences were changed following enactment of GATT to allow parties other than those residing and inventing in the United States to obtain a patent in a dispute with another party also claiming the same subject matter by demonstrating that they were the first to conceive and reduce to practice. Interference law is very complicated. In the biotechnology area, the dates of inventorship are frequently within weeks of each other. Moreover, the courts have increasingly altered the law regarding what is conception and reduction to practice as applied to the biotechnology field (17). As a result, it has become much more difficult to predict what acts ultimately will be critical in showing priority of inventorship. Accordingly, accurate record keeping by all members of a research group is extremely important.

Infringement

In addition to changes in patent term and creation of provisional patent applications, passage of GATT changed the definition of infringement in the United States. One who, without authority, makes, uses, offers to sell, or sells any patented invention within the United States or imports into the United States any patented invention during the term of the patent therefor infringes the patent (18). In the United States, a claim for infringement cannot be made until after issuance of the patent. In some other countries, including the European Patent Convention countries, translated claims can be filed prior to issuance of the patent, and damages can be backdated to the date of filing the translated claim once the patent issues. In the United States, a patent application is secret until it is issued as a patent, at which point it is published and can be asserted against parties whom the patent owner or exclusive licensee of the patent believes are infringing the claims, that is, against those they believe are making, using, selling, or importing subject matter falling within the scope of the issued patent's claims.

A party who believes that an issued U.S. patent is not valid may file a request for reexamination, citing art that was not made of record during the prosecution of the patent. If the patent is asserted against the party, that party may go into federal district court and ask for a declaratory judgment that the patent claims are invalid or that they are not infringed. In Europe, and in many other countries, there is a postgrant opposition proceeding available. In the European Patent Office, there is also a process whereby one may file observations during the prosecution of an application, which is public, unlike in the United States. Third-party observations can be used as a means to bring relevant prior art, mischaracterized prior art, or problems relating to enablement to the attention of the European patent examiner and may result in revocation of the patent or narrowing of the claims.

TRADE SECRETS, COPYRIGHTS, AND TRADEMARKS

Other types of intellectual property that may have applicability to drug delivery technology include trade secrets and, to a lesser degree, copyrights and trademarks. Trade secret protection of an invention may be an appropriate alternative to patent protection for an invention or discovery in certain competitive circumstances. Copyrights and trademarks, which do not protect ideas or inventions, may have value in protecting other facets of a business related to the drug delivery technology. These three types of intellectual property are only briefly described in the following sections.

Trade Secrets

Trade secrets can be compositions or methods of manufacture or even uses that are maintained in secrecy. Most companies that have optimized methods for manufacture (e.g., methods for processing polymers to impart the most desirable physical and chemical properties) keep them secret. Trade secrets are unlimited in term but must be actively protected; they are lost if another party independently derives the same method or composition that is being maintained as a trade secret. Unlike patents, trade secrets are defined by and enforced pursuant to state laws. Trade secrets may be protected by asserting laws relating specifically to trade secrets as well as unfair competition and business practices.

To maintain the process or product as a secret, one must (*1*) not disclose the process or product in public and (*2*) take affirmative steps to protect the information from public disclosure. This duty includes informing parties who may accidentally become aware of the technology, as well as those who are intentionally informed regarding the technology, that the material is a trade secret and is to be maintained in confidence. Laboratory notebooks describing processes or products that are considered proprietary should be maintained in designated areas labeled "confidential" or "restricted access." Employees involved in the use of the trade secrets should be informed that the material is to be maintained as confidential and that breach of any agreement with the company by disclosing the trade secrets to a third party could result in irreparable harm and therefore be subject to injunctive relief. Trade secrets cease to be trade secrets upon public disclosure, as already discussed, or when they are independently developed by another party. If a third party independently develops the trade secret, the original holder of the trade secret has no recourse unless she can prove that the secret was acquired by theft, fraud, or other improper means. Unlike patents, which have a defined term during which the patentee can exclude others from competition, trade secrets are subject to no similar limitation. One of the most famous trade secrets is the formula for the original Coca-Cola®, which has been kept in secret for decades and is enormously valuable,

demonstrating that it is not just patents that have value as an asset to a company.

Copyrights

Copyright protects original works of authorship fixed in any tangible medium of expression (19). Unlike patent and trade secret law, however, copyrights do not protect an idea but only the expression of that idea. Copyright protection may extend, for example, to visual depictions of products or to advertising material associated with the use and sale of products. Also, copyright may protect computer software programs, publications, protocols, or other materials. In many cases where the author is employed or engaged as a consultant, the copyrights will be owned by the party contracting with the author, the journal publishing the work, or the employer. Copyrights, which also can be extremely valuable, are transferable and enforceable under U.S. law and in many foreign jurisdictions as a result of international agreements relating to copyrights.

Trademarks

Trademarks are typically associated with the sale of goods or services and are used to denote the origin of the goods or services. Advantages of trademarks are that they are not limited in term, and rights arise upon use in either intra- or interstate commerce. One very well-known trademark is Coca-Cola®, which has been in continuous use since before the turn of the century. The company has used the trademark in combination with retaining the formula as a trade secret to create enormous value for itself. A company name, as well as a product name, can be a trademark. A trademark can be a name design or combination thereof. The trademark cannot be generic or totally descriptive of the product, and it must be distinct enough from other trademarks in a similar field of use or similar good or service to avoid any likelihood of confusion as to the origin of the good or service among the consumers of the trademark good or service. Trademarks can be protected under either state or federal law. An applicant for a trademark registration must show that the trademark has been used in *intra*state commerce for a state registration and *inter*state commerce for a federal registration. A federal "intent to use" application can be used to preserve the right to use a trademark prior to actual use in commerce. This provides for an initial determination of the registerability of the trademark, in other words, that the mark is not already in use by another in a way that would be confusingly similar to the applicant's use and that the mark is not generic or descriptive and not contrary to the public interest.

EXPLOITING INTELLECTUAL PROPERTY RIGHTS

As is now evident, intellectual property rights help increase the value of technology. This is easiest to place in perspective and understand in relation to patents. Patents give the patent owner the right to exclude competition. This is accomplished by asserting the patent against third parties who are marketing a product or service that falls within the scope of the claims. Referred to as *infringement*, the criteria are totally different from the criteria for obtaining a patent, referred to as *patentability*. In simple terms, a patent claim consists of elements in a defined relationship. Certain phrases expand or limit the scope of the claim. For example, the term *comprising* can be translated as "including at least," whereas *consisting* means "including only." If a claim reads as follows: "Composition comprising: A, B, and C," then the claim would cover any composition including A, B, C, and any other component. Use of the term *consisting* would restrict the claim to a composition including *only* A, B, and C.

In determining infringement, one must look to the claims of the patent. Claims may be clear on their face or require reference to the specification, or description, of the patent. Claims may also be limited by agreements made during prosecution, a doctrine referred to as "file wrapper estoppel." For example, if the prosecuting attorney argues that the claims distinguish over the prior art on the basis that the prior art does not disclose a particular feature that the attorney argues is essential to the claims in the patent, then the claims will be construed to require that limitation, even if not explicitly recited in the claims as issued.

Asserting a patent allows the alleged infringer to file an action for declaratory judgment in a federal district court, asking the judge to declare the patent invalid or noninfringed. Litigation is very expensive and especially detrimental to small companies, thus providing a great deal of incentive to license the technology on terms favorable to both parties.

SUMMARY

Intellectual property rights provide a means for the owners of technology to recover their investment in the technology and, in some cases, to make a profit. More importantly, intellectual property rights provide a means for financing the incredibly expensive research and development and testing required for commercialization of new products and processes in the medical and biotechnology field. When the intellectual property rights have been lost or given away by publication, many times it is not possible to obtain the money required to see a product or process reach the clinic and benefit those for whom it is intended. It is only by protecting the technology that it can be used to help those who need it the most.

INTRODUCTION

The term *polymer therapeutics* has been coined to encompass polymeric drugs (in which the polymer backbone itself displays biological activity), polymer–drug conjugates, polymer–protein conjugates, and polymeric micelles that include a covalent polymer–drug linker (1) (Fig. 1). These compounds are considered as "new chemical entities" by regulatory authorities, and this is the basis for using the term polymer therapeutics to describe this family of polymeric drugs, prodrugs, and drug delivery systems. Being synthetic, hybrid macromolecular systems polymer therapeutics constitute an innovative opportunity to design novel pharmaceuticals that have real potential to improve efficacy in life-threatening diseases such as cancer. Additionally, they may provide the multicomponent technologies needed to assist delivery of other macromolecular drugs such as peptide, protein, and gene therapeutics. The last decade has seen the emergence of the first polymer therapeutics into routine clinical use as anticancer agents, and many more are now in the clinical development pipeline. Development of the first compounds as anticancer agents is understandable because cancer (in its many forms) has last year for the first time become the major cause of mortality in the United Kingdom (2). It is predicted that "cancers" will also become the leading cause of mortality in the United States within 5 years. Statistically in the United States and Europe 1 in 3 people will have

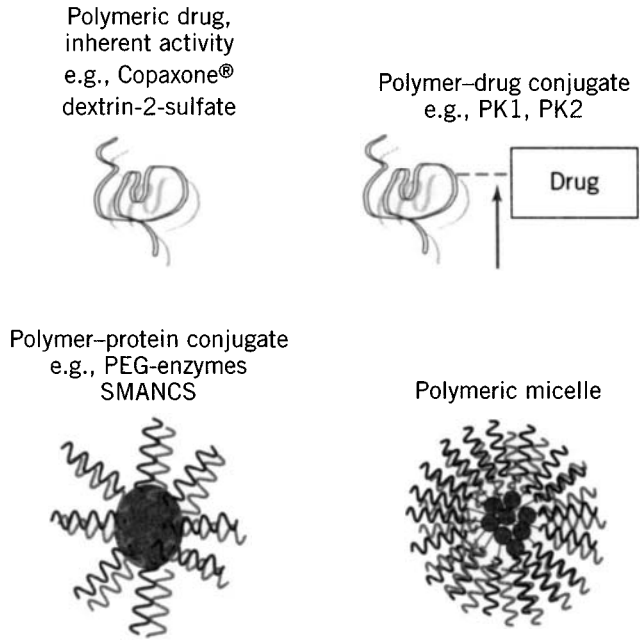

Figure 1. Polymer therapeutics.

INTRODUCTION

The term *polymer therapeutics* has been coined to encompass polymeric drugs (in which the polymer backbone itself displays biological activity), polymer–drug conjugates, polymer–protein conjugates, and polymeric micelles that include a covalent polymer–drug linker (1) (Fig. 1). These compounds are considered as "new chemical entities" by regulatory authorities, and this is the basis for using the term polymer therapeutics to describe this family of polymeric drugs, prodrugs, and drug delivery systems. Being synthetic, hybrid macromolecular systems polymer therapeutics constitute an innovative opportunity to design novel pharmaceuticals that have real potential to improve efficacy in life-threatening diseases such as cancer. Additionally, they may provide the multicomponent technologies needed to assist delivery of other macromolecular drugs such as peptide, protein, and gene therapeutics. The last decade has seen the emergence of the first polymer therapeutics into routine clinical use as anticancer agents, and many more are now in the clinical development pipeline. Development of the first compounds as anticancer agents is understandable because cancer (in its many forms) has last year for the first time become the major cause of mortality in the United Kingdom (2). It is predicted that "cancers" will also become the leading cause of mortality in the United States within 5 years. Statistically in the United States and Europe 1 in 3 people will have

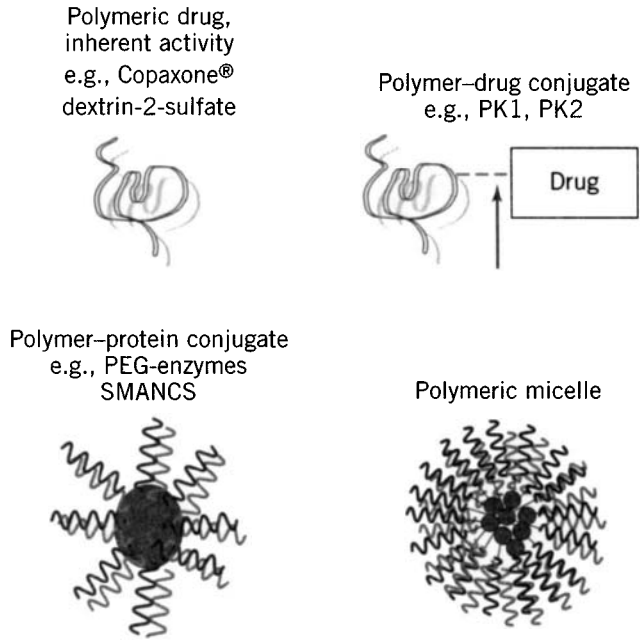

Figure 1. Polymer therapeutics.

some form of cancer at some stage in their lifetime and 1 in 4 will die from these diseases. Therefore the need for improved therapies is evident.

Covalent conjugation of a therapeutic agent to a polymer can improve its therapeutic index if biodistribution is beneficially altered compared with that of the unconjugated pharmacophore. Conjugation provides the opportunity for cell- or organ-specific targeting. By judicious selection of the polymer–drug linker it is possible to control both the site and rate of drug liberation in vivo. Historically polymer–drug conjugation has been achieved by either linking the drug using pendent chains along the polymer backbone (this allows several drug molecules to be conjugated per polymer chain) or by conjugation to one or both endgroups of the polymer chain (Fig. 2). The latter method has been preferred for binding monomethoxy poly(ethylene glycol) to proteins, where several polymer chains are conjugated per protein molecule in order to "coat" the protein surface. Elsewhere in this volume poly(ethylene glycol) (PEG) prodrugs and PEG-protein conjugates are described in detail, and several reviews discuss this topic (3–9).

Many excellent reviews have already described the evolution of polymer–drug conjugates and micellar drug carriers (1,3,4,10–21). Here we describe the basic rationale for the design of pendent chain polymer–drug conjugates. Experience suggests that careful selection of all the components of the polymer–drug conjugate; the polymer itself, the pendent chain linker, and the drug is required for development of a construct with increased efficacy and that is also amenable to industrial scale-up and clinical development. Examples are largely drawn from the field of polymeric anticancer agents and those compounds which are furthest in development, i.e., in vitro and in vivo observations correlate.

BIOLOGICAL RATIONALE FOR DESIGN

Whereas cellular uptake of low molecular weight molecules usually occurs by rapid transmembrane passage, the uptake of soluble macromolecules occurs almost exclusively by endocytosis (Fig. 3). The mechanism of endocytosis has been reviewed elsewhere (22,23). Endocytosis is a constitutive process common to all cell types and results in membrane invagination leading to the capture of extracellular fluid and all macromolecules contained therein.

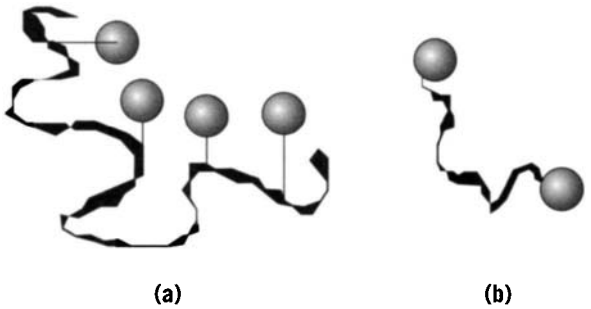

Figure 2. Polymer–drug conjugates: (**a**) pendent chain and (**b**) endgroup conjugation.

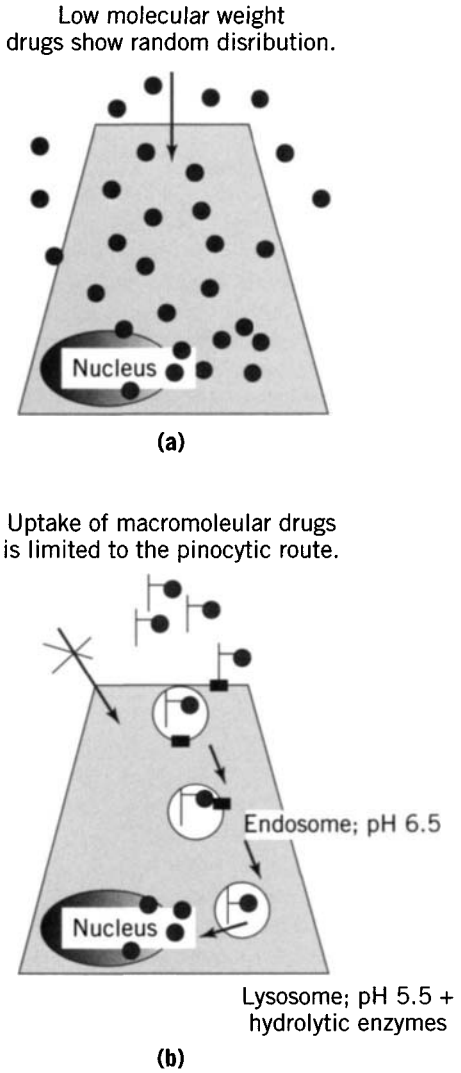

Figure 3. Mechanisms of cellular uptake of (**a**) low molecular weight anticancer agents and (**b**) polymer–drug conjugates.

Uptake of macromolecular solutes is referred to as fluid-phase pinocytosis (23). If a macromolecule is also internalized after binding to specific receptors on the plasma membrane or by binding through nonspecific hydrophobic or electrostatic membrane interactions, capture is designated adsorptive-pinocytosis. This results in rapid uptake and often significant concentration of macromolecules within the cell. After their formation at the plasma membrane, pinocytic vesicles migrate into the cytoplasm and, by a series of fusion events, enter the endosomal compartment of the cell where the pH falls to 6.5. Further fusion events lead to transfer of the vesicles' contents into the secondary lysosomal compartment. There pH falls to approximately 5.5. Furthermore, lysosomes contain a vast array of hydrolytic enzymes including proteases, esterases, glycosidases, phosphates, and nucleases (24). Internalized macromolecules that are substrates for these enzymes are degraded within the lysosomes to their constituent molecular fragments which, if small enough, subsequently dif-

fuse through the lysosomal membrane into the cytoplasm for cellular metabolism or removal. Macromolecules which are not degraded accumulate in the secondary lysosomes and can only be released slowly by exocytosis or upon cell death.

Lysosomotropic Delivery

De Duve and colleagues first suggested that macromolecules, particularly proteins, might be used to conjugate drugs and therefore restrict drug uptake by cells to the pinocytic route. This ensures that the secondary lysosomal compartment acts as a gateway for drug entry into the cell. They coined the term "lysosomotropic drugs" to describe compounds that exhibit pharmacological properties after internalization and delivery via this route (25).

Possessing the knowledge that macromolecular uptake by cells is limited to the pinocytic route (25,26), and that soluble synthetic polymers could be used as blood expanders (27,28), as prophylactics against radiation exposure (29), and as pharmacologically active agents (30–33), Ringsdorf proposed that polymers could also be systematically developed into targetable drug carriers (21,34,35), and that hydrophilic polymeric carriers could be used to solubilize poorly water-soluble drugs. His now famous model described how a polymer–drug linker might be used to allow controlled drug liberation at the target site. The model also proposed the coconjugation of targeting moieties capable of mediating cell-specific targeting.

The change in milieu during cellular internalization and the presence of specific lysosomal hydrolases provides the opportunity to design polymer–drug linkers from which drug is cleaved from the polymer only in the environment of the endosome or lysosome. This has allowed the design of polymeric anticancer conjugates that are essentially nontoxic in the extracellular environment (18). Ultimate antitumor activity is dependent on the efficient liberation of an active form of the drug from the polymer which can then permeate through the lysosome membrane into the cytoplasm to reach the pharmacological target. Structural characteristics of the released molecules including charge and hydrophobicity can influence the permeation rate of these molecules out of the lysosome; however, diffusion from the lysosome readily occurs at molecular weights below 200–220 Da (36–38).

Passive and Active Targeting of Polymer–Drug Conjugates

As conjugation of low molecular weight drugs to polymeric carriers restricts cellular uptake to the endocytic route, the biodistribution of conjugated drug is significantly changed. Increasingly, unequivocal evidence has shown that solid tumors exhibit enhanced or hyperpermeability of the tumor vasculature (39–44), and this, combined with the decreased lymphatic drainage of tumor tissue compared with healthy tissue (39,45), can produce significant tumor targeting of polymer–drug conjugates and particulate carriers that have a lengthy plasma residence time. Maeda and coworkers termed the passive targeting of polymer conjugates to solid tumor tissue the "enhanced permeability and retention" (EPR) effect (Fig. 4) (39,45).

Many macromolecules (39,46,47) passively accumulate within solid tumors, including albumin (48–55), antibodies (56,57), polymers (58,59), and polymer–drug conjugates (60,61). Tumor to blood ratios of the polymer–protein conjugate styrene maleic anhydride-neocarzinostatin (SMANCS) of up to 2,500 were measured in a rabbit tumor model (62,63) and *N*-(2-hydroxypropyl)methacrylamide (HPMA) copolymer–doxorubicin conjugates have shown tumor accumulation ranging from 2 to 20% dose/g in a B16F10 tumor model (64,65). Observations that tumor blood vessels are permeable to liposomes and particles in the size range 200 to 600 nm (44,66), and that neither the human colon xenograft LS174T (44), B16F10, or sarcoma 180 tumors (60) exhibited differences in tumor uptake of macromolecules in the 10,000 to 800,000 Da molecular weight range are indicative that passive tumor targeting by the EPR effect can be accomplished using polymeric and micellar carriers across a wide molecular weight and size range. Tumor accumulation of polymer–drug conjugates begins immediately after intravenous (i.v.) administration and the plasma concentration of polymer is the main driving force controlling the extent of tumor capture observed (47).

After i.v. administration polymers that do not bind to blood proteins display a plasma clearance that is primarily governed by the rate of kidney glomerular filtration and the rate of liver uptake. Macromolecules of molecular weight of 40,000–70,000 Da readily pass through the kidney glomerulus and are excreted. However, as the solution size of a molecule increases with molecular weight (or by forming supramolecular aggregates), extended blood clearance times result. Structural features including polymer flexibility, charge, and hydrophobicity affect the renal excretion threshold for macromolecules within this size range (67). Neutral, hydrophilic polymers including HPMA copolymers, poly(vinylpyrrolidone) (PVP) and PEG have flexible, loosely coiled solution structures, whereas proteins tend to be charged and exhibit more compact solution structures. For example, the molecular weight threshold limiting glomerular filtration of HPMA copolymer-tyrosinamide in the rat was approximately 45,000 Da (68) and the threshold for proteins is approximately 60,000 Da.

In addition to passive targeting, polymeric–drug conjugates can be targeted to specific cells by incorporation of targeting moieties into the polymer backbone (15,18). This process is termed *active targeting*. Although receptor-mediated endocytosis is highly efficient, particularly when cells display a high density of ligand-specific receptors, localization of a significant percentage of the dose of drug within the target in vivo by active targeting has not been very successful. Many candidate receptors proposed for tumor targeting have broad cellular distribution. For example, transferrin, low density lipoprotein, and growth factor receptors, which display elevated levels on tumor cells, have ubiquitous distribution. Many so-called tumor-specific receptors are actually only tumor-enhanced in terms of numbers of receptors per cell (69–74). Cell-specific receptors are present in the liver (75–78), and these have been used successfully to target polymer–drug conjugates after i.v. administration. For example, HPMA copolymer-doxorubicin containing additionally galactosamine (PK2,

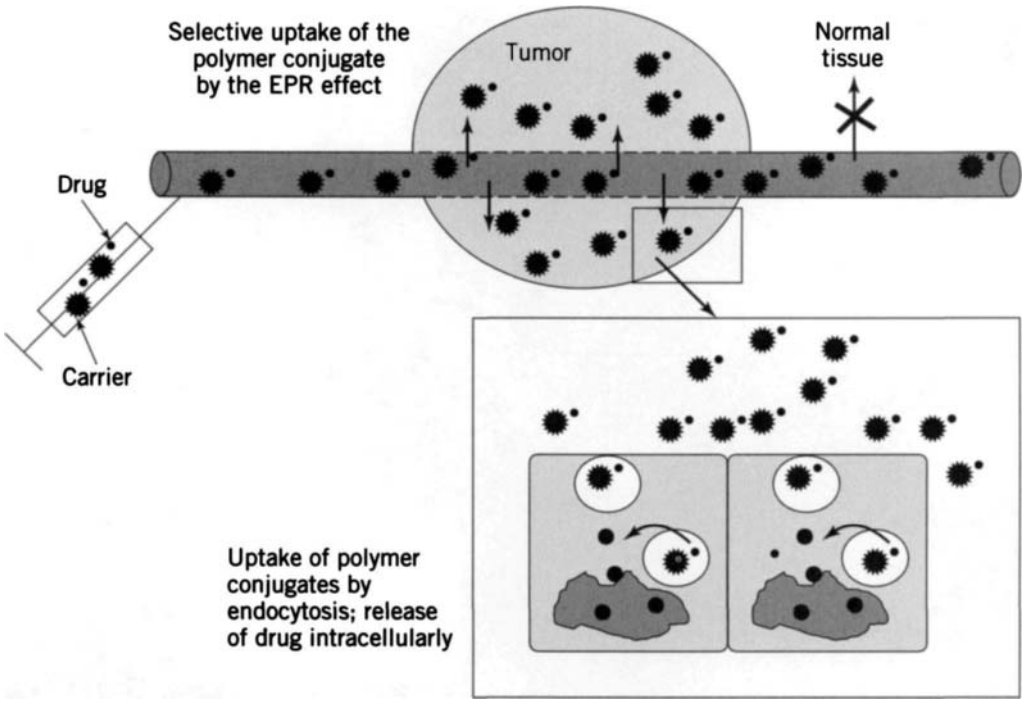

Figure 4. Passive tumor targeting by the EPR effect.

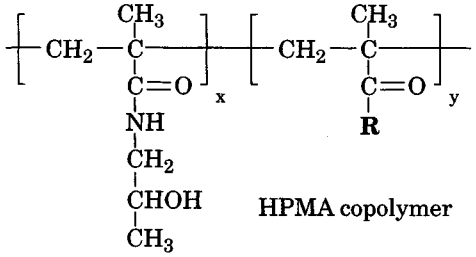
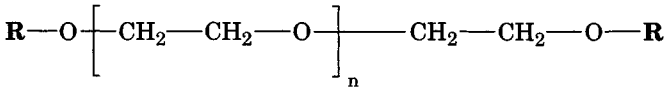
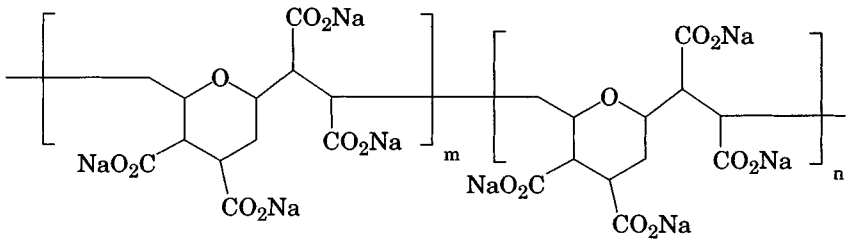
FCE 28069) localizes selectively in the liver due to uptake by the hepatocyte asialoglycoprotein receptor (79,80).

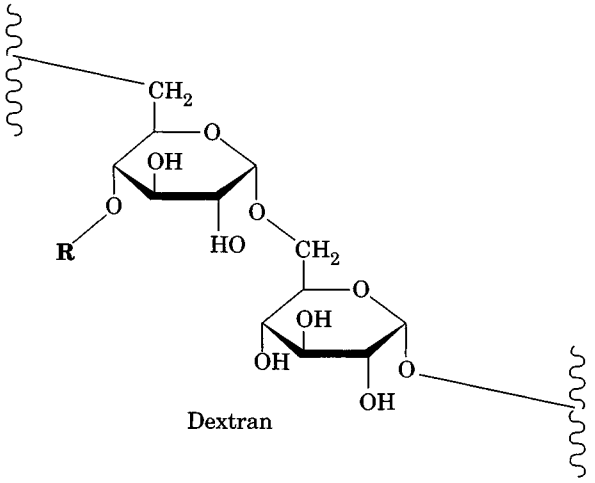
To be effective, it is important that polymer–drug conjugates are designed to improve drug localization in the target tissue, diminish drug exposure in potential sites of toxicity, and optimize drug release rate. Incorporation of a polymer–drug linker that only releases drug at the target site can reduce peak plasma concentrations, thus reducing drug-mediated toxicity. If the drug release rate is optimized, exposure at the target can be tailored to suit the mechanism of action of the pharmacophore being used (e.g., use of cell-cycle dependent antitumor agents) and to prevent the induction of resistance.

SOLUBLE POLYMERIC CARRIERS

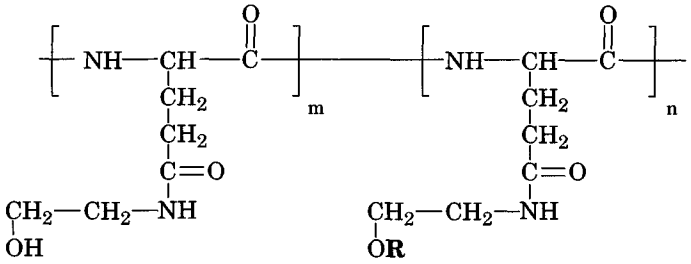


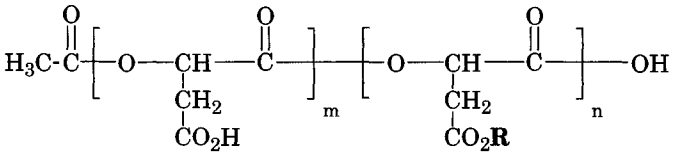


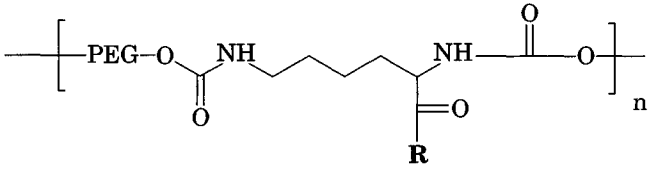


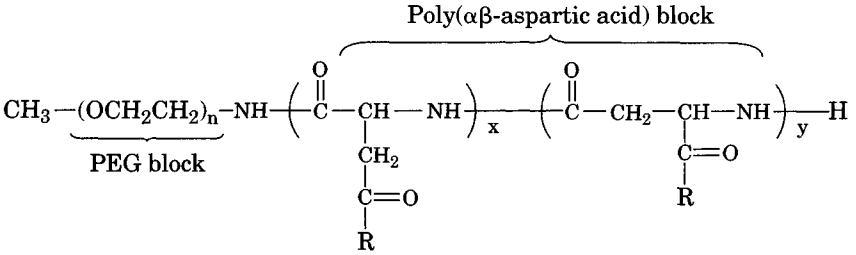


An increasing number of soluble polymers have been used as macromolecular partners for pendent chain drug conjugation. Shown in Table 1 are representative examples of several polymers that have been used to prepare polymer–drug conjugates. Many of these polymers have been extensively studied and can be organized into two broad classes: (*1*) nondegradable synthetic polymers and (*2*) potentially degradable synthetic polymers and natural polymers. Although several polymers with intrinsic therapeutic activity (81) have been used to conjugate drugs, e.g., copolymers derived from divinylether and maleic anhydride (DIVEMA) and some polysaccharides (82,83), many polymers used for conjugation were selected because they were water-soluble and biocompatible (e.g., did not bind blood proteins and were nonimmunogenic).









Nondegradable Synthetic Polymers

The synthetic polymers PEG and HPMA copolymers have been extensively studied as polymeric drug carriers. They are hydrophilic and are well tolerated in man, but their main disadvantage is that the polymer backbone is not biodegradable in vivo. Only polymers of molecular weight lower than the renal threshold can be used for systemic administration.

Poly(ethylene glycol). PEG is generally recognized as safe and is used in a wide range of pharmaceutical and consumer products (7,84–86). Monodisperse PEG is commercially produced in a range of molecular weights from 200 to over 100,000 Da with various endgroup chemical functionality and morphology, i.e., linear, graft, and star. Although PEG has been widely used to prepare polymer–protein conjugates it is only now being used more widely to conjugate anticancer drugs such as doxorubicin (87), camptothecin (88–90), and paclitaxel (Fig. 5) (91,92). PEG–drug conjugates can be prepared by linking via one terminus or both termini of an end functionalized PEG (see Fig. 5). Usually the PEGs selected for protein conjugation have a molecular weight of 3,400 or 5,000 Da, but for preparation of drug conjugates a wider range of molecular weights has been explored (91,93). Many conjugation strategies have been described (3,4,86). One potential disadvantage is the extent of polymer drug loading, which is limited by the availability of only two reaction sites at the termini of the linear PEG molecule. However, branched PEG polymers (87), alternating PEG polymers [e.g., PEG-lysine (94,95)] and copolymers [e.g., PEG-oligopeptide-PEG (96,97)] with pendent chains capable of conjugating

Table 1. Polymers Used for Pendant Drug Conjugation

Polymer	Linker	Example polymer structures[a]
	Nondegradable synthetic polymers	
HPMA copolymers	Pendent chain; peptidic or acid labile for lysosomal release of covalently conjugated drugs. Pendent chains can be derivatized to chelate metals.	 HPMA copolymer
PEG	Typically endgroup (terminal) drug conjugation. Both peptidic and acid labile linkers have been used, but PEG also directly conjugated to drug (i.e., via an ester bond).	 PEG
DIVEMA	Metals (e.g., platinum) can be conjugated by chelation directly to the polymer side chains, which are carboxylates.	 DIVEMA
	Potentially degradable polyers	
Polysaccharides Dextran Chitosan Carboxymethyl chitin Carboxymethyl pullulan Alginate	Most of these polymers are naturally occurring or can be synthesized from natural metabolites. Polymer usually derivatized to have caboxylate, amine, aldehyde, or reactive moiety on side chain, which is then conjugated with the drug. Can be conjugated with an appropriately derivatized drug to give either peptidic or acid labile pendent chain for lysosomal drug release. Pendent chains are also used to conjugate ligands for multivalent binding onto a cellular membrane surface.	 Dextran

Poly(amino acids) Poly[^{5}N-(2-hydroxyethyl)-L-glutamine) (PHEG) β-Poly(2-hydroxyethyl aspartamide) (PHEA) Poly(glutamic acid) Poly(aspartic acid) Polylysine	Polymer side chains tend to be derivatized analogous to polysaccharides to give pendent chain conjugation that can be either peptidic or acid labile. Pendent chains also used to conjugate ligands for multivalent ligand binding on the membrane surface.	 Poly[^{5}N-(2-hydroxyethyl)-L-glutamine]
Polyesters Poly(α or β-malic acid)	Pendent chain options are similar to poly(amino acids).	 Poly(α-malic acid)
Alternating polymers PEG-lysine	Provides practical means to incorporate pendent chains in a polymer which is predominantly PEG.	
Block copolymers Poly(ethylene glyco-aspartate)	Formation of polymeric micelles capable of both drug conjugation and entrapment. Linker potential similar to poly(amino acids).	

[a]**R** denotes a pendent chain linker with a conjugated drug.

a drug along the polymer backbone, and PEG block copolymers that can form polymeric micelles have recently been prepared (10,11,98–100).

***N*-(2-Hydroxypropyl)methacrylamide Copolymers.** Many synthetic hydrophilic polymers used for drug conjugation are derived from methylacrylamides (e.g., HPMA copolymers). These polymers have generally been prepared by free radical polymerization. HPMA homopolymer is nontoxic up to 30 g/kg, does not bind blood proteins, and is not immunogenic. It was initially developed as a plasma expander (101,102), and copolymers derived from HPMA have been widely used for drug conjugation using pendent chain attachment (Fig. 6) (12,15,18). Early confirmation of low protein binding (103), low complement activation (104), and low immungencity (105–108) was instrumental in establishing the potential of HPMA homo- and copolymers to be used for drug conjugation. Although HPMA copolymers of molecular weight less than 40,000 Da are readily excreted, HPMA copolymers of molecular weight above the renal threshold remain in circulation for long periods and are retained in the body, typically exhibiting accumulation in the reticuloendothelial system (RES) and skin (68). It is imperative that the systemic use of nondegradable polymers such as HPMA copolymers, PEG, and PVP is limited to molecules of a molecular weight that is readily cleared, otherwise long-term deleterious accumulation in healthy tissue could result (68,109–112).

Potentially Biodegradable Polymers

Polysaccharides. Some polysaccharides have the advantage of being enzymatically biodegradable, e.g., dextran, and can therefore be administered over a wider molecular weight range without the fear of prolonged accumulation in the body. However, polysaccharides lack structural uniformity and exhibit the propensity upon chemical modification (i.e., drug conjugation) to become immunogenic or nondegradable (113,114). Dextran is used safely as a blood plasma substitute (115) and has been investigated for use as polymeric carrier (14,116–123). The dextran backbone is composed of glucose repeat units. These hydroxylated, cyclohexyl units result in a more rigid polymer compared with many synthetic polymers (e.g., HPMA copolymers, PEG, and PVP), so dextran tends to exhibit a more compact solution structure than these polymers. Consequently, it has a higher renal threshold for excretion [55,000 Da (124) to 70,000 Da (46)]. Chemical modification of dextran by introduction of anionic moieties (carboxylates) reduces its rate of clearance (46), and addition of other substituents such as fluorescein isothiocyanate or sugar residues (113,125) promotes liver capture. Other polysaccharides that have been investigated include chitosan (126), alginate (127,128), hyaluronic acid (129), 6-*O*-carboxymethyl chitan (130) and 6-*O*-carboxymethyl pullulan (131). Typically, commercially available coupling agents have been routinely used to bind drugs to polysaccharides by direct conjugation to the polymer.

Polymers Derived From Natural Metabolites. Often hydrophilic polymers have been prepared from amino acids (e.g., poly(glutamic acid), poly[^{5}*N*-(2-hydroxyethyl)-L-glutamine) (PHEG), β-poly(2-hydroxyethyl aspartamide) (PHEA), poly(L-glutamic acid), and polylysine. Other polymers and copolymers including pseudo-poly(amino acids) (132) and polyesters such as poly (α or β-malic acid) (133,134), and alternating polymers such as PEG-lysine (94,95) and poly(lysine citramide) (133) have also been investigated for drug conjugation. These polymers can be prepared by condensation or ring opening (135) polymerization reactions.

In principle, proteins can also be used to conjugate drugs, and albumin has been a popular candidate. Albumin with a molecular weight of approximately 66,000 Da is the most abundant protein in the circulatory system. It

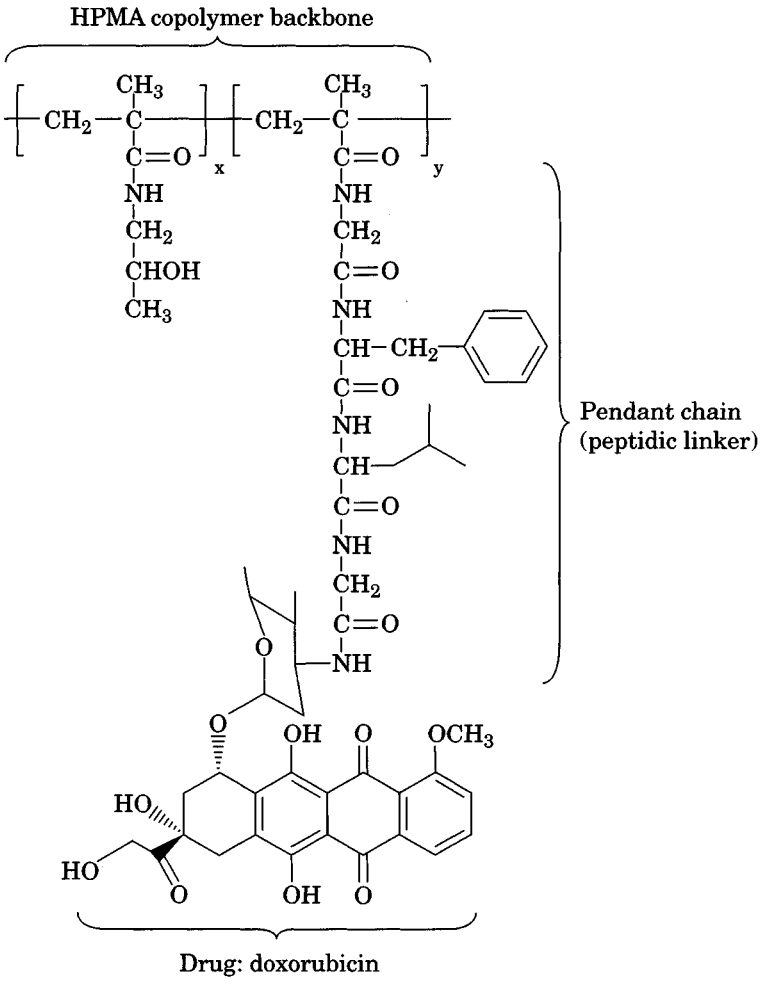

Figure 6. HPMA copolymer-doxorubicin conjugate (PK1, FCE 28068), an example of pendent chain drug conjugation using a peptidic linker (12,15). The conjugate has a M_W of approximately 30,000 Da and a doxorubicin content of approximately 8 wt %.

exhibits a circulation half-life of 19 days (only 2.2 days in the rat) and is found in every tissue and bodily secretion (136). Albumin continues to be actively investigated as a macromolecule candidate for drug conjugation (137–144), but the major limitations of proteins when compared with synthetic polymers as drug carriers are their increased propensity for inducing immunogenicity, denaturation, and nonspecific degradation. Other proteins such as transferrin [which binds to the transferrin receptor and thus have the potential to undergo receptor-mediated uptake (145,146)], and various immunoconjugates (57,147–158) have also been investigated. Narrow molecular weight distribution is often claimed to be a significant advantage for using proteins to conjugate drugs, but this can only be useful if a single species of the protein–drug conjugate can be created that is stable on storage. This has frequently been difficult to achieve in practice.

Polymer Micelles

Block copolymers, comprising hydrophilic and hydrophobic blocks, form polymeric micelles in solution (98,100,159–162) and self-assembling micellar delivery systems are receiving increasing attention (10,163–165). A significant advantage of these systems is the ability to design higher molecular weight micellar aggregates that display prolonged circulation times that can maximize tumor capture by the EPR effect. Upon micelle disassociation, the individual block copolymer molecules are safely excreted, and as long as they are of low enough molecular weight these polymers can be nonbiodegradable. For example, poly(ethylene glycol-aspartate) block copolymer doxorubicin conjugates form micelles ranging in size from 20 to 60 nm that accumulate in solid tumors and exhibit antitumor activity (11,98,160,161,166). The doxorubicin is conjugated by its free amine directly to either the α- or β- pendent carboxylates in the poly(aspartic acid) block. Details of this conjugate are further described in the section entitled "Other Linkers." Frequently physical entrapment of drug has accompanied conjugation (167), and with stable block copolymer micelles drug entrapment has become a viable strategy to deliver cytotoxic drugs to tumors (10,99,167–169). This aspect of block copolymer micelles is beyond the scope of this review (10).

PENDENT CHAIN LINKERS

Preparation and Characterization of Polymer–Drug Conjugates

Three distinct strategies have been employed to prepare polymer–drug conjugates incorporating pendent chain linkers.

1. Reaction of the linker or drug with functional groups already present in the polymer main chain. Generally, polymer side chains are activated using coupling reagents or by prior reaction. In this way, for example it is possible to derivatize -NH_2 groups in poly-L-lysine or -OH groups in polysaccharides.
2. Preparation of reactive polymeric intermediates by copolymerization using a monomer with a reactive pendent chain to which drugs or targeting groups can subsequently be bound (for example, conjugation of drugs to HPMA copolymers bearing pendent side chains containing reactive esters).
3. During polymerization use of a monomer containing the linker drug to produce the homopolymer or copolymer bearing linker and drug as pendent chains.

A significant amount of methodology for the conjugation of drugs to polysaccharides (170–172) has been developed using dextran as the model because this polysaccharide has been developed clinically as a blood plasma substitute (113,173) (for example, (*1*) partial periodate oxidation to give reactive aldehyde groups (113,174–177), (*2*) succinoylation (Fig. 7) or analogous derivatization (120,127) to give free carboxylates that can be conjugated, and (*3*) chloroformate (113,174) or cyanogen bromide (178) activation followed directly by reaction with a drug or drug derivative). Polymers derived from amino acids such as PHEG (179–181) and poly(L-glutamic acid) (182) have been directly conjugated to drugs using a commercial coupling agent (Fig. 8).

The majority of HPMA copolymer conjugates have been prepared by synthesis of polymeric precursors derived from free radical copolymerization of HPMA monomer and methacryolyated peptides terminating in *p*-nitrophenol. Subsequent aminolysis of the polymer precursor has been used to introduce covalently bound drug, drug analogue, or targeting ligand (183–192). This procedure for the preparation of polymer–drug conjugates is known as a polymer analogous reaction (101,102,108,184,193,194), and it has the significant advantage of allowing preparation of a common polymeric intermediate that can then be used to prepare different conjugates all having the same molecular weight characteristics (195). In the case of HPMA copolymers the polymeric precursor is prepared under very mild conditions by free radical precipitation polymerization (193). During aminolysis of the pendent chain terminal *p*-nitrophenol ester, the drug loading can be varied simply by using different drug stoichiometries (Fig. 9). The major limitations of the polymer analogous reaction are (*1*) incomplete removal of all free drug, which in the case of potent anticancer agents is essential to minimize potential toxicity associated with systemic administration, and (*2*) the difficulty in fully characterizing a complex polymer–drug conjugate.

Polymer–drug conjugates can also be prepared by copolymerization of underivatized and drug derivatized monomers (Fig. 10) (15,20). Copolymerization of such comonomers often requires optimization of the polymerization chemistry to maintain molecular weight characteristics, comonomer incorporation, and conversion (yield) at different drug loadings.

Whatever the route of synthesis, it is essential that polymer–drug conjugates developed for clinical evaluation be carefully characterized. HPMA copolymer conjugates destined for clinical use have been characterised by detailed NMR (to confirm identity), gel permeation chromatography, and viscosimetry (to describe molecular weight averages and distribution) (195) and by high-performance liquid chromatography (HPLC) techniques to quantify total and free drug in the preparation (196,197). Typically an acceptable level of free drug in a polymeric conjugate produced on a commercial scale is approximately 1% of the total drug in the preparation, although laboratory synthesis can frequently yield compounds with $\leq$0.1% free drug.

In the case of conjugates containing potent anticancer agents it is important to note that such traces of free drug can contribute significantly to the observed in vitro cytotoxicity. This limits the opportunity to use a simple in vitro bioassay to confirm activity/toxicity of polymeric drugs. Whereas the free drug generally diffuses rapidly through the plasma membrane into the cell, the polymer conjugate is taken up slowly by endocytosis and, if a peptidyl linker is used, liberation of active agent is also a lengthy process. Thus in vitro cytotoxicity assays are frequently inappropriate for predicting the in vivo potential of candidate anticancer polymer conjugates; they often simply give an indication of the free drug content of a preparation or reflect a fast rate of release of drug from the conjugate during incubation in tissue culture medium. For example, the in vitro cytotoxicity testing of HPMA copolymer-doxorubicin conjugates showed that toxicity was caused by the unconjugated doxorubicin impurity (Fig. 11) (198). This was corroborated by HPLC analysis (196). If the biological reproducibility of commercial batches of a polymer conjugate are to be determined, carefully designed in vitro and in vivo tests are required depending on the therapeutic target of the bound drug.

The molecular weight distribution or polydispersity of a polymer is defined as a ratio of molecular weight averages, specifically, M_w/M_n (weight average molecular weight/number average molecular weight). If all molecules of a polymer sample have the same size (e.g., proteins), this ratio is 1. The higher this ratio (it is never less than 1), the broader the distribution of molecular weights. Polymer therapeutics must be rigorously characterized with respect to their molecular weight and polydispersity because biodistribution and pharmacological activity are known to be molecular-weight-dependent. For example, blood circulation half-life (199), renal clearance, deposition in organs (27), rates of endocytic uptake (200,201), and biological activity can depend on polymer molecular weight characteristics (81,202–206). If a polymer analogous reaction is used for drug conjugation, determination of polymer molecular

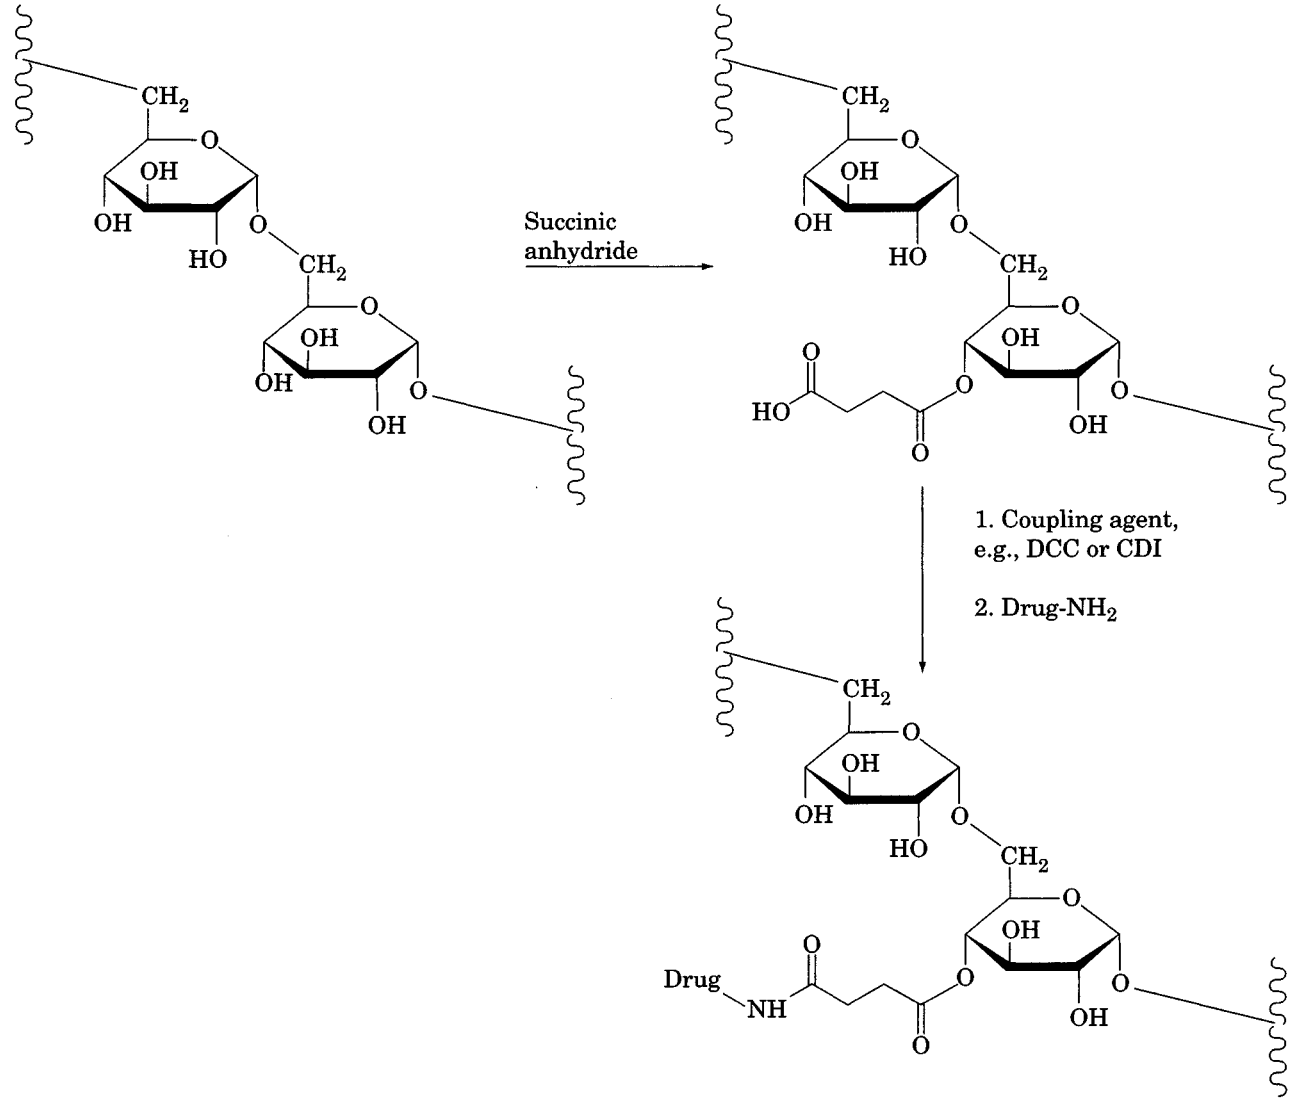

Figure 7. Succinylation of dextran, an example of polysaccharide derivatization often required prior to drug conjugation (113,173).

weight before and after the reaction ensures there has been no significant increase in molecular weight due to cross-linking.

Pendent Chain Linkers

A wide variety of linkages have been used to covalently bind a drug to the polymeric carrier (12,13,15,20). Several examples are illustrated in Table 2. Conjugation of metals to polymers by chelation has also been investigated (e.g., platinate anticancer conjugates (129,207–214; E. Gianas et al., unpublished data) and chelated conjugates for imaging (215–219)). Following the concept of lysosomotropic drug delivery (25,138) two broad classes of pendent chain linkers have emerged as the main focus of research over the last two decades.

1. Peptidyl linkers designed to be stable in the bloodstream but degradable by lysosomal enzymes and thus able to release the drug intracellularly (38,138,183,220–223).
2. Acid-labile, pH-dependent linkers designed to remain stable in plasma at neutral pH (7.4) but release drug intracellularly by hydrolysis in the more acidic environment of the endosome and lysosome (pH 5.5 to 6.5) (127,149,224).

Peptidyl Linkers

Early studies involving albumin-peptide-daunorubicin conjugates demonstrated that peptide linkers are able to mediate lysosomotropic drug delivery (138,225,226). It has become apparent that the best control of the rate and location of drug release from pendent chain polymers have occurred when a drug is bound to the polymer backbone via a peptidyl side chain, and the largest body of infor-

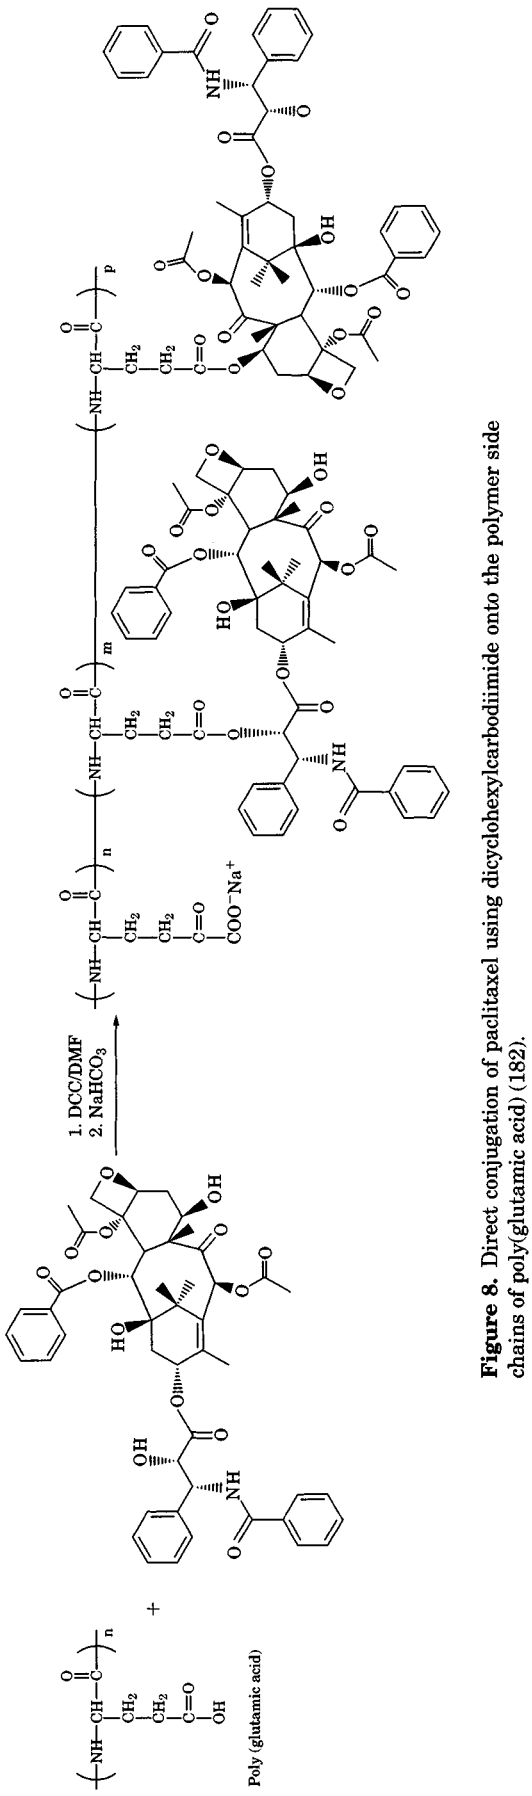

Figure 8. Direct conjugation of paclitaxel using dicyclohexylcarbodiimide onto the polymer side chains of poly(glutamic acid) (182).

mation has been collected thus far using HPMA copolymers synthesized to contain pendent peptide side chains for drug conjugation.

Since the discovery that peptidyl side chains in HPMA copolymers could be designed for cleavage by model enzymes such as chymotrypsin, trypsin, and papain (183,220,227–232), the last two decades have seen the systematic development of HPMA copolymer–anticancer conjugates containing peptidyl linkers tailored for cleavage by lysosomal proteases (15,18). Such linkers have now become more widely used in many different polymer conjugates (12,13,15). Initial studies using HPMA copolymers containing peptidyl pendent side chains terminating in *p*-nitroanilide (NAp) as a model compound found that mixtures of lysosomal enzymes (tritosomes) were not able to cleave many sequences in the absence of the reducing agent (reduced glutathione; GSH) (233), and indeed under these conditions the rate of NAp release was very slow (Table 3). In most cases, addition of GSH increased the rate of NAp release significantly (Table 3), and this, coupled with the observation that leupeptin inhibited degradation, indicated that the lysosomal thiol–dependent proteases (cathepsins B, H, and L) were particularly important for the degradation of such tri- and tetrapeptide sequences (220,222,230,231). It is preferable that a polymer–drug linker does not degrade in plasma and serum. Using similar HPMA copolymer conjugates, it was shown that release of NAp in rat serum was less than 5% in 5 h, varying to some extent depending on the exact structure of the peptide linker used (Table 4) (221).

Later studies sought to optimize the design of peptidyl linkers in HPMA copolymer conjugates as a means to control the site and rate of liberation of antitumor agents, particularly doxorubicin (223,227,228,232–234). As HPMA copolymer-Gly-Phe-Leu-Gly-doxorubicin (PK1, FCE 28068) (see Fig. 6) liberated doxorubicin over approximately 48 h when incubated with tritosomes (Fig. 12), this conjugate showed the ability to localize in solid tumors by the EPR effect (235–237) and demonstrated antitumor activity against a panel of solid tumor models including M5076 (237), Walker sarcoma (238), human colon xenograft LS174T (236,237), and established subcutaneous P388 (198) and B16 melanoma models (239). This compound was selected for clinical development.

HPMA copolymer-Gly-Phe-Leu-Gly-doxorubicin is stable in human serum, in vitro (223) and does not lead to liberation of drug in the circulation in vivo (240). The rate of anthracycline (doxorubicin and epirubicin) release from HPMA copolymers correlates with in vivo efficacy and toxicity (18,236,237). When doxorubicin conjugates with the slower releasing tripeptide linkers P-Gly-Phe-Gly-Dox and P-Gly-Leu-Gly-Dox were administered intraperitoneally (i.p.) to treat mice bearing an i.p. L1210 ascitic tumor model they proved more effective than conjugates with the faster-releasing tetrapeptide spacers. The slower release kinetics of the tripeptide linkers maintained a more sustained and relatively lower level of doxorubicin for a longer period of time in vivo. HPMA copolymer-doxorubicin conjugates containing a nondegradable linkers (e.g., P-Gly-Gly-Dox) did not display antitumor activity (241,242), confirming the need for lysosomotropic delivery with drug liberation.

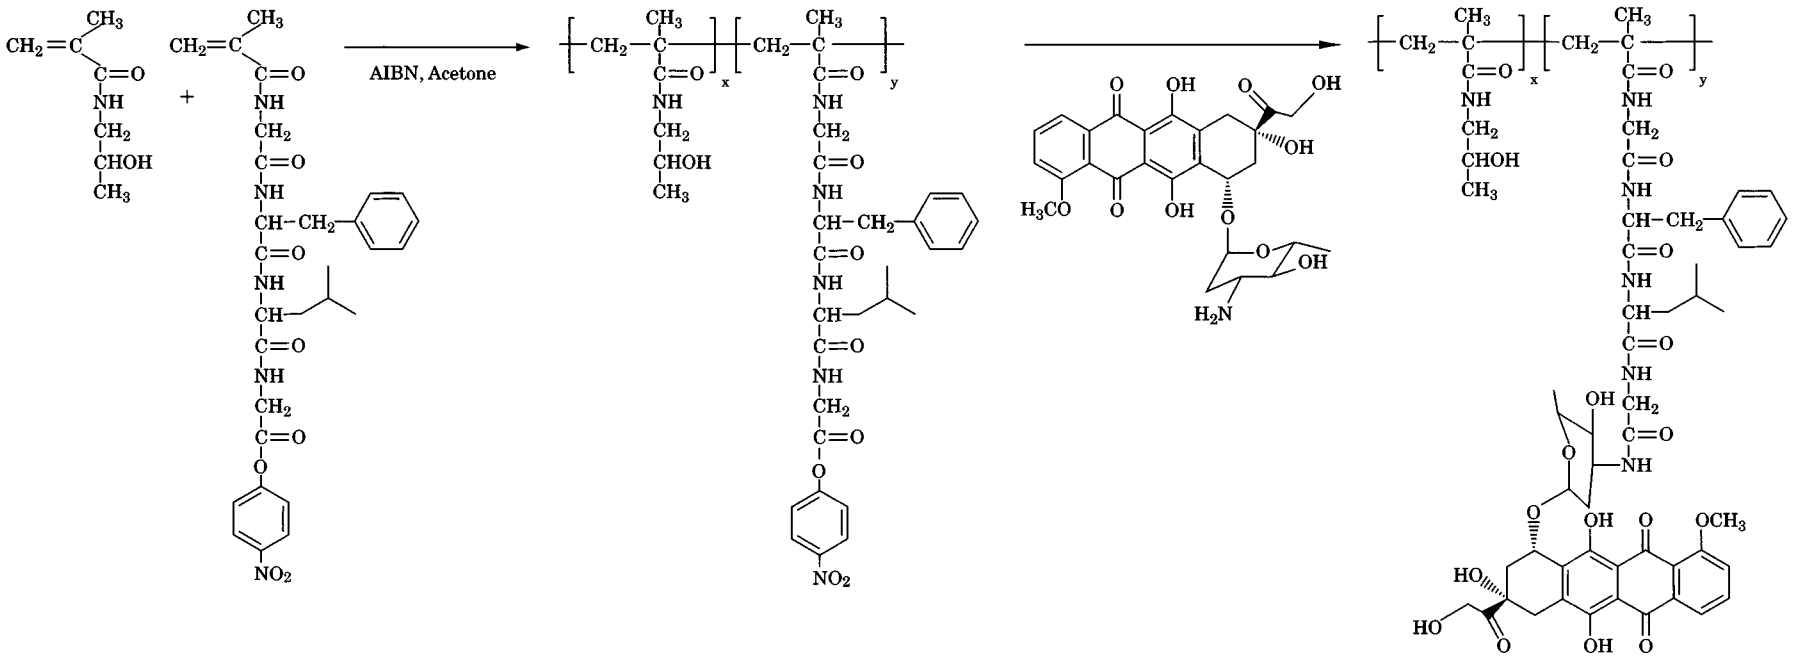

Figure 9. Aminolysis of a HPMA copolymer, an example of the polymer analogous reaction (184).

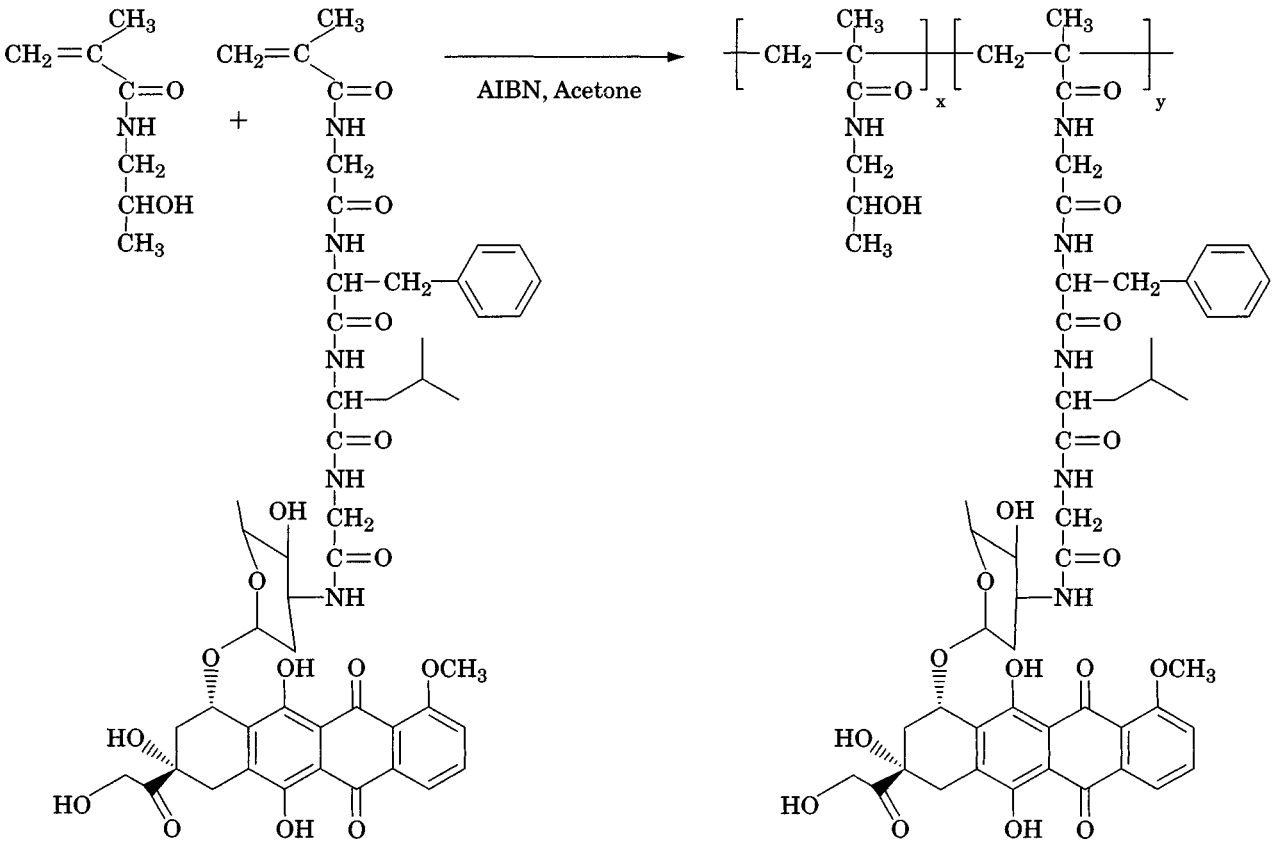

Figure 10. Preparation of HPMA copolymer-doxorubicin conjugate by the copolymerization of hydroxyproplymethacrylamide and a methacrylated doxorubicin tetrapeptide derivative (20).

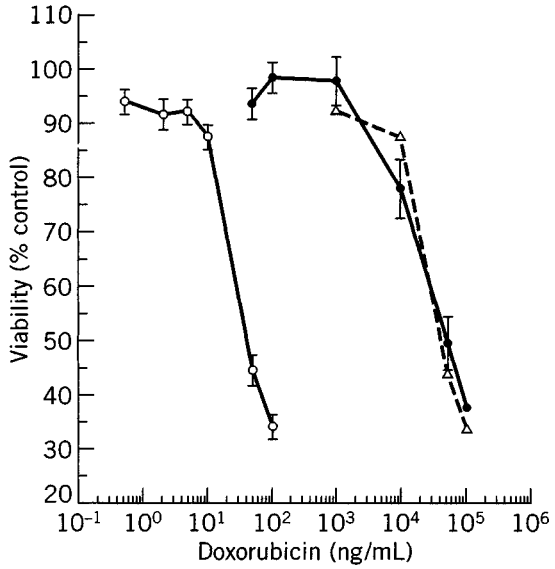

Figure 11. In vitro cytotoxicity of HPMA copolymer doxorubicin (PK1) during incubation with L1210 cells. Cytotoxicity of doxorubicin (○), PK1 (●), and the free doxorubicin present in the PK1 preparation (△) as measured by the MTT assay (72h) are shown (198).

Alkylating agents have also been conjugated to HPMA copolymers using peptidyl linkers (234). For example, HPMA copolymer–melphalan conjugates prepared with a variety of peptidyl linkers were less toxic than free melphalan and exhibited improved antitumor activity against Walker sarcoma (subcutaneous). Again, the peptidyl linker structure influenced drug release in vitro and this release rate correlated with anticancer activity seen in vivo. No antitumor activity was observed when melphalan was conjugated to HPMA copolymers via a nondegradable linker (P-Gly-Mel), again confirming that drug liberation was required for antitumor activity to be observed.

The rate of drug release from the polymer chain can also vary according to the polymer molecular weight and the amount of drug conjugated to the polymer. As greater amounts of hydrophobic drug are conjugated onto a hydrophilic polymer, the possibility to form polymeric micelles increases (243). Micellar conjugate structures may hinder access of the lysosomal enzymes to degrade the linker and release the conjugated drug. Additionally, hydrophilic polymers conjugated to hydrophobic drugs can exhibit a lower critical solution temperature where phase separation occurs and the conjugate becomes insoluble. Simple turbidometric assays (244) have been used as a preliminary screen to determine the propensity for phase separation of various HPMA copolymer-doxorubicin conjugates of different molecular weight and drug loading (245). As a

drug is released from a polymer conjugate, it would be expected that changes in polymer conformation will occur that might also lead to differences in drug release rate with time (246,247) and therefore pharmacological properties. The extent of drug loading and its influence on polymer solution properties is an important and yet poorly understood phenomenon and may well have a fundamental effect on the in vivo properties of therapeutic polymer conjugates.

A second HPMA copolymer conjugate containing the Gly-Phe-Leu-Gly-doxorubicin side chain has entered clinical testing, PK2 FCE 28069 (Fig. 13) (79,248–251). This conjugate benefits from the liver targeting mediated by introduction of galactosamine into the PK2 structure and demonstrated antitumor activity in two liver metastatic models: i.v. administered M5076 (237) and B16 melanoma (252).

A variety of anticancer agents have now been conjugated to other macromolecules using peptidyl linkers (12). For example, doxorubicin has been conjugated to poly(L-glutamic acid) (19,253,254), carboxymethylpullulan (131) and 6-*O*-carboxymethylchitin (130) via peptidyl linkers. Other anticancer agents including mitomycin (180) and paclitaxel (255–257) have also been conjugated to different polymers using peptidyl linkers (12,13,130,180,181). These cytotoxic compounds are potent and, when administered to patients, share similar problems as observed with doxorubicin, e.g., high toxicity and low solubility. The stability of mitomycin C (MMC) conjugated to PHEG (M_w~20,000 Da) (Fig. 14) (180,258) using peptidyl linkages has been systematically studied by measuring drug release in the presence of lysosomal enzymes (tritosomes, cathepsins B and D) and type IV collagenase in vitro. As expected, release characteristics were dependent on the structure of the peptide linker used (13,181).

The longer length spacers such as the hexapeptide (P-Gly-Phe-Leu-Gly-Phe-Leu-MMC) and the tetrapeptide (P-Gly-Phe-Ala-Leu-MMC) were readily degraded by tritosomes to release up to 80% of the conjugated MMC in 5 h, whereas tripeptide linkers released <10% MMC in the same time period (259). However, it was noted that the PHEG-hexa- and PHEG-tetrapeptide-MMC conjugates released Leu-MMC and Gly-MMC as well as free drug. These single amino acid–mitomycin derivatives were hydrolyzed (95%) in buffer (3 h) to give free MMC and were considerably less stable than the PHEG–MMC conjugates. This increased stability was attributed to the formation of polymeric intramolecular micelles with the MMC localized within the micellar core and thus making it less accessible for hydrolytic release (13,181). The in vivo antitumor activity of PHEG–MMC conjugates against P388 leukemia and C26 colorectal carcinoma solid tumors was highest for

the linkers with the best hydrolytic stability, e.g., P-Gly-Phe-Leu-Gly-Phe-Leu-MMC and P-Gly-Phe-Ala-Leu-MMC.

Peptidic linkers have also been used to bind the antimetabolite 5-fluorouracil (5-FU) to a variety of different polymers (259–263). The clinical dose of 5-FU is relatively high (often more than 500 mg/m^2), thus, this anticancer agent may not be the best candidate for polymer conjugation unless high levels of polymer substitution can be achieved, or the tumor targeting mediated by the EPR effect results in significantly increased therapeutic benefit. 5-FU is, however, an interesting candidate, as unlike other commonly used anticancer agents such as doxorubicin and mitomycin, 5-FU is not polycyclic nor is lipophilic. These structural differences might allow the higher polymer loading of 5-FU needed while maintaining favorable physicochemical characteristics of such conjugates, e.g., plasma solubility, low blood protein binding, and the relatively open polymer conformation needed for enzymatic lysosomal degradation and drug liberation.

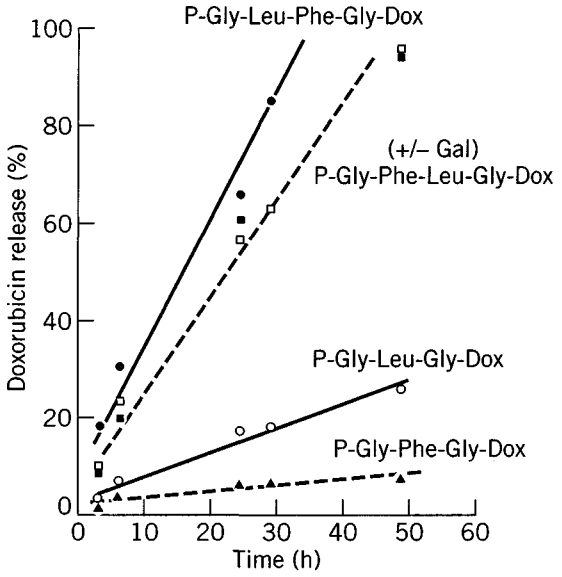

Figure 12. Release of doxorubicin from HPMA copolymer-peptide-doxorubicin conjugates during incubation with rat liver lysosomal enzymes (tritosomes). *Source:* Ref. 223.

PEG-, dextran- and PHEG-5-FU conjugates with about 1–4 wt % loading exhibited in vitro release of 5-FU that was dependent on the linker amino acid sequence (259,260). The peptide linkers chosen to bind 5-FU to these polymers had the structure P-Gly-Phe-X-Gly(5-FU)OEt (OEt is an ethyl moiety; on an acid denotes an ethyl ester) where P is the polymer backbone and X was Gly, Ala, Leu or Phe (Fig. 15). 5-FU was conjugated at the α-position of the glycine ethyl ester at the linker terminus. Initially cleavage by lysosomal enzymes gave X-Gly(5-FU)OEt (13), which then underwent further hydrolysis to produce free 5-FU. The release rate due to hydrolysis was slower in buffer at pH 5.5 (maximum drug release was 3% in 24 h) than at pH 7.4. (Maximum release ranged between 10 and 20% in 24 h depending on the structure of the peptide linker.) The degree of 5-FU liberation was greatest in the order PEG>PHEG>dextran and decreased with increased 5-FU content in the polymer.

Similar studies have been conducted using HPMA copolymers possessing peptidyl linkers terminated with an α-glycine derivative of 5-FU (2–3 mol %) (Fig. 16). These conjugates also exhibited release profiles that were a function of linker structure (261,262), and 5-FU was released as a dipeptide 5-FU derivative (261). The total length of the oligopeptide sequence (tetra- vs. hexapeptide), the stereochemistry of 5-FU substitution at the α-position of glycine (L or D) and the hydrophobicity of the penultimate

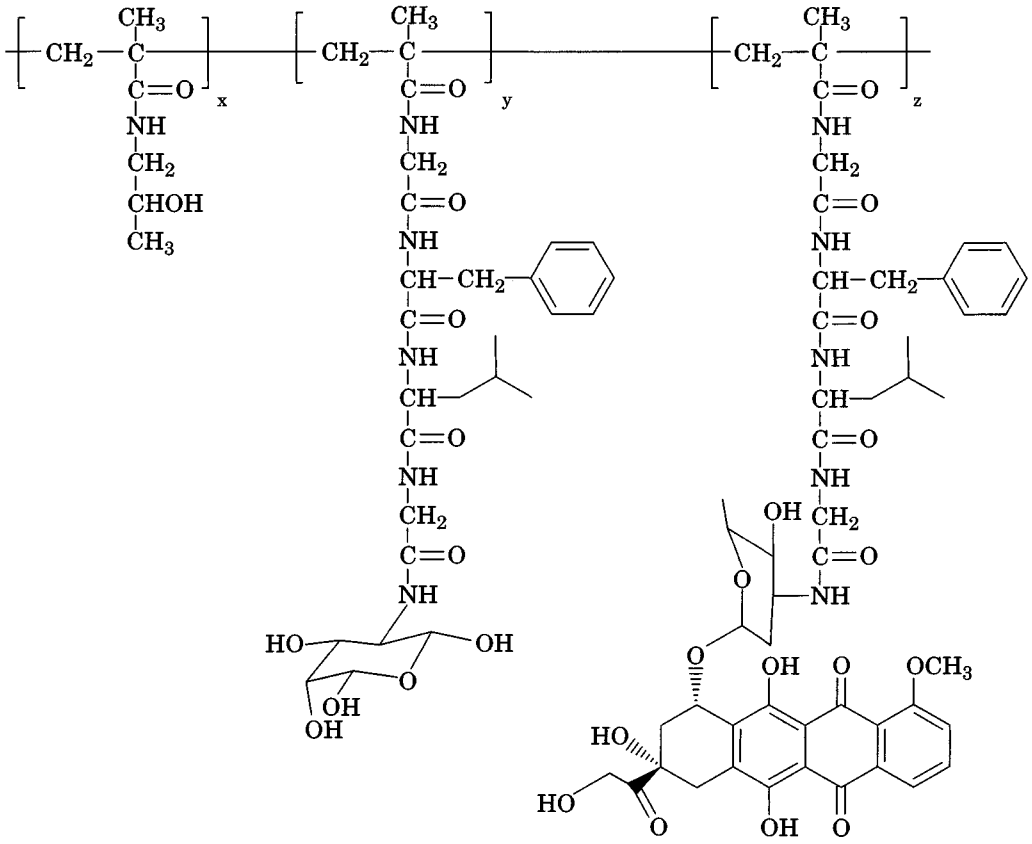

Figure 13. Structure of PK2. The conjugate has a molecular weight of approximately 28,000 Da, a doxorubicin content of approximately 7 wt %, and approximately 4 mol % galactosamine.

amino acid (Ala or Leu) all influenced the in vitro enzymatic release of 5-FU from HPMA copolymers, but in contrast with the studies mentioned already where tetrapeptide linkers in PEG, PHEG, and dextran resulted in 5-FU release, only the hexapeptide linkers in the HPMA copolymers underwent in vitro enzymatic cleavage to release 5-FU (261).

HPMA copolymers containing the -Gly-Phe-Leu-Gly linker used to prepare PK1 and PK2 have recently been used as a platform for conjugation of other antitumor agents. HPMA copolymer–paclitaxel conjugates (Fig. 17) contain an ester bond between a paclitaxel hydroxyl (C-2′) and the amino acid carboxylate at the terminus of the pen-

dent chain (255–257,264). In this case, the terminal bond linking the drug to the peptide pendent chain is not a hydrolytically stable amide bond (265,266). This may give rise to other possible hydrolytic mechanisms for drug liberation. These HPMA copolymer–paclitaxel conjugates were prepared to create a water-soluble paclitaxel conjugate that would slowly release free paclitaxel as the ester bond underwent hydrolysis, and in vivo studies (B16F10, M109, and M5076 murine models) showed that the conjugate exhibited greater efficacy of the conjugate compared to free paclitaxel.

Recently two types of HPMA copolymer–platinum chelates have been described. HPMA copolymers containing peptidyl side chains (Gly-Gly or Gly-Phe-Leu-Gly) terminating in carboxylate groups were allowed to react with cisplatin (E. Gianasi et al., unpublished data), or alternatively the same HPMA copolymers containing peptidyl sequences terminating in a diamine were allowed to react with potassium tetrachloroplatinate (Fig. 18) (E. Gianasi et al., unpublished data). The resultant HPMA copolymer platinates had a M_w of 25,000–31,000 Da with a platinum loading of 3–10 wt %. In vitro the HPMA copolymer platinates displayed a range of platinum release rates at pH 7.4 and 5.5; from <5%/24 h in the case of the diamino species, which requires lysosomal enzymatic degradation, up to >80%/24 h in the case of the carboxylate, which is a relatively poor hydrolytically labile ligand. Cisplatin and not surprisingly the fast-releasing carboxylate species displayed IC_{50} values of ~10 μg/mL Pt-equivalent against B16F10 cells in vitro, whereas the slow-releasing conjugates were not cytotoxic over the dose range studied. When conjugates were administered i.p. to treat i.p. L1210 tumors, the antitumor activity seen was within the range for free cisplatin. However, when conjugates were administered i.v. to treat subcutaneous (s.c.) B16F10 tumors grown to palpable size, free cisplatin was not active, but the HPMA copolymer platinates bearing carboxylate and diamine platinates showed significant antitumor activity. Activity in the solid tumor model was attributed to the tumor targeting by the EPR effect; a ~60-fold increase in Pt AUC in B16F10 tumor tissue than was achieved after administration of cisplatin (E. Gianasi et al., unpublished data).

Hydrolytically Labile Pendent Chain Linkers

The relatively low pH within the endosomal and lysosomal compartments and the observation that the extracellular, interstitial environment in some tumors is also acidic (267,268) has inspired the development of pendent chain linkers that hydrolytically degrade more quickly at pH values less than 7.4. *Cis*-aconityl acid and Schiff base derivatives are the two predominant types of hydrolytically labile linkers that have been explored. An advantage of conjugating a drug via an acid-labile linker is that free drug alone can be released from the pendent chain rather than amino acid or peptide drug derivatives, which can occur with peptidyl linkers.

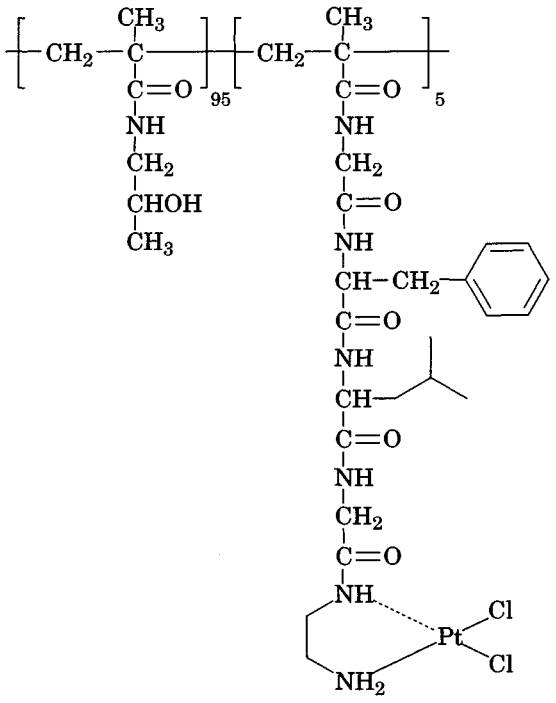

Figure 18. Structure of a HPMA copolymer-platinate (E. Gianasi et al., unpublished data).

The first example employing *cis*-aconityl linkers was the conjugation of daunomycin to poly(D-lysine) and Affi-Gel 701 (amionethyl polyacrylamide beads) (224). Poly(L-lysine) was not selected because it was thought in vivo degradation of this polymer would compete with release of daunomycin (269). When linked to Affi-Gel the *cis*-aconityl linker had a half-life for hydrolysis of 96 h at pH 6 but only 3 h at pH 4. The *cis*-aconityl linker has subsequently been used to conjugate anthracyclines to other synthetic poly(amino acids) (147,270), egg-white lysozyme (271), polysaccharides (127), lectins (272), alginates (synthesis shown in Figure 19) (127) and to monoclonal antibodies (Fig. 20) (149,158,273,274). Daunomycin release from alginate-*cis*-aconityl conjugates (127) incubated in buffers of different pH increased with lowering pH (Fig. 21). It has been pointed out that in some studies uncertainty exists as to which carboxylate is conjugated to the macromolecule (13). However, improved synthetic strategies have been developed so the *cis*-aconityl moiety can be unambiguously conjugated to the polymer at the requisite carboxylate to ensure pH-dependent drug release (272,273). Two possible mechanisms for *cis*-aconityl hydrolysis (275) are based on neighboring group interactions of the *cis*-carboxylic acid at lower pH values that accelerate the hydrolytic release of the conjugated drug (Fig. 22) (11,13).

Hydrazone-derived Schiff base bonds linking doxorubicin [and other drugs (276)] to polymers (277) have been prepared. These adducts may have slowly released doxorubicin while both in circulation and upon endocytosis (277). Analogous doxorubicin-immunoconjugates have also been studied (153,154,278). Doxorubicin conjugated via a Schiff base to oxidized dextran (176,177,279–281) has undergone Phase I evaluation (282). The Schiff base was prepared first by the mild periodate oxidation of dextran to generate aldehyde functionality then by reaction of the amino moiety on doxorubicin.

Other Linkers

Linkers which are not lysosomally degradable peptides or pH-labile moieties have been used to prepare soluble polymer–drug conjugates. As with the aforementioned polymer–drug conjugates, circulation times tend to be increased compared to the free drug. Slow release of drug may occur resulting in prolonged drug action (21,34). Typically the drug can be conjugated directly to an existing pendent chain or endgroup as, for example, the conjugation of paclitaxel to the side chains of poly(L-glutamic acid) (182) or the endgroups of PEG (91–93,283). Drug can also be conjugated by chelation (Figs. 18 and 23) (129,207–214; E. Gianasi et al., unpublished data).

Sometimes an amino acid (e.g., ϵ-aminocaprioticacid or lysine) or an aliphatic spacer serves as a conjugating linker. Amide or ester bonds are generally the limiting degradable bonds in these linkers (i.e., the bond expected to be cleaved to release drug), but carbonate, iminocarbonate, urea, and dithiol moieties along with metal chelates have also been used (12,13,15,20). Pendent chain degradation to release the drug in these conjugates is probably a combination of both enzymatic and hydrolytic release mechanisms. For example, conjugation of *cis*-hydroxy proline to PEG–lysine copolymers (Fig. 24) (284–286) by an amide bond resulted in higher activity compared to conjugates bound by a more hydrolytically labile ester bond (285). Such observations may be due to a combination of release mechanisms or by multivalent interactions. This example also illustrates the possibility for direct conjugation of a drug to an existing polymer side chain.

Conjugates of 5-FU with poly(α-1,4-galactosamine) and *N*-acetyl-α-1,4-polygalactosamine linked with a hexamethlene spacer via urea bonds had drug loadings ranging from 17 to 58 mol % (126). Unfortunately these conjugates were poorly water soluble. Hydrolysis of the urea bonds was faster than the degradation of the glycosidic bonds of the polysaccharide backbone. Administration of the conjugates to animals bearing P388 lymphocytic leukemia resulted in life span increases greater than seen with free 5-FU. This prolongation in survival correlated with increased 5-FU loading and dose of the conjugate. To improve solubility, 5-FU was conjugated to another polysaccharide, 6-*O*-carboxymethyl chitin (287). Conjugation was via amide and ester bonds through pentamethylene linkers and produced 5-FU loading of up to 35.2 mol %. Release from the chitin was slower (6% over 20 h) compared to the chitosan conjugates (25% over 20 h). Again with the P388 lymphocytic leukaemia model (i.p. tumor and i.p. treatment), life span increased with increasing dose of the chitin conjugate. Conjugates of 5-FU via amide, ester, and carbamoyl bonds to poly(α-malic acid) have also been investigated (134).

As mentioned previously, the micelle-forming properties of macromolecules comprised of both hydrophobic and hydrophilic domains can influence the rate of drug release in the lysosome. This property can be exploited to carry

large amounts (up to 37 mol %) of doxorubicin within micelles which spontaneously form with PEG-poly(α,β-aspartic acid) AB-block copolymers (11,100,161,162,165,166, 289,290). Doxorubicin was conjugated by an amide bond directly to the pendent carboxyl moieties of the block copolymer (Fig. 25). Although the M_w of the block copolymer was approximately 14,000 Da and would have been expected to clear relatively quickly from circulation, these conjugates did exhibit increased tumor uptake. Micelle formation involved aggregation of several polymer chains to give constructs with an effective molecular weight exceeding 10^6 Da with a diameter of 50 nm. The hydrophilic PEG existed predominantly on the outer shell and the more hydrophobic poly(aspartic acid)-doxorubicin blocks existed within the micelle structure. The micelle remained stable in the presence of serum proteins (165) with low RES accumulation and prolonged circulation with 10% of the conjugate still in the blood after 24 h (160). These observations were attributed to minimal interaction of the PEG micellar surface with circulating proteins and with PEG-induced micellar stabilization. Biodistribution was dependent on micelle stability because with less stable micelles, free polymer was readily excreted. There was lowered toxicity (1/20 compared with free doxorubicin) and reduced nonspecific accumulation in major organs including heart, lung, and liver. In vivo studies with several murine and human solid tumor models (C 26, C 38, M 5076, and MX-1) resulted in higher antitumor activity compared with free doxorubicin.

It is increasingly evident that multivalent interactions (290) of polymeric molecules at cell surfaces can cause important biological effects (291,292); therefore, it is not necessary to rely on lysosomal delivery to exhibit pharmacological activity. Hence in this case, it is necessary to design linkers that do not degrade specifically in the lysosome. For example, the amino acid lysine has been used to link a carbohydrate, lysoganglioside GM_3 (a sialyl moiety), sphingosine, and a fluorescent probe to poly(glutamic acid) (Fig. 26) (293). This conjugate was designed to act as a multivalent inhibitor of influenza hemagglutinin at receptors on the cell surface. Affinities for carbohydrate–receptor interactions may potentially be increased using polymers conjugated with monomeric carbohydrate ligands to act as multivalent ligands. In vitro studies indicated that this conjugate inhibited the influenza virus by a dual mechanism: (*1*) by the action of the sialyl moieties binding hemagglutinin proteins on the surface of the virus and (*2*) by hydrophobic interactions at the membrane caused by the conjugated sphingosine.

CLINICAL PROGRESS

Although the literature contains many examples of polymeric anticancer conjugates only dextran-doxorubicin (AD-70, DOX-OXD) (282) and three HPMA copolymer conjugates (of molecular weight approximately 30,000 Da) incorporating the peptidyl (Gly-Phe-Leu-Gly) side chain (PK1, PK2, and PNU 166945) have so far entered controlled Phase I/II clinical trials.

In Phase I studies HPMA copolymer-Gly-Phe-Leu-Gly-doxorubicin (PK1, FCE 28068) (see Fig. 6) given once every 3 weeks displayed greatly reduced toxicity compared with free doxorubicin and showed evidence of activity in chemotherapy refractory patients (240,294,295). The maximum tolerated dose (MTD) of PK1 was 320 mg/m^2 (doxorubicin equivalent), and this is 4–5 times higher than the usual clinical dose of free doxorubicin. There was no evidence of the PK1-related cardiotoxicity (despite individual cumulative doses of up to 1,680 mg/m^2 doxorubicin-equivalent), and the dose limiting toxicity was bone marrow suppression. No polymer-related toxicity was observed, and PK1 is currently undergoing Phase II trials. In contrast, the dextran-doxorubicin conjugate (AD-70, DOX-OXD) of molecular weight of approximately 70,000 Da also administered on a thrice-weekly schedule had an MTD of 40 mg/m^2 doxorubicin-equivalent (282), somewhat lower than that seen for doxorubicin alone (60–80 mg/m^2). The severe hepatotoxicity seen after administration of AD-70, DOX-OXD was attributed to uptake of the conjugate by the RES. This could have been simply caused by the choice of dextran as a carrier and/or the fact that doxorubicin was conjugated to dextran via a Schiff base. Although a structural study of a doxorubicin-oxidized dextran conjugate was published after the clinical trial (177), no details of the preparation or properties of the conjugate used in this Phase I study (e.g., loading of doxorubicin, amount of free unconjugated doxorubicin) are available. Further information relating to the formulation used and the kinetics of doxorubicin release might help establish exactly why the increased toxicity was observed. Observations from one study suggest that doxorubicin might be released from dextran prior to tumor cell uptake of the conjugate (176). Reduction of the Schiff base in the dextran–doxorubicin conjugates to give a nonhydrolytic (and presumably nondegradable) amine bond (296–298) did show increased therapeutic indices compared with free doxorubicin, but the antitumor activities were not high enough to warrant continued development (176).

There was no evidence of the PK1-related cardiotoxicity (despite individual cumulative doses of up to 1,680 mg/m^2 doxorubicin-equivalent), and the dose limiting toxicity was bone marrow suppression. No polymer-related toxicity was observed, and PK1 is currently undergoing Phase II trials. In contrast, the dextran-doxorubicin conjugate (AD-70, DOX-OXD) of molecular weight of approximately 70,000 Da also administered on a thrice-weekly schedule had an MTD of 40 mg/m^2 doxorubicin-equivalent (282), somewhat lower than that seen for doxorubicin alone (60–80 mg/m^2). The severe hepatotoxicity seen after administration of AD-70, DOX-OXD was attributed to uptake of the conjugate by the RES. This could have been simply caused by the choice of dextran as a carrier and/or the fact that doxorubicin was conjugated to dextran via a Schiff base. Although a structural study of a doxorubicin-oxidized dextran conjugate was published after the clinical trial (177), no details of the preparation or properties of the conjugate used in this Phase I study (e.g., loading of doxorubicin, amount of free unconjugated doxorubicin) are available. Further information relating to the formulation used and the kinetics of doxorubicin release might help establish exactly why the increased toxicity was observed. Observations from one study suggest that doxorubicin might be released from dextran prior to tumor cell uptake of the conjugate (176). Reduction of the Schiff base in the dextran–doxorubicin conjugates to give a nonhydrolytic (and presumably nondegradable) amine bond (296–298) did show increased therapeutic indices compared with free doxorubicin, but the antitumor activities were not high enough to warrant continued development (176).

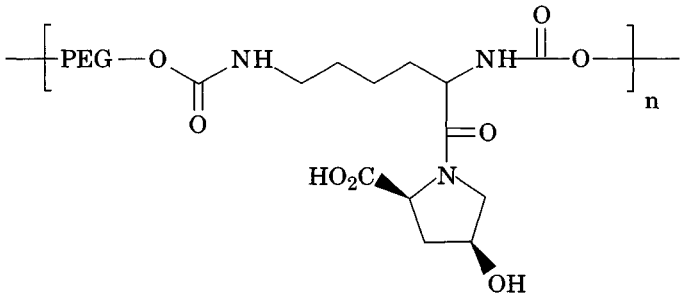

Figure 24. Structure of a PEG–lysine copolymer–hydroxyproline conjugate. Direct conjugation to a polymer side chain (284–286).

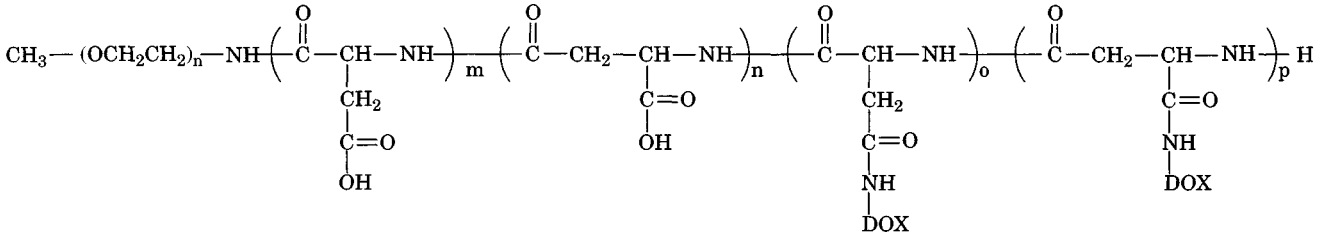

Figure 25. Structure of a PEG/poly(α,β-aspartic acid) AB-block copolymer–doxorubicin conjugate that can form polymeric micelles (11,98).

In Phase I/II trials of the HPMA copolymer doxorubicin–galactosamine conjugate, PK2 (see Fig. 13) (79,248–251), which is currently ongoing, the MTD for bolus (short infusion) administration of PK2 was found to be 160 mg/m^2 doxorubicin-equivalent with a dose limiting toxicity of neutropenia. Using an imaging analogue of PK2, γ camera imaging in humans verified that liver targeting of the conjugate occurred in patients having primary or secondary liver cancer. Liver targeting is now being maximized using a 24 h infusion rather than a rapid infusion.

During Phase I evaluation of an HPMA copolymer–paclitaxel conjugate (PNU 166945, see Fig. 17) (257) 13 patients were treated every 3 weeks with a 1 h infusion of conjugate at paclitaxel-equivalent doses of 80, 100, 140, and 196 mg/m^2. No significant myelosupression was observed up to the highest doses used, but grade 3 neurotoxicity was observed at 146 mg/m^2 paclitaxel-equivalents in one patient. Antitumor activity was observed (refractory breast cancer [1 patient] and disappearance of sigmoid cancer ascites [1 patient]), but the trial was interrupted due to concerns about neurotoxicity.

There are currently several other polymer–drug conjugates in preclinical development, and these compounds will soon to be evaluated clinically as anticancer compounds. They include an HPMA copolymer–camptothecin analogue, an HPMA copolymer platinate (see Fig. 18), poly(glutamic acid)-paclitaxel (see Fig. 8) (182), and a polymeric micelle containing noncovalently bound doxorubicin (168,169).

The two HPMA copolymer conjugates, like their previous relatives, contain the -Gly-Phe-Leu-Gly polymer–drug linkage. Although it is too early to draw definitive conclusions concerning the optimum means of polymer–drug conjugation, it is clear from the clinical experience emerging with PK1 and PK2 that drug conjugation via a peptidyl linker can only liberate anticancer agent after cleavage by lysosomal proteases is able to reduce the toxicity of the bound drug and may produce increased efficacy. Early

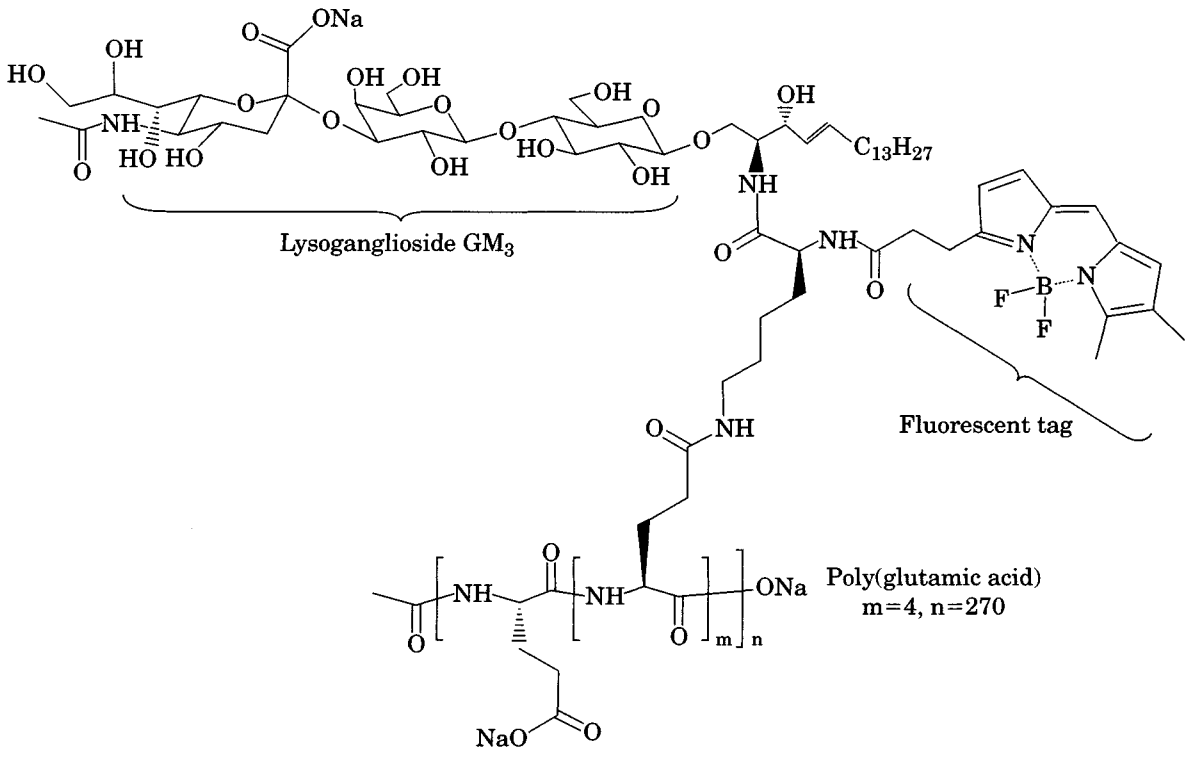

Figure 26. Structure of a multivalent poly(glutamic)–lysoganglioside conjugate designed for multivalent inhibition of influenza hemagglutinin at receptors on the cell surface (293).

clinical trials in oncology are designed to evaluate the safety of the therapy and determine the optimum dose (and schedule) for the later efficacy studies, not antitumor activity. However, the anticancer activity observed with PK1, PK2, and PNU 166945 is very encouraging, particularly as there is still an opportunity to maximize tumor targeting of such conjugates by the EPR effect with the aid of an optimal dosing schedule or polymer conjugate administration. There is also an opportunity to tailor further the rate of drug liberation from HPMA copolymer conjugates to suit the mechanism of action of the individual antitumor agent used in each case.

Most of the polymer–anticancer conjugates thus far described contain a relatively low drug payload (typically 5–10 wt % drug). Higher loading is often prohibited by loss of solubility. The clinical data emerging with the use of HPMA copolymer conjugates would advocate selection of more potent (than doxorubicin) anticancer agents for conjugation. Alternatively there is an obvious need for more hydrophilic carriers with greater solubilizing capacity.

CONCLUSIONS

It is evident from the early studies with anticancer compounds that polymer–drug conjugates have the potential to provide improved chemotherapy. The three basic components of a polymer–drug conjugate (i.e., polymer, linker, and drug) must be optimally matched to maximize therapeutic potential. Although the sophistication of synthetic chemistry can provide a plethora of structures, design based on the biological rationale and incorporating cost and simplicity is imperative if compounds of real clinical value are to emerge. There is a need for continued basic research in chemistry to produce novel, preferentially biodegradable, polymers and to examine the effects of polymer architecture (e.g., dendrimers and hyperbranched polymers) on pharmacokinetics at the whole organism and cellular level. Further effort is needed to understand the details of the biological fate of polymer–drug conjugates. Although considerable progress has been made with peptidyl linkers, there is the possibility that research could fall into the "Me too" trap. New families of linkers designed with a clear rationale for bioactivation are required. Each polymer–drug conjugate is a unique molecule, so increased effort will be needed to prepare uniform conjugates. Systematic and improved analytical methods are required to correlate structure–property relationships required to optimize the biological profile of preclinical candidates.

Undoubtedly polymer–drug conjugates will progress from clinical trials in cancer patients to use in treatment of other diseases. These compounds will only succeed if designed to accommodate the pathophysiology of a chosen disease. Future success in developing polymer–drug conjugates will hinge upon the ability of people in the disciplines of pharmaceutical science (e.g., chemistry, biology, and medicine) to look at drug development with a new perspective focused on the properties of large molecules.

INTRODUCTION

Efficacious delivery of protein and peptide drugs is taking on increasing significance as biotechnology companies mature and begin commercializing their products. As a result, there has been increasing interest in the development of protein and peptide delivery systems. The high level of interest is attributable to several factors. As the pharmaceutical and biotechnology industries consolidate and mature, there is an interest in value-added technologies, which drug delivery systems can provide. There is also an impending stream of patent expirations, which is fueling the demand for the rapid development of new products that may be realized by drug delivery technologies.

Drug delivery systems provide a number of advantages, including one or more of the following:

- Improved patient convenience
- Improved patient compliance
- Cost reduction
- Reduced frequency of administration
- Reduced adverse effect profile
- Patent protection extension
- Potential to reduce product development time and costs
- Possible new and broader therapeutic applications

However, to realize these advantages, it is critical to define clearly why a drug delivery technology is being sought and understand thoroughly the advantages and disadvantages of each delivery system, the unique physicochemical and biological properties of the protein or peptide of interest, and the requirements of the therapeutic indication.

The production of proteins by recombinant technology was an important milestone in the development of this new class of therapeutic agents. Proteins and peptides are poorly suited to the standard oral delivery route for administering small-molecule drugs because of the enzymatic and absorption barriers posed by the gastrointestinal tract; therefore, virtually all protein and peptide drugs are administered parenterally by subcutaneous or intramuscular injection (the immunosuppressant cyclosporine, a cyclic polypeptide, is a rare exception). However, the half-life of these drugs injected parenterally is only a few hours in most cases, necessitating multiple injections per week (typically 3–7) for therapeutic effectiveness. As a result, parenterally administered drugs generally have lower compliance levels than orally administered drugs. One way of improving compliance and minimizing discomfort arising from frequent injections is to couple protein and peptide drugs with sophisticated parenteral delivery systems that reduce the frequency of injection by providing a sustained release of the drug over time. Alternatively, these advantages may be achieved by immediate or sustained delivery to the systemic circulation via nonoral

INTRODUCTION

Efficacious delivery of protein and peptide drugs is taking on increasing significance as biotechnology companies mature and begin commercializing their products. As a result, there has been increasing interest in the development of protein and peptide delivery systems. The high level of interest is attributable to several factors. As the pharmaceutical and biotechnology industries consolidate and mature, there is an interest in value-added technologies, which drug delivery systems can provide. There is also an impending stream of patent expirations, which is fueling the demand for the rapid development of new products that may be realized by drug delivery technologies.

Drug delivery systems provide a number of advantages, including one or more of the following:

- Improved patient convenience
- Improved patient compliance
- Cost reduction
- Reduced frequency of administration
- Reduced adverse effect profile
- Patent protection extension
- Potential to reduce product development time and costs
- Possible new and broader therapeutic applications

However, to realize these advantages, it is critical to define clearly why a drug delivery technology is being sought and understand thoroughly the advantages and disadvantages of each delivery system, the unique physicochemical and biological properties of the protein or peptide of interest, and the requirements of the therapeutic indication.

The production of proteins by recombinant technology was an important milestone in the development of this new class of therapeutic agents. Proteins and peptides are poorly suited to the standard oral delivery route for administering small-molecule drugs because of the enzymatic and absorption barriers posed by the gastrointestinal tract; therefore, virtually all protein and peptide drugs are administered parenterally by subcutaneous or intramuscular injection (the immunosuppressant cyclosporine, a cyclic polypeptide, is a rare exception). However, the half-life of these drugs injected parenterally is only a few hours in most cases, necessitating multiple injections per week (typically 3–7) for therapeutic effectiveness. As a result, parenterally administered drugs generally have lower compliance levels than orally administered drugs. One way of improving compliance and minimizing discomfort arising from frequent injections is to couple protein and peptide drugs with sophisticated parenteral delivery systems that reduce the frequency of injection by providing a sustained release of the drug over time. Alternatively, these advantages may be achieved by immediate or sustained delivery to the systemic circulation via nonoral

or transmucosal routes such as the nasal, pulmonary, vaginal, rectal, and, in some cases, the transdermal routes (e.g., iontophoretic delivery of insulin). Thus, the availability of these new biopharmaceuticals has made their formulation and delivery an important part in the treatment of various disease states.

To address the challenges of protein and peptide delivery, a number of approaches are being pursued. One approach involves providing a controlled or sustained release of the drug by the parenteral route. Controlled delivery implies the incorporation of one or more elements of control on the release of an active ingredient from a dosage form to obtain a well-defined pharmacokinetic profile. A major advantage of controlled-release formulations over conventional dosage forms is the ability to manipulate the components of the dosage form to obtain a particular release profile. Sustained-release formulations are controlled-release dosage forms that have been engineered to release the active ingredient over an extended time period in a well-defined and reproducible fashion (1). As noted earlier, advantages include fewer injections and perhaps a therapeutic benefit for a sustained drug-release profile. For example, a short half-life may be increased either by chemically modifying the protein by coupling it to a moiety such as poly(ethylene glycol) (PEG) or by developing a degradable polymeric sustained-release formulation that would release therapeutic concentrations of the drug over an extended time period as the device degrades. A good example where a sustained drug serum concentration is actually required for therapeutic benefit is the sustained delivery of synthetic analogues of gonadotropin. It was demonstrated that the serum concentration of the drug needed to be above a certain threshold to produce a pharmacodynamic response, testosterone suppression in males and suppression of estrus in females.

Another delivery approach involves using nonparenteral routes for immediate or sustained release. A wide variety of dosage forms have been developed for the delivery of conventional small-molecule drugs for delivery via the oral, parenteral, buccal, transdermal, ocular, intravaginal, intrauterine, pulmonary, and nasal routes. Each of these routes of delivery has its own unique advantages and challenges that are a function of the physiology of the sites. The delivery of proteins via any of these routes requires special considerations that must be borne in mind in the development of protein formulations.

There are several sustained-release formulations of peptides on the market and, to our knowledge, there are no commercialized long-acting formulations containing a protein for humans; however, one long-acting protein-containing parenteral product is available for enhancing milk production in dairy cattle. Also, though there are a number of products for the delivery of proteins and peptides by nonparenteral routes in various stages of preclinical and clinical development, none (except cyclosporine), to our knowledge, have been commercialized for oral administration. One of the key reasons for the absence of novel protein formulations is their fragility and the need for suitable process and formulation approaches to maintain the protein structure while achieving desirable release characteristics. This article reviews the technical considerations in developing delivery products for proteins and peptides, focusing on injectable polymeric delivery systems as an example. Major stability, release, and manufacturing challenges in developing these products are discussed along with approaches to overcome them. Though we focus on polymeric delivery systems here, many of the principles presented are broadly applicable to a variety of peptide and protein drug delivery systems.

PROTEIN AND PEPTIDE STABILITY

Proteins differ from conventional small-molecule drugs in several respects, including size, but one of the most important differences affecting delivery and biological effectiveness is the complexity of protein structure. The full biological activity is dependent on preserving the integrity of this complex structure. The body has evolved ways of maintaining the specificity of action of proteins. This is controlled to a large extent by the different levels of organization within each molecule, that is, the primary, secondary, tertiary, and quaternary structure. Because of the close correlation between protein efficacy and the molecular three-dimensional structure, it is essential to maintain the structural integrity through all the formulation steps of a delivery system and while the drug is released from the dosage form at the site of delivery; otherwise, the activity of the protein or peptide drug may be reduced or lost entirely. Because of the fragile nature of proteins and peptides, the processes involved in the fabrication of the drug delivery systems may damage the protein and therefore, reduce its biological activity or render the protein immunogenic. For example, aggregated human growth hormone has less biological activity than the native monomeric form (2). The issues associated with ensuring the stability of a protein or peptide drug in various matrices have been discussed by several authors (3,4).

Strategies for stabilizing the protein in sustained-delivery systems are often more complex than those for proteins in solution for several reasons. First, the protein must survive the matrix fabrication process steps. It must also remain biologically active in the delivery system for an extended period in vivo where the protein may be subjected to pH, concentration, and temperature conditions conducive to degradation. In fact, overcoming the propensity for proteins to undergo degradation processes during incorporation into the delivery system or after injection into the body awaiting release is one of the key hurdles in bringing delivery systems for these drugs to market. It is therefore important to understand the degradation processes and the effects of protein stability on the biological response and release to devise formulation strategies to preserve protein stability. These approaches may include the addition of stabilizing excipients and the development of fabrication processes for delivery systems that are benign to proteins.

This section provides an overview of protein degradation pathways and discusses protein stability issues associated with the fabrication and delivery of protein drugs in sustained-release systems. Armed with this information, a variety of formulation approaches for developing stable formulations for delivery systems are presented.

Protein Degradation Pathways

The degradation mechanisms that proteins undergo can be divided into two classes, physical and chemical. Chemical degradation results in the modification of the protein's primary structure. In physical degradation, the native structure of the protein is modified by changes to its higher-order structure, that is, the secondary, tertiary, or quaternary structure. Degradation may be facilitated by environmental conditions such as pH, concentration, temperature, and the proximity of surfaces or chemically reactive groups. Examples of protein degradation pathways are shown in Table 1. Chemical degradation processes are usually preceded by a physical process such as unfolding, which then makes usually inaccessible amino acid residues available for chemical reactions.

Physical Instability. Proteins, because of their polymeric nature and ability to form higher-order structures, can undergo nonchemical changes (i.e., changes to the secondary, tertiary, or quaternary structure) that can alter their biological activity. The primary structure of a protein determines the native secondary and tertiary (and higher-order) conformation. In general, in globular proteins, hydrophobic residues are buried in the interior and hydrophilic residues are available near the surface for interaction with the aqueous solvent. Denaturation refers to the loss of the native globular structure and leads to protein unfolding. Once unfolded, newly exposed amino acid residues may interact with their surroundings by adsorbing to surfaces or aggregating with other protein molecules (5).

Denaturation may be reversible or irreversible and is caused by changes in the environment of the protein such as an increase or decrease in temperature, pH changes, the introduction of liquid interfaces by the addition of organic solvents, or the introduction of hydrophobic surfaces. In reversible denaturation, the protein refolds once the denaturing stimulus is removed, for example, unfolding when the temperature is increased and refolding correctly once the temperature is reduced. In irreversible denaturation, the native conformation is not regained by the removal of the stimulus (5). Precipitation often is the final result of self-association or aggregation of protein molecules. The aggregation of insulin has been well characterized and is thought to depend on unfolding of the insulin molecule (6).

Chemical Instability. Chemical degradation processes may occur at several points during the formulation and delivery of an encapsulated protein drug. It is important to be aware that the manifestation of a degradation process may occur sometime after the initial triggering step. For example, the pH of the buffer before freeze-drying can affect the stability of the lyophilized protein formulation (7).

Oxidation. Tryptophan, methionine, cysteine, histidine, and tyrosine amino acid side chains contain functionalities that are susceptible to oxidation. Methionine and cysteine can be oxidized by atmospheric oxygen and fluorescent light (2). Oxidation has been observed both in solution (8) and in the solid state (9). Oxidation of the methionine residues may cause a loss of bioactivity and, in the case of cysteine residues, the formation of nonnative disulphide bonds. Oxidation by atmospheric oxygen or auto-oxidation can be accelerated in the presence of certain metal ions such as copper and iron. Methionine residues under acidic conditions are especially prone to oxidation by reagents such as hydrogen peroxide, producing methionine sulphoxide. Oxidation by peroxide may be a concern if the protein is processed in a manufacturing area that is sterilized using hydrogen peroxide vapor or using equipment that is so treated (10). In this case, experiments must be performed and procedures put in place to ensure that the protein is not oxidized during manufacturing. A procedure for manufacturing sterile microspheres in an environment that was sterilized using vaporized hydrogen peroxide without oxidizing a protein has been described (11). Under conditions of higher pH, other groups, such as disulphide and phenol groups, may undergo oxidation reactions.

Deamidation. Deamidation is the hydrolysis of a side-chain amide on glutamine and asparagine residues to yield a carboxylic acid. The deamidation reaction has been extensively studied and is widely observed in therapeutic proteins and peptides (12). Some protein delivery system processing and formulation conditions that result in an increase in temperature or pH have been shown to facilitate deamidation. The deamidation process is important because of the potential loss in protein activity or function. Deamidation contributes to the reduction in catalytic activity of lysozyme (5) and ribonuclease at high temperatures (13).

Peptide Bond Hydrolysis. Aspartic acid residues have been implicated in the cleavage of peptide bonds, which have led to a decrease in biological activity. When lysozyme was heated to 90–100°C at pH 4, the loss in biological activity was attributed to hydrolysis of Asp-X bonds (5).

Disulphide Exchange. Many therapeutic proteins contain cysteine residues that form disulphide bonds. These bonds are important components of the structural integrity of proteins (14). Incorrect linkages of these disulphide bonds often lead to a change in the three-dimensional structure of the protein and therefore its biological activity. The reaction proceeds in both acidic and alkaline media, but the mechanisms are different. In neutral and alkaline media, the reaction is catalyzed by thiols. Thiols may be introduced during formulation (e.g., mercaptoethanol as an antioxidant) or by degradation of existing disulphide bonds via beta elimination of cysteine residues (15). The aggregation of lyophilized formulations of bovine serum albumin, ovalbumin, β-lactoglobulin, and glucose oxidase was attributed to disulphide interchange (16).

Table 1. Examples of Protein Degradation Pathways

Physical	Chemical
Noncovalent aggregation	Oxidation
	Deamidation
	Peptide bond hydrolysis
	Disulphide exchange
	Covalent aggregation

Protein Formulation Strategies

There is a large body of literature on protein-stabilizing excipients (especially for proteins in lyophilizates and solutions) including a number of excellent reviews on the subject (14,17,18). Some general approaches are reviewed in this section that are useful in developing stable protein formulations for incorporation in sustained-release systems (19,20).

Additives for Protein Stabilization. Stabilizing additives used in the formulation of proteins are diverse and include proteins, sugars, polyols, amino acids, chelating agents, and inorganic salts. These additives can stabilize the protein in solution and also in the frozen and dried states, although not all the additives confer stability under all three conditions. The stabilization mechanism in the solution or frozen state is different from that which occurs in the dried state. For example, carbohydrates in particular have the ability to stabilize proteins in the dried state (18,21). Thus, for many delivery systems that involve a number of formulation and processing steps, multiple additives may be required to produce a stable formulation (18). For example, a stable liquid protein formulation is a usually prerequisite because it will often form the starting bulk material for processing. If subsequent processing steps involve the transformation of the protein from a liquid to a powder by, for example, lyophilization or spray-drying, additional stabilizers may be needed for the dry state (22). Also, additives may be required for maintaining protein stability in a powder upon hydration to ensure stability during release and perhaps long-term storage (16). Approaches have been described to stabilize protein powders during hydration to prevent aggregation in lyophilizates and in polymeric microspheres (7,23–25).

Many additives used in protein formulations (e.g., sugars, salts, amino acids, and polyols) stabilize proteins by a similar mechanism (26–28). Sugars such as trehalose, sucrose, maltose, and glucose have been used as protein stabilizers. Their addition causes an increase in the glass-transition temperature of a number of proteins including collagen, ribonuclease, and ovalbumin (29). Similarly, salts such as potassium phosphate, sodium citrate, and ammonium sulphate have also been shown to increase the glass-transition temperature of proteins, thereby imparting thermal stability. All these additives increase the self-association of protein molecules and reduce their solubility. It has been proposed that these cosolvent stabilizers are preferentially excluded from the surface of the protein, thereby imparting stability (29). On the other hand, stabilizers such as magnesium chloride bind to the protein surface. Cyclodextrins have also been used as stabilizing excipients in protein and peptide formulations (30,31). Hydroxypropyl cyclodextrin (HPCD) stabilized formulations of porcine growth hormone against thermal and interfacial denaturation (32). The mechanism is poorly understood but is thought to involve changes in the properties of the solvent. Cyclodextrins have been found to complex with peptides, resulting in enhanced solubility of the drug (30,31). The addition of heparin, a polyanion, stabilized acidic fibroblast growth factor by increasing the unfolding temperature by 15–30°C by a direct interaction between the polyanion and the protein (33).

Surfactants are frequently added as stabilizers to protein formulations (34). They serve various useful functions in sustained-release formulations. Several commercial preparations of proteins, for example, Nutropin® (recombinant human growth hormone, Genentech Inc.), contain surfactants such as the polysorbates (2). Because of the amphipathic nature of proteins, they have a tendency to adsorb and accumulate at interfaces. This interfacial adsorption may lead to unfolding and eventually loss of solubility, aggregation, and biological activity (35). The addition of surfactants may be an important step in stabilizing the three-dimensional structure of a protein during incorporation into a delivery device, for example, during emulsification processes (36). The surfactant, polysorbate 20, was found to be useful in stabilizing human growth hormone incorporated in a poly(lactide-*co*-glycolide) (PLG) polymer matrix (37). Sustained-delivery devices having relatively hydrophobic surfaces may induce unfolding of the protein by adsorption. In this instance, the addition of a surfactant with a high hydrophilic–lipophilic balance (HLB) would reduce protein adsorption because the surfactant itself would adsorb to the device surface via its hydrophobic moieties, leaving the hydrophilic moieties exposed to the surrounding milieu (34). The ability of a surfactant to stabilize a protein upon rehydration has also been demonstrated (38). Therefore, the addition of a surfactant can stabilize a protein against denaturation during several stages from incorporation to release at the site of delivery.

The addition of certain metals has been shown to confer stability on proteins (39). Cunningham et al. showed that certain transition metals stabilized human growth hormone (hGH) against urea induced denaturation (40). They hypothesized that the presence of zinc in the secretory granules of the anterior pituitary (where growth hormone is secreted) stabilizes the hormone during storage before it is released into the circulation. Johnson et al. showed that an hGH–Zn complex was a viable formulation for encapsulation into a sustained-release formulation of PLG microspheres (25). The hGH–Zn complex was more stable in PLG microspheres compared with hGH in the uncomplexed form. The authors demonstrated in primates (rhesus monkeys) that biologically active protein was released over a 1-month period as determined by measuring sustained serum hGH levels and elevated levels of insulinlike growth factor I (IGF-I), a pharmacodynamic marker for hGH. Although the addition of metals may stabilize some proteins, the presence of metals may also catalyze the oxidation of cysteine residues. To overcome this, chelating agents such as ethylenediaminetetraacetate (EDTA) were added to stabilize a formulation of acidic fibroblast growth factor (33). Under accelerated storage conditions at 45°C, it was shown that the addition of EDTA stabilized a freeze-dried formulation of ribonuclease A (41). Where there is evidence that the presence of trace amounts of metals accelerate protein degradation, the addition of chelating agents should be considered.

Protein Stabilization in the Solid State. Changing the state of a protein or peptide from the liquid to the solid

state by lyophilization or spray-drying increases the storage stability of proteins (17). However, in addition to this obvious advantage, incorporation of the protein into a delivery device in the form of a lyophilized powder may also significantly reduce the potentially damaging stresses to which a protein solution would be subjected. For example, proteins in the solid state would be less susceptible to shear forces that occur during emulsification or atomization steps or denaturation at oil-water interfaces because the protein would not be in solution. These processes are described more fully in the later in this article.

Special precautions should be taken during freeze-drying because the drying process itself will expose the protein to destabilizing stresses; therefore, suitable excipients are often included in formulations for stability during freeze-drying (36). Additives that are normally added to stabilize a formulation that will be lyophilized may include a bulking agent (sucrose, dextrose, mannitol) to prevent collapse of the freeze-dried cake (18). Cryoprotectants are also added to lyophilized formulations to stabilize the protein to freezing (37). Some of the salts, polyhydric alcohols, and sugars described earlier stabilize a protein to withstand the effects of freezing, but additional stabilizers may be required to impart stability during the drying and rehydration steps. Carbohydrates, disaccharides in particular, stabilize proteins during drying (21). Using infrared spectroscopy, it was shown that hydrogen bonding occurs between these dissacharides and the proteins (bovine serum albumin and lysozyme). As the protein becomes dehydrated during the lyophilization process, these disaccharides are thought to act as water substitutes and are able to hydrogen bond to the proteins, thereby maintaining the integrity of the protein. The physical state of the carbohydrate stabilizer is also thought to be important (9,42). A surfactant is often added to facilitate dispersion of the protein and reduce adsorption (and unfolding) of the protein to the walls of the dissolution vessel.

It should be borne in mind that a lyophilized formulation is not stable indefinitely. Over time the protein may become denatured and lose activity. The effect of excipients on moisture-induced aggregation of human serum albumin under conditions designed to simulate the environment within sustained-delivery devices has been investigated (7,19,23,43). The authors showed that the aggregation could be induced via both covalent and noncovalent routes and suggested some rational solutions based on an understanding of the underlying aggregation mechanisms. These approaches included the effect of the buffer pH before lyophilization, the addition of high-molecular-weight polymers such as dextran and carboxymethyl cellulose, the modification of the hydrophilic properties of the delivery matrix to reduce water uptake, and manipulation of the protein molecule itself to chemically alter the residues involved in the degradation pathway. The studies described underline the importance of understanding the underlying degradation process. The more information there is on these degradation pathways, the more likely a rational approach can be successfully applied. Finally, in developing products with commercial potential, the U.S. FDA *Inactive Ingredients Guide* serves as an invaluable resource in identifying additives that have a history of use in approved pharmaceutical products (44).

Protein Stability within a Delivery Matrix

In addition to the considerations given to protein stabilization during the formulation and incorporation processes, the environment that the protein encounters within the delivery device should be considered in the formulation development. For sustained-release or depot formulations, the objective is to have a reservoir of the protein or peptide drug that is released over a period of days to months. Potential interactions between the protein and its surroundings over this prolonged period of time should be investigated during protein formulation. In addition to interactions between protein molecules discussed earlier, important interactions to consider include those between the protein and the matrix such as adsorption and those due to the changing internal environment of the device as, for example, polymer degradation occurs. The nature of these interactions are described in the following section along with formulation approaches to minimize them.

Interactions between the Delivery Matrix and the Protein. The incorporation of protein pharmaceuticals into solid delivery matrices exposes them to a high surface-to-volume environment, creating ample opportunity for adsorption to the delivery device. One obvious drawback of adsorption is that it may severely limit the amount of free unadsorbed protein that is available for release. It has been shown that salmon calcitonin adsorbs to the surface of PLG matrices (45). Another consequence of adsorption may be surface-induced changes in the three-dimensional structure of the protein that could result in a loss of biological activity. A number of factors affect the adsorption of proteins to a solid interface. These include the charges on both the protein and the surface and the effect of the environment, that is the pH, ions present, specificity of adsorption, surface area, and temperature (46). The surface activity of a protein depends on its amino acid composition and three-dimensional structure. The primary structure determines which amino acid residues are exposed to the surface in the three-dimensional structure and are therefore available for interaction with its surroundings. Because proteins are ampholytes, the pH and ionic strength of the surrounding medium will determine the net surface charge and therefore affect the nature of the interaction with the surface. Consequently, there will be a stronger interaction between the matrix surface and the protein when both possess opposite charges.

In aqueous solution, the three-dimensional structure of a protein in its native conformation results in more hydrophobic residues being buried within the interior and more hydrophilic amino acid residues exposed to the aqueous solution. However, when the same protein comes into contact with a hydrophobic surface, there will be an entropic driving force for the hydrophobic residues that are normally buried within the three-dimensional structure to interact with the surface, perhaps causing unfolding or other structural rearrangements. Conformational changes in the protein at a surface may also be driven by electrostatics. The adsorption of a hard protein (characterized by a low adiabatic compressibility, greater hydrophilicity, and high thermal stability) often occurs owing to electrostatics and

thus is less likely to adsorb to a similarly charged surface. A soft protein (characterized by a high adiabatic compressibility), however, can often adsorb to a similarly charged surface because it may experience greater conformational changes in the adsorption process (47,48). The extent and effect of adsorption on the biological activity of a protein is thus protein specific. The adsorption of antibodies on solid matrices in immunoassays suggests that interactions with solid matrices do not automatically result in a loss of activity.

The adsorption isotherms of proteins to solid surfaces display a saturation phenomenon. There is an initial rapid phase of adsorption in a particular medium that eventually reaches a plateau at a given protein concentration and temperature. The saturation point approximates a monolayer, suggesting that there is a fixed number of adsorption sites. The kinetics of adsorption may be controlled by either the transport of the protein to the surface (transport-limited adsorption) or by the intrinsic kinetics of adsorption at the surface (surface-limited adsorption). For example, bovine serum albumin (BSA) adsorption to PLG films was found to be surface-limited (S.M. Butler, M.A. Tracy, and R.D. Tilton, unpublished data).

Adsorption in a sustained-delivery system may be reduced by several formulation approaches. One of the most effective ways of formulating a protein to reduce adsorption to the delivery matrix or surface is the incorporation of a surface-active agent or the addition of another protein to compete for adsorption sites. Addition of albumin to insulin solution was found to reduce adsorption of the latter to solid surfaces. Addition of surfactants such as polysorbate or sodium dodecyl sulphate reduces the interfacial tension at the solid–liquid interface and therefore the driving force for the protein to adsorb (34).

Internal Environment of the Delivery Matrix. Many sustained delivery system matrices utilize biodegradable materials. Therefore, the protein is exposed to a changing environment as the delivery matrix degrades over time. For example, a number of implantable devices have been fabricated from polyesters made from lactide and glycolide monomer units that degrade ultimately to lactic acid and glycolic acid when exposed to water. It is feasible that the generation of acidic oligomers as these materials degrade could cause an increase in the acidity of the interior of the delivery device. The degree of isolation between the interior of the device and exterior will depend on the porosity and geometry of the device (49). There have been few studies to investigate the internal pH of PLG-based devices (50,51), but once implanted, it is unlikely that the interior of a porous device is totally isolated from the perfusion and buffering capacity of physiological fluids. It seems intuitive that if a large molecule such as a protein is able to exit the matrix (by diffusion through polymer networks or pores), then small molecules such as buffer salts or the soluble monomeric or oligomeric degradation products of biodegradable matrices should also be able to diffuse out of the matrix. If transport of acidic degradants out of a device is limited (due to perhaps a low porosity or a large size), it may be necessary to employ formulation approaches to overcome an acidic microclimate within the device. For example, basic salts may be incorporated as a buffering system into the matrix to counteract the increase in acidity produced by the degradation of the polymer into lactic and glycolic acids (52,53).

PROTEIN RELEASE FROM POLYMERIC DELIVERY SYSTEMS

In addition to maintaining the drug stability during processing and release, another key obstacle in producing protein and peptide sustained delivery systems is developing processing and formulation approaches to achieve a target release profile and duration. Developing such approaches begins with an understanding of the microstructure of the delivery system and the mechanism of release of macromolecules from the device.

Sustained release of biologically active macromolecules from biocompatible polymer matrices was first described by Langer and Folkman in 1976 (54). Prior to this discovery, it had been shown that small molecules (<600 Da) could be released slowly from polymeric materials (3,55). However, it was thought that macromolecules such as proteins and peptides were too large to slowly diffuse through polymeric materials because of their low porosity even after swelling. Langer and Folkman (54) showed that by solvent casting normally impermeable hydrophobic polymers in volatile solvents containing powdered macromolecules, molecules of nearly any size could be released for periods of greater than 100 days. The encapsulation of macromolecules in this manner resulted in the formation of a series of interconnecting channels within the polymer matrix that were large enough to permit macromolecular release and sufficiently tortuous to allow release in a controlled, prolonged fashion. A variety of polymers have been used to demonstrate macromolecular sustained release including nondegradable ethylene-vinyl acetate copolymers, degradable lactide–glycolide copolymers, and even hydrogels such as poly(vinyl alcohol) (3,54,56,57). Hydrogels typically release proteins for shorter periods than more hydrophobic polymers (3,54).

It has been found from microscopy that matrices produced by the processes described here consist of two major phases distributed throughout the device, one consisting of the macromolecule drug and the other consisting of the polymer (58). The drug release from nondegradable polymers occurs by dissolution and diffusion through interconnecting pores formed by the macromolecules themselves (54,55,58–66). Thus, the size of the drug powder and loading are important factors affecting the release rate. Saltzman and Langer (61) presented a detailed model for macromolecule release from nondegradable systems in which release by diffusion was due to the following variables: drug physical properties such as the drug concentration in the pores, its solubility, its aqueous diffusion constant, and the effect of the pore geometry and connectivity, including the porosity and the size distribution and shapes of the pores. Release from biodegradable matrices is determined by the polymer degradation and erosion rates in addition to diffusion (Fig. 1). Drug stability also may influence release because the solubility of nonnative forms, such as protein or peptide aggregates, is often reduced.

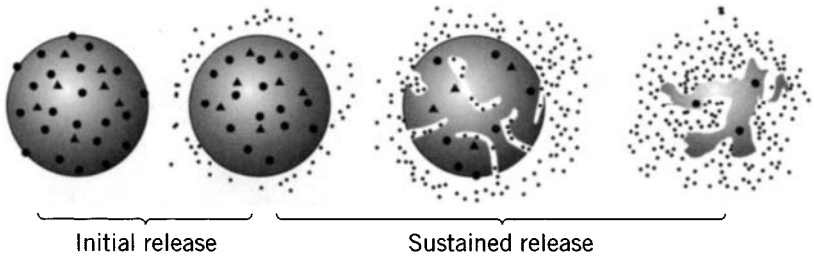

Figure 1. Mechanism of release from PLG microspheres. The initial release phase is controlled by diffusion of drug molecules that are on the surface or have access to the surface via pores in the microsphere matrix. The sustained-release phase is determined by the erosion of the polymer. As the polymer erodes, entrapped drug molecules are released from the delivery matrix. *Source:* Ref. 25.

Interactions between the drug and the polymer may also impact release whether or not there is an affect on drug stability. For example, the sustained release of leuprolide from biodegradable PLG microspheres (Lupron® Depot) is thought to be due, in part, to a charge interaction between the peptide and the carboxylic acid endgroup of the PLG used in the formulation (67,68).

Strategies for Obtaining a Desired Release Profile

The effects of various process and formulation variables on drug release and pharmacokinetics from biodegradable systems have been studied extensively by several authors (56,57,62,68). One of the most commonly used biodegradable polymers is PLG because of its biocompatibility and history of use in pharmaceutical products. The release profiles from PLG microspheres are usually described by two exponential curves attributed to drug diffusion and polymer erosion. After injection, there is an initial release phase, or "burst," that is thought to be dependent on dissolution and diffusion of drug at or near the surface of the microspheres. There may or may not be a lag period of little or no drug release depending on the characteristics of the polymer. The secondary release phase depends on erosion of the polymer, thereby exposing remaining encapsulated drug for dissolution and release (69). The onset and duration of the secondary release phase is modulated by polymer molecular weight, lactide glycolide ratio, and endgroup chemistry.

The initial release phase is affected by factors such as drug loading, drug particle size, drug solubility, microsphere diameter, and porosity. When the microsphere is hydrated after injection, for example, any entrapped drug that is present on the surface or that has unconstrained access to the surface via microscopic pores and channels will dissolve and diffuse out of the microspheres. This process usually occurs within 24–48 h after hydration. The proportion of encapsulated drug that is released during the initial phase is important for a number of reasons. Firstly, a large burst may pose safety and clinical concerns for narrow-therapeutic-index drugs. Secondly, if a significant proportion of the entrapped drug is released in the initial phase, there may be insufficient drug available for release later to provide a therapeutic benefit. Finally, there is also an economic imperative to reduce the burst and therefore, minimize drug wastage. Thus, formulation and processing approaches have been developed to minimize the initial burst. Formulation approaches for proteins and peptides include reducing drug solubility by complexing the drug for example with metal ions such as zinc (25). Alternatively, processing approaches may be used, for example, utilizing additional processing steps such as sonication or homogenization to reduce the encapsulated drug particle size (11,70). Finally, particles may be coated to reduce the fraction of drug immediately soluble.

The sustained-release phase is controlled by polymer erosion, and this phase is therefore controlled by the factors that affect polymer degradation (53,71–76). PLG polymers degrade by hydrolytic chain scission. This degradation process is affected by factors such as water sorption and solubility, the polymer morphology (crystalline or amorphous), device geometry (monolithic implants or microspheres), glass-transition temperature, molecular weight, chemistry (e.g., lactide glycolide monomer ratio, presence of residual monomer, and endgroup chemistry), the nature of encapsulated drug (acidic, basic), additives to the polymer phase, and the site of implantation (77). If polymer degradation and therefore erosion is delayed significantly (for example, for a high-molecular-weight, high-lactide-content polymer) so that the diffusion and erosion phases do not coincide, there is a lag phase with little or no drug release. Okada (67) showed that the addition of a hydrophilic surfactant, monoleic acid, had no impact on the lag phase but reducing the molecular weight of the PLG from 22 to 14 kDa eliminated the lag phase. Pulsatile release may be desirable for vaccine formulations but for most protein applications, a continuous-release profile is preferred. Vert et al. (78) demonstrated that in microspheres, degradation proceeds via a homogeneous hydrolytic process in which the degradation rate is the same throughout the microspheres. In monolithic implants, however, there is a heterogeneous process where the polymer degradation rate is faster within the core than it is on the outside (49). It has been suggested that the difference in degradation rate may be due to a buildup of self-catalyzing acidic monomers or oligomers within the core of the device. Also, certain additives have been found to affect the degradation rate of some PLGs (79). For example, the incorporation of slightly soluble basic salts such as zinc carbonate decreased the degradation rate of PLG microspheres in vitro and in vivo, probably because of the neutralization of acidic oligomers (52,53).

Characterization of Release from Delivery Systems

In addition to understanding the in vitro physical and chemical characteristics of the protein and the delivery system, it is important to understand and characterize drug release from a delivery system in vivo as part of the development of a sustained-delivery product for proteins

and peptides. This is invaluable in the development and selection of formulations with desirable release kinetics. It has been reported that in vivo release in small animal models such as rats was more predictive of release in primates and humans than in vitro release tests for proteins (11). As a result, microsphere formulations of rhGH were evaluated with respect to release in vivo. Once formulations with desirable release kinetics were identified, an in vitro release method was developed that correlated with in vivo release for quality control purposes. Kamijo et al. (80) also used in vivo models to confirm release of leuprolide from PLG microspheres and developed an in vitro release test to mimic in vivo release data as a quality control method for clinical samples. Variables that they investigated to develop a suitable in vitro test included the buffer pH, buffer salt concentration, the addition of additives such as mannitol or sodium chloride, and the mass of microspheres.

Drug release in vivo is affected by the physiology of the site of delivery because for systemic delivery, the drug, after being released from the delivery system, must be transported through the tissue at the site of administration before being absorbed into the bloodstream. Thus, before evaluating release from the delivery system, it is important to first characterize the drug absorption from the administration site and systemic clearance as a function of concentration and time by administering the drug as a solution bolus injection. Because the process of drug absorption from the administration site may depend on the kinetics of drug release, evaluating the pharmacokinetics of sustained delivery of the drug via osmotic pumps implanted in animals is useful in interpreting results from a new formulation of a delivery system.

In interpreting in vivo release data from sustained-delivery systems, it is important to characterize the expected biological responses. Parenteral introduction of any dosage form will induce a tissue response in vivo as a natural consequence of injection and the body's recognition of the presence of a foreign body (77,81,82). Release from the device may be affected by this response, so it is important to characterize its time course to aid in interpretation of release data (53,75). Also, a human protein or peptide is a foreign one to animals. Thus, they are expected to elicit an antibody response to the drug. The presence of antibodies (which reach measurable levels as soon as a couple of days after administration for IgM and about 7–10 days for IgG antibodies) may limit or prevent the ability to measure human protein levels. Antibodies may either impact the circulating levels of the drug or interfere with the assay (such as radioimmunoassays or ELISAs) used to quantify the drug in serum. Procedures have been developed to suppress antibody formation allowing the study of release from animal models beyond 7 days (83). Transgenic animal models may also be used to assess release and formulation immunogenicity in an animal producing circulating levels of a human protein (83).

PROCESSES FOR MAKING POLYMERIC DELIVERY SYSTEMS

A variety of processes have been developed to encapsulate drugs to produce biocompatible drug-containing polymeric matrices for sustained release that are capable of being implanted or injected. These processes most often involve the preparation of a drug solution, suspension, or emulsion with the polymer in solution followed by an extrusion or compression molding step for implants or a droplet formation step for microspheres. Processing solvents are removed by extraction and/or drying to produce the final microsphere or implant product. The fabrication steps must be performed under carefully controlled conditions of temperature, pH, and mixing to preserve the integrity of fragile proteins and peptides (84). Emulsion, coacervation, and extrusion/spray methods are described in the following sections with an emphasis on the protein stability implications of processing via these approaches.

Emulsification

Most microsphere fabrication processes are based on emulsification. Briefly, the water-soluble drug is dissolved in an aqueous solution (or water), and the polymer is dissolved in an organic solvent such as ethyl acetate or methylene chloride. A key characteristic is that the protein is processed in solution. The two solutions are mixed in the appropriate ratio to create a water-in-oil (w/o) emulsion. This primary emulsion is then again emulsified into a second aqueous solution containing an emulsifier such as poly(vinyl alcohol). The final product is a water-in-oil-in-water (w/o/w) emulsion (85). The organic solvent is then removed from the emulsion by evaporation under reduced pressure, filtration, or a moderate increase in temperature. The microspheres are then harvested and dried. There are variations on this basic approach where a range of aqueous and organic solvents and a range of aqueous phase emulsifiers are used. Alternatively, a single emulsion may be used for drugs that are dissolved or suspended in the polymer solution by forming an oil (containing dissolved polymer with dissolved or suspended drug) in water emulsion to create the microsphere droplet that is hardened as just described.

A commercial microsphere formulation of the peptide leuprolide acetate called Lupron® Depot is manufactured using a w/o/w double-emulsion method (56,68). Briefly, as depicted in Figure 2, the leuprolide acetate (Luprorelin) and gelatin are dissolved in water and added to a solution of the PLG polymer (in methylene chloride). The mixture is emulsified to produce a water-in-oil emulsion. This primary emulsion is then emulsified in an aqueous solution of poly(vinyl alcohol). The resulting w/o/w emulsion is stirred gently until the methylene chloride solvent evaporates and the wet microspheres are washed, collected, and freeze-dried. During the washing process, mannitol is added as an anticaking agent to prevent microsphere aggregation during drying and storage of the vialed commercial product.

The formation of an emulsion and its associated interfaces can create the potential for denaturation of fragile proteins and some peptides resulting from the use of mechanical agitation to facilitate formation of the droplets, exposure to organic solvent interfaces, and significant fluctuations in temperature, concentration and pH. There are a number of reports on the damaging effects on proteins of emulsification and exposure to organic solvent/aqueous in-

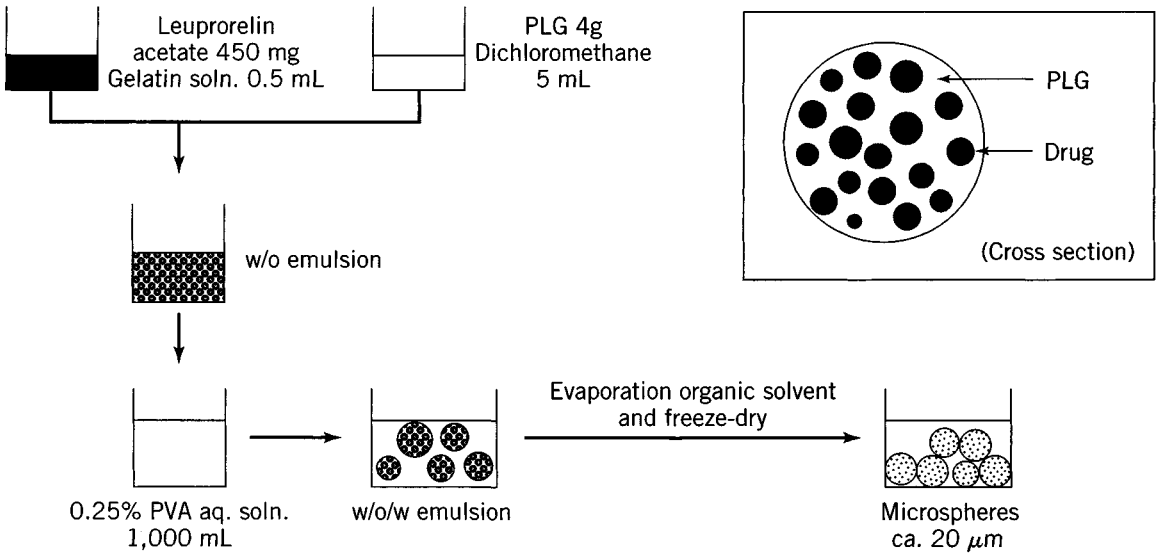

Figure 2. Schematic diagram of the double-emulsion process used to manufacture Lupron Depot®. The primary emulsion consists of leuprorelin acetate in an aqueous solution containing gelatin dispersed in a solution of PLG in methylene chloride. The water-in-oil emulsion is then emulsified in a solution of poly(vinyl alcohol) (surfactant and stabilizer). The microspheres are formed by evaporation of the methylene chloride, which is the continuous phase of the primary emulsion.

terfaces (86–88). In some cases, though, proteins have retained most of their biological activity after incorporation by an emulsion process (66,89). Emulsification is achieved by disrupting a mixture of the aqueous solution that contains the protein drug with other water soluble excipients and the organic water-immiscible phase that contains the polymer or matrix material. Emulsion droplets are formed by the input of energy, which may be mechanical, as with a homogenizer, or ultrasonic, with the use of an ultrasonic probe.

Formation of emulsion droplets is an energy-intensive process. It is initiated by film formation, generation of surface waves, deformation of the aqueous/organic solvent interface, and cavitation. Turbulence created by high-speed homogenization can cause the disruption of the interface and droplet formation. Cavitation is the main process by which ultrasonic waves form emulsion droplets, and it is the sudden formation and collapse of bubbles containing vapor that results in the generation of high pressures on the order of 10^{10} Pa and shock waves. It is the combination of high pressures, intense shock waves, and the dissipation of both over a short period that causes the formation of droplets. The energy that is generated is accompanied by an increase in temperature. Although these conditions may be short-lived, damage can still be done to the protein (90). Loss of protein activity or potency is often observed after encapsulation using these steps. The high shear rates that are generated during emulsification may be enough to cause foaming (adsorption of the protein at the air–water interface or at the aqueous–nonaqueous interface of the emulsion droplets) (9). As a result, emulsion processes are best suited for peptides and proteins that are sufficiently stable to these conditions. One advantage of an o/w versus a w/o/w emulsion process is that the protein may be encapsulated starting with a suspension rather than a solution of the drug in the polymer solution. Proteins in the solid state are less sensitive than proteins in solution to many mechanisms of degradation that may occur during emulsion, such as shear-induced denaturation.

Also, owing to the high cost of protein and peptide drugs, a high efficiency of incorporation of the protein or peptide into microspheres during processing is an important objective. This is particularly a concern for emulsion processes utilizing solvents for the protein or peptide during the last emulsion step. For example, proteins are soluble in water, which is the solvent used in the second emulsion of the w/o/w process. Thus, the process must be optimized to minimize loss of the protein during this process step.

Coacervation

Microparticles containing a protein may also be formed by coacervation. In simple coacervation, a hydrocolloid containing the protein is desolvated by the addition of another substance (such as a salt or an alcohol) that competes for the solvent by virtue of its higher hydrophilicity, solubility, or concentration. In complex coacervation, the charge of the hydrocolloid is opposite to that of the competing substance so that on addition of the latter, a complex of the two is formed, and the mixed coacervate is separated by dilution (91). The microcapsules formed are then "cured" by the addition of a cross-linking agent such as glutaraldehyde. Hydrocolloids that are used in pharmaceutical formulations include gelatin, acacia, and chondroitin sulphate (92). For example, cytokines have been encapsulated in gelatin–chondroitin sulphate microspheres. The cytokine IL-2 (interleukin 2) was dissolved in chondroitin sul-

phate solution, and a solution of gelatin was added to form microspheres. The microspheres were then cross-linked using glutaraldehyde. In addition to the stresses that the protein molecules undergo as a result of pH changes during the coacervation process, the cross-linking step with glutaraldehyde is indiscriminate and cross-links the microsphere matrix as well as the encapsulated protein or peptide drug. This lack of selectivity accounts for some of the loss in bioactivity of protein drugs encapsulated in microspheres that utilize a chemical cross-linking process.

Another coacervation method for preparing PLG microspheres was described by Cleland and is shown in Figure 3 (93). In this process, the PLG polymer is dissolved in an organic solvent, and the drug is either dissolved in an aqueous medium and added to the polymer solvent or dispersed as a solid in the polymer solvent. The emulsion or dispersion is then added to a nonsolvent for both phases

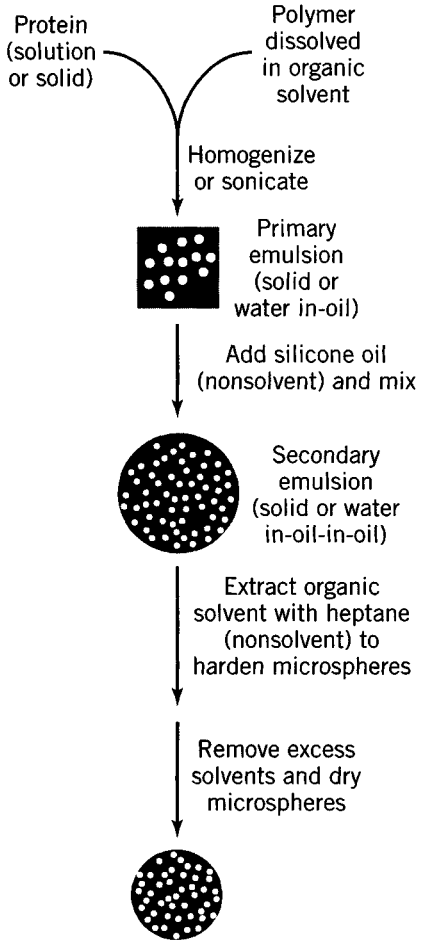

Figure 3. Schematic diagram of a coacervation process for the production of PLG microspheres. Silicone oil is a nonsolvent for methylene chloride; therefore, the primary emulsion can be emulsified in silicone oil to form a water-in-oil(methylene chloride)-in oil (silicone oil) emulsion. The microspheres are formed by extracting the methylene chloride from the primary emulsion droplets. This is achieved by the addition of heptane, which is a solvent for methylene chloride but a nonsolvent for silicone oil. *Source:* Reproduced from Ref. 93.

(e.g., silicone oil) and emulsified to give a water-in-oil-in-oil emulsion or a solid dispersion-in-oil-in-oil. A second nonsolvent for the outer oil phase (e.g., heptane) is then added to the double emulsion to extract the organic polymer solvent (e.g., methylene chloride) to harden the microspheres, and the silicone oil is then removed and the microspheres are dried. As discussed in the section on emulsions, steps in which immiscible phases are mixed must be carefully evaluated for their effects on the stability of the drug being encapsulated. In general, higher efficiencies of drug incorporation compared to w/o/w or w/o emulsions are expected from this coacervation approach because the last water phase is replaced with silicone oil and heptane, both nonsolvents for proteins and peptides.

Extrusion and Spraying Methods

Extrusion or spraying methods may be used in the fabrication of drug delivery systems to form droplets or in the formation of monolithic injectable delivery devices (85). In the former case, where extrusion or spraying is employed to form microspheres, the core material or matrix containing the protein drug, incorporated as a solution or particulate, is ejected from the orifice of a fine tube, syringe, or nozzle to form microdroplets. For example, in spray-drying, microspheres are produced by atomizing the polymer solution containing the drug at an elevated temperature to evaporate the solvent. The size of the droplets and, therefore, the final dosage form depends on the properties of the liquid (melt, solution, or suspension) to be sprayed and on the operating conditions of the extruder such as orifice diameter and jet velocities (94). The main considerations as far as the stability or integrity of protein is concerned are the processing conditions such as the melting temperature if a melt extrusion method is employed (84), the temperature for spray-drying processes, and the effect of the high shear forces that may be generated from the orifice at high jet velocities. Processes for producing sustained-release implants that maintain peptide and protein activity have been described in the literature. For example, Fujioka et al. (95,96) describe a low-temperature process for preparing an injectable rod implant containing α-interferon.

The ProLease® process, a spray method of producing microparticles containing proteins using a cryogenic process, has also been described (70). In this method, as depicted in Figure 4a and 4b, the protein drug is incorporated as a lyophilized powder, and all manipulations involving the matrix polymer (PLG) and the protein are performed at low temperatures ($\leq -80°C$). The fabrication process may be divided into two distinct processes. In the first process, the protein is formulated to form a stable, lyophilized product. During the protein-formulation process, stabilizing excipients such as surfactants or sugars may be incorporated. In the case of Nutropin Depot, hGH is complexed to zinc to form a Zn–hGH complex with reduced solubility. The encapsulation of this complexed form was demonstrated to stabilize hGH against aggregation postencapsulation (25). In the second part of the fabrication process, the protein powder is dispersed in a solution of the polymer in a solvent such as ethyl acetate, acetone, or methylene

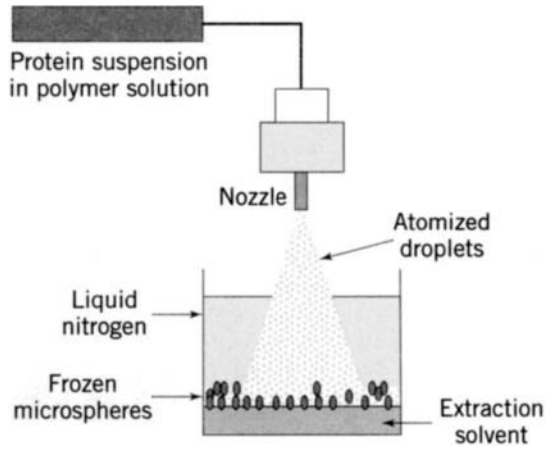

Figure 4. (**a**) Schematic diagram of the ProLease® encapsulation process (laboratory scale). The lyophilized protein formulation is dispersed in a solution of the PLG polymer and then atomized into a vessel containing frozen ethanol overlaid with liquid nitrogen. The droplets freeze as they travel through the cold nitrogen gas and liquid nitrogen and settle on top of the bed of frozen ethanol. As the ethanol melts, it extracts the methylene chloride (which is miscible with ethanol), and the microspheres harden. (**b**) Process steps in the production of ProLease® microspheres. The bulk protein may be formulated by the addition of stabilizing excipients or release modifiers or exchanged into a compatible buffer, spray-frozen, and lyophilized. The spray-freezing is performed with liquid nitrogen, and freezing occurs very rapidly. This rapid freezing may arrest degradation processes. The lyophilized drug is encapsulated as described in (**a**), and the dried microspheres are collected as a white or off-white, free-flowing powder and vialed. *Source:* Ref. 25.

chloride. The polymer and protein powder dispersion is homogenized to give a uniform suspension and then atomized over a bed of frozen ethanol overlaid with liquid nitrogen. The suspension droplets freeze as they travel through the liquid nitrogen and settle on the bed of frozen ethanol. The temperature of the frozen ethanol is increased, and the ethanol melts. Ethanol is miscible with the polymer solvents, so the polymer precipitates as the ethanol extracts the polymer solvent from the droplets. This solvent extraction process causes the microspheres to set and harden, and the microspheres are harvested by filtration. The wet microspheres are vacuum dried and vialed as a white or off-white free-flowing powder.

This fabrication process has several important benefits; first, the protein is in the more stable dry form, and any degradation processes that it is liable to undergo even in the dry state are hindered by the very cold temperatures. Additionally, stabilizing excipients may be included in the formulation during the lyophilization process. Because there are no aqueous phases, the protein is not subjected to freeze–thaw stresses or organic–aqueous solvent interfaces (which are present in emulsion-based processes) where some proteins may denature. This process effectively solves the issue of protein denaturation during incorporation or fabrication, provided a stable lyophilized formulation is available. It has been used to produce a stable microsphere formulation for hGH (25).

PROCESS SCALE-UP, MANUFACTURING, AND REGULATORY CONSIDERATIONS

The previous sections discuss approaches for stabilizing proteins, making polymeric sustained-delivery systems, and obtaining desirable release kinetics. Another major hurdle in developing a product is establishing the capability to produce the product in sufficient quantities for clinical testing and commercialization. This section reviews scale-up, manufacturing, and regulatory considerations in developing delivery systems for proteins and peptides, with a focus on polymeric microsphere systems for parenteral administration.

Scale-Up Considerations

The processes described in the previous sections are scalable. As noted in earlier sections, commercial products for peptides produced by emulsion and extrusion processes are on the market. Herbert et al. (97) described the scale-up of a cryogenic spray process for making microspheres. An effective scale-up effort begins with a detailed understanding at the laboratory scale of the effects of process unit operations on product characteristics and performance. Based on this knowledge and an estimate of the commercial scale batch size, suitable scalable unit operations can be selected and the operation conditions optimized to achieve the desired product characteristics. The equip-

ment used at the small scale may not be suitable at larger scales owing to, for example, higher throughput requirements. For example, sonicating probes often used to produce microspheres are not easily scalable to the batch sizes usually required; therefore, it is prudent to select equipment scalable to commercial scale at the initial process scale-up stage (98). Table 2 compares unit operations used for the ProLease® process at the small, laboratory scales and at the large scale (11). In scaling up the process from the lab scale, unit operations that were scalable to commercial scale were selected and combined to produce a sterilizable, enclosed process suitable for producing sterile microspheres with the characteristics of the lab scale batches. Selecting scalable unit operations as early as possible in development will help minimize unforeseen effects of processing variables on microsphere performance. For example, adding, removing, or changing a unit operation may cause a subtle change in the porosity or surface characteristics of microspheres affecting release.

One of the prerequisites of successful scale-up and process development is having a comprehensive microsphere characterization scheme in place. It is essential to understand the effects of various fabrication variables on the physicochemical properties of the microspheres and, if possible, to relate these physicochemical properties to a biological performance criterion. Some physical properties that should be characterized include particle composition (drug load, residual solvents), particle size (volume and number mean or median, polydispersity or other measure of diameter distribution), microsphere morphology (by, for example, microscopy), particle density, particle porosity, polymer glass-transition temperature, molecular weight, and encapsulated protein integrity. It is often valuable to relate one or more of these physical attributes to microsphere performance characteristics such as in vitro release kinetics or in vivo pharmacokinetic or pharmacodynamic criteria. For example, the effect of various process variables on C_{max} (the maximum serum protein concentration) may be evaluated. With leuprolide acetate microspheres, it was shown that a reduction in particle size had an effect on initial release although the effect was small and not directly proportional to the surface area of the microspheres (68).

The use of statistical experimental design during the scale-up of microsphere fabrication processes is useful in optimizing process operating parameters. One of the advantages of this approach is that key fabrication variables and relationships between them can be identified with a relatively small number of experiments (99). This approach is ideal for troubleshooting complex processes where there are a large number of variables to study with limited time and drug supply. For example, important process variables in emulsion processes include the polymer and drug concentrations, the emulsifying agent, processing temperature, volumes of the oil and water phases, the mixing rate and time, the extraction solution composition, filtration device, and drying method (100). Key variables for spray methods include the mixer speed, homogenization and atomization pressures, the atomization nozzle type, and the extraction solvent and drying temperature/time profiles. Figure 5 shows the results of optimizing processing parameters for two unit operations of the ProLease process using experimental design methods (11). C_{max} was a sensitive variable reflecting improvements in the amount of protein initially released from the microspheres as the process conditions were optimized.

Manufacturing Considerations

For commercial manufacture, the fabrication process for parenterally administered polymeric protein and peptide delivery systems must be performed under well-controlled aseptic conditions to produce a sterile product because the final product cannot be sterilized by autoclaving or γ-irradiation after manufacturing and vialing (called *terminal sterilization*). Either terminal sterilization process may degrade both the drug and the polymer. A common approach for aseptic manufacturing in the pharmaceutical industry is to produce the drug product in a Class 100 clean room. A concern with this approach is the challenge of ensuring sterility in an environment where personnel can come in direct contact with the product during manufacturing.

A new approach to resolving the issue of sterile microsphere production is to couple isolation (or barrier) technology to the microsphere fabrication process (11). Isolation technology has been used extensively in microbiological testing and it is an effective way of maintaining the sterility of a drug product while providing handling access. An isolator is a soft- or hard-walled enclosure in which the environment may be controlled for particulate count, sterility, temperature, and humidity. The enclosure provides a barrier between personnel handling the product and the product itself, providing increased sterility assurance compared to a traditional clean room. Asepsis is maintained within the isolator by the use of vapor-phase hydrogen peroxide (VHP). Filters and various air treatment devices are attached to control the particulate count, temperature, and humidity. Reaction vessels may be autoclaved and transferred aseptically to the isolator using transfer ports. So-

Table 2. Microsphere Process Development and Scale-Up

Unit operation	Laboratory-scale process	Large-scale process
Protein spray freeze-drying	Ultrasonic spray nozzle/lyophilizer	Air atomizer/lyophilizer
Protein particle size reduction	Probe sonicator	High-pressure homogenizer
Microsphere droplet formation	Ultrasonic spray nozzle	Air atomizer
Solvent extraction	Frozen ethanol bed at $-80°C$	Temperature-controlled stirred tank containing liquid ethanol
Residual solvent removal	Vacuum dryer	Vacuum dryer

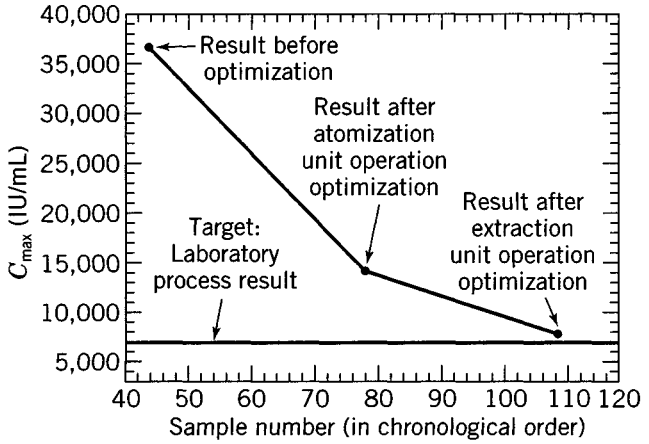

Figure 5. ProLease® process optimization. A target level of a critical performance characteristic (C_{max} in an animal model) was set based on the laboratory scale process. Samples 42–79 show the effect of varying atomization conditions on the C_{max}, and samples 80–110 show the effect of optimizing the extraction conditions combined with the optimized atomization settings. The optimization process was performed using a statistical design approach. *Source:* Ref. 11.

lutions may be sterile-filtered directly into the reaction vessels within the isolator.

Additionally, equipment such as lyophilizers, filter dryers, and filling machines may be coupled directly to the isolator, ensuring that the sterility of the microsphere product is maintained. The use of isolation technology enables the operation of complex, multistep microsphere production processes with a high degree of sterility assurance. Figure 6 shows a schematic of a manufacturing suite in which a microsphere production process is coupled to an isolator for aseptic manufacturing (11).

Regulatory Considerations

One of the considerations in manufacturing microspheres is minimizing the residual solvent and residual polymer monomer content in the microspheres. It has been suggested that bulk PLG polymers should be treated after manufacture to remove residual monomer or oligomers that may catalyze chain scission and, therefore, polymer erosion. Virtually all microsphere fabrication processes require the use of an organic solvent such as methylene chloride or ethyl acetate for polymer dissolution. Acceptable residual amounts of these solvents are determined by the regulatory agencies. For example, the International Conference on Harmonization (ICH) guideline for permissible methylene chloride content is 6 mg per day (101); unless it can be shown that the residual solvent is released in a sustained fashion over several days, the effective limit is <6 mg of methylene chloride per dose. Other solvents such as ethanol or other alcohols may not pose a direct safety hazard but may have a significant impact on the stability of the microsphere product. For example, high residual ethanol levels may reduce the glass-transition temperature of the polymer, which could impact the physical stability of the microspheres, causing them to agglomerate or clump either immediately or under long-term storage, and may result in poor injectability. Additionally, the presence of residual solvents at high levels may have a direct impact on encapsulated protein stability. Key regulatory issues in developing peptide products were reviewed by Niu and Chiu (102).

ADMINISTRATION OF MICROSPHERE DELIVERY SYSTEMS

The microspheres are vialed as a free-flowing powder and need to be resuspended in an aqueous medium before injection. To ensure that the microspheres do not sediment when dispersed in the injection vehicle, it is usually necessary to use a viscous medium. One of the most widely used suspending agents is a soluble, substituted cellulose, carboxymethyl cellulose. It is soluble in aqueous media at physiological pH. It is often necessary to add a wetting agent such as a hydrophilic surfactant to the vehicle to facilitate microsphere dispersion. Additionally, inclusion of a tonicifier and buffer are advisable to ensure that the microsphere suspension is isotonic and at (or close to) physiological pH upon injection. Successful injection of the microsphere dispersion is affected by factors such as microsphere diameter, microsphere concentration, and needle gauge. Large microspheres, or a high microsphere concentration, may cause clogging of the needle; therefore, it is important to conduct the appropriate studies to determine the optimum combination of microsphere diameter, concentration, vehicle, and needle gauge for successful injection.

SUSTAINED-RELEASE FORMULATIONS OF PEPTIDES AND PROTEINS

There are several sustained-release formulations of peptides (luteinizing hormone–releasing hormone [LH-RH] analogs) on the market. However, there is only one long-acting protein formulation, Posilac® (bovine somatropin), for increasing milk production in dairy cattle. Incorporating proteins into sustained-delivery systems has been a significant challenge compared to smaller peptide drugs because of the relative instability of proteins and the need to maintain their fragile three-dimensional structure for biological activity. Alkermes, Inc., in collaboration with Genentech, Inc., are in late-stage clinical trials with a protein sustained-release formulation for humans of rhGH (Nutropin Depot®). This section describes several products. More details on these and others can be found in the literature or directly from the companies producing them or their Web sites (103).

Lupron Depot®

One of the first peptide sustained-delivery products on the market was Lupron Depot®, a sustained-release formulation of leuprorelin acetate (Des-Gly-(d-Leu)–LH-RH ethylamide acetate) (56,67,68,103). Leuprorelin acetate is an LH-RH superagonist with a 10-fold higher biological activ-

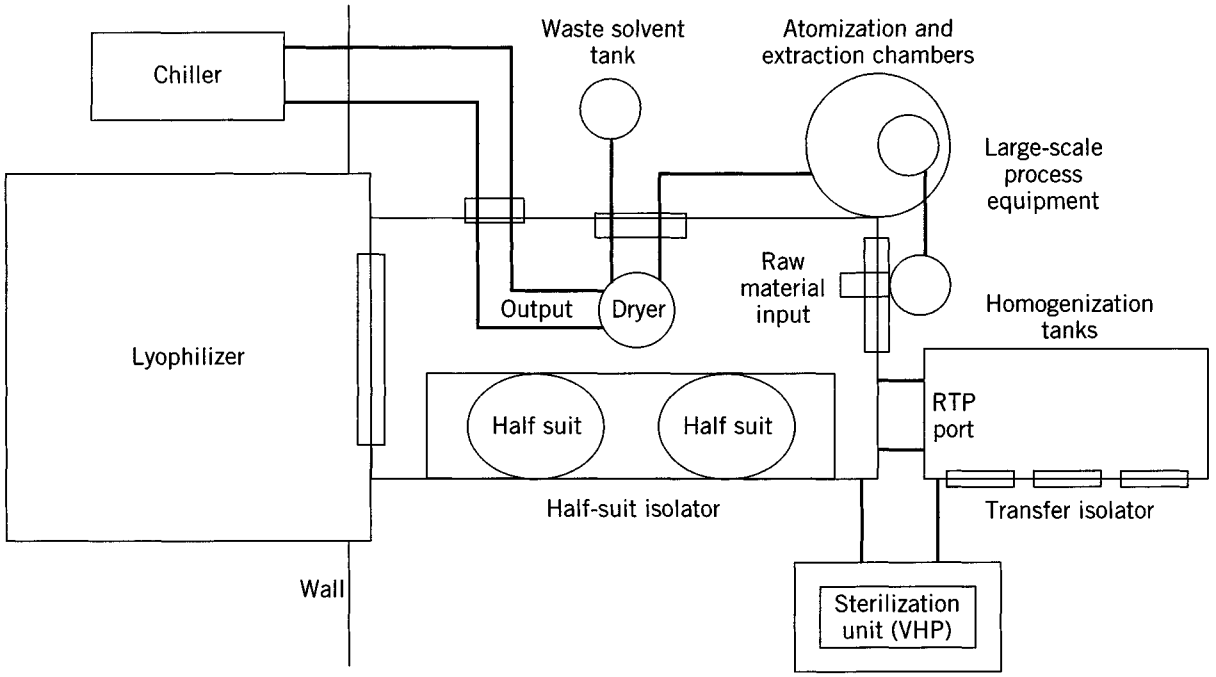

Figure 6. Isolator technology coupled with ProLease® microsphere production. Combining isolator technology with microsphere production enables the production of microspheres under controlled conditions (temperature, humidity, and Class 100 environment) and ensures the sterility of the product. The inside of the isolator is sterilized with vapor-phase hydrogen peroxide, and the non-autoclavable materials (protein and PLG polymer) are introduced into the isolator as sterile-filtered solutions. All subsequent processing, such as atomization, lyophilization, and extraction, occurs within the isolator or in equipment that is connected to the isolator and may be presterilized with VHP or steam. The operators are completely separated from the product being processed, but the half suits are comfortable and provide the dexterity required for the various manipulations. RTP = rapid transit port. *Source:* Ref. 11.

ity than native LH-RH. LH-RH and its analogs have a variety of effects on the gonads depending on the administered dose. At acute doses, the peptides stimulate gonadotropin production by the pituitary gland and production of the sex hormones in the genitals. Chronic administration at a higher dose causes "chemical castration," or an inhibition of testicular and ovarian production of the sex hormones. In this chronic administration regimen, LH-RH agonists are used in the treatment of endometriosis, uterine fibroids, and prostate and ovarian cancers. The chronic administration regimen required for these indications was an excellent opportunity to try and develop a long-acting formulation of the peptide. Okada (68) describes the problems associated with oral and transmucosal delivery (nasal, vaginal, rectal). The problem was poor absorption and, therefore, low bioavailabilities, which ranged from <0.1 to 1–5% for the transmucosal routes. In the presence of absorption enhancers, the bioavailability was increased to 5–10% for nasal and vaginal delivery. It was observed that sustained levels of the hormone produced a stronger castrating effect, suggesting that a sustained-release formulation might offer therapeutic benefits.

The microsphere formulations were based on the biodegradable polymers of lactic and glycolic acid, polylactic acid (PLA), and poly(lactic/glycolic acid). These polymers had long been used in biomedical applications such as suture and orthopedic implants and were known to be biocompatible and nonimmunogenic and could be easily synthesized to give different physicochemical properties, so they seemed to be ideal candidates for the development of implantable drug delivery devices. The scientists at Takeda Industries in the early 1980s synthesized the polymers in their laboratories and evaluated the effect of various physicochemical properties of the PLA and PLG family of polymers on the encapsulated drug-release properties in vitro and in vivo. Figure 7 shows leuprolide release over time from the microsphere formulation.

Zoladex®

Zoladex is a long-acting formulation of a synthetic decapeptide analogue of LH-RH called goserelin acetate. Goserelin acetate is dispersed in a matrix of D, L-lactic and glycolic acid copolymers and is presented as a sterile, white- to cream-colored, 1-mm-diameter cylinder. The implantable device comes preloaded in a special single-use syringe with a 16-gauge needle and is administered by subcutaneous injection to give continuous release of goserelin over 1–3 months. The encapsulated drug is released by a combination of diffusion and erosion-controlled mechanisms (104). However, because the delivery device is a monolith, heterogeneous hydrolysis is thought to be the predominant erosion process.

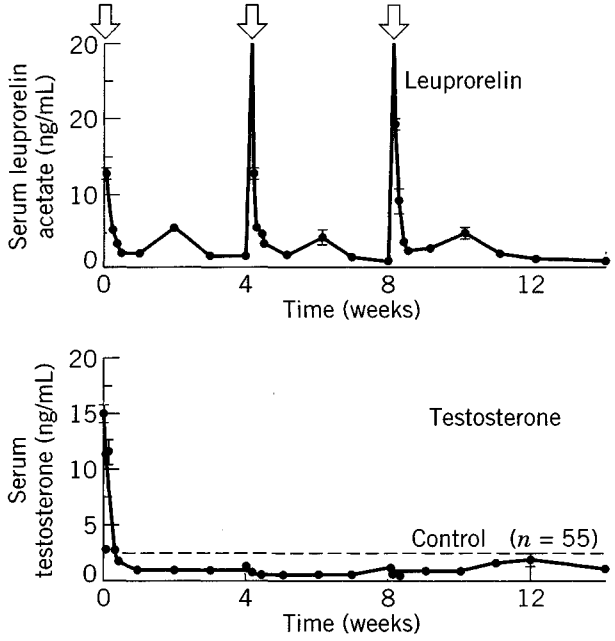

Figure 7. Serum levels of leuprorelin and testosterone following monthly im administration of Lupron Depot® in rats. The pharmacodynamic response, testosterone suppression, is achieved as long as the serum leuprorelin concentrations are above a threshold level. *Source:* Ref. 68.

De-Capeptyl® SR

De-capeptyl® SR is a long-acting formulation of triptorelin, another LH-RH agonist. Triptorelin is a decapeptide that functions in a manner similar to leuprorelin. The formulation contains microspheres made from a lactide–glycolide copolymer along with mannitol, polysorbate 80, and carboxymethyl cellulose sodium. For injection, the formulation is reconstituted using a vehicle containing mannitol in water. Injections are to be given every 4 weeks, usually in the buttocks.

Posilac®

Bovine somatotropin (bST), or bovine growth hormone, is secreted by the anterior pituitary gland and has growth-stimulating effects by direct stimulation of receptors or via mediators such as IGF-I. Posilac® is a sustained-release formulation of recombinant bST, sometribove, and is manufactured by Monsanto to increase milk production in dairy cattle. The formulation consists of the protein complexed to zinc and an oily base of aluminum stearate (5% w/w). The Zn–bST solid is dispersed in a hydrophobic gel matrix (semisolid at room temperature) of aluminum stearate and sesame oil. Oil-based formulations typically contain a vegetable-based oil such as sesame oil, a viscosity-imparting agent, and an antihydration substance. The increased viscosity is required for drug particle stability and injectability, and the antihydration agent is added to minimize moisture-induced degradation of the protein.

The development of oil-based injectable formulations for veterinary applications was appealing for several reasons. Firstly, the oil-based formulations are easier and usually cheaper to manufacture aseptically than microsphere-based systems because there are fewer fabrication steps. Secondly, because the formulations can be prepackaged in a syringe and because of the low moisture content, the formulations are stable, and administration and storage on the dairy farm is convenient. For these reasons, oil-based formulation approaches are attractive for cost-sensitive veterinary applications. Several companies including Upjohn and Elanco have evaluated these formulations, although only Monsanto has a formulation, Posilac, that is commercially available. Posilac is administered subcutaneously to dairy cows in the tailhead or shoulder at a dose of 500 mg of bST (36 mg of bST per day). The dose is administered every 14 days and consists of 1.4 cc of injectate in a prepacked 2-mL syringe with a 16-gauge needle. The drug is administered to healthy cows from the ninth week after lactation begins, and the increase in milk production is rapid, with the maximum increase observed after three to four injections. Figure 8 shows the effect of Posilac on milk production.

Nutropin Depot®

Recombinant growth hormone is used to treat short stature in children resulting from growth hormone deficiency, and the current treatments are daily or thrice weekly injections. It is therefore a suitable candidate for a sustained-release formulation. Although the endogenous secretion of hGH follows a pulsatile pattern, clinical studies have shown that continuous infusion via pumps gives serum hGH and IGF-I comparable with that obtained by daily injections. The protein is stabilized and encapsulated in a PLG microsphere matrix (25). The microsphere fabrication process (ProLease®) involves formulation of the protein into a stable lyophilized powder; then the solid protein particles are dispersed in a solution of the polymer in methylene chloride and atomized over liquid nitrogen into cold or frozen ethanol. The ethanol acts as a curing solvent and removes the methylene chloride, and the microspheres harden. The wet microspheres are collected and dried under vacuum and vialed as a white, free-flowing powder. Immediately before subcutaneous administration, the microspheres are suspended in an aqueous vehicle and injected.

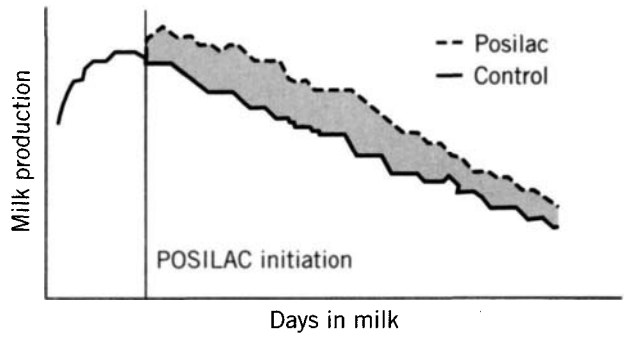

Figure 8. Effect of Posilac® on milk production in dairy cattle. Administration of Posilac to dairy cattle results in increased milk production compared with a control group of animals.

Preclinical studies in juvenile rhesus monkeys showed that a formulation that contained hGH in the complexed form, Zn–hGH, resulted in elevated serum hGH concentration for about 3 weeks, and serum IGF-I levels were elevated for 3–4 weeks. Four groups of animals each received 24 mg of hGH as a single, daily subcutaneous bolus injection for 28 days in a subcutaneously administered microsphere formulation or in a continuous-release osmotic pump. To mimic the expected release pattern from the microspheres, the pump group received 15% of the 24-mg dose as a single injection to mimic the initial, burst release phase, and the rest was delivered by the pump continuously. The serum hGH profiles for the microsphere formulation and the osmotic pump groups showed sustained hGH levels for 28–30 days (Fig. 9). The microsphere formulation group showed an initial release with a C_{max} of 260 ng/mL, and then the serum hGH concentration was maintained at about 10 ng/mL up to 30 days and then dropped to 4–5 ng/mL until 60 days. The animals that received the pump maintained serum hGH concentrations at ~16 ng/mL until day 28, when the pump was excised. A pharmacodynamic marker for hGH, IGF-I, was also measured. The serum IGF-I concentrations followed the serum hGH profile, with IGF-I levels above baseline for 1 month. The study demonstrated that it was possible to encapsulate a protein within a microsphere delivery system and obtain sustained release of the protein and biological activity of the released protein. This formulation is currently undergoing evaluation in phase III clinical trials.

CONCLUSIONS

Since it was first reported in the mid-1970s that sustained release of proteins and peptides from polymers was feasible, significant developments have occurred in the field to the point where there are now several peptide and protein sustained-release products on or close to market. The purpose of this article is to review the key research results and considerations in developing delivery systems for proteins and peptides, with emphasis on polymeric injectable delivery approaches. Both the challenges in formulating products for the marketplace and the achievements to date are emphasized. Unfortunately, there is not a single, simple approach to ensure the successful formulation of protein or peptides for sustained delivery. Rather, successful formulation and product development result from a thorough understanding of protein and peptide degradation processes, the diverse environments that the drug will encounter during processing and release, the mechanism of release from the delivery system, and an understanding of scale-up, manufacturing, and regulatory issues in developing pharmaceutical products.

Key obstacles in developing protein and peptide delivery products include stabilizing the drug, obtaining desirable release kinetics, and scaling up the fabrication process to support clinical testing and commercialization. In general, though suitable for many peptides, incorporation processes, such as emulsion and coacervation processes, that involve interfaces may not be suitable for proteins that are susceptible to denaturation at aqueous–organic interfaces. Because proteins are generally more stable in the solid state than in solution, it is advantageous to incorporate proteins into delivery systems in a solid form, such as a lyophilized powder. If, as in the case of human growth hormone, the protein can be encapsulated in a stable form with reduced aqueous solubility, then the potential for degradation during release at the site of delivery is greatly reduced owing to decreased protein molecular mobility. Also, the mechanism of release must be well understood to develop formulation or processing approaches to achieve a target release profile. For polymeric delivery systems, the polymer chemistry and degradation characteristics are very important as is the ability to process the drug to achieve a desired particle size prior to encapsulation. In addition, approaches for scaling up and manufacturing sustained polymeric delivery systems were presented. Thus, with the examples presented here, we have demonstrated that sustained protein and peptide delivery is commercially feasible and offers significant therapeutic advantages. This reality, coupled with the development of an increasing number of injectable, macromolecular drugs (which require chronic administration), suggests that the future is indeed bright for improved delivery technologies.

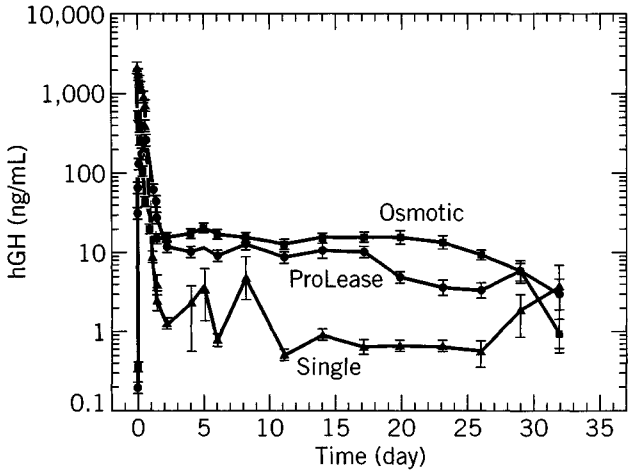

Figure 9. Serum hGH concentration from Nutropin Depot—juvenile rhesus monkeys. The ProLease® group show sustained serum hGH levels for about 28 days. The serum hGH profile was similar to the osmotic pump group that was preprogrammed to release hGH for 28 days.

ACKNOWLEDGMENTS

We would like to thank our colleagues at Alkermes for their insightful comments in the preparation of this manuscript.

INTRODUCTION

The pharmacological response of drugs can be better correlated with the concentration of the drug (or its active metabolite) in blood or in some other biophase than with the dose administered. The concentration of the drug in blood or the biophase depends on disposition factors including distribution, metabolism, excretion, and on the efficiency and design of the drug delivery system. The drug delivery system is the sequence of events that provides the drug to the site of action. The pharmacological action of a drug is determined by its intrinsic activity, and drug delivery to the site of action is governed by physicochemical properties of the drugs.

The study of the relationship between the physicochemical properties of a drug in a dosage form and the pharmacologic, toxicologic, or clinical response of the drug after its administration is termed biopharmaceutics. Advancement in biopharmaceutics has primarily resulted from a better understanding of a descriptive discipline called pharmacokinetics (1).

Pharmacokinetics is a theoretical framework of the principles for determining the time course of drug absorption, distribution, metabolism, and excretion, as well as the study of the relationship of these processes to the intensity and time course of therapeutic and adverse effects of these drugs (2). Pharmacokinetics involves the application of mathematics and biochemistry in a physiologic and pharmacologic context. Two related disciplines have emerged from better understanding of pharmacokinetics. Clinical pharmacokinetics deals with the application of pharmacokinetics to safe and effective therapeutic management of patients. Toxicokinetics encompasses the study of the kinetics of absorption, distribution, metabolism, and elimination of large (toxic) doses of drug in the body, and the safety evaluation and assessment of adverse reactions caused by the excessive drug dose (3). The assessment of how drugs exert their therapeutic and toxic effects on the body by studying the relationship of drug concentration in a biophase to its therapeutic or toxic effect is called pharmacodynamics. Thus pharmacokinetics may be described as "what the body does to the drug," and pharmacodynamics can be described as "what the drug does to the body" (4).

Application of pharmacokinetics is critical to the development of various drug delivery technologies. The process of drug delivery includes the administration of the dosage form, the release of the drug from the dosage form, and transport of the drug across biological membranes to the site of action. Thus, increasing the rate and extent of drug delivery would improve the efficiency of the system leading to earlier onset of action and better intensity of pharmacological response. Administration of different formulations of the same drug does not necessarily produce the same response (5). The availability of the drug from different dosage forms may be affected. The term bioavailability is used to describe the rate and extent of drug absorption from a dosage form.

The goal of drug therapy is to produce therapeutic drug concentrations to produce the pharmacological effect without producing toxicity (6). This requires the maintenance of drug concentrations at effective levels while maintaining a reasonable dosing frequency such as once or twice daily. Conventional dosage forms are rapidly absorbed, producing rapid peak concentration and then declining as a function of the drug half-life. Drugs from such dosage forms usually require more frequent dosing due to half-life and duration of pharmacological effect requirements. A drug with a short half-life requires more frequent dosing than drugs with long half-life. The frequency of dosing is also affected by the therapeutic index of the drug. The therapeutic index of a drug is defined as the ratio of the concentration producing a toxic effect to that producing a safe and effective pharmacological effect. Thus, conventional dosage forms are significantly dependent on the pharmacokinetics of the drug (6). The rate and extent of drug absorption can be altered to produce controlled drug delivery via concepts such as sustained release, prolonged release, and delayed release. The discussion of various principles of controlled drug delivery is described in several other articles and is beyond the scope of this article. The goal of this article is to familiarize oneself with the fundamental principles of pharmacokinetics and its role in designing controlled drug delivery systems.

BACKGROUND

Currently four different approaches are used to describe the pharmacokinetics of drugs. The traditional approach is called compartmental analysis, which considers the rates of absorption, distribution, and elimination in terms of rate constants, usually of first-order. This approach is sometimes also called model-dependent approach to pharmacokinetic analysis. The main advantage of this traditional pharmacokinetic analysis is the ability to simulate and predict blood drug concentrations during altered physiological or pathological conditions and during chronic medication. The major disadvantage of the compartmental approach is the mathematical complexity of equations and the difficulty in obtaining reliable estimates of rate constants (2).

A second approach to describe pharmacokinetics is termed noncompartmental analysis. The parameters used to describe the pharmacokinetics of the drug are determined using statistical moments and are derived from relationships involving the area under the zero moment curve (AUC) and the area under the first moment curve (AUMC) of the blood drug concentration-time curve. The advantage of this approach is the ease of determination of these parameters and the lack of requirements of detailed description of the disposition of the drug (hence sometimes referred to as model-independent approach). However, knowledge of noncompartmental pharmacokinetic parameters is insufficient to predict or simulate blood drug concentration profiles in the body (2).

The third major approach to pharmacokinetic analysis focuses on the fundamental anatomical and physiological factors that influence drug uptake and disposition and is referred to as physiological pharmacokinetics. Individual organ systems are studied with respect to partitioning of drug between blood and the organ, the binding of drug in blood and tissues, and blood flow through the organ. Mass balance equations are developed to describe the rate of change in each organ system. The equations for all organs are solved simultaneously and change in drug concentration over time is predicted. The advantage of this approach is that the effects of changes in real physiological variables such as blood flow can be evaluated. This approach also provides reasonable predictions for human pharmacokinetics based upon preclinical animal data. However, the requirements of extensive computing power and unavailability of partitioning or tissue binding data for all species results in limited application of this approach for clinical studies (2).

Recently, with the availability of faster and better computers, a new approach termed population pharmacokinetics has been developed. The major advantage of this approach is the ability to collect sparse data from many subjects in clinical studies and predict the concentration-time profile in a population of patients. This approach allows one to understand inter- and intraindividual variability and is able to determine the role of different factors such as age, sex, and disease in the altered disposition of drugs. Thus, it is rapidly becoming more popular in the design and analysis of clinical studies. A major disadvantage of this approach is the requirement of a good understanding of statistics and mathematics and the need for powerful computers to perform the analysis of data.

Fundamental Pharmacokinetic Parameters

Although the pharmacokinetic approaches are different in the process, they are not mutually exclusive. Two fundamental parameters of pharmacokinetics are drug clearance and its volume of distribution (2). These two parameters can be estimated using any of these approaches and are invaluable to the understanding of pharmacokinetics. Furthermore, noncompartmental analysis can be used to determine some of the parameters for compartmental approaches, and the two approaches are often combined in pharmacokinetic analysis. Similarly, population pharmacokinetic analysis primarily provides an estimate of the drug clearance and its volume of distribution. A physiological pharmacokinetic approach requires the determination of organ clearance and volume of distribution, which can again be used to predict or simulate drug concentration-time profile in the body.

It has been suggested that for any pharmacokinetic analysis, 10 critical pharmacokinetic and pharmacodynamic parameters should be determined (7). These 10 parameters are (*1*) clearance, (*2*) effective drug concentrations, (*3*) extent of availability from a dosage form, (*4*) fraction of dose excreted unchanged, (*5*) blood/blood concentration ratio, (*6*) half-life, (*7*) toxic concentrations, (*8*) protein binding, (*9*) volume of distribution, and (*10*) rate of availability from a dosage form.

The estimates of clearance, effective drug concentration, and extent of availability are necessary to define the appropriate dosing rate (amount/day) of the drug by a particular route of administration (7). The knowledge of the fraction of the dose excreted unchanged in the urine allows one to estimate the nonrenal clearance of the drug (which may be assumed to represent the hepatic clearance). The ratio of blood to blood concentration ratio allows one to convert the more easily measured blood concentrations into blood concentrations. The ratio of hepatic blood clearance to hepatic blood flow subtracted from one allows an estimate of maximum oral bioavailability.

Half-life and toxic concentrations are very important in drug development. Half-life of the drug defines its dosing interval. Half-life is a derived parameter from clearance and volume of distribution of the drug. Hence, it should not be used as a tool to determine the disposition of the drug (7). The knowledge of toxic concentrations is important because the dosing frequency results in accumulation of drug, and the goal of drug therapy is to maintain effective and safe drug concentrations without entering the toxic concentration range. The knowledge of protein binding of the drug is important in the determination of drug clearance, and it is presumed that the unbound drug is responsible for pharmacological action of the drug because it is able to cross biological membranes.

The knowledge of volume of distribution is important in understanding drug distribution. The volume of distribution allows one to predict steady-state trough and maximum drug concentrations. Of most importance is the use of volume of distribution to determine whether disease states have affected the drug distribution rather than drug clearance (7). For this purpose, the estimation of the volume of distribution at steady-state, which relates the concentration of the drug in systemic circulation to the amount of drug in the body following multiple dosing of the drug. The rate of drug availability from a dosage form is considered a formulation parameter because it can be modified by a change in the formulation from a conventional dosage form to a controlled drug delivery system.

OVERVIEW OF THE THEORETICAL PRINCIPLES OF PHARMACOKINETICS

Several textbooks and review articles are available to provide a more detailed and thorough understanding of the fundamental concepts and mathematical principles of pharmacokinetics (8–10). This overview intends to provide the basis for the use of pharmacokinetics in the development of dosage forms. A brief description of different methods used in developing the mathematical basis for pharmacokinetics is provided in this section. These methods are generally applicable to the evaluation of pharmacokinetics regardless of whether compartmental, noncompartmental, physiological, or population pharmacokinetic methods are used in data analyses.

This review also intends to provide the reader with a general understanding of various methods available to allow the estimation of the fraction of the dose absorbed following extravascular administration for the assessment of

in vivo absorption kinetics. For a more detailed understanding on assessment of drug input rate from a controlled drug delivery system, the reader is referred to reviews of this subject (11–14).

Laplace Transforms

Rate equations that describe apparent zero-order or first-order processes are termed linear equations. The Laplace transform is used for solving linear differential equations. Hence, the Laplace transform is applicable to the solution of many equations used in pharmacokinetic analysis. The basic idea of the Laplace transform is to replace the time domain of a rate expression by the complex domain of the Laplace operators. This is achieved by eliminating the independent variable (in pharmacokinetics that being time). The Laplace transform enables complex rate expressions to be manipulated easily by conventional algebraic techniques. The transformed expression can be rearranged into a form that is commonly found in tables of Laplace transforms (15–17). Upon transformation of the Laplace domain into time domain, the complete solution of the linear differential equation is obtained. A table of Laplace transforms of common pharmacokinetic functions is provided in *Pharmacokinetics* (8).

Linear Mammillary Models

A method has been developed using simple treatments to derive equations for any linear mammillary compartment model with any first- or zero-order, or bolus input process. This is accomplished by the use of general input and disposition functions, a method for solving partial fractions to obtain solutions to Laplace transforms, and a multiple dosing function. The input function and the disposition function are defined such that the product of these two functions yields the Laplace transform of the equation describing the time course of a drug in a model compartment. A disposition function defines the model necessary to describe the levels of the drug in the body or a compartment and includes all distribution and elimination processes. Input functions describe the processes needed to get the drug into the body. The following general equation has been empirically derived to describe the Laplace transform for the disposition function of the central compartment in a linear N-compartment mammillary model, where elimination of the drug from any compartment is allowed:

$$d_{s,c} = \frac{\prod_{i=2}^{N} (s + E_i)}{\prod_{i=1}^{N} (s + E_i) - \sum_{j=2}^{N} \left[(k_{lj}k_{jl} \prod_{\substack{m=2 \\ m \neq j}}^{N} (s + E_m) \right]} \quad (1)$$

wherein $d_{s,c}$ is the disposition function for the central compartment (#1); it is a function of the Laplace operator, s, Π is the continued product where any term is defined as equal to 1 when the index takes a forbidden value, i.e., i = 1 in the numerator or m = j in the denominator, Σ is the continued summation where any term is defined as equal to zero when the index takes a forbidden value, $k_{ij} \cdot k_{jl}$ are the first-order intercompartmental transfer rate constants, E_i, E_m are the sum of the exit rate constants out of compartments i or m; and N is the number of driving force compartments in the disposition model (i.e., compartments having exit rate constants).

Various input function rates for different processes of input such as instantaneous bolus input, continuous intravenous infusion, or first-order extravascular administration are described (18). The product of the input and disposition function yields the Laplace transform for the amount of drug in the central compartment, $a_{s,c}$.

$$a_{s,c} = in_s \cdot d_{s,c} \quad (2)$$

One can use either the anti-Laplace of the resulting transform or use the general partial fraction theorem (19) to solve for the amount of drug in the central compartment.

Method of Residuals

The method of residuals is a commonly used technique in pharmacokinetics for resolving a curve into its various exponential components (8). This method is sometimes also referred to as feathering, peeling, or stripping the curve. The residual method entails the logarithmic representation of the blood concentration-time curves, followed by the subtraction of the observed blood concentrations from the extrapolated log-linear curves, yielding a series of residual values. A log-linear plot of residual concentrations versus time allows one to estimate rates of absorption, distribution, etc.

Method of Estimating Areas Under the Curve

The estimation of areas under the curve are required for pharmacokinetic analysis by compartmental or noncompartmental analysis. These areas are usually determined by using an approximate integration formula. The trapezoidal rule is one such formula used for estimating the AUC. This particular method involves the description of a given blood concentration-time curve by a function that depicts the curve as a series of straight lines, thereby enabling the area under the curve to be divided into a number of trapezoids. The area of each trapezoid is determined, and the sum of all the areas of trapezoids yield an estimate of the true AUC. The area under each trapezoid for a given segment of a blood concentration-time curve is given by:

$$AUC(t_1, t_2) = (t_2 - t_1) \cdot (C_1 + C_2)/2 \quad (3)$$

The accuracy of the approximation of AUC by this method is dependent on the number of blood concentration-time points sampled within the time interval from 0 to t. Yeh and Kwan (20) have shown that the area under the curve is overestimated by linear interpolation between data points using the trapezoidal rule. In cases where there are long intervals between samples, or changes in curvature, the linear interpolation of the logarithmically transformed data has been suggested. In the log trapezoidal method, the area under a given segment is obtained as:

$$AUC(t_1, t_2) = (C_1 - C_2)(t_2 - t_1)/(\ln C_1 - \ln C_2) \quad (4)$$

Two alternative algorithms based on known interpolating functions have been described in the literature. These include the Lagrange interpolation, in which the linear interpolation is replaced by a cubic polynomial function, and the spline method, in which the cubic functions are modified so that the fitted curves are smooth. The advantages and disadvantages of these interpolation techniques, relative to trapezoidal or log-trapezoidal methods, are discussed in detail by Yeh and Kwan (20).

Principle of Superposition

Fitting the blood concentration-time data requires some assumptions regarding the absorption kinetics of the drug. An alternative approach that requires no assumptions regarding the pharmacokinetic model or absorption kinetics is based upon the principle of superposition, and it employs the overlay technique (21,22). This method requires the following assumptions:

1. Each dose of the drug acts independently of every other dose.
2. The rate and extent of absorption and average systemic clearance are the same for each dosing interval.
3. Linear pharmacokinetics apply so that a change in dose during the multiple dosing regimen can be accommodated.

The overlay technique requires that the concentration-time profile of the drug should be completely characterized following a single dose.

The in vivo performance of controlled drug delivery systems can be influenced by various factors, which may be physiological, biochemical, and/or pharmacological (6). Physiological factors influencing the performance of controlled drug delivery systems include prolonged gastrointestinal absorption, variability in gastrointestinal emptying and motility, gastrointestinal blood flow, and presence or absence of food. Biochemical (or pharmacokinetic) factors influencing controlled delivery systems include dose dumping, first-pass metabolism, variability in excretion organs, and enzyme induction or inhibition following multiple dosing of the drug. The pharmacological factors affecting controlled drug delivery systems include the changes in drug effect following multiple dosing and tolerance or sensitization to the drug following repeated dosing. In order to minimize the influence of such factors, one normally selects drugs with long half-lives to minimize the frequency of dosing and/or develops sustained or controlled release dosage forms. The ultimate purpose of the latter approach is to maintain uniform blood concentrations through reducing the ratio of maximum to minimum concentrations and improving the therapeutic management of patients.

General Principles of Pharmacokinetics

It is important to note that following drug administration (by any route) there are dynamic processes reflecting drug absorption, distribution, and elimination (1). The amount of drug at the absorption site decreases with time as the drug is absorbed into the systemic circulation and distributed throughout the body. As soon as the drug reaches the systemic circulation, various elimination processes are initiated and the excretion of the drug (as parent or metabolite) in urine and other excretory fluids occurs. Thus the amount of the drug in the body continually changes as a function of these absorption and elimination processes.

In case the drug is administered directly into the systemic circulation (such as with an intravenous bolus injection), there is no absorption process and the dynamics of the drug in the body are simply a function of the elimination processes. Hence, some basic concepts of pharmacokinetics are discussed here assuming intravenous bolus injection administration. For purposes of simplicity, the distribution of the drug following intravenous administration is assumed to be instantaneous (i.e., one-compartment kinetics), and only elimination processes are considered. The reader is referred to an excellent book on pharmacokinetics (8) for more details on any of the following concepts.

Elimination Rate Constant. A simple first-order elimination process usually describes the elimination of most drugs. Thus, the rate of elimination of a drug from the body following intravenous administration is described by

$$-dA/dt = dA_e/dt = k_e A \quad (5)$$

where A is the amount of drug in the body at time t, A_e is the amount of drug eliminated from the body (by all routes) at time t, k_e is the apparent first-order elimination rate constant, and $-dA/dt$ and dA_e/dt are the rates of change in the amount of drug in the body and the elimination rate, respectively, at time t. Integrating equation 5 describes the amount of the drug in the body at any time t as,

$$A = A_0 e^{-ket} \quad (6)$$

where A_0 is the intravenous dose and equal to the initial amount of drug in the body.

The elimination rate constant can be estimated from equation 6 by simple transformation of drug amounts to their natural logarithm values. Thus, equation 6 can be rewritten as

$$\ln A = \ln A_0 - k_e \cdot t \quad (7)$$

This equation assumes the properties of a straight line and the slope of the line is equal to the elimination rate constant of the drug. Because common logarithms are used more frequently, equation 7 can be described in common logarithms as

$$\log A = \log A_0 - k_e \cdot t/2.303 \quad (8)$$

Thus, the elimination rate constant can be obtained by multiplying the slope of the line obtained from a semilogarithmic plot of A versus time by 2.303.

Half-life. A more commonly used term in clinical studies to describe the rate of elimination of drug from the body is the half-life. The half-life of a drug ($t_{1/2}$) is the time required for the amount in the body to decline to one-half its initial amount. The half-life is related to the elimination rate constant and can be obtained as

$$t_{1/2} = 0.693/k_e \tag{9}$$

Bioavailability. The fraction of an oral dose that reaches the systemic circulation is termed oral bioavailability (F). It is defined as the rate and extent of absorption of a drug. Bioavailability can be estimated as the ratio of the area under the blood concentration-time curve (AUC) following oral administration, to that obtained following an intravenous dose of the drug, corrected for the dose levels.

$$F = D_{iv}AUC_{oral}/D_{oral}AUC_{iv} \tag{10}$$

When the intravenous AUC is used as the reference, the bioavailability is termed *absolute* bioavailability. However, other routes of administration can be used as the reference, and an estimate of "relative" bioavailability can be obtained for any drug.

Volume of Distribution. Because there is a relationship between the amount of drug in the body and the drug concentration in the blood, we can rewrite the differential equation describing the rate of change of drug in the body as

$$-d(VC)/dt = -VdC/dt = k_e \cdot (VC) \tag{11}$$

or

$$-dC/dt = k_e \cdot C \tag{12}$$

where V is the apparent volume of distribution of the drug and is the ratio of the amount of drug in the body to the concentration of drug in the blood (C_b) at time t, i.e.,

$$V = A/C_b \tag{13}$$

The apparent volume of distribution is calculated by modifying equation 13 as

$$V = A_0/C_b^0 \tag{14}$$

where A_0 is the intravenous dose and C_b^0 refers to the initial drug concentration in the blood obtained by back extrapolating the semilogarithmic plot of blood concentration versus time to obtain the y-intercept. It is important to note that the volume of distribution varies from extremely low to extremely high values and does not correspond to any anatomical or physiological space. Instead, the principal factors that govern the volume of distribution are the blood and tissue binding of the drug. This can be better understood from the following:

$$A = A_b + A_t \tag{15}$$

where A is the amount of drug in the body, A_b is the amount of drug in the blood, and A_t is the amount of drug in the tissue compartment. By substituting the amount with the product of volume of distribution and concentration we get

$$V \cdot C_b = V_b \cdot C_b + V_t \cdot C_t \tag{16}$$

where V, V_b, and V_t are the apparent volume of distribution, physiological volume occupied by blood, and physiological space occupied by the tissues, respectively, and C_b and C_t refer to the drug concentrations in blood and tissue, respectively. Dividing equation 16 by the blood concentration (C_b), we obtain

$$V = V_b + V_t \cdot (C_t/C_b) \tag{17}$$

It should be noted that the total drug concentration in blood represents the sum of the bound and unbound fractions of the drug, and it is the free (unbound) fraction of drug that is able to freely diffuse out of blood into tissue spaces. Thus,

$$C_b^u = fu \cdot C_b \tag{18}$$

$$C_t^u = fu_t \cdot C_t \tag{19}$$

where C_b^u and C_t^u represent the unbound drug concentrations in blood and tissue compartments, respectively. Because the free concentration of drug is the same between blood and tissue, it is understood that

$$C_u^u = C_t^u \tag{20}$$

By substituting the relationships for C_b^u and C_t^u in equation 20, we get

$$C_t/C_b = fu/fu_t \tag{21}$$

Substituting this relationship in the relationship for volume of distribution in equation 21, we obtain

$$V = V_b + (fu/fu_t) \cdot V_t \tag{22}$$

Equation 22 shows that the volume of distribution is determined by the physiological spaces into which the drug distributes and the relative affinity of binding of the drug to blood and tissue components (2). As seen from this relationship, drugs with a high binding affinity to blood and plasma components have low volumes of distribution, whereas drugs with high tissue binding have high volumes of distribution.

Systemic (Total Body) Clearance. The most important pharmacokinetic parameter of a drug is its systemic blood clearance (Cl_s). Clearance is defined as the volume of fluid from which the drug is completely removed in a given period of time (volume/time). The clearance of drugs can be obtained at a total body level (systemic) or for individual organs. By definition, the total body (systemic) clearance

is the ratio of the overall rate of elimination (dA/dt) to the drug concentration in blood (C_b) (2,8)

$$Cl_s = (dA/dt)/C_b \quad (23)$$

Integrating the right hand side of the equation from time $t = 0$ to $t = \infty$, yields

$$Cl_s = \int_0^\infty (dA/dt)dt \Big/ \int_0^\infty C_b \cdot dt \quad (24)$$

It is seen that the term $\int_0^\infty (dA/dt)dt$ is equal to the total amount of drug that is ultimately eliminated, i.e., the intravenous dose administered (D_{iv}), whereas the term $\int_0^\infty C_b \cdot dt$ is equivalent to the total area under the curve of the drug concentration in blood versus time curve (AUC). Thus,

$$Cl_s = D_{iv}/AUC \quad (25)$$

By analogy, we can also prove that the systemic clearance of a drug is equal to the rate of intravenous infusion of a drug (k_0) divided by its steady-state blood concentration (C_{ss}^b),

$$Cl_s = k_0/C_{ss}^b \quad (26)$$

It can be also shown that systemic clearance can be estimated as the ratio of the dosing rate (in amount/time) to the average steady-state blood concentration of the drug

$$Cl_s = \text{Dosing rate/Avg } C_{ss}^b \quad (27)$$

Renal Clearance. Following drug administration, polar drugs and metabolites are removed from the body by the kidney. The rate of drug excretion by the kidney can be estimated as

$$dA/dt = Cl_r \cdot C_b \quad (28)$$

where Cl_r is the renal clearance of the drug, and C_b is the concentration of drug in the blood. Renal clearance is determined by three factors: glomerular renal filtration (Cl_{GFR}), active tubular secretion (Cl_{TS}), and passive tubular reabsorption (Cl_{TR}), of the drug. Thus, Cl_r can be represented as

$$Cl_r = Cl_{GFR} + Cl_{TS} - Cl_{TR} \quad (29)$$

If the drug is not bound in the blood, its renal filtration rate is equivalent to the glomerular filtration rate (measured as inulin or creatinine clearance). Protein-bound drugs are unable to cross the glomerular membrane, and their renal filtration rate is expressed as fu · GFR (2). Thus, equation 29 becomes

$$Cl_r = \text{fu} \cdot \text{GFR} + Cl_{TS} - Cl_{TR} \quad (30)$$

Renal clearance can be determined by dividing the total amount of the unchanged (unmetabolized) drug excreted in the urine (A_u^∞) with the area under the blood concentration versus time curve (AUC).

$$Cl_r = A_u^\infty/\text{AUC} \quad (31)$$

Following administration of an intravenous dose, the systemic clearance can be determined as described in equation 31, and difference between the systemic and renal clearance is referred to as nonrenal clearance of the drug.

$$Cl_{nr} = Cl_s - Cl_r \quad (32)$$

Hepatic Clearance. The difference between the systemic and renal clearance estimates is termed nonrenal clearance. For certain drugs, we can assume that the nonrenal clearance is the hepatic clearance, which is defined as the clearance of the drug from the body by the liver. For drugs that are completely metabolized (i.e., negligible renal clearance), the systemic clearance can be assume to be equal to the hepatic clearance. Under the latter assumption, hepatic clearance can be defined as the product of the hepatic blood flow (Q_h, about 1.5 L/min in humans) and the hepatic extraction ratio (E_h, ranging from 0 to 1). Thus,

$$Cl_h = Q_h \cdot E_h \quad (33)$$

The extraction ratio is defined as fraction of the drug removed by any organ and can be estimated from the difference in the arteriovenous concentration of the drug as

$$E = (Ca - Cv)/Ca \quad (34)$$

where Ca represents the concentration entering the organ (arterial blood) and Cv represents the concentration leaving the organ (venous blood). Because the extraction ratio is a fraction, it varies between 0 and 1 for all drugs. The extraction ratio is related to the fraction of drug escaping removal by the organ (F) by

$$F = 1 - E \quad (35)$$

This relationship is very important for highly extracted drugs, because orally administered drugs must pass through the liver before entering the systemic circulation. For drugs that are highly extracted by the liver, a much smaller fraction of the orally administered dose reaches the systemic circulation. This phenomenon of removal of the drug prior to its entering the systemic circulation is termed a first-pass effect.

The extraction ratio of the drug is dependent on the fraction of the drug bound in the blood and the intrinsic clearance (Cl_{int}) of the drug by the liver. Intrinsic clearance is defined as the maximal ability of any organ to irreversibly remove the drug in the absence of any blood flow limitations to the organ (2). In case of the liver, intrinsic clearance is directly related to the ratio of Vmax to Km (Michaelis-Menten kinetic parameters for drug metabolism). An equation that relates the extraction ratio of any drug to its intrinsic clearance and binding in blood is

$$E_h = (\text{fu} \cdot Cl_{int})/(Q_h + \text{fu} \cdot Cl_{int}) \quad (36)$$

Substituting this term for Eh in equation 36 for hepatic clearance, we obtain

$$Cl_h = Q_h \cdot [(\text{fu} \cdot Cl_{int})/(Q_h + \text{fu} \cdot Cl_{int})] \quad (37)$$

Equation 37 has two limiting conditions. For highly extracted drugs, $Cl_{int} \gg Q_h$, which results in the elimination of the Q_h term in the denominator. Thus, equation 37 is reduced to

$$Cl_h = Q_h \quad (38)$$

In case of drugs which are poorly extracted by the liver, $Q_h \gg Cl_{int}$, which results in the elimination of the Cl_{int} term in the denominator. For such drugs,

$$Cl_h = \text{fu} \cdot Cl_{int} \quad (39)$$

As seen from the last two equations, highly extracted drugs are limited by blood flow to the liver, and poorly extracted drugs are limited by drug binding in blood and its intrinsic clearance.

First-Pass Effect. For some drugs with high extraction, a significant portion of an oral dose is removed by the liver and/or the gut, resulting in a reduced fraction of the oral dose reaching systemic circulation. This phenomenon is referred to as first-pass effect. The extraction phenomenon is sometimes called first-pass metabolism or presystemic elimination. Assuming complete gastrointestinal absorption, the fraction of an oral dose reaching the circulation (bioavailability, F) is given by

$$F = 1 - E \quad (40)$$

where E is the extraction ratio of the drug. As defined earlier, bioavailability can be estimated as the ratio of AUC_{oral} to AUC_{iv} (assuming same intravenous and oral dose levels). Substituting the AUC ratio for F and expanding the relationship for E, we obtain

$$AUC_{oral}/AUC_{iv} = 1 - [(\text{fu} \cdot Cl_{int})/(Q_h + \text{fu} \cdot Cl_{int})] \quad (41)$$

Rearranging equation 41 and multiplying both sides of the equation by the administered dose, we obtain

$$D(Q_h + \text{fu} \cdot Cl_{int})/Q_h AUC_{iv} = D/AUC_{oral} = Cl_{oral} \quad (42)$$

Because D/AUC_{iv} is defined as the systemic clearance, and substituting for clearance as

$$Cl_h = Q_h \cdot [(\text{fu} \cdot Cl_{int})/Q_h + \text{fu} \cdot Cl_{int})] \quad (43)$$

we obtain

$$Cl_{oral} = \{Q_h \cdot [(\text{fu} \cdot Cl_{int})(Q_h + \text{fu} \cdot Cl_{int})]\} \div \{(Q_h)(Q_h + \text{fu} \cdot Cl_{int})\} \quad (44)$$

Upon canceling terms, we find that

$$Cl_{oral} = \text{fu} \cdot Cl_{int} \quad (45)$$

Thus, one can obtain an estimate of the intrinsic hepatic clearance of a drug of a drug from the area under the blood concentration-time curve following oral administration.

The extent to which a drug may be subject to first-pass effects can be estimated from either the oral or intravenous area under the blood concentration-time curve as follows:

$$F = 1 - E_h = 1 - (Q_h \cdot E_h)/Q_h = 1 - D/(Q_h \cdot AUC_{iv}) \quad (46)$$

Multiplying equation 46 with AUC_{oral}, we obtain

$$F \cdot AUC_{oral} = AUC_{oral} - [(D \cdot AUC_{oral})/(Q_h \cdot AUC_{iv})] \quad (47)$$

or

$$F \cdot AUC_{oral} = AUC_{oral} - FD/Q_h \quad (48)$$

Rearranging equation 47, the bioavailability of highly extracted drugs can be determined as

$$F = Q_h/\{[Q_h + (D_{oral}/AUC_{oral})]\} = Q_h/(Q_h + Cl_{int}) \quad (49)$$

Thus the systemic bioavailability of a drug (subject to first-pass metabolism) can be estimated by determining the AUC_{oral} and substituting an appropriate value for hepatic blood flow. As evident from equation 49, the higher the intrinsic hepatic clearance of any drug, the lower the anticipated oral bioavailability of the drug.

Gut Wall Clearance. The systemic availability of drugs subject to both first-pass hepatic and intestinal mucosa metabolism can be estimated as described by Gibaldi and Perrier (8). These authors have shown that the oral bioavailability (F) can be estimated as

$$F = (Q_h \cdot Q_{pv})/\{(Q_h + Cl_{hint})(Q_{pv} + Cl_{giint})\} \quad (50)$$

where Q_h is the hepatic blood flow (sum of hepatic arterial blood flow and portal venous blood flow), Q_{pv} is the portal venous blood flow, Cl_{hint} is the hepatic intrinsic clearance, and Cl_{giint} is the intrinsic intestinal mucosal clearance.

Lung Clearance. The lung is an important extrahepatic route of elimination of drugs. As already described, in the absence of significant lung clearance, systemic clearance is estimated as the ratio of the intravenous dose and the AUC_{iv}. Because of the unique anatomical position of the lungs, the true systemic clearance should be estimated from the intraarterial area under the blood concentration-time curve (AUC_{ia}). The fraction of a dose escaping the lung can be estimated as the ratio of AUC_{iv} to AUC_{ia}. Because the gastrointestinal mucosa, the liver, and the lungs are anatomically presented in series, the oral bioavailability of any drug (F) is the product of the fractions escaping first-pass metabolism by each of these organs, i.e.,

$$F_{oral} = f_{gi} \cdot f_h \cdot f_l \quad (51)$$

where f_{gi} is the fraction escaping first-pass metabolism by the gastrointestinal mucosa, f_h is the fraction escaping the first-pass metabolism by the liver, and f_l is the fraction escaping the first-pass metabolism by the lungs.

Multiple Dosing. Repeated administration of a drug results in accumulation in the body, particularly if the drug has a long half-life. When the drugs reach steady-state, the maximum and minimum concentrations of the drug fluctuate in a fixed manner. The peak concentration at steady-state should be (ideally) maintained below the toxic level, whereas the trough (minimum) concentration should be in an effective range. For drugs with narrow therapeutic index, this range has to be carefully maintained to avoid toxicity or therapeutic failure. It has been shown that the maximum and minimum concentrations (C^n_{max} and C^n_{min}) in the blood after n repeated doses are given by

$$C^n_{max} = (\mathrm{D/V})\{(1 - e_{-nke}{}^{T})/(1 - e^{-keT})\} \quad (52)$$

$$C^n_{min} = (\mathrm{D/V})\{(1 - e_{-nke}{}^{T})/(1 - e^{-keT})\}e^{-keT} \quad (53)$$

where T is the dosing interval of the drug.

Equations 52 and 53 also describe the peak and trough concentrations achieved at steady-state following repeated administration. Under steady-state conditions, the product of $n \cdot \mathrm{ke} \cdot T$ becomes very large, resulting in e-$n$ke$T$ approaching zero. Thus,

$$C^{max}_{ss} = (\mathrm{D/V})\{1/(1 - e^{-keT})\} \quad (54)$$

$$C^{min}_{ss} = (\mathrm{D/V})\{1/(1 - e^{-keT})\}e^{-keT} \quad (55)$$

And the average concentration at steady-state is obtained as the ratio of the dosing rate to the drug clearance.

$$C^{avg}_{ss} = \{(\mathrm{Dose}/T)\}/Cl \quad (56)$$

It should be noted that the time taken to reach steady-state is usually at least four to five half-lives of the drug. About seven half-lives of the drug are required to reach 99% of the steady-state drug concentration in the blood.

As mentioned earlier, repeated dosing results in accumulation of the drug in the body (R). Accumulation can be estimated by dividing the minimum concentration in blood at steady-state by the minimum concentration of the drug following a single dose, i.e.,

$$R = (C^{min}_{ss})/(C^{min}_{l}) \quad (57)$$

If one assumes that all the doses were administered in the postdistributive phase of the drug, or if the drug concentration profile can be described by one-compartment model, the accumulation factor (R) can be obtained from

$$R = 1/(1 - e^{-keT}) \quad (58)$$

Thus accumulation of the drug can be predicted by knowing the half-life and dosing interval of the drug.

Compartmental Analysis Approach

The most common approach in pharmacokinetics is to represent the body as a system of compartments, although these compartments have no anatomical or physiological reality. Further, one assumes that the transfer between compartments and the rate of drug elimination from these compartments follow first-order or linear kinetics. Thus, the one-compartment model represents the body as a single, kinetically homogenous unit. This model is useful for drugs that rapidly distribute throughout the body, and the plasma is usually the anatomical reference to the compartment. The assumption is that the rate of change in the blood concentration quantitatively reflects the change in drug concentration throughout the body.

However, most drugs entering the systemic circulation require a finite amount of time to distribute throughout the body into various tissues. This is usually seen following intravenous bolus injection of drugs. During this distributive phase, the drug concentration in plasma declines more rapidly than that observed in the postdistributive phase. Assuming that drug distribution is blood flow–dependent, the highly perfused tissues such as liver and kidney achieve rapid equilibrium with blood. Hence, conventionally the blood and all accessible fluids and tissues are represented as a kinetically homogenous unit and are referred to as the central compartment. On the other hand, poorly perfused tissues show an increase, followed by a decrease during the distribution phase and achieve a pseudodistribution equilibrium with the central compartment. Because the rates of transfer to the poorly perfused tissues are different but cannot be distinguished from blood concentration-time data, the poorly perfused tissues are lumped into a single peripheral compartment. Such representation of the body as multiple, kinetically homogenous units is referred to as multicompartment analysis (e.g., two-compartment, three-compartment). Drug elimination from multicompartment models is assumed to occur in a first-order (linear) fashion. Transfer of drug between body compartments is also assumed to occur by first-order processes. The mathematical basis and details of compartmental analysis are reviewed in great detail in several books and chapters (1,2,8,10).

CLASSIC LINEAR COMPARTMENTAL MODELS

One-Compartment Open Models with Linear Elimination

The blood concentration-time data for a one-compartment open model following a bolus intravenous dose are described by:

$$C = (\mathrm{D_{iv}}/V)e^{-ket} \quad (59)$$

Similarly, the blood concentration-time data for a one-compartment model with zero-order input (such as continuous intravenous infusion) are described by

$$C = (\mathrm{k_0}/V\mathrm{k_e})(1 - e^{-ket}) \quad (60)$$

The data for a one-compartment open model following first-order input (such as oral or other extravascular routes of administration) are described by:

$$C = (FD/V)\{(k_a/(k_a - k_e)\}\{e^{-ket} - e^{-kat}\} \quad (61)$$

One-Compartment Open Model with Michaelis-Menten Elimination

The blood concentration-time data for drugs showing one-compartment characteristics with nonlinear elimination (Michaelis-Menten) can be described by

$$dC/dt = V'_m C/(K_m + C) \quad (62)$$

where V'_m is the ratio of the maximum velocity of metabolism (V_m, mass/time) and the apparent volume of distribution (V); K_m refers to the Michaelis constant.

The integration of equation 62 yields:

$$C_1 - C_2 + K_m(\ln C_1 - \ln C_2) = V'_m(t_1 - t_2) \quad (63)$$

where C_1 and C_2 are any two points on the blood concentration-time curve corresponding to times t_1 and t_2, respectively, and $V'_m = V_m/V$.

Two-Compartment Open Models with Linear Elimination from Central Compartment

For drugs with two-compartment kinetics with central compartment elimination, the blood concentration-time data following intravenous bolus input are described by

$$C = [(D_{iv}/V_c(\lambda_2 - \lambda_1)]\{(k_{21} - \lambda_1)e^{-\lambda 1t} - (k_{21} - \lambda_2)e^{-\lambda 2t}\} \quad (64)$$

For a two-compartment open model with central compartment elimination, following zero-order input such as continuous intravenous infusion, the blood concentration-time data are described by

$$C = k_0/V_c\{[(k_{21} - \lambda_1)(e^{+\lambda 1t} - 1)e^{-\lambda 1t}/\lambda_1(\lambda_2 - \lambda_1)] + [(k_{21} - \lambda_1)e^{+\lambda 2t} - 1)e^{-\lambda 2t}/\lambda_2(\lambda_1 - \lambda_2)]\} \quad (65)$$

The postinput equation corresponding to equation 65 is simply obtained by replacing $e^{+\lambda 1t}$ by $e^{+\lambda 1T}$ and $e^{+\lambda 2t}$ by $e^{+\lambda 2T}$, where T is the zero-order input time and t remains the time from the beginning of the zero-order input.

The blood concentration-time profile of drugs following two-compartment open model with first-order input (extravascular administration such as oral) and central compartment elimination are described by:

$$C = (kaFD/V_c)\{[(k_{21} - \lambda_1)e^{-\lambda 1t}/(\lambda_2 - \lambda_1)(ka - \lambda_1)] + [(k_{21} - \lambda_2)e^{-\lambda 2t}/(\lambda_1 - \lambda_2)(k_a - \lambda_2)] + [(k_{21} - k_a)e^{-kat}/(\lambda_2 - k_a)(\lambda_1 - k_a)]\} \quad (66)$$

In equation 66, $\lambda_1 < \lambda_2$, and $\lambda_1 + \lambda_2 = k_{12} + k_{21} + k_{10}$, and $\lambda_1\lambda_2 = k_{21}k_{10}$.

Linear Two-Compartment Open Model with Peripheral Compartment Elimination

For drugs displaying two-compartment kinetics with elimination from the peripheral compartment, the blood concentration-time data following a bolus intravenous injection are given by

$$C = (D_{iv}/(V_c(\lambda_2 - \lambda_1)))\{(k_{20} + k_{;21} - \lambda_1) \cdot e^{-\lambda 1t}(k_{20} + k_{21} - \lambda_2)e^{-\lambda et} \quad (67)$$

where $\lambda_1 + \lambda_2 = k_{12} + k_{21} + k_{20}$, and $\lambda_1\lambda_2 = k_{12}k_{20}$

Noncompartmental Analysis

Noncompartmental methods are sometimes referred to as model-independent methods of data analysis. These methods do not require any assumptions regarding a specific compartmental model, but do assume linear pharmacokinetics. The noncompartmental approach for the determination of absorption, distribution, and elimination parameters is based on the theory of statistical moments (23,24). The zero moment of drug concentration in plasma versus time is referred to as the AUC from time zero to infinity. The AUC from time zero to time t is estimated using standard methods such as trapezoidal rule, whereas the area under tail of the curve from time t to infinity is estimated as:

$$AUC_{(t-\infty)} = C/k_e \quad (68)$$

Estimates of AUC are useful in calculating not only bioavailability but also drug clearance, which of all the pharmacokinetic parameters is the most useful for clinical application. Noncompartmental methods have also been used in estimating the apparent volume of distribution, the fraction of dose converted to a specific metabolite, the average steady-state concentration of a drug or a metabolite, and the time required to reach a given fraction of the steady-state concentration.

The first moment of a blood concentration-time profile is the area under the curve of a plot of the product of concentration and time versus time from zero to infinity (AUMC). As with AUC, the area under the moment curve from time zero to time t can be estimated using the trapezoidal rule. The area under the tail (time t to infinity) of the first moment curve can be estimated from:

$$AUMC_{(t-\infty)} = (C \cdot t)/k_e + C/k_e^2 \quad (69)$$

The AUM assumes that the sampling has been conducted such that the last sample is in the postabsorptive and where applicable, in the postdistributive phase of the curve.

Statistical Moments. The time course of drug concentration can usually be regarded as a statistical distribution curve (25). Irrespective of the route of administration, the first three (zero to second) moments are defined as follows:

$$AUC = \int_0^\infty C dt \quad (70)$$

$$MRT = \int_0^\infty t \cdot C dt \Big/ \int_0^\infty C dt = AUMC/AUC \quad (71)$$

$$\text{VRT} = \int_0^\infty t^2 \cdot C\mathrm{d}t \Big/ \int_0^\infty C\mathrm{d}t = \int_0^\infty (t - \text{MRT})^2 C\mathrm{d}t/\text{AUC} \tag{72}$$

where MRT is the mean residence time of the drug in the body and VRT is the variance of the mean residence time of the drug in the body. The AUC, MRT, and VRT are termed zero, first and second moment, respectively, of the drug blood concentration-time curve (8). As already noted, the area under the curve of the plot of the product of concentration and time versus time from zero time to infinity is called the area under the (first) moment curve (AUMC) (26).

Bioavailability (F) refers to the fraction of an oral dose of a drug that reaches the systemic circulation. In statistical moments, bioavailability is the ratio of the zero moments after oral and intravenous administration of the drug, adjusted for the dose levels. Thus,

$$F = \text{D}_{\text{iv}}\text{AUC}_{\text{oral}}/\text{D}_{\text{oral}}\text{AUC}_{\text{iv}} \tag{73}$$

The fraction of the oral dose reaching systemic circulation can be compared to other routes of administration (F_r) using similar equations.

Clearance of a drug can be estimated by noncompartmental methods as the reciprocal of the zero moment of a blood concentration-time curve normalized for dose, i.e.,

$$Cl_s = \text{D}_{\text{iv}}/\text{AUC}_{\text{iv}} \tag{74}$$

Clearance is usually estimated after an intravenous dose, but sometimes may be calculated after an intramuscular dose of the drug. Following oral administration, an apparent clearance can be estimated as,

$$Cl/F = \text{D}_{\text{oral}}/\text{AUC}_{\text{oral}} \tag{75}$$

The first moment of a blood concentration-time profile (MRT) is the statistical moment equivalent of half-life of drugs. MRT refers to the time required for 63.2% of the dose to be eliminated from systemic circulation. If the drug follows first-order elimination, MRT_{iv} would represent the reciprocal of the elimination rate constant (k_e)

$$\text{MRT}_{\text{iv}} = 1/\text{k}_\text{e} \tag{76}$$

$$\text{Half-life } (t_{1/2}) = 0.693\text{MRT}_{\text{iv}} \tag{77}$$

MRT is a function of the route of administration and is always greater than the MRT observed for intravenous administration. Thus the mean residence time after oral administration can be used to estimate the mean absorption time (MAT). In general,

$$\text{MAT} = \text{MRT}_{\text{oral}} - \text{MRT}_{\text{iv}} \tag{78}$$

When drug absorption can be described by first-order process, MAT represents the reciprocal of the absorption rate constant, i.e.,

$$\text{MAT} = 1/\text{k}_\text{a} \tag{79}$$

According to the statistical moments theory, the apparent volume of distribution at steady-state (V_{ss}), is a product of clearance and MRT after a single intravenous bolus dose. Thus,

$$V_{ss} = Cl \cdot \text{MRT} = \text{D}_{\text{iv}} \cdot \text{AUMC}/\text{AUC}^2 \tag{80}$$

Following an intravenous infusion, equation 80 can be amended to represent

$$V_{ss} = [\text{Infused Dose} \cdot \text{AUMC}/\text{AUC}^2] - [\text{Infused dose} \cdot T/2 \cdot \text{AUC}] \tag{81}$$

For extravascular administration (e.g., oral), the volume of distribution at steady-state is estimated as

$$V_{ss} = [(F \cdot \text{D}_{\text{oral}} \cdot \text{AUMC})/\text{AUC}^2] - [(F \cdot \text{D}_{\text{oral}})/(\text{k}_\text{a} \cdot \text{AUC})] \tag{82}$$

Nonlinear events cannot be described by noncompartmental methods. Furthermore, most noncompartmental parameters assume central compartment input, elimination, and sampling and thus may be considered to be a derivative of a compartmental mammillary model (10,27).

Physiologically Based Pharmacokinetic Models

A physiological pharmacokinetic model is composed of a series of lumped compartments (body regions) representing organ or tissue spaces whose drug concentrations are assumed to be uniform. The model requires that the volume, blood flow, and other properties of the lumped compartments be physiologically meaningful. An important consideration in the development of physiological pharmacokinetic model is the selection of which organs or tissues should be included in the model. An initial choice is made based upon the pharmacokinetic, pharmacodynamic, and physicochemical properties of the drug, as well as the anatomy and physiology of the body. The kind of information required for the model to be physiologically meaningful include (*1*) anatomical (e.g., organ or tissue volume), (*2*) physiological (e.g., blood flow rates and enzyme reaction parameters), (*3*) thermodynamic (e.g., protein binding isotherms), and (*4*) transport (e.g., membrane permeability of the drug). The models may be simplified to fit the information available because it is very likely that transport parameters may not be available, and the protein binding and enzyme reaction parameters may be available in simplified terms.

The concept of flow-limited conditions is used for all body regions. Mass balance equations are written for each lumped compartment. It is important to understand that physiologically based pharmacokinetic models are used to simulate the concentration data, not fit the concentration-time data. The degree of closeness of the simulation to real data can be quantitated using statistical parameters such as coefficient of determination (r^2). Some drugs require membrane-limited transport conditions. In such models,

all concentrations represent the free drug concentrations, and mass balance equations are written to describe drug in the extracellular and intracellular spaces and various tissues. These models are even more cumbersome than the blood flow-limited models because simple diffusion is usually not sufficient to describe membrane-limited uptake into certain tissues. However, membrane-limited models have been used to describe data for certain drugs including methotrexate and actinomycin D.

Because the correlation between simulated and real data is sparse in the literature, and because these models simulate an average concentration given that the models are based on average blood flows and average tissue partition coefficients, it is difficult to obtain any information on inter- or intrasubject variability using these models. However, these models are good tools to predict changes in disposition kinetics due to altered physiological or pathological conditions and provide a good mechanism to scale-up the data from preclinical studies to humans (28). The reader is referred to more detailed reviews of physiologically based pharmacokinetic models by Gibaldi and Perrier (8), Bischoff and Dedrick (29), and Bischoff (30).

Population Pharmacokinetics

The principles of population pharmacokinetics have been extensively studied, particularly by Sheiner, Beal, and others (31–35). Population pharmacokinetic parameters quantify population mean kinetics, interindividual variability, and residual variability including intraindividual variability and measurement error (35). An important issue in population kinetics is the identification of which pathophysiologic factor(s) influence the dose-concentration relationship and the degree to which they do so (34). Population kinetics are also popular because they require a fewer samples than traditional pharmacokinetic studies, thus making them amenable during the clinical use of the drug. Population pharmacokinetic studies are normally conducted during the clinical evaluation of a drug. They provide additional information regarding the drug but cannot be used to substitute the classic pharmacokinetic characterization of a drug.

NONMEM (Nonlinear Mixed Effects Model) is a software program developed for estimating population pharmacokinetic parameters from routine patient data (36). It is able to simultaneously determine all parameters including variance parameters, estimate intra- and interpatient variability, and using the extended least squares method, is able to take care of inadequate pharmacokinetic modeling, analytical error, and residual error. However, the use of NONMEM requires the specification of a model for the population being evaluated, and the individual data may be significantly different from the population mean. Although the use of NONMEM and population pharmacokinetics is increasing slowly, it is not yet used in the development of strategies for controlled drug delivery, although it has been used in the evaluation of data following administration of different dosage forms to patients.

ASSESSMENT OF DRUG INPUT RATE FROM CONTROLLED DRUG DELIVERY SYSTEMS

The measurement of the extent of absorption from a controlled drug delivery system provides useful but incomplete information of the absorption process. Additional information on the rate of absorption (i.e., rate of delivery to the systemic circulation) is needed to obtain a better understanding of the drug input (14). The pharmacokinetic principles described earlier provide simple measures such as maximum blood concentration (C_{max}) or time needed to reach the maximum blood concentration (t_{max}). Some more information can be obtained from statistical moments approach regarding the absorption rate. This is achieved via the estimation of mean absorption (input) time. However these single-parameter approaches are inadequate to provide an understanding of drug input rate. Hence more informative approaches involving the characterization of the full time course of the input process such as mass balance and deconvolution methods are used for assessment of drug input rate from controlled drug delivery systems. These methods require the assumption that the drug disposition should follow linear pharmacokinetics.

Mass Balance Methods for the Assessment of Input Rate

The estimation of the amount of the drug in the body at time t, $A(t)$, is determined via the measurement of blood concentrations of the drug following extravascular administration. The estimate of $A(t)$ requires the assumptions of one-compartment or two-compartment models for the disposition of the drug. The Wagner-Nelson method (37) assumes a one-compartment disposition of the drug, whereas the Loo-Riegelman method (38) is applicable to a drug following two-compartment disposition.

Wagner-Nelson Method. Assuming one-compartment disposition, the mass balance equation for the total amount absorbed up to time t is given by

$$A_{abs}(t) = V \cdot C(t) + Cl \int_0^t C(T)\mathrm{d}T \tag{83}$$

where $\int_0^t C(T)\mathrm{d}T$ is the area under the blood concentration-time curve up to time t, i.e., (AUC_{0-t}), V is the volume of distribution and $C(t)$ is the concentration at time t. Thus equation 83 may also be written as

$$A_{abs}(t) = V \cdot C(t) + Cl \cdot \mathrm{AUC}_{0-t} \tag{84}$$

The total amount of drug ultimately absorbed (at time infinity), noting that the drug concentration in the body at time infinity is zero, is given by

$$A_\infty = Cl \int_0^\infty C(T)\mathrm{d}T \tag{85}$$

where $\int_0^\infty C(T)\mathrm{d}T$ at time infinity is the area under the blood concentration-time curve ($\mathrm{AUC}_{0-\infty}$). The fraction of drug absorbed up to time t can be estimated from the ratio

$$A_{abs}(t)/A_\infty = (V \cdot C(t) + Cl \cdot \mathrm{AUC}_{0-t})/(Cl \cdot \mathrm{AUC}_{0-\infty}) \quad (86)$$

It should be noted that the Wagner-Nelson method makes no assumptions for the absorption process. However, if a semilogarithmic plot of percent drug remaining to be absorbed (i.e., $100(1 - [A_{abs}(t))/A_\infty])$ versus time yields approximately a straight line, it suggests an apparent first-order absorption process and the apparent first-order rate of absorption, k_a, can be estimated from the slope of the line. Similarly, a straight line from the plot of percent remaining to be absorbed versus time on rectilinear coordinates suggests zero-order absorption of the drug.

In order to analyze data from microsphere systems used in sustained or prolonged release controlled drug delivery systems, one may not be able to sample the plasma samples until the entire dose has been released from the delivery system. Recognizing that the product of the systemic clearance and the area under the blood concentration-time curve at time infinity is equal to the total amount of dose administered, the amount absorbed at time t is given by

$$A_{abs}(t)/A_\infty = [V \cdot C(t) + Cl \cdot \mathrm{AUC}_{0-t}]/\mathrm{Dose} \quad (87)$$

The fraction of the drug absorbed at time t may also be estimated from the urinary excretion data as discussed by Gibaldi and Perrier (8). The blood concentration at time t, $C(t)$ may be estimated from the urinary excretion data as

$$C(t) = [dA_u/dt]/[k_e \cdot V] \quad (88)$$

where k_e is the apparent first-order excretion rate constant, and dA_u/dt is the rate of excretion of the drug. Following substitution and rearrangement of the resulting equation, the amount of the drug in the body at time t, is given by

$$A_{abs}(t) = [(dA_u/dt)_T]/k_e + (k/k_e)(A_u)_T \quad (89)$$

where k is the first-order elimination rate constant from the body, and $A_{u(T)}$ is the amount recovered unchanged in the urine following administration of the controlled drug delivery system. At time infinity, the amount of the drug excreted in the urine is given as

$$A_{abs\infty} = [k/k_e] \cdot A_{u\infty} \quad (90)$$

Multiplying both sides by $V \cdot k_e$ (i.e., renal clearance Cl_r) in equations 89 and 90, yields

$$Cl_r \cdot A_{abs}(t) = V \cdot [(dA_u/dt)_T] + Cl \cdot (A_u)_T \quad (91)$$

and

$$Cl_r \cdot A_{abs\infty} = Cl \cdot A_{u\infty} \quad (92)$$

The ratio of equations 91 and 92 yields the fraction of the drug absorbed at any time t as

$$A_{abs}(t)/A_{abs\infty} = \{V \cdot [(dA_u/dt)_T] + Cl \cdot (A_u)_T\}/(Cl \cdot A_{u\infty}) \quad (93)$$

In theory, the fraction of the dose absorbed following administration can be solely calculated from the urinary excretion data. However, the collection of urine over an adequate period to allow the estimation of the pharmacokinetic parameters may not be practical in case of some controlled drug delivery systems.

The most serious limitation of the Wagner-Nelson method is that it is applicable only to drugs displaying one-compartment disposition. In all other cases, it is shown to be an approximation. For drugs displaying multicompartment disposition, the Wagner-Nelson method results in an underestimation of the time at which absorption ceases, and an overestimation of the absorption rate (8). One approach to overcoming this problem is to use the Loo-Riegelman method (38), described later. However, the application of the latter method requires concentration-time data, following both intravenous and the intended route of administration of the drug, which may or may not be available at all times. For this reason, the Wagner-Nelson method serves as a valuable approximation method for the determination of the input rate following administration of pharmaceutical controlled drug delivery systems.

Cohen et al. (39) presented a modified version of the Wagner-Nelson method for the assessment of in vivo release rate from liposomal formulations intended for sustained release over a month, following subcutaneous (s.c.) administration. These investigators determined the input rate into the surrounding tissues (s.c. space) and in the plasma following drug absorption. Based upon the mass balance equation, the concentration of the drug in the plasma can be obtained from

$$dA_p/dt = F \cdot k_a \cdot V_s \cdot C_s - k_{el} \cdot V_d \cdot C_p \quad (94)$$

where F is the extent of absorption of the drug from a solution of the drug administered subcutaneously, k_a and k_{el} are the absorption and elimination rate constants, V_s and V_d are the volume of the subcutaneous space and the volume of distribution, respectively, and C_s and C_p are the concentrations of the drug in the subcutaneous space and plasma, respectively. Rearranging and integrating equation 94 yields the following relationship between the plasma and subcutaneous drug concentration:

$$F \cdot V_s \cdot k_a \cdot \int_0^t C_s(T)dT = V_d C_p(t) + k_{el} V_d \int_0^t C_p(T)dT \quad (95)$$

The amount of drug in the subcutaneous space can be estimated from

$$V_s dC_s/dt = R_0 - k_a V_s C_s \quad (96)$$

where R_0 is the instantaneous release rate of the drug from the controlled drug delivery system into the s.c. space. The rate of release from the controlled drug delivery system into the s.c. space can be obtained by rearrangement and integration of equation 96 to yield

$$\int_0^t R_0(T)\mathrm{d}T = V_s C_s + k_a V_s \int_0^t C_s(T)\mathrm{d}T \qquad (97)$$

Dividing equation 97 by the total dose of the drug administered, the fraction of the dose released from the controlled drug delivery system can be estimated as

$$A_{abs}(t)/A_{abs\infty} = [V_d/F \cdot \text{Dose}] \cdot \{C_p \cdot (1 + k_{el}/k_a) + k_{el} \int_0^t C_p(T)\mathrm{d}T + (1/k_a)(\Delta C_p/\Delta t)\} \qquad (98)$$

This method is again restricted to compounds with one-compartment disposition and assumes that the estimates for the rates of absorption and elimination remain constant among studies. Furthermore, depending upon the error in the estimation of the absorption rate constant, an error is introduced in the fraction of the dose absorbed, usually leading to an overestimation of the fraction of the dose absorbed. Nevertheless, this method allows a reasonable first approximation of the in vivo release rate of the drug from prolonged release microsphere controlled drug delivery systems.

Loo-Riegelman Method. The Loo-Riegelman method (38) is applicable to a drug following two- or multicompartment disposition. It requires the blood concentration-time data following intravenous administration to assess the fraction of the dose absorbed at time t. The mathematical basis for a drug with two-compartment disposition is based upon the mass balance equation

$$A_{abs}(t) = A_1(t) + A_2(t) + A_{el}(t) \qquad (99)$$

where $A_1(t)$ and $A_2(t)$ are the amounts of the drug in the central and peripheral compartments, and $A_{el}(t)$ is the total amount eliminated from the body by all pathways. Assuming elimination from the central compartment only, the amount in the central compartment is given by

$$A_1(t) = V_1 \cdot C_1(t) \qquad (100)$$

where V_1 and $C_1(t)$ are the volume of the central compartment and the measured blood or blood concentration, respectively. The differential equation for the rate of change of the amount of drug in the peripheral compartment is given by

$$\mathrm{d}A_2/\mathrm{d}t = k_{1.2}A_1 - k_{2.1}A_2 \qquad (101)$$

where $k_{1.2}$ and $k_{2.1}$ are the first-order intercompartmental transfer rate constants. Loo and Riegelman (38) used a linear approximation for $C_1(t)$ over each data interval, and the amount of the drug absorbed at time t was estimated as

$$A_{abs}(t) = V_1 C_1(t) + V_2 C_2(t) + Cl \int_0^t C(T)\mathrm{d}T \qquad (102)$$

where

$$C_2(t) = C_2(t-1)e^{-k_{2.1}\Delta t} + [k_{1.2}/k_{2.1}]\{C_1(t-1)(1 - e^{-k_{2.1}\Delta t})\} + [k_{1.2}/(k_{2.1})^2]\{[C_1(t) - C_1(t-1)]/\Delta t\} \cdot (e^{-k_{2.1}\Delta t} - k_{2.1}\Delta t - 1) \qquad (103)$$

Loo and Riegelman assumed that the sampling period was relatively short so that the term $k_{2.1}\Delta t$ was less than or equal to 0.5; thus allowing the third term in the expression for $C_2(t)$ to be reduced using a Taylor expansion (i.e., $e^{-x} = 1 - x + x^2/2$) to

$$\{k_{1.2} \cdot [(C_1(t) - C_1(t-1))/\Delta t] \cdot (\Delta t)^2\}/2 \qquad (104)$$

Boxenbaum and Kaplan (40) have shown that this approximation is a potential source of error and should be avoided. Although the Loo-Riegelman approach is limited due to the requirement of intravenous concentration-time data, it is a very useful approach for the evaluation of absorption kinetics. Furthermore, the method can be used for drugs that distribute in any number of compartments, provided elimination occurs from the central compartment. Wagner (41) has shown that the Loo-Riegelman method can also be applied when the elimination occurs from the peripheral compartment. Expressions analogous to that presented for the estimation of $C_2(t)$ must be written for each peripheral compartment and the amount of drug absorbed in the body at time t can be estimated from the mass balance equation. A modification of the Loo-Riegelman approach without the need for intravenous reference data is presented by Gerardin et al. (42). However, this approach requires the unrealistic condition that distribution occurs much more slowly than the input (13).

Cutler (43) has also shown that both the Wagner-Nelson and Loo-Riegelman methods are applicable to compounds showing a variable clearance and/or nonlinear disposition. Although the mass balance approaches provide a reasonable approximation of the input rate, they are still restricted by assumptions and are "model-dependent." These limitations may be overcome by "model-independent" methods termed deconvolution, which are described in the next section.

Assessment of Absorption Rate by Deconvolution Techniques

The process of determination of the drug input rate from a measured response (for example, blood concentration-time profile) is referred to as deconvolution. The prediction of a response from drug input is known as convolution. It is reported that the deconvolution process is very sensitive to noise in the output data, and the error is amplified in the estimation of the drug input rate. On the other hand, the variation in the drug input rate is dampened when estimating the output. The methods used for deconvolution of output data for microsphere systems is similar to the available methods for other traditional controlled drug delivery systems. Several methods have been proposed in the literature for estimating the drug input rate using deconvolution from pharmaceutical controlled drug delivery systems (13,43–45).

Deconvolution techniques are used to analyze the pharmacokinetics of drug input following administration of the controlled drug delivery system. These methods arise from considering the body as a linear system with respect to drug disposition. It is a model-independent approach and uses two fundamental properties of linear response systems. First is the property of superposition, i.e., the sum or superposition of any two inputs, $f_1(t) + f_2(t)$, results in a response that is the superposition, $c_1(t) + c_2(t)$, of the individual responses for their respective input rates. The second property of linear response systems used in analysis using deconvolution techniques is the convolution integral property. This convolution integral property defines the relationship between the input function and the observed response following the input and is given by the following equation:

$$G(t) = \int R(I)G_\partial(t - T)\mathrm{d}T \tag{105}$$

where $R(t)$ is the input rate of the drug into the body, and $G(t)$ is the resulting response from the input. $G_\partial(t)$ is the response following a unit dose impulse input (such as an intravenous bolus dose). Excellent reviews on the mathematical basis of deconvolution are available in the literature (43–45). The major assumptions underlying the convolution integral property are that the response is linearly related to the input, and the system is time-invariant, i.e., the unit impulse response, $G_\partial(t)$, is independent of the time of administration. The limitations of the deconvolution approaches include its applicability to noninteracting inputs only (14). Prior to applying deconvolution techniques to assess the input rate, the system should be evaluated for the principle of superposition and interaction.

The convolution integral defined in equation 105 can be evaluated either analytically or numerically, when $R(t)$ and $G_\partial(t)$ are known, to predict the response (such as drug concentration) following drug input. This operation is termed *convolution*. When $G(t)$ and $G_\partial(t)$ are known, equation 105 serves as the basis for the estimation of the input rate. This procedure of estimating $R(t)$ from the convolution integral is termed *deconvolution*. Many methods have been proposed for numerical deconvolution. These include the finite difference methods, the least-squares methods, and Fourier analysis (14). The objective of this section is to define some of the mathematical basis for these approaches.

Rationale for the Development of Methods for Numerical Deconvolution. Vaughan and Dennis (46) discuss the need for numerical evaluation of data to determine the input function. They have shown that even if $G(t)$ and $G_\partial(t)$ are known analytically in the convolution integral

$$G(t) = \int R(T)G_\partial(t - T)\mathrm{d}T \tag{106}$$

the integral function defined by equation 106 cannot be solved, except in certain cases, because the Laplace transform of the equation

$$g(s) = r(s)\, g_\partial(s) \tag{107}$$

with solution

$$r(s) = g(s)/g_\partial(s) \tag{108}$$

cannot be transformed back into time space by the convolution theorem, because $1/g_\partial(s)$ is not a Laplace transform (47). In general, numerical evaluation of $g(s)$ and $g_\partial(s)$, with subsequent numerical calculation of $r(s)$ and inversion, is unsuccessful because of instability (48,49). Although Coulam et al. (49), have shown that Fourier transform methods are reasonably accurate, these methods are cumbersome, and the use of simple numerical methods would be advantageous in the deconvolution of blood concentration-time data to assess the input rate (46).

Finite Difference Methods for Numerical Deconvolution. The application of the finite difference method for deconvolution was initially introduced by Rescigno and Segré (50) as the area-area method. The deconvolution method requires no assumptions regarding the number of compartments or the kinetics of absorption. However, this method needs data following intravenous administration in addition to that following the intended route of administration. Furthermore, the concentrations must be measured at the same times following both routes of administration. However, the concentrations do not need to be measured at equally spaced intervals.

The mathematical basis for the area-area method is somewhat ambiguous. It approximates the absorption rate by a constant over a time interval. Essentially this method approximates the absorption rate as an equal pulse length "staircase" function (14). Upon deconvolution, Vaughan and Dennis (46) have shown that this product of the pulse lengths and exact output is interpreted as the actual area of the output function itself. These investigators have also shown that via simulations that the area-area method results in large and unpredictable errors in the estimation of the 'staircase' input function.

Benet and Chiang (51) have suggested that the area-area method is only appropriate when the characteristic response is a single exponential function. Vaughan and Dennis (46) have shown that the response to a 'staircase' input function can be derived for both, equal and unequal pulse lengths, by the application of the Laplace transformation methods. If $Y(p_j)$ is the concentration (exact output) at time point p_j, then the response can be obtained from

$$Y(p_j) = \sum_{i=1}^{j} I_i\left\{\int_0^{p_j - p_{i-1}} G_\partial(T)\mathrm{d}T - \int_0^{p_j - p_i} G_\partial(T)\mathrm{d}T\right\} \tag{109}$$

where $j = 1, 2, 3 \ldots$, $p_0 = 0$, and $Y(0) = 0$, and $\int G_\partial(T)\mathrm{d}T$ is the AUC following intravenous bolus administration over the defined time interval.

If all the staircase pulse lengths are equal, i.e., $p_j - p_{j-1} = a$ for all j, then the substitution of $p_j = ja$ and $p_i = ia$ into equation 110 yields:

$$Y(ja) = \sum_{i=1}^{j} I_i \int_{(j-i)a}^{(j-i+1)a} G_\partial(T)\mathrm{d}T \qquad (110)$$

where $j > 0$, $Y(0) = 0$, and $\int G_\partial(T)\mathrm{d}T$ is the AUC following intravenous bolus administration over the time interval.

Vaughan and Dennis (46) have shown that once the exact output, $Y(p_j)$ at time point p_j, or $Y(ja)$ at time point ja, and the response to a unit impulse dose are known, a particular staircase input function can be obtained from either equations 109 or 110, for unequal or equal pulse lengths, respectively.

Proost (52) proposed a general numerical deconvolution equation for drug concentration-time data with unequal lengths, applying model-independent methods. It was demonstrated that it is not necessary to know the response to a unit impulse input as an analytical function, i.e., curve fitting, and the drug concentration-time data from the unit impulse dose could be used directly. This method is an approximation of the method proposed by Vaughan and Dennis (46), with the exception that the integrals for $G_\partial(t)$ are obtained by the application of either linear or log-trapezoidal rule, and the concentration at time zero following an intravenous dose is estimated by logarithmic extrapolation. Proost (52) showed that the staircase approximation of the input rate, I_n, obtained by the trapezoidal approximation of the unit impulse data or an analytical solution for the integral of $G_\partial(t)$ yielded similar input rates. The cumulative fraction of the dose absorbed was estimated by the numerical integration of I_n as:

$$F_n = \sum_{i=1}^{j} [(I_{i-1 \text{ to } i})(T_i - T_{i-1})] \qquad (111)$$

where T_i is the ith sampling time point, and $I_{i-1 \text{ to } i}$ is analogous to the staircase input function of Vaughan and Dennis (46) in equation 111, with the exception that the integral of $G_\partial(t)$ is replaced by the trapezoidal approximation of the integral. The method of Proost (52) only assumes that the pharmacokinetics of the drug are linear.

A numerical deconvolution method has been derived for the determination of the in vivo input rates based upon the linear interpolation of the observed drug concentrations and deconvolution of the resulting trapezoidal function (53). The derived in vivo input functions are discontinuous and a general expression for the cumulative drug input is also derived. The expression for cumulative drug input was shown to be a generalization of the Loo-Riegelman equation, and it yielded similar results to the point-area method using the staircase approximation for input functions.

Wagner (54) has shown that the fraction of the drug remaining to be absorbed at the site of administration can be obtained from a similar expression. In terms of the sampling interval (Δt), the fraction unabsorbed (FR) can be obtained from:

$$FR_{n\Delta t} = [H_{(n+1)\Delta t}/H_{n\Delta t}] - \sum_{i=2 \text{ to } n+1}^{j=1 \text{ to } n} \{[F_{i\Delta t}/F_{\Delta t}][FR]_{(j-1)\Delta t}\} \qquad (112)$$

where $n\Delta t$ is the time after n sampling intervals equal to Δt, H is a function describing the drug concentration-time curve following the intended route of administration, and F is a function describing the drug concentration-time curve following intravenous bolus administration. $F_{n\Delta t}$ may be expressed as the drug concentration at time $n\Delta t$, or as the area under the curve between $n\Delta t$ and $(n-1)\Delta t$. $H_{n\Delta t}$ can only be expressed in terms of drug concentration. When both, H and F are expressed in terms of drug concentrations, the method is referred to as the point–point method (8). Benet and Chiang (51) recommended the use of the point–area method, in which F should be expressed as the area under the drug concentration-time curve following intravenous administration, and H should be expressed in terms of drug concentration in equation 112. Vaughan and Dennis (46) also designate their method of deconvolution as the point–area method, because specific output data points, $Y(p_j)$, and the integral of $G_\partial(t)$, is used to derive the staircase input function.

Chiou (55) proposed a finite difference method for numerical deconvolution using an instantaneous midpoint-input principle. This assumes that all the drug absorbed during a given interval, regardless of the complexity of the absorption kinetics, is absorbed instantaneously at the midpoint of the interval. This assumption is based upon the finding that the blood concentration for a one-compartment model system following an intravenous infusion can be approximated by assuming that the entire dose was administered as a bolus at the midpoint of the infusion period (56). This approximation is valid when the infusion period is much shorter than the half-life of the drug. The deconvolution method proposed by Chiou (55) requires no assumptions regarding the pharmacokinetic models or the site of drug elimination. The fraction of the dose absorbed at time $t(F)$ can be calculated from:

$$F_1 = C_{t1}/C_{\text{i.v.}(0.5t1)} \qquad (113)$$

where C_{t1} is the blood drug concentration at time $t1$ after dosing, and $C_{\text{i.v.}(0.5t1)}$ is the blood drug concentration at time $0.5t1$, following an intravenous bolus dose. The amount of drug absorbed between times $t1$ and $t2$ can be estimated by a similar comparison, provided the drug concentration is corrected for the contribution from the drug absorbed prior to $t1$ (C_{p1}). To estimate C_{p1}, it is assumed that all drug prior to time $t1$ is instantaneously absorbed at time $0.5t1$, and the contribution is estimated as

$$C_{p1} = F_1 C_{\text{i.v.}(t2-0.5t1)} \qquad (114)$$

where $C_{\text{i.v.}(t-0.5t1)}$ is the theoretical blood concentration at time $(t2 - 0.5t1)$, when the same extravascular dose is administered as an intravenous bolus dose. This principle is used to estimate the fraction absorbed during other sampling intervals as follows:

$$F_n = \left[C_{tn} - \sum_{i=1}^{n-1} C_{pi}\right] \Big/ C_{\text{i.v.}0.5(tn-tn-1)} \qquad (115)$$

Vaughan (57) has shown that the method described by Chiou (55) is an approximation of the point–area method (53). Furthermore, the midpoint–input method is similar

to the approximation of the area–area method (50), which uses rectangular functions to approximate the integrals of $G_\partial(t)$ centered about the midpoint of integration. Vaughan (57) cautions against the use of approximations of the point–area method for the estimation of staircase input, because it leads to large errors in the cumulative drug input functions.

The finite difference methods for numerical deconvolution provide a simple method to estimate the drug input rates without assumptions regarding the pharmacokinetic models or absorption kinetics. Their main drawback is the instability in presence of data noise, which may require smoothing procedures (58). Cutler (43) has pointed out that the smoothing procedures may yield errors in the estimates of the input functions. Because the finite difference methods are computationally simple, they can be used without the use of complex algorithms and computers, needed for the more complex, but stable, deconvolution methods such as the least-squares (11,12).

Least-Squares Method for Numerical Deconvolution. The least-squares method provides the determination of the best estimate of the true input rate. The criteria for determining the best estimate for the input function relies on the accuracy of the prediction of the response $G(t)$. Thus the proximity of the predicted $G(t)$ values with the observed $G(t)$ values determine the accuracy of the estimated input rate. The least-squares deconvolution method requires assumptions and specifications regarding the mathematical form of the input function. Once the function describing the input function is specified, it is introduced into the convolution integral and the observed response, $G(t)$, is compared with the predicted response, $G'(t)$.

When little or no information is available regarding the nature of the input function, Cutler (43) has proposed the use of polynomial functions to describe the input function. Cutler (11) has shown that an exponential input function and the cube-root dissolution law represent adequate approximations of the input rate with simulated data. Cutler (12) proposed the use of orthogonal functions to derive the polynomial functions for approximations of the input function. This approach was proposed based upon the difficulty in estimating the input function using a polynomial approximation by Gamel et al. (58), which was attributed to the ill-conditioned set of polynomial equations. The least-squares approach is more stable to data noise, but is computationally more complex and requires the use of fairly extensive and specialized programs to determine the drug input functions.

Veng-Pedersen (44,45,59) has also proposed a least-squares deconvolution method for estimating the drug input rate using both a polynomial and a polyexponential approximation of the input rate. This approach has led to the development of a method using an adaptive least-squares cubic spline function for the approximation of the input rate. Based upon simulated data, this method is reported to have significant advantages over the method proposed by Cutler (12). These include the superiority of fitting the bolus input response by a polyexponential expression which is a smoothing function and does not oscillate between the data points as a polynomial expression does. Furthermore, the Veng-Pedersen (44) approach provided a simple and explicit mathematical function for the rate and extent of drug input rate, which alleviates the complexity of the back-transformation and summation of terms in the Cutler approach (12). Because the input function is calculated directly by linear regression in the Veng-Pedersen method, it is purported to be computationally simpler and does not require the extensive and specialized methods for deconvolution.

The least-squares method for deconvolution are considered model-independent even though they require the determination of the unit impulse response parameters by fitting the data to some function (e.g., polyexponential). The unit impulse response parameters require their determination by nonlinear regression. However, these estimated parameters do not require any uniqueness, and their actual values have no influence on the accuracy of the determination of the input function (60). The input function is approximated by a polynomial expression that uses these estimated parameters collective rather than individually. Hence, the least-squares method is not affected by the individual errors in the estimation of the parameters. Furthermore, because the input function is determined by linear rather than nonlinear regression, it is computationally simpler, and the problems of multiple minima are eliminated with this approach (60).

Despite the advantage of the stability of the least-squares deconvolution methods in presence of data noise, these methods require complex algorithms to determine the input functions. A simpler algorithm for easier implementation of this deconvolution technique has been provided (61). It is based upon a polyexponential approximation of the absorption response and the the response from intravenous bolus or infusion administration. The absorption response is represented by:

$$c(t) = \sum_{i=1}^{m} b_i e^{-\beta_i t_+} \tag{116}$$

where $t_+ = (t - t_{lag})_+$ and $c(0) = 0$; t_{lag} is the estimated lag time prior to appearance of the drug into systemic circulation following extravascular administration. The characteristic response from a unit impulse dose $c\partial(t)$ is obtained from the polyexponential approximation of the intravenous bolus response:

$$c_{iv}(t) = \sum_{i=1}^{n} a_i e^{-\alpha_i t} \tag{117}$$

where $\alpha_i > 0$. Thus, $c_\partial(t)$ can be obtained as:

$$c_\partial(t) = c_{iv}(t)/D_{iv} \tag{118}$$

where D_{iv} is the intravenous bolus dose.

The cumulative amount of drug absorbed, expressed as a percentage of the dose (PCT) has been shown to be:

$$\mathrm{PCT}(t) = [100/\mathrm{D}] \int_0^t f(t)\mathrm{d}t \tag{119}$$

where $f(t)$ is the rate of direct input. This expression has been shown to be equivalent to:

$$\mathrm{PCT}(t) = u_0 + \sum_{i=1}^{m+n-1} u_i e^{-v_i t} + \quad (120)$$

The absorption rate has been shown to be

$$f(t) = [\mathrm{D}/100] \sum_{i=1}^{m+n-1} u_i(-v_i)e^{-v_i t} + \quad (121)$$

where $v_i = \beta_i$ for $i = 1, 2, 3 \ldots, m$; and $v_i = -\gamma_{i-m}$ for $i = (m + 1), (m + 2), \ldots, (m + n - 1)$. u_i is defined as:

$$u_i = \mathrm{K}_4 b_i \left\{ \mathrm{K}_1 - (\mathrm{K}_3/\beta_i) - \sum_{j=1}^{n-1} (g_j/\gamma_j(\gamma_j + \beta_i)) \right\} \quad (122)$$

for $i = 1, 2, 3, \ldots, m$; and

$$u_i = \mathrm{K}_4(g_{i-m}/\gamma_{i-m}) \sum_{j=1}^{m} (b_j/(\gamma_{i-m} + \beta_j)) \quad (123)$$

for $i = (m + 1), (m + 2), \ldots, (m + n - 1)$. u_0 is obtained as:

$$u_0 = - \sum_{i=1}^{m+n-1} u_i \quad (124)$$

The parameters $\{g_i, \gamma_i\}_1^{n-1}$ are obtained from the parameters $\{a_i, \alpha_i\}_1^n$. The γ parameters are $(n - 1)$ roots of the $(n - 1)$th polynomial and can be obtained by conventional numerical methods (61). The remaining parameters in the expression for PCT have been described by Veng-Pedersen (61).

This approach to deconvolution is purported to be computationally easier and Veng-Pedersen (61) has provided a computer subroutine for easy implementation of the algorithm. Although the use of least-squares deconvolution approach has been simplified by the use of more user-friendly algorithms, they still require the use of fairly extensive and specialized computer programs to estimate the input functions. These requirements, along with the a priori assumptions regarding the approximation of the input function, limit the routine use of this approach for deconvolution of data from extravascular administration of controlled drug delivery systems.

Miscellaneous Methods for Deconvolution of Extravascular Data. Berman (62) proposed a deconvolution scheme for the calculation of input function given a system and its response. It is based upon the conversion of the convolution integral equation to an initial value problem. This technique is particularly simple and advantageous when dealing with compartmental systems. Foster et al. (63) have illustrated the use of this deconvolution approach, using compartmental analysis, with commonly available numerical integration software. The scheme can be used to determine an unknown input over time, from the measured response and the impulse response of the system. These investigators report that this method requires the solution of two systems of differential equations; those specifying the compartmental systems for the response function and the impulse response of the system. The input function can be calculated using simulations of these compartmental models. The accuracy of the simulations is determined from the goodness-of-fit of the function to the observed response data from the system.

A novel approach for deconvolution based upon the principle of maximum entropy has been introduced by Charter and Gull (64). The resulting input functions have been shown to be physiologically realistic and smooth, blood samples are not required to be taken at equally spaced intervals, and no preliminary smoothing or interpolation of data is required. The maximum entropy approach is conceptually complex, and it is proposed that the maximum entropy may offer the most reliable deconvolution for drugs exhibiting nonlinear kinetics (13).

CONCLUSIONS

This article has provided an overview of the mathematical basis and applications of pharmacokinetic principles in the design and analysis of drug from various dosage forms, with a particular emphasis toward controlled drug delivery systems. The choice of the appropriate pharmacokinetic models for the analysis of data depends on the availability of data from intravenous and extravascular routes of administration. The pharmacokinetic evaluation of any drug usually entails the determination of the pharmacokinetics of the drug following intravenous and/or the extravascular (intended) route of administration. Model-dependent and model-independent pharmacokinetic parameter estimates should be obtained from in vivo experiments to obtain a proper handle on the bioavailability (extent of absorption), systemic clearance, volume of distribution, and half-life of the drug.

In addition to the information on the extent of absorption from controlled drug delivery systems, mass balance and deconvolution techniques allow the estimation of in vivo input of drug into the biological system. Using the method of preference, one calculates the input rates from the controlled drug delivery system. The input rates allow the estimation of the fraction of the dose absorbed as a function of time. Cumulative amount of drug absorbed (in vivo) versus time plots are constructed, and are compared with in vitro dissolution rate plots to establish meaningful in vitro–in vivo correlation. Such correlation precludes the need for the conduct of expensive and time-consuming pharmacokinetic experiments during formulation development and/or optimization and provides a tool for quality control purposes. Thus, the appropriate understanding of pharmacokinetic principles leads to considerable advancement in the development of better controlled drug delivery systems for various drugs.

Bibliography

The development of bioerodible drug delivery implants has now been an area of great importance for a number of years. A major driving force in developing such implants is the ability to deliver therapeutic agents directly to the systemic circulation, which is important with drugs that undergo significant inactivation by the liver. Two major areas of application deserve special mention. These are the development of bioerodible drug delivery devices for protein delivery and site-specific delivery for the improved treatment of cancer.

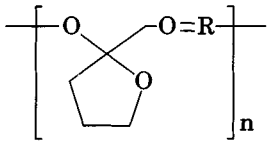
At the present time, there are three major classes of totally synthetic bioerodible polymers under active development. These are polyesters, polyanhydrides, and poly(ortho esters). Poly(ortho esters) have been under development since 1970, and three major families have been described. These are shown in Scheme 1.

Because the history of their development and applications prior to 1992 has been comprehensively reviewed (1,2), it is not the purpose of this article to again comprehensively review all past work. Rather, we concentrate on significant developments that have taken place since the last review, but for the sake of completeness, for each polymer system we present a brief, updated review with pertinent references and refer the reader to the original literature for additional details.

POLY(ORTHO ESTER) I

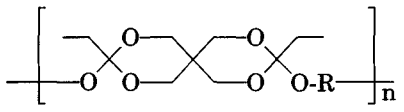
Poly(ortho ester) I, the first such polymer prepared, has been developed at the Alza Corporation and described in a series of patents by Choi and Heller (3–7). This polymer was originally designated as Chronomer™ but the name was later changed to Alzamer®. The polymer is prepared as shown in Scheme 2. However, the Alza Corporation has now discontinued all work with poly(ortho ester), and because the polymer is no longer available, collaborative efforts have also been discontinued.

Polymer Erosion



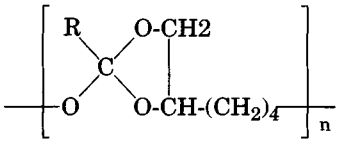
When placed in an aqueous environment, the polymer hydrolyzes as shown in Scheme 3. Because ortho ester linkages are acid sensitive and hydrolysis of this polymer produces γ-butyrolactone, which rapidly opens to γ-hydroxybutyric acid, the polymer must be stabilized with a base such as Na_2CO_3 to avoid an uncontrolled, autocatalytic hydrolysis reaction.

Drug Release



Even though a considerable amount of work with this polymer has been carried out at Alza, there is little detailed published information available, Alza publications do not specifically disclose the structure of the polymer, and only code names are used. However, it is now known that the code name of C111 represents a polymer prepared using 1,6-hexanediol, and C101ct is a polymer prepared using *cis/trans* cyclohexanedimethanol. The polymer has been used in the treatment of burns (8), in the delivery of the narcotic antagonist naltrexone (9), and in the delivery of the contraceptive steroid levonorgestrel (10). The polymer has also been investigated by Sudmann in a number of orthopedic applications (11–19).

Typical Synthetic Procedure



To 45 g (0.312 mole) of anhydrous *cis/trans*-1,4-cyclohexanedimethanol and 0.05 g polyphosphoric acid in a commercially available polymerization reactor is added with constant stirring under an inert nitrogen environment and normal atmospheric pressure 50 g (0.312 mole) of anhydrous 2,2-diethoxytetrahydrofuran. Next, the mixture is heated to 110–115°C and held at that temperature for 1.5 to 2 h with slow distillation of ethanol. Then, while main-

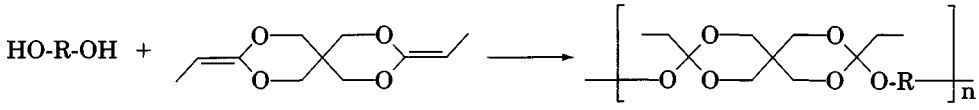
taining the temperature, the pressure is gradually reduced to 0.01 mm Hg, and at this reduced pressure the temperature is slowly increased to 180°C. The reaction is continued at this temperature for 24 h. The polymer is isolated by extrusion from the reactor.

POLY(ORTHO ESTER) II

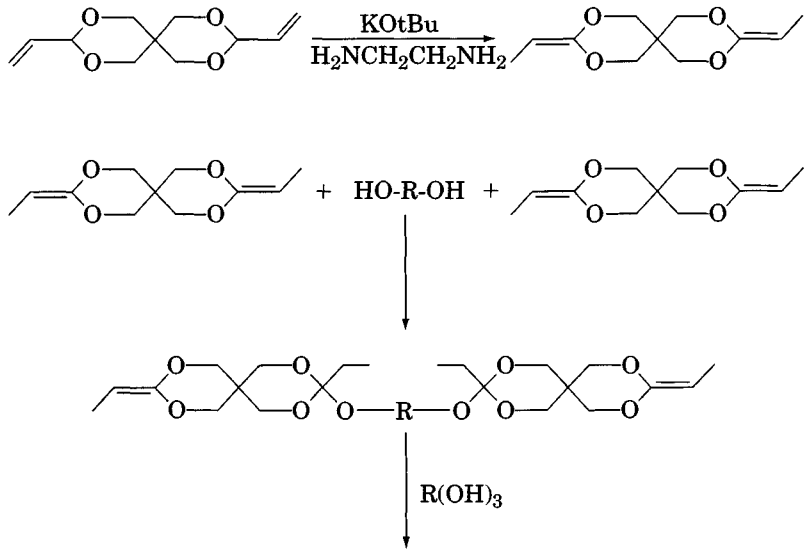
Poly(ortho ester) II was developed at the Stanford Research Institute, now known as SRI International, under contract with the National Institute of Child Health and Human Development, and was prepared as shown in Scheme 4. A history of the development of this polymer has been published (1).



The diketene acetal, 3,9-diethylidene-2,4,8,10-tetraoxaspiro [5.5] undecane is not commercially available, but can be readily synthesized as shown in Scheme 5 (20).

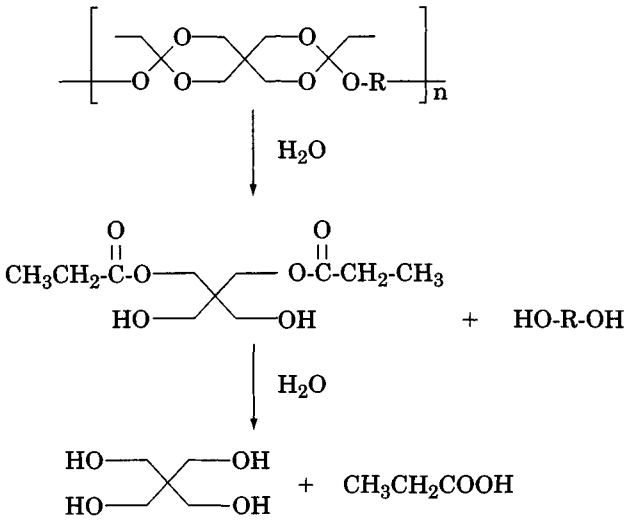
Because a condensation between a diketene acetal and a diol, just like that between a diisocyanate and a diol, proceeds without the evolution of volatile by-products, dense, cross-linked materials can be produced by using reagents having a functionality greater than two (21). To prepare cross-linked materials, a molar excess of the diketene acetal is used, and the resulting prepolymer with ketene acetal end-groups is reacted with a triol or a mixture of diols and triols. This synthesis is shown in Scheme 6.

Polymer Erosion



Use of Excipients. As shown in Scheme 7, this polymer hydrolyzes to initially neutral products so that it is not necessary to use bases to neutralize acidic hydrolysis products. Details of the hydrolysis mechanism have been published (22).

Even though ortho ester linkages are quite labile, polymers belonging to this family are extremely hydrophobic, and uncatalyzed poly(ortho esters), as shown in Figure 1, are very stable. Therefore, in order to achieve shortened erosion times, it is necessary to use small amounts of acidic excipients that are physically incorporated into the polymer (23,24). Then, rate of hydrolysis can be manipulated



Scheme 4.

Scheme 5.

Scheme 6.

Scheme 7.

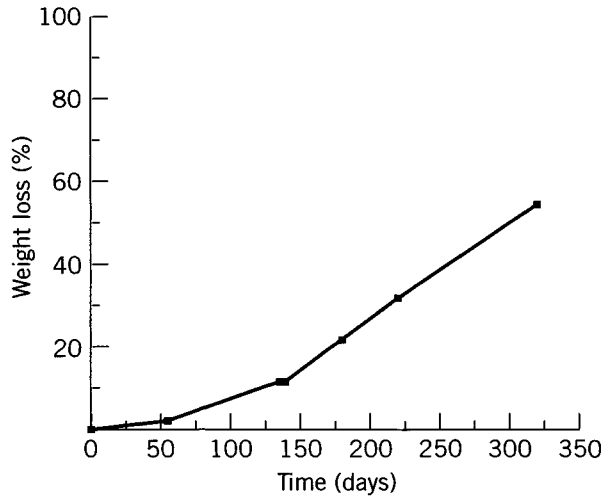


Figure 1. Weight loss as a function of time for a polymer prepared from 3,9-dimethylene-2,4,8,10-tetraoxaspiro [5.5] undecane and 1,6-hexanediol. 0.05 M phosphate buffer, pH 7.4, 37°C.

by varying the pKa and/or concentration of the acidic excipient. Although a number of different acidic excipients have been used with poly(ortho esters) (25), good results can be achieved by using suberic acid. When long delivery rates are desired, bases such as $Mg(OH)_2$ have been used to retard polymer erosion (21).

When the hydrophobic polymer with a physically dispersed acidic excipient is placed into an aqueous environment, water diffuses into the polymer, dissolves the acidic excipient in the surface layers, and the lowered pH accelerates hydrolysis of the acid-sensitive ortho ester bonds. This process is shown schematically in Figure 2, where it has been analyzed in terms of the movement of two fronts, F_1, the movement of a hydrating front, and F_2, the movement of an erosion front (26). The ultimate behavior of a device is then determined by the relative movement of these two fronts. If $F_1 > F_2$, the thickness of the reaction zone gradually increases, and at some time, the matrix is completely permeated by water. At that point, all ortho ester linkages hydrolyze at comparable rates and bulk hydrolysis takes place. However, if $F_1 = F_2$, then hydrolysis is confined to the surface layers and only surface hydrolysis takes place. In this latter case, rate of polymer erosion is completely determined by the rate at which water intrudes into the polymer.

Water sorption by poly(ortho esters) II has been found to be relatively small, about 0.30 to 0.75%, with a diffusion coefficient ranging from a high of 4.07×10^{-8} cm$^2 \cdot$ s^{-1} for a polymer based on 1,6-hexanediol (T_g 22°C) to a low of 2.11×10^{-8} cm$^2 \cdot$ s^{-1} for a polymer based on *trans-*

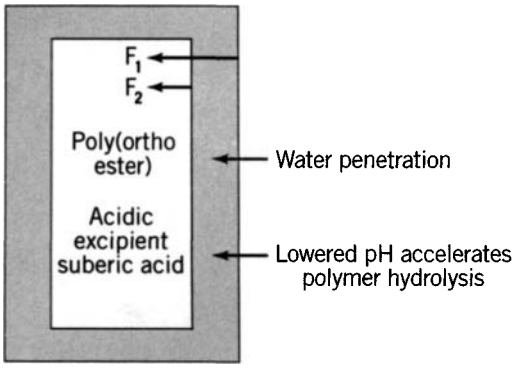

Figure 2. Erosion of a poly(ortho ester) containing dispersed suberic acid. F_1 is movement of eroding front, F_2 is movement of hydration front.

cyclohexanedimethanol (T_g 122°C) (27). Assuming a disk thickness of about 2 mm and using the lowest diffusion coefficient, the disk would be completely permeated by water in about 20 days if water penetrates only from one side of the disk and in about 10 days if water penetrates from both sides of the disk. Thus, the use of acidic excipients limits the design of surface-eroding devices to lifetimes that do not exceed 2–4 weeks, depending on the actual device size.

However, because ortho ester linkages are stable in base, very long time surface erosion is possible if the polymer is stabilized with a base that prevents hydrolysis even though the matrix is completely permeated by water. A plausible mechanism for erosion of devices that contain the base $Mg(OH)_2$ is shown in Figure 3. According to this mechanism, $Mg(OH)_2$ stabilizes the interior of the device, and erosion can only occur in the surface layers where the base has been eluted or neutralized. This is believed to occur by water intrusion into the matrix and diffusion of the slightly water-soluble $Mg(OH)_2$ out of the device where it is neutralized by the external buffer. Polymer erosion then occurs in the $Mg(OH)_2$-depleted layer (23).

Self-Catalyzed Polymers. Although the use of excipients represents a useful means of controlling rate of polymer erosion, when acidic excipients are used, diffusion of the excipient from the polymer is a serious problem that not only complicates kinetics of drug release, but more importantly, eventually leads to an excipient-depleted polymer

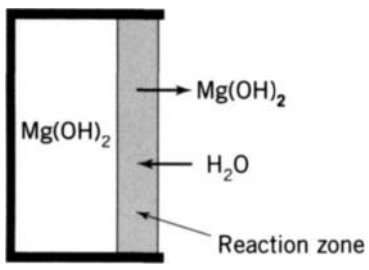

Figure 3. Water intrusion, $Mg(OH)_2$ diffusion, and erosion for one side of a bioerodible device containing dispersed $Mg(OH)_2$.

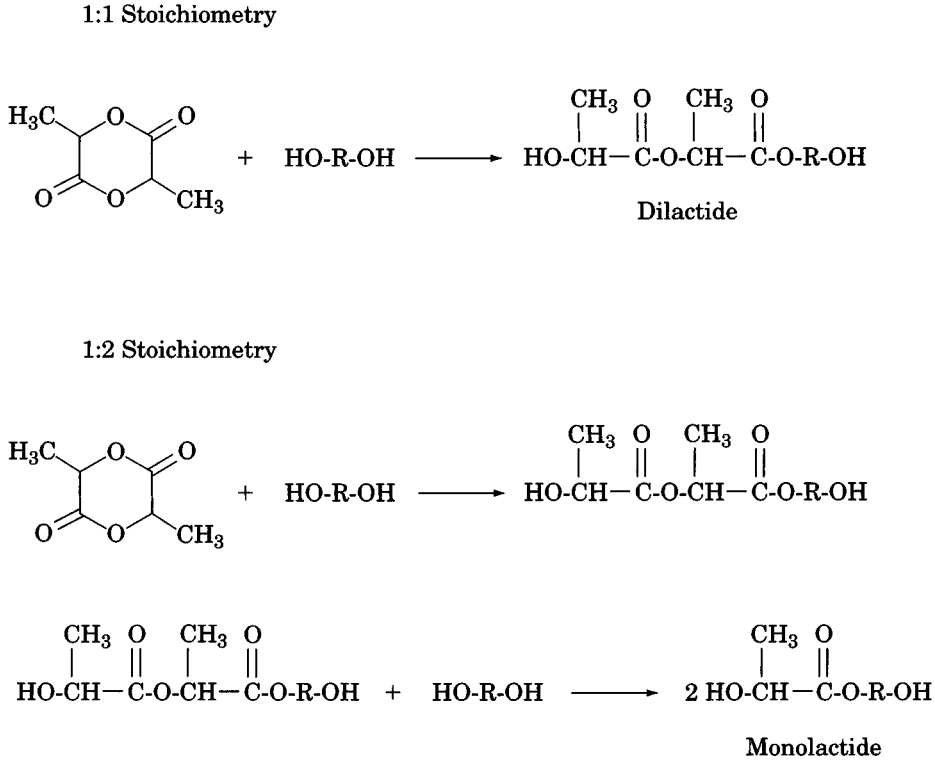
that remains in the tissues for a significant time. This residual polymer has been referred to as *ghosts*, and its formation has been mathematically modeled (28,29).

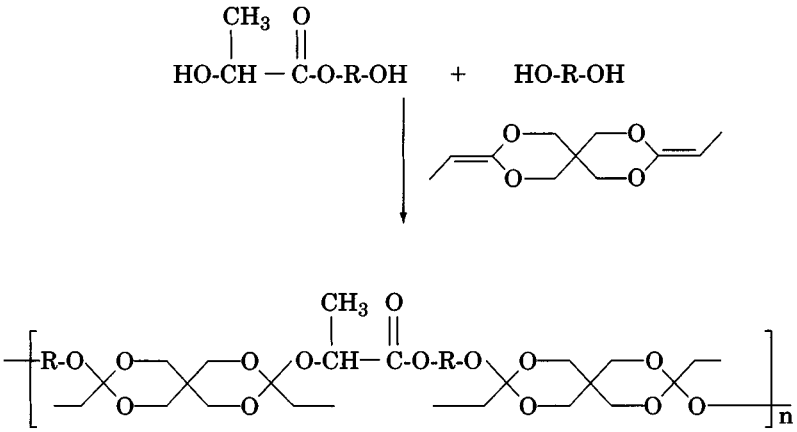
To eliminate complications inherent in using a low molecular weight excipient, the use of macromolecular excipients could be considered. However, a better approach is to incorporate into the polymer backbone a short segment that readily hydrolyzes to an acidic product that acts as the acidic excipient and catalyzes the hydrolysis of ortho ester linkages in the polymer. Then, by controlling the concentration of such a segments in the polymer, rate of erosion can be accurately controlled without complications arising from excipient diffusion (30).

We have found that a useful segment is one based on glycolic acid or lactic acid. Because the natural metabolite is L-lactic acid, this is the preferred segment. Lactic acid or glycolic acid segments can be readily incorporated into the polymer by first preparing a diol containing a hydroxy-acid segment, as shown in Scheme 8, by reacting a diol with either a cyclic lactide or glycolide. By controlling stoichiometry, the diol contains either mono or dilactic acid, or mono or diglycolic acid segments.



A polymer is then prepared, as shown in Scheme 9, and by varying the relative amounts of the two diols, polymers containing varying amounts of mono or dilactic acid, or mono or diglycolic acid segments can be prepared.

Hydrolysis of a polymer containing a diglycolic acid segment proceeds, as shown in Scheme 10, where the most labile segment, the diglycolic acid segment, hydrolyzes first, liberating glycolic acid, which then catalyzes erosion of the acid-labile ortho ester linkages. A similar hydrolysis can also be written for a polymer containing dilactic acid segments.

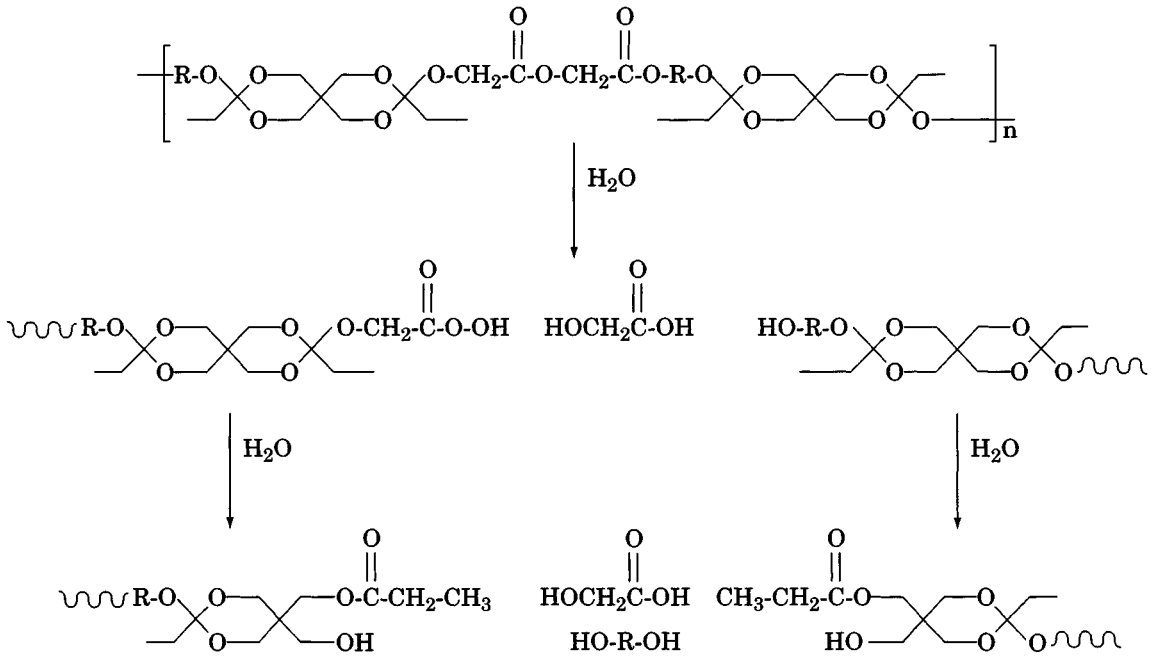


Weight loss of a polymer prepared from *trans*-cyclohexanedimethanol and *trans*-cyclohexanedimethanol diglycolide, shown in Scheme 11, are presented in Figure 4 (30). Clearly, incorporation of diglycolic acid segments into the polymer not only results in excellent erosion control, which proceeds by close to zero-order kinetics to completion, but also allow an accurate control over erosion rates, which range from days to many months.

Figure 5 shows weight loss and changes in number average molecular weight as a function of time for a 50/50 copolymer of *trans*-cyclohexanedimethanol and *trans*-cyclohexanedimethanol diglycolide (30). The points represent weights of remaining polymer and molecular weights of the remaining polymer. There is a slight induction period of about 2 days where no weight loss nor molecular weight decrease is detected, after which the molecular weight decreases steadily until about day 20, after which it remains relatively constant at about one-half of the original value. Rate of weight loss remains relatively constant throughout the entire study carried out over 60 days.

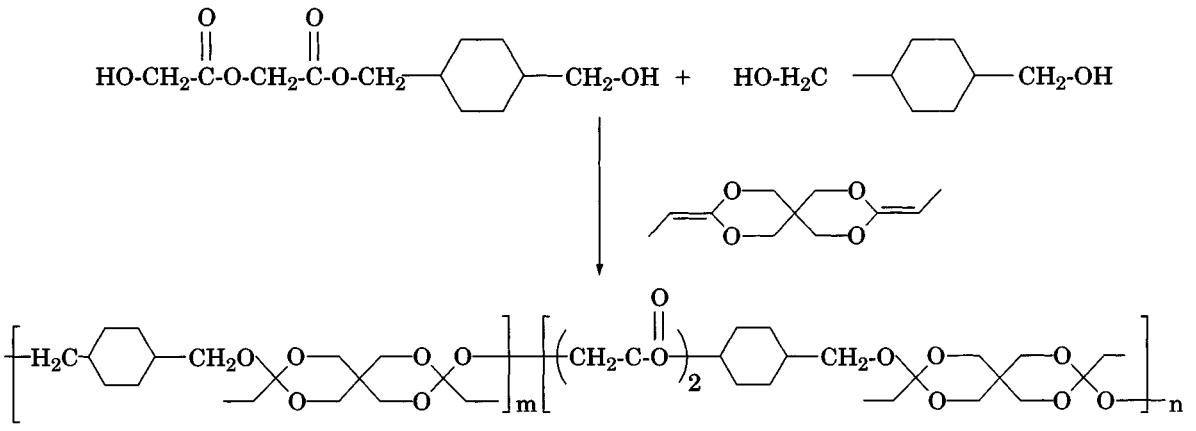
In view of the relatively high concentration of glycolic acid dimer segments in the polymer backbone, it is clear that these segments hydrolyze gradually because rapid hydrolysis of all glycolic acid dimer segments in the polymer would result in a decrease of polymer molecular weight to a value of about 350. Thus, the linearity of weight loss and the slow changes in molecular weights are consistent with a process that occurs predominantly in the surface layers

Scheme 8.



Scheme 9.

of the device with a gradual production of glycolic acid. At this point the discontinuity in the rate of molecular weight change that occurs at day 20, and details of the process are not yet fully understood. However, these preliminary results are encouraging and suggest that with this system, long-term surface erosion may perhaps be possible.



Polymer Physical Properties

The usefulness of a drug delivery system depends not only on an ability to control erosion rate and kinetics of drug release, but also depends on an ability to vary mechanical properties so that devices that have physical properties tailored to a specific application can be prepared. Poly(ortho esters) II are unique among all biodegradable polymers in that mechanical properties can be readily varied by choosing appropriate diols, or mixtures of diols in their synthesis. Thus, materials can be prepared that are rigid, flexible, or low melting solids, or that at room temperature are semisolids. The semisolid materials can either be fluid enough so that they can be injected at room temperature, or at the body temperature of 37°C are so viscous that little deformation takes place, even when pressure is applied, but at temperatures below 45°C soften enough so that the warm polymer can be injected.

Polymers Without the α-Hydroxyacid Segment. Figure 6 shows glass-transition temperatures for materials prepared from 3,9-diethylidene-2,4,8,10-tetraoxaspirol[5.5]-undecane and a mixture of *trans*-cyclohexanedimethanol and 1,6-hexanediol (31). The data show an excellent cor-

Scheme 10.

Scheme 11.

relation between mole ratios of the diols and glass-transition temperature and materials having glass-transition temperatures between 115 and 20°C can be readily prepared.

Materials having very low glass-transition temperatures can be prepared by using α,ω-diols. In Figure 7 is shown a correlation between the number of carbons in the diol and the glass-transition temperature (32).

Self-Catalyzed Polymers. The same variation in mechanical properties can also be achieved with polymers that incorporate an α-hydroxyacid segment. Depending on the desired mechanical properties, the α-hydroxyacid segment is incorporated into either the rigid or flexible diol.

Of particular interest are polymers that at room temperature are either fluid, ointment-like materials, or that can be converted to such materials by gentle heating. Because therapeutic agents can be incorporated by a simple mixing procedure in the absence of solvents, at very low temperatures, and without an organic solvent–water interface, such materials offer significant benefits for the delivery of sensitive therapeutic agents such as peptides and proteins. Although not yet verified, such delivery devices should be able to deliver peptides and proteins without loss of activity.

Semisolid materials can be prepared by using the triethylene glycol glycolide/triethylene glycol monomer pair, shown in Scheme 12. By varying the ratio of the two components, it is possible to prepare materials that at the body temperature of 37°C are so viscous that they do not show significant flow even when moderate pressure is applied, but at temperatures no higher than about 45°C are suffi-

ciently fluids so that they can be injected with a hypodermic syringe. Table 1 shows the effect of monomer ratios on polymer softening temperatures. However, injection of such materials requires a large needle, and the whole injection assembly must be heated prior to injection. This is clearly not an optimal means of administration, and for this reason, a high-pressure, heated injector has been developed at the University of Geneva.

By using the long-chain aliphatic diols shown in Scheme 13, it is also possible to prepare materials that are soft, low melting solids (33). Some properties of such materials are shown in Table 2.

Drug Release

Polymers Without the α-Hydroxyacid Segment. Because as already mentioned, these materials erode at rates that

are too low for useful drug delivery, it is necessary to accelerate rate of hydrolysis by using acidic excipients.

Short-Term Delivery. In a preliminary study (34), 10 wt % 5-fluorouracil (5-FU) was incorporated into a polymer prepared from 3,9-diethylidene-2,4,8,10-tetraoxaspiro-[5.5]undecane and 1,6-hexanediol containing 0.15 wt % of the acidic excipient suberic acid, and release of 5-FU and polymer erosion determined. During this short release time, and as shown in Figure 8, 5-FU was released at a constant rate, and because release occurred concomitantly with polymer erosion, surface erosion was the dominant mechanism of release.

Subsequent to that study, two studies designed to test the effectiveness of such a device in the treatment of leukemia and colorectal carcinoma were carried out. In the first study (35), DBA_2 mice were inoculated with L1210 leukemia and the 5-FU containing polymer disks administered intraperitoneally. As shown in Figure 9, untreated mice, or those treated with polymer placebos, all died within two weeks, but those treated with the 5-FU–containing polymer showed a significant increase in survival time. When this study was compared with one where free 5-FU was administered, animals receiving a dose of 500 mg/kg did not survive longer than 10 days due to acute toxicity problems. Animals receiving free 5-FU at doses of 200 mg/kg and 100 mg/kg showed increased survival, but significantly less so than that with the intraperitoneally administered 5-FU–containing polymer.

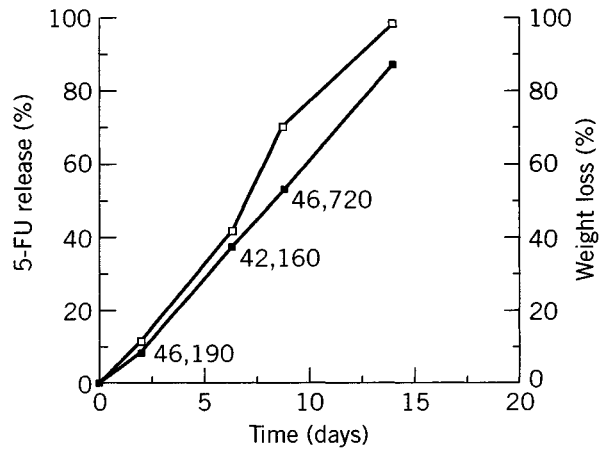

Figure 8. Cumulative weight loss (■) and cumulative release of (5FU) (□) from polymer disks prepared from 3,9-diethylidene-2,4,8,10-tetraoxaspiro [5.5] undecane and 1,6-hexanediol at pH 7.4 and 37°C. Figure 9. Survival times of DBA_2 mice inoculated with L1210 tumor. (□) control, (●) polymer alone, (○) polymer with 5-FU. Reprinted from Ref. 35, p. 7, with permission of Elsevier Science.

In view of these encouraging results, a more detailed study using LS174T human colorectal carcinoma in a subcutaneous xenograft in nude mice was carried out (36). Before 5-FU–containing polymers were administered, the potential toxicity of the polymer was investigated. In this study, 1, 2, 3, and 4 polymer disks, each weighing approximately 70 mg, were implanted intraperitoneally and animal weight loss determined. Results are shown in Figure 10. All animals survived for 60 days, but 2 of 3 mice that received four implants did exhibit some toxic effects, manifested by acute lethargy and slight trembling. The third animal receiving 4 implants survived with no signs of toxicity for 60 days. Based on these data, the polymer can be considered to be nontoxic.

The effect of implants, each containing approximately a 5-FU dose of 280 mg/kg, on tumor size is shown in Figure 11. In animals receiving 2 implants, average tumor size

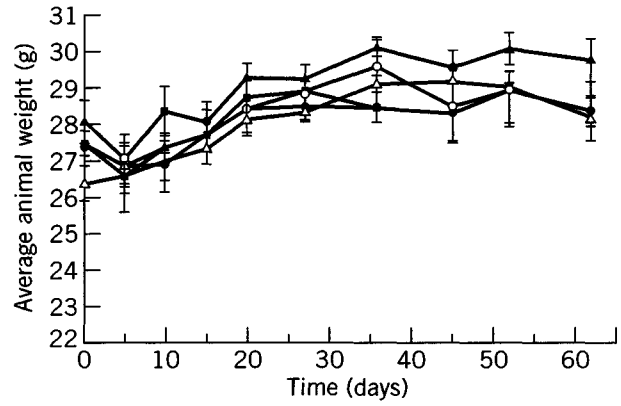

Figure 10. Effect of implantation of drug-free poly(ortho ester) matrices on animal weight. never exceeded 130 mm^2. In animals that received 3 implants, tumor growth was inhibited by more than 70%, and there were no overt signs of toxicity in the first days, but at day 6 they suffered substantial weight loss. Animals that received 4 implants showed very little tumor growth, but due to acute toxicity median survival was only 7 days.

These data suggest that a single dose intermediate between 260 and 580 mg/kg would be optimal for antitumor activity. However, this dose must be released at constant kinetics so as to avoid overdosing. Although the devices described here released 5-FU by excellent zero-order kinetics in vitro, we believe that in vivo 5-FU was not released at a constant rate. Additional work is in progress.

One of the current treatments of opiate addiction is to use narcotic antagonists, which generally have a chemical structure similar to those of opiates and which can preferentially occupy the body's opiate receptors and thus block the opiate's euphoric effect. This makes opiate intake pleasureless and removes the addict's incentive for continuing use (37,38). A commonly used narcotic antagonist is naltrexone, but a single oral dose is only effective for about two days. Thus, long-term therapy depends on continuing oral naltrexone intake. Because discontinuing naltrexone therapy produces no withdrawal effects, significant patient motivation is required and a much improved therapy could be achieved if the decision to continue naltrexone treatment is removed from the patient. Clearly, development of an implant that could release naltrexone for at least one month is desirable.

Because naltrexone is a base with a pK_a of 8.13, a saturated aqueous solution has a pH of about 10. Thus naltrexone exerts a stabilizing effect on poly(ortho esters). For this reason, the neutral naltrexone pamoate was used. An additional benefit is that naltrexone pamoate has a water solubility of only 0.5 mg/mL, about eight times less than naltrexone, which has a water solubility of 4 mg/mL.

Although the exact therapeutically effective blood plasma concentration of naltrexone is not known with certainty, it has been estimated that it is in the range of 0.5 to 1 ng/mL (39). To achieve this blood plasma level, a minimum 3.0 mg/day delivery is required. Thus, a very high drug loading is necessary if reasonably sized devices are to be used. For this reason, a soft polymer prepared from 3,9-diethylidene-2,4,8,10-tetraoxaspiro[5.5]undecane and 1,6-hexanediol was used with a naltrexone pamoate loading of 50 wt % (40).

Figure 12 shows release of naltrexone pamoate from polymer slabs from an uncatalyzed polymer and as a function of suberic acid concentration. Good correlation between suberic acid concentration and release has been achieved. It is interesting that the uncatalyzed device released naltrexone pamoate at reasonably linear kinetics at about 1 mg/day for 50 days. The best device was one containing 1 wt % suberic acid because it released naltrexone

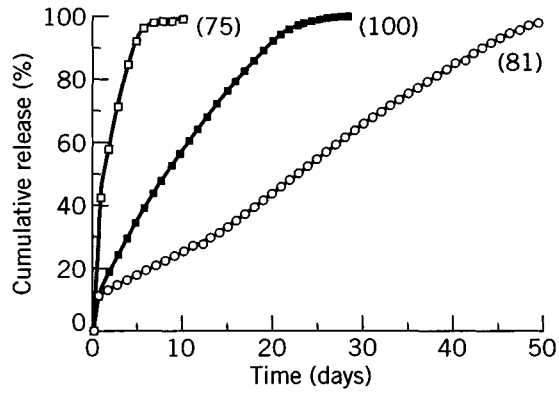

Figure 12. Cumulative release of naltrexone pamoate from polymer slabs (25 × 4 × 1.25 mm) prepared from 3,9-diethylidene-2,4,8,10-tetraoxaspiro [5.5] undecane and 1,6-hexanediol at pH 7.4 and 37°C. Numbers in parentheses indicate percent weight loss. Devices contain 50 wt % drug and varying amounts of suberic acid (SA). (□) 3 wt % SA, (■) 1 wt % SA, (○) no SA. *Source:* Reprinted from Ref. 40, p. 26, with permission of Elsevier Science.

pamoate at the desired 3 mg/day and because in this particular device drug depletion coincided with total polymer erosion.

Unfortunately, attempts to fabricate devices using a transfer molding procedures to produce rod-shaped devices for animal studies were not successful because at the temperatures and times necessary to produce devices, a naltrexone pamoate–induced polymer decomposition took place. Injection molding studies that could minimize heating times were not carried out because suitable small volume injection molding equipment was not available.

Malaria, dengue, yellow fever, and filiarisis are caused by stings of mosquitoes that introduce parasites into the body. Every year several hundred million people are infected (41). To this day, chemoprophylaxis remains the principal means of prevention, but because weekly administration of agents such as quinazoline, sulfadiazine, or pyrimethamine are necessary, poor compliance is responsible for one to two million deaths a year. Clearly, if an implant could be developed that would reduce the frequency of dosing, a significant improvement in prophylaxis could be achieved.

Pyrimethamine has been incorporated into a polymer prepared from 3,9-diethylidene-2,4,8,10-tetraoxaspiro-[5.5]undecane and a 40/60 mole ration of 1,6-hexanediol and *trans*-cyclohexanedimethanol. Disks containing 21 wt % pyrimethamine and varying amounts of suberic acid were then prepared and pyrimethamine release at pH 7.2 and 37°C investigated. Results are shown in Figure 13 (42). There is a very good correlation between amount of suberic acid, and good release kinetics have been achieved. Because pyrimethamine is a basic drug that stabilizes the polymer, fairly high amounts of suberic acid were needed.

Blood plasma levels of rabbits with implanted devices containing 5 wt % pyrimethamine are shown in Figure 14

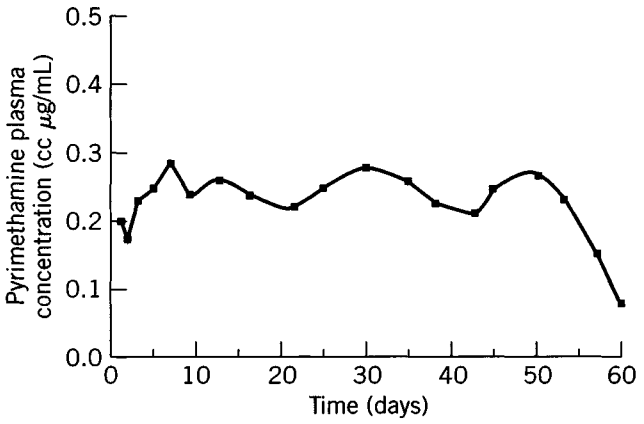

Figure 14. Plasma concentration of pyrimethamine in rabbits after administration of a disk, 25 × 3.0 mm containing 21 wt % pyrimethamine and 5 wt % suberic acid. *Source:* Reprinted from Ref. 42, p. 212, with permission of Elsevier Science.

(42). The values vary between 0.2 μg/mL and 0.3 μg/mL for 50 days after which they decline to zero, indicating that the implants have probably bioeroded, or at least have released their drug content. These results are highly encouraging because they demonstrate that constant blood plasma levels can be achieved for at least 50 days. Based on these results, development of delivery devices that could release pyrimethamine for 6 months at therapeutically useful levels should be possible.

The ability of the implants to protect mice injected with *P. berghei* is shown in Figure 15 (42). When pyrimethamine crystals were used, protection of the mice was limited to 3 weeks. However, when polymer implants with pyrimethamine and 5 wt % suberic acid were used, good chemoprophylaxis of malaria for 7–9 weeks was achieved, a very significant improvement.

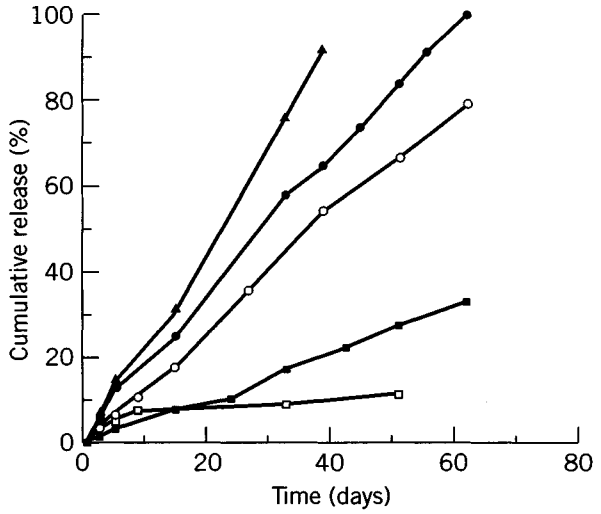

Figure 13. Release of pyrimethamine as a function of amount of incorporated suberic acid (SA). (□) no SA, (■) 1 wt % SA, (○) 3 wt % SA, (●) 5 wt % SA, (▲) 10 wt % SA. Tobramycin sulfate has been used in the treatment of osteomyelitis and its in vitro release from poly(ortho esters) has been investigated (43). After an initial burst (20 wt %), reasonably constant release kinetics for up to 25 days were achieved with lactic acid or oleic acid excipients.

Long-Term Delivery. Long-term in vivo surface erosion using $Mg(OH)_2$ has been documented with cross-linked polymers prepared as shown in Scheme 5 (21). In these studies, devices were fabricated by first preparing a ketene acetal terminated prepolymer derived from two equivalents of the diketene acetal 3,9-diethylidene 2,4,8,10 tetraoxaspiro [5.5] undecane and one equivalent of 3-methyl-1,5-pentanediol. Then, 30 wt % micronized levonorgestrel, 7 wt % micronized $Mg(OH)_2$, and a 30 mole % excess of 1,2,6-hexanetriol were mixed into the semisolid prepolymer, and this mixture then was extruded into rods and cured. Erosion and drug release from these devices was studied by implanting the rod-shaped devices subcutaneously into rabbits, explanting at various time intervals and measuring weight loss and residual drug (21). Levonorgestrel blood plasma levels were also determined (44).

The explanted devices were also examined by scanning electron microscopy, and results are shown in Figure 16 (26). The pictures clearly show a progressive diminution of a central uneroded zone and the development of voids around the periphery of the rod-shaped device. The presence of voids suggest that once erosion starts, generation of hydrophilic degradation products at that location accelerates further polymer hydrolysis.

Modified Polymer. The need for a better therapy to control diabetes is now well recognized, because it is evident that simple replacement of insulin by periodic injections is unable to prevent the serious consequences of the disease (45). Consequently, the development of an implantable insulin delivery system that can meter out insulin in response to blood glucose levels is an important area of research.

Poly(ortho esters) have been used in the construction of a self-regulated insulin delivery device. In this approach, insulin was dispersed in an acid-sensitive polymer surrounded by a hydrogel containing immobilized glucose oxidase (46). When glucose diffuses into the hydrogel, it is oxidized by the enzyme glucose oxidase to gluconic acid, and the consequent lowered pH accelerated polymer erosion and concomitant insulin release.

Because poly(ortho esters) based on 3,9-diethylidene 2,4,8,10 tetraoxaspiro [5.5] undecane and ordinary diols are not sufficiently acid sensitive to adequately respond to the small pH changes caused by the gluconic acid generated by the glucose/glucose oxidase reaction, polymers containing a tertiary amine in the backbone were developed. By using a tertiary amine in the backbone, pH sensitivity was significantly increased. The structure of a polymer from 3,9-diethylidene 2,4,8,10 tetraoxaspiro [5.5] undecane and *N*-methyldiethanolamine is shown in Scheme 14.

When disks containing insulin dispersed in the polymer were subjected to well-controlled low pH pulses and the cumulative amount of insulin released during each pulse determined by radioimmunoassay, results shown in Figure 17 were obtained (46). The progressive decrease with repeated stimulation represents a gradual depletion of insulin from the device.

Self-Catalyzed Polymers. Because one of the more important applications of bioerodible polymers is in the treatment of cancer, where a bioerodible device containing an antineoplastic agent is used to deliver the agent systemically, or where the implant is located at the site from which a tumor has been excised, studies with devices containing 5-FU have been carried out. 5-FU release from a polymer constructed from *trans*-cyclohexanedimethanol glycolide and *trans*-cyclohexanedimethanol, used at varying ratios, is shown in Figure 18 (47).

These data show that excellent linear release has been achieved. Most importantly, when all drug has been delivered, only traces of polymer remain. Further, rate of release can be controlled by the concentration of the glycolic acid dimer segment in the polymer. Although devices containing 15 and 20 wt % of monomer with a glycolic acid dimer segment erode at about the same rate, release rates of 1, 2 and 3 weeks have been achieved. These are therapeutically useful release rates.

Release of 5-FU from the low melting polymers prepared from diols shown in Scheme 13 are shown in Figures 19 and 20 (48).

Figure 19 shows the effect of increasing amounts of a dilactide diol incorporated into a polymer prepared from 1,12-dodecanediol and 1,12-dodecanediol dilactide. As shown, only the polymer containing 20 mole % dilactide eroded completely. However, 70% of the polymer containing 10 wt % dilactide eroded at a time when 80% of the drug has been released. Because this experiment was stopped before release was complete, it is possible that this polymer would also have eroded to completion. At the time the experiment was stopped, the polymer containing 5 wt % dilactide had released about 80% of the drug, but only about 35% weight loss was observed. Thus, it is unlikely that this polymer would have eroded to completion. Clearly, complete erosion requires a certain minimum dilactide content.

Figure 20 shows release of 5-FU from polymers prepared from the C8, C10, and C12 diols, all containing 20 wt % dilactide. In this series, all polymers eroded to completion, and 5-FU release rate was a function of diol chain length, suggesting that polymer hydrophobicity is an important factor.

Release of 5-FU from an ointment-like material prepared from 50 mole % triethylene glycol, 40 mole % decanediol, and 1 mole % triethylene glycol monolactide is shown in Figure 21. This materials is highly viscous at body temperature, but at temperatures below about 45°C it can be injected with a hypodermic syringe. Release occurs after an induction period of about 10 days, after which time excellent linear kinetics for about 30 days are noted. Such kinetics are of interest because no burst of drug occurs and good control over amount of drug administered with repeated injections is achieved, provided such injections are appropriately spaced to take into account the lag time.

Some initial result of bovine serum albumin (BSA) release from an ointment-like material prepared from 99

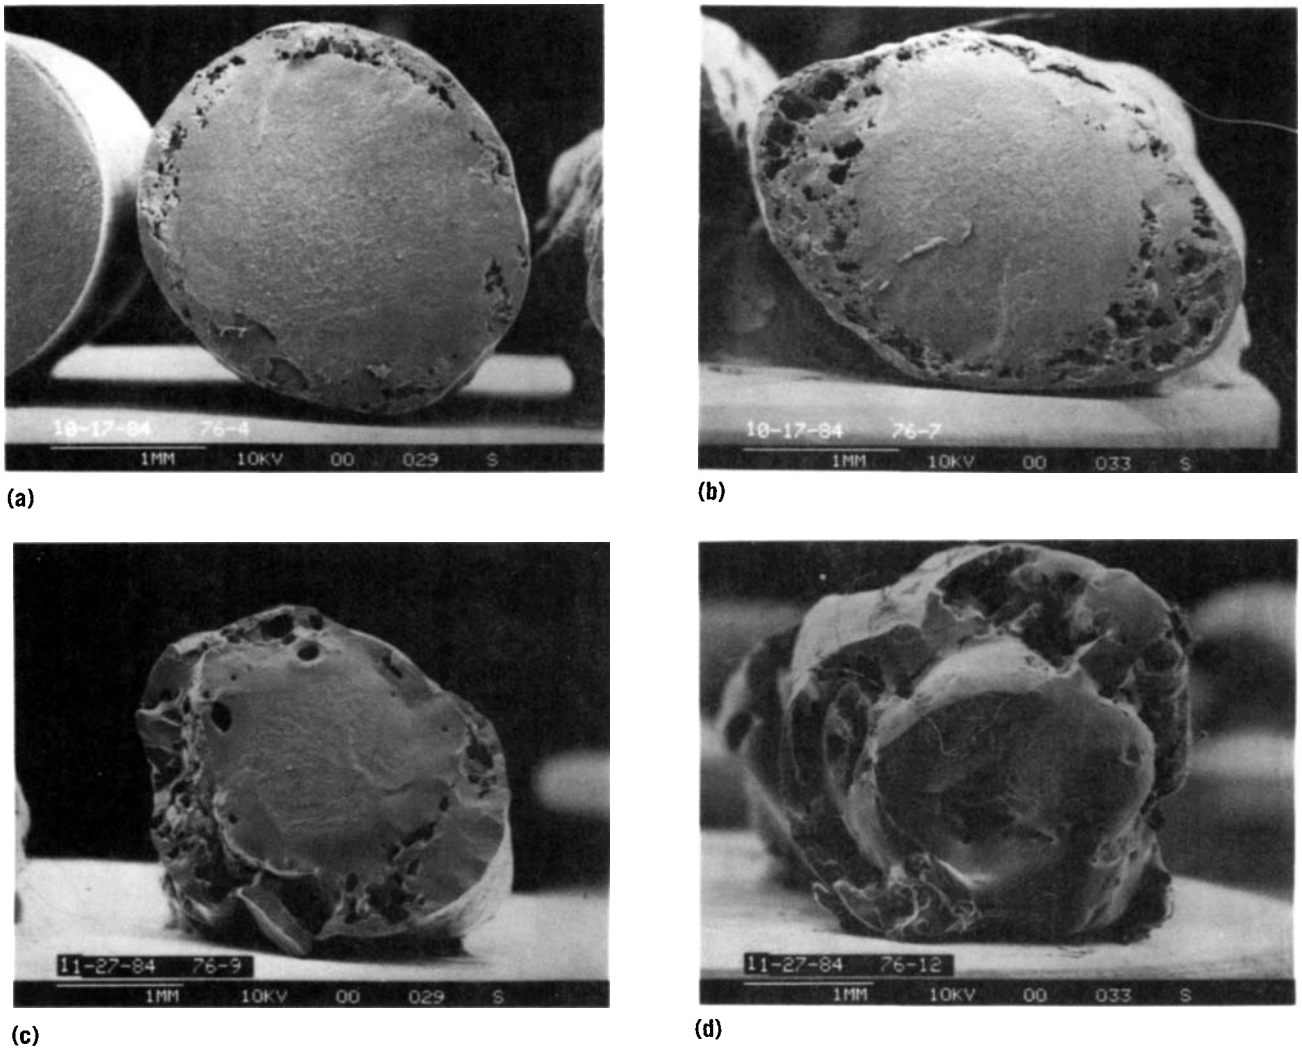

Figure 16. Scanning electron micrographs of cross-linked polymer prepared from 3,9-diethylidene-2,4,8,20-tetraoxaspiro [5.5] undecane/3-methyl-1,5-pentanenediol prepolymer cross-linked with 1,2,6-hexanetriol. Prepolymer contains 1 mole % copolymerized 9,10-dihydroxystearic acid. Polymer rods 2.4 × 20 mm containing 30 wt % levonorgestrel and 7.1 mole % $Mg(OH)_2$. Devices implanted subcutaneously in rabbits. mole % triethylene glycol and 1 mole % triethylene glycol mono L-lactide is shown in Figure 22. These initial encouraging results indicate that ointment-like materials can release proteins at close to zero-order kinetics.

Typical Synthetic Procedures

Preparation of 3,9-diethylidene-2,4,8,10-tetraoxaspiro [5.5] undecane. In a 3-L three-necked flask filled with a mechanical stirrer, argon inlet tube, thermometer, and rubber septum is placed 1.2 L of ethylene diamine. The flask is cooled with ice water, and the contents kept at about 8°C under an argon atmosphere. A hexane solution of 130 g (2 moles) on *n*-butyllithium is added via a stainless steel hypodermic U-tube pushed through the rubber septum using carefully controlled argon pressure over a period of 1 h.

Next, a mixture of 530 g (2.5 moles) of 3,9-divinyl-2,4,8,10-tetraoxaspiro [5.5] undecane and 0.5 L of ethylenediamine is cooled to 8°C and added to the three-necked flask. After stirring at 8°C for 3 h, the reaction mixture is poured into 3 L of ice water with vigorous stirring. The aqueous mixture is extracted twice with 1-L portions of hexane. The combined hexane extracts are washed three times with 1-L portions of water, dried over anhydrous magnesium sulfate, and filtered under suction. The filtrate is evaporated to dryness on a rotary evaporator to give 413 g (78%) of crude material containing 90% of 3,9-diethylidene 2,4,8,10-tetraoxaspiro [5.5] undecane.

The crude product is dissolved in 2 L of hexane containing 10 mL of triethylamine, and the solution placed in a 4-L filter flask, sealed, and stored in a freezer at −20°C for 2 days. The crystals thus formed are collected by basket

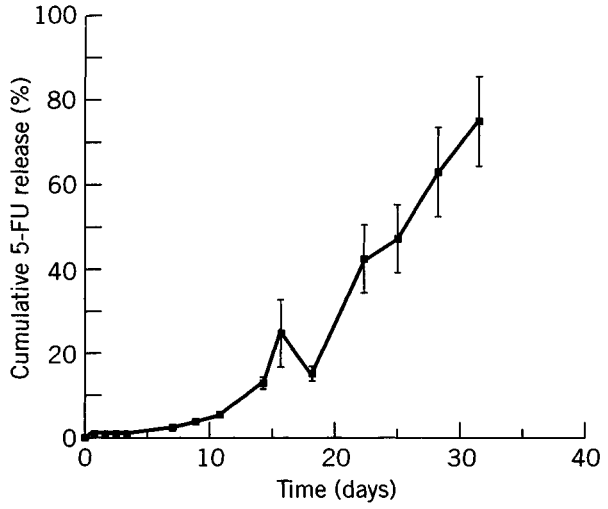

Figure 21. 5-FU release from a polymer prepared from 3,9-diethylidene 2,4,8,10-tetraoxaspiro [5.5] undecane, 50 mole % triethylene glycol, 49 mole % *n*-decanediol, and 1 mole % triethylene glycol DL-dilactide at pH 7.4 and 37°C. Drug loading 10 wt %.

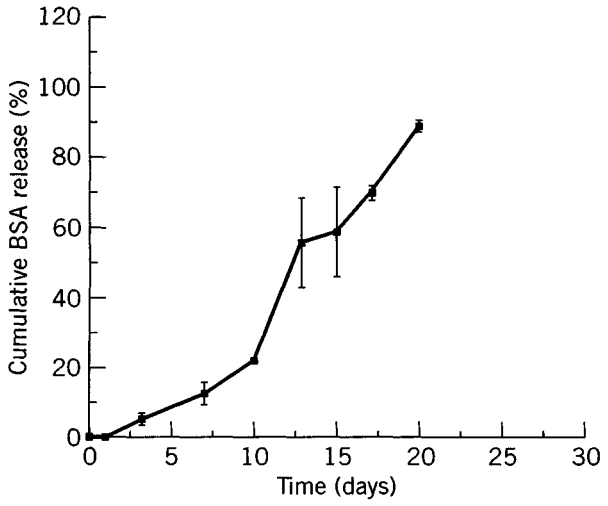

Figure 22. BSA release from a polymer prepared from 3,9-diethylidene 2,4,8,10-tetraoxaspiro [5.5] undecane, 99 mole % triethylene glycol, and 1 mole % triethylene glycol mono-DL, lactide at pH 7.4 and 37°C. Drug loading 10 wt %.

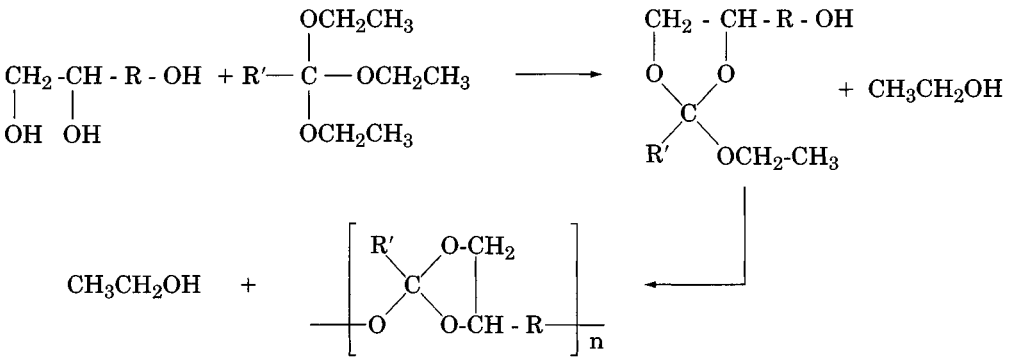
centrifugation at −5°C under an argon atmosphere. Distillation of the brownish product through a 12-inch vigreaux column at reduced pressure gives 313 g (61%) of 3,9-diethylidene 2,4,8,10-tetraoxaspiro [5.5] undecane as a colorless liquid, b.p. 82°C (0.1 torr), which crystallizes at room temperature, m.p. 30°C; characteristic IR band at 1700 cm^{-1}.

Preparation of Linear Polymers. Into a 5-L, three-necked flask equipped with an overhead stirrer, an argon inlet tube, and a condenser are placed 89.57 g (0.621 mole) of *trans*-cyclohexanedimethanol, 39.52 g (0.334 mole) of 1,6-hexanediol, and 1.8 L of distilled tetrahydrofuran. The mixture is stirred until all solids have dissolved; then, 200 g (0.942 mole) of 3,9-diethylidene 2,4,8,10-tetraoxaspiro [5.5] undecane is added. The polymerization is initiated by the addition of 2 mL of a solution of *p*-toluenesulfonic acid (20 mg/mL) in tetrahydrofuran.

The polymerization temperature rapidly rises to the boiling point of tetrahydrofuran and then gradually decreases. Stirring is continued for about 2 h, 10 mL of triethylamine stabilizer added, and the reaction mixture then very slowly poured with vigorous stirring into about 15 gallons of methanol containing 100 mL of triethylamine. The precipitated polymer is collected by vacuum filtration and dried in a vacuum oven at 60°C for 24 h. The weight of the dried polymer is 325 g (98.8% yield).

Preparation of Cross-Linked Polymers. To a solution of 31.84 g (0.159 mole) of 3,9-diethylidene 2,4,8,10-tetraoxaspiro [5.5] undecane in 200 mL of distilled tetrahydrofuran is added 10.42 g (0.100 mole) of 2-methyl-1,4-butanediol. The solution is stirred under argon and 0.5 mL of *p*-toluenesulfonic acid solution in tetrahydrofuran (20 mg/mL) is added to initiate the reaction. After the heat of reaction has subsided, the solution is stirred until the temperature returns to ambient and then concentrated on a rotary evaporator followed by heating in a vacuum oven at 40°C to remove residual solvent.



Devices are then prepared by mixing into the prepolymer an excess of 1,2,6-hexanetriol and the desired excipients and curing the mixture in a mold at 75°C for 5 h. Best results are obtained when the mole ratio hydroxyl to ketene acetal is about 1:3.

Synthesis of Diols Containing a Glycolide Segment. The following represents a typical preparation. In a dry-box, 15.07 g (100 mmoles) of triethylene glycol and 11.06 g (100 mmoles) of glycolide were weighed into a 50 mL flask. The flask was sealed with a rubber septum and heated overnight at 180°C in an oil bath. Similar reactions were also conducted with *trans*-cyclohexanedimethanol and with 1,10-decanediol. The resulting oils were not purified and used directly in the polymerization reactions.

Polymerization. The following represents a typical preparation. Under anhydrous conditions 13.515 g (90 mmoles) of triethylene glycol and 2.663 g (10 mmoles) of the triethylene glycol monoglycolide described earlier were weighed into a 250 mL flask, and the mixture dissolved in 50 mL of tetrahydrofuran. Then 19.103 g (90 mmoles) of 3,9-diethylidene-2,4,8,10-tetraoxaspiro [5.5] undecane were added. After the exothermic reaction subsided, the solution was first concentrated on a roto-evaporator and the remaining solvent removed in a vacuum oven at 40°C.

POLY(ORTHO ESTER) III

The third family of such polymers was originally developed at SRI International (49) and is also under active development at the University of Geneva (50). It is prepared as shown in Scheme 15. The intermediate does not have to be isolated, and continuing reaction produces the final polymer.

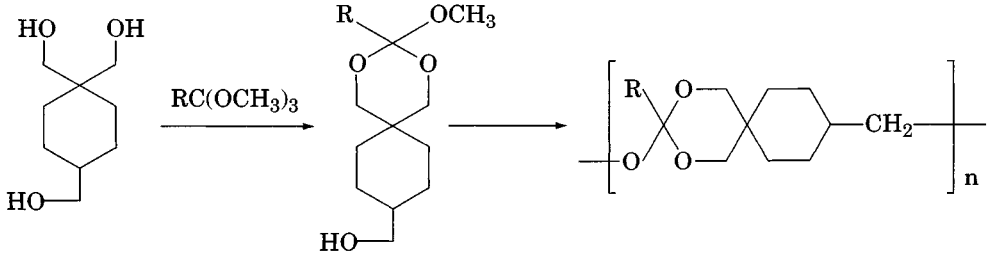
Scheme 15.

When R is $-(CH_2)_4-$, the polymer is a semisolid at room temperature even though molecular weights can exceed 35 kDa. This semisolid consistency provides a number of unique advantages. Dominant among these is the ability to incorporate into the polymer therapeutic agents by a simple mixing procedure without the need to use solvents or elevated temperatures. The semisolid consistency also allows some unique means of administration of the polymer.

The general synthetic procedure shown in Scheme 15 can also be used to prepare solid polymers. To do so, it is only necessary to replace the flexible triol, such as 1,2,6-hexanetriol, with a rigid one, such as 1,1,4-cyclohexanetrimethanol, as shown in Scheme 16 (51). As before, the intermediate does not have to be isolated, and continuing reaction produces a polymer.

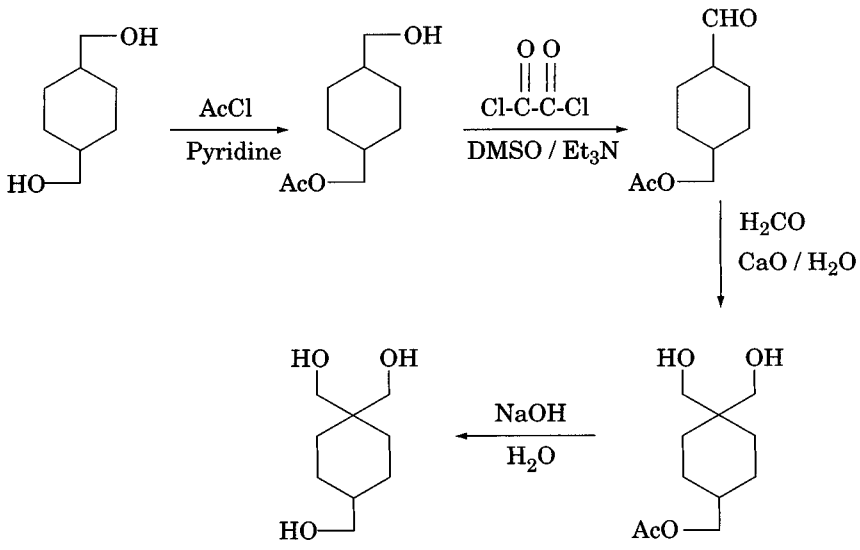
The triol, 1,1,4-cyclohexanetrimethanol can be prepared as shown in Scheme 17 (51).

Unfortunately, even though small-scale preparations proceeded with no difficulties, attempts to scale-up the synthesis were unsuccessful, and large amounts of the monomer remained elusive. Thus, it was deemed unlikely that a viable commercial product could be developed, and further work with this polymer has been discontinued. Nevertheless, this is an interesting system, and one member of this family where R = CH_3 is highly crystalline, whereas polymers where R = CH_3CH_2 and higher, are totally amorphous. To this date, the methyl homologue remains the only crystalline poly(ortho ester) ever prepared. X-ray diffraction of the methyl and *n*-propyl homologues are shown in Figure 23.



Polymer Erosion

Polymer hydrolysis occurs as shown in Scheme 18 for a polymer prepared from 1,2,6-hexanetriol (49). However, a similar scheme can also be written for the solid form (51). As with poly(ortho ester) II, initial hydrolysis occurs at the labile ortho ester bonds to generate one or more isomeric monoesters of the triol. This initial hydrolysis is followed by a much slower hydrolysis of the monoesters to produce a carboxylic acid and a triol. Thus, as with the poly (ortho ester) II, no autocatalysis is observed. Details of the hydrolysis mechanism for polymers based on 1,2,6-hexanetriol and 1,1,4-cyclohexanetrimethanol have been published (51,52).



Unlike poly(ortho esters) II, which are extremely hydrophobic (27), poly(ortho esters) III prepared from alkyl orthoacetates and 1,2,6-hexanetriol are quite hydrophilic, and water uptake at a relative humidity of 80% is shown in Figure 24 (53). For this reason, and as will be shown later, the uncatalyzed erosion of this polymer proceeds at a relatively rapid rate.

Polymer Characterization

Radiation Sterilization. Due to the moisture sensitivity of poly(ortho esters) and their susceptibility to degradation at elevated temperatures, conventional methods such as dry heat or steam sterilization cannot be used. Although poly(ortho esters) can been successfully sterilized with ethylene oxide (54), there is the possibility that residues can remain in the polymer despite rigorous outgassing. This is clearly not desirable because mutagenic and possibly car-

Scheme 16.

Scheme 17.

Figure 23. Copyright 1997 American Chemical Society.

cinogenic properties of such residues have been reported (55). Thus, γ-radiation sterilization was used. However, the use of radiation sterilization can lead to changes in polymer molecular weight, and polymer structure and the magnitude of such changes is largely determined by the structure of the polymer and by the radiation dose used. For γ-sterilization, depending on the dose, two different mechanisms have been observed (56). For doses lower than 2.0 Mrad the dominant degradation mechanism is scission of the polymer chain. As shown in Figure 25, such cleavage leads to a decrease in polymer molecular weight and a consequent decrease of dynamic viscosity. At doses higher than 2.0 Mrad, chemical changes begin to take place, as evidenced by an increase in the peak at 1750 cm^{-1} noted in the fourier transform infrared spectrum (56). The exact nature of the chemical changes is not clear, but a degradation mechanism similar to polymer hydrolysis seems to occur, even in the rigorous absence of moisture.

Purity and Stability. Poly(ortho esters) III prepared from alkyl orthoacetates and 1,2,6-hexanetriol contain residual monomer and low molecular weight oligomers and have a polydispersity (M_w/M_n) of about 3. After dissolution in tetrahydrofuran and precipitation into methanol, the low molecular weight components can be virtually eliminated, and two more precipitations reduce the polydispersity to about 2.1 (53). Residual solvent can be removed by drying at 40°C and 5 mbar for 24 h. Drying temperature must be selected so as to avoid thermal degradation, which, as shown in Figure 26, starts at about 45°C.

Preferred storage conditions are in sealed glass bottles under an argon atmosphere. Under these conditions, the average molecular weight remained virtually unchanged for 180 days (53).

Drug Release

This polymer has been used in a number of applications (2). The two most recent applications are the development of devices for the treatment of periodontal disease and as an adjunct for glaucoma filtration surgery.

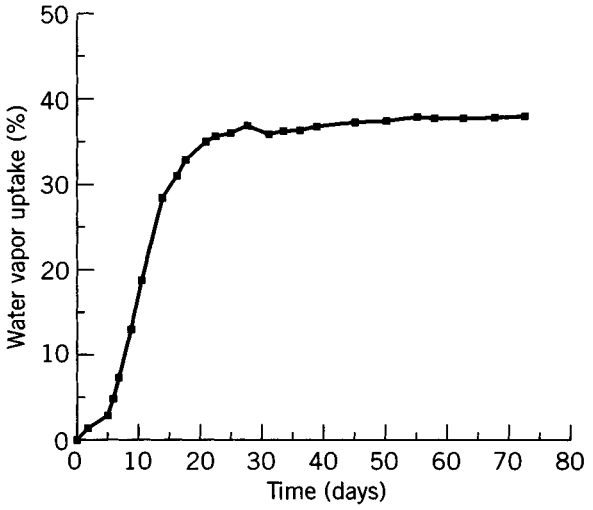


Figure 24. Water vapor uptake of a 21.5 kDa polymer prepared from a trimethyl orthoacetate and 1,2,6-hexanetriol at 80% relative humidity. *Source:* Reprinted from Ref. 53, p. 900, with permission of Elsevier Science.

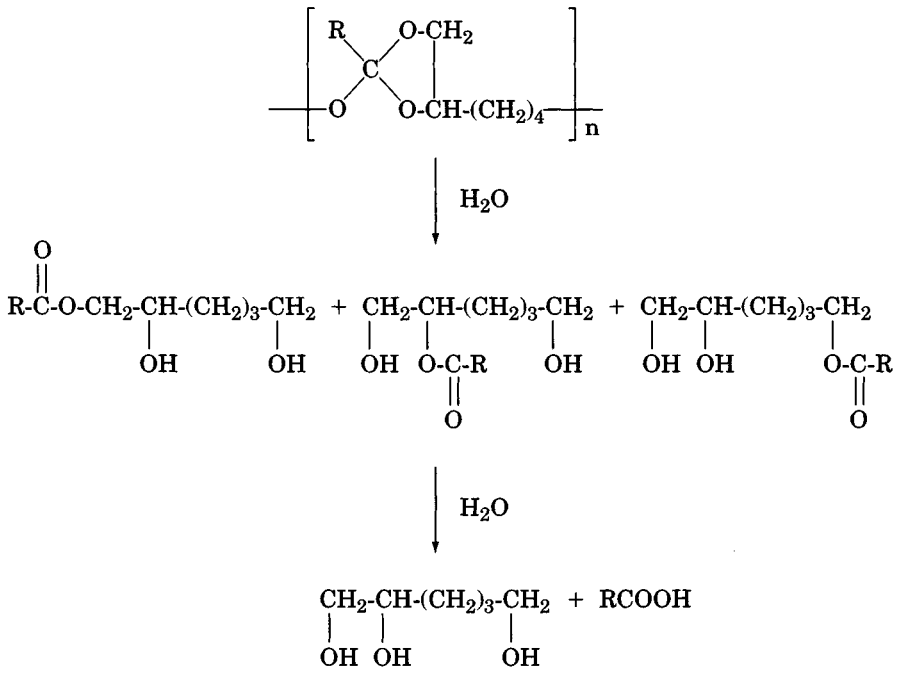

Treatment of Periodontal Disease. Periodontitis is a group of dentoalveolar infections that are one of the major causes of teeth loss. These infections are caused by a pathogenic flora, established within the gingival sulcus, which later deepens to form a periodontal pocket. Treatments are based on strategies that shift the microflora within the periodontal pocket to that observed around healthy teeth and gingiva, and a widely used treatment is to mechanically remove plaque and calculus followed by local treatment with antimicrobial agents. Clearly, controlled release devices that would maintain a therapeutically effective concentration of an antimicrobial agent within the pocket for the desired length of time would significantly improve treatment (57).

Ointment-like poly(ortho esters) III have been investigated as a tetracycline delivery device for the treatment of periodontal disease (58). In this application the ointment-like polymer with incorporated tetracycline was injected into the periodontal pocket using a blunt needle. Then if the polymer is dentoadhesive, it would reside in the periodontal pocket for 7 to 10 days, gradually releasing tetracycline. And because total erosion would take place, no removal of an expended polymer would be required.

Tetracycline Release. Figure 27 show release of tetracycline from a propionate polymer (R = CH_3CH_2) as a function of amount of $Mg(OH)_2$ dispersed in the polymer matrix (58). Release of tetracycline in the absence of $Mg(OH)_2$ was very rapid, but the addition of as little as 0.5 wt % $Mg(OH)_2$ resulted in a sustained release over about 10 days. Addition of 1 wt % Mg(OH)2 prolonged the release to about 25 days and addition of 2 wt % $Mg(OH)_2$ produced a release estimated to last about 75 days. In all cases drug depletion coincided with total polymer erosion so that satisfactory control over device lifetime and rate of tetracycline release should be possible.

Dentoadhesiveness. To test dentoadhesiveness, a microload cell was developed, and because the adhesiveness of human and bovine teeth are not significantly different (59,60), extracted bovine anterior teeth were used as adhesive substrates (56). It was found that for the pure polymer, the required force of detachment was 392 mN cm^{-2}. However, because the detachment occurred by cohesive failure of the polymer and not by failure of the bond between the polymer and the bovine tooth, this value was a minimal value, and the true value of the adhesive bond is very likely significantly higher.

However, this test was carried out with the neat polymer with no incorporated drug and excipient. Further, it

Scheme 18.

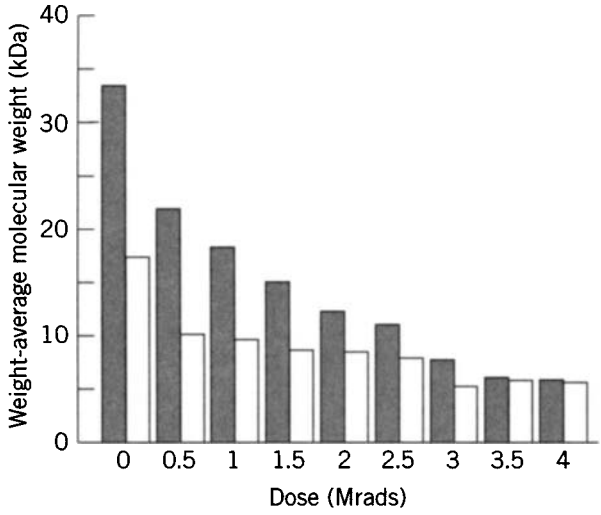

Figure 25. Influence of γ-radiation on the gel permeation chromatography average molecular weight of two different molecular weight polymers prepared from trimethyl orthoacetate and 1,2,6-hexanetriol as a function of radiation dose. (■) 33.3 kDa, (□) 17.4 kDa.

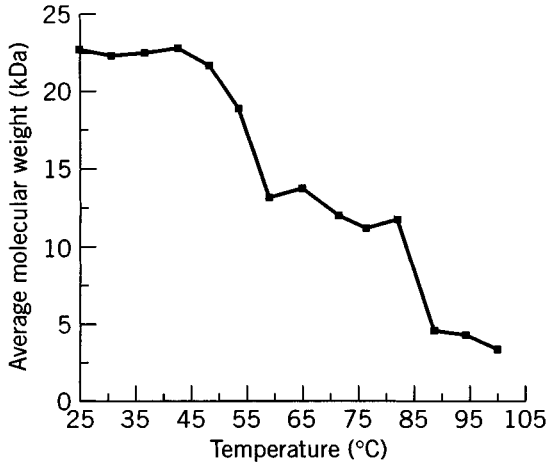

Figure 26. Gel permeation chromatography determination of the molecular weight of a polymer prepared from trimethyl orthoacetate and 1,2,6-hexanetriol after 24 hours of storage at different temperatures under anhydrous conditions (n = 3). *Source:* Reprinted from Ref. 53, p. 899, with permission of Elsevier Science.

was carried out on teeth surfaces that have not been exposed to proteins normally present in the oral environment. When the adhesion study was repeated using a formulation containing 10 wt % tetracycline and 1.0 wt % $Mg(OH)_2$ using teeth that had been exposed to dog serum (Sigma), rinsed with saline, and kept wet with saline, the detachment force decreased to 118 mN cm^{-2}. Again, as with the pure polymer, separation occurred by cohesive failure of the polymer and not between the bond between the specimen and polymer. The lower value indicates that polymer integrity has been weakened by the incorporation of tetracycline and $Mg(OH)_2$. However, it is clear that the

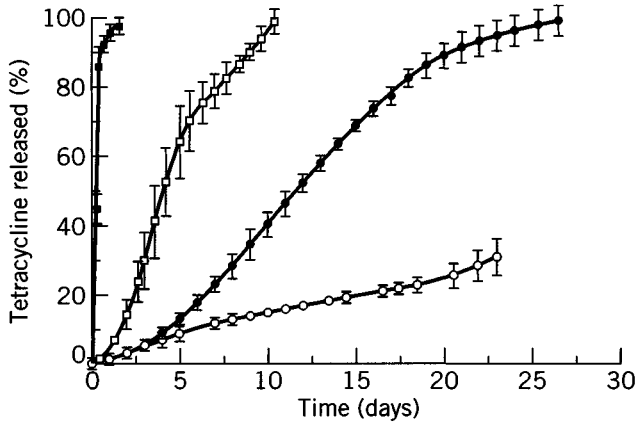

Figure 27. Cumulative release of tetracycline from a 27 kDa polymer prepared from trimethyl orthoacetate and 1,2,6-hexanetriol at pH 7.4 and 37°C as a function of $Mg(OH)_2$ content. 0.1 M phosphate buffer, flow rate 1 ml h^{-1}, drug loading 10 wt %. (○) 0%, (●) 0.5%, (□) 1.0%, (■) 2.0%. Error bars are standard deviation, n = 3. *Source:* Reprinted from Ref. 58, p. 316, with permission of Elsevier Science.

final formulation is also capable of strongly adhering to teeth. Thus, as judged from these in vitro studies, adequate residence time in the periodontal pocket should be possible.

Toxicology. Because there is the potential for ingestion of the polymer during treatment, acute and chronic feeding studies were carried out (61). Further, during bioerosion of the polymer, systemic absorption of hydrolysis products takes place so that acute intravenous toxicity studies using polymer hydrolysate were also carried out. All toxicological studies were carried out using adult Sprague Dawley rats using a doubly precipitated polymer that was then irradiated at 2.5 Mrad and stored in a dry-box at room temperature until use.

1. *Acute oral toxicity of intact polymer.* The intact polymer was emulsified in a vehicle consisting of 2 w/v % aqueous methyl cellulose solution with the aid of 1.6 w/v Tween 80 and administered to rats at a dose level of 3.3 g/kg. No deaths or adverse clinical signs were observed during the study, and no gross abnormalities were observed during necropsy. Thus, the polymer is nontoxic when administered as a single dose of 3.3 g/kg to rats.
2. *Chronic oral toxicity (28-day) of intact polymer.* The emulsified polymer prepared as already described was administered daily to rats at doses of 0.76, 1.64 or 3.27 g/kg for 28 days. At necropsy, no gross abnormalities were observed in the tissues or external features.

   Histopathologic examination revealed no significant microscopic findings and no target organs for poly(ortho esters) toxicity. All hematology and clinical chemistry parameters were in the normal range. Thus, the polymer is nontoxic when administered daily at a maximum oral dose of 3.3 g/kg for 4 weeks.
3. *Acute intravenous toxicity of polymer hydrolysate.* Sterile polymer was hydrolyzed by placing a known

weight of the polymer in sterile buffered saline, pH 7.4 at 37°C for 15 days. The hydrolyzed polymer was filtered through sterile 0.2 μg filters and diluted as necessary. Rats were given 10 ml/kg of sterile phosphate buffered saline containing hydrolyzed polymer equivalent to 0.5, 1.0, or 1.5 g/kg, based on the weight of starting polymer. Rats given doses greater than 1.0 g/kg had ataxia immediately following dosing, but recovered within 30 seconds and exhibited no other adverse clinical symptoms. The rats were kept under observation for 15 days. No gross abnormalities were observed following necropsy.

4. *In vivo studies.* The polymer with incorporated tetracycline has been investigated for effectiveness in the treatment of beagle dogs with naturally occurring periodontitis. These studies failed to show effectiveness due to rapid loss of polymer from the periodontal pocket. However, it is likely that this failure is due to anatomical differences between beagle dogs and humans, in that beagle dogs only develop a very shallow periodontal pocket, whereas humans develop a deep periodontal pocket. The shallowness of the periodontal pockets in beagle dogs makes placement of the polymer very difficult. Further, dentoadhesiveness only takes place if the tooth can be dried, which was not possible due to the presence of a great deal of blood and pus. Plans to carry out a study with human volunteers are currently being formulated.

5-FU Delivery as an Adjunct for Glaucoma Filtering Surgery. ***Drug Release.*** Postoperative subconjunctival 5-FU injection is used to increase the success in glaucoma filtering surgery in patients with poor surgical prognoses. These include glaucoma in aphakia or pseudophakia and previously unsuccessful filtering procedures (62–64). The antimetabolite 5-FU, a water-soluble pyrimidene analogue, acts by suppressing fibroblast proliferation and subsequent scarring following trabeculectomy (65,66). The application of 5-FU as an adjunct to glaucoma surgery has been investigated in animal studies and in human clinical trials (64,67,68). In order to maintain an effective concentration of the drug, daily injections of 5.0 to 7.5 mg of 5-FU for up to 7 days are used (67–69). This postoperative therapy has the disadvantage of frequent administration, patient discomfort associated with the injection, conjunctival incision, and needle track leaks. Other side effects frequently reported include corneal epithelial erosion, hypotonia, and endophthalmitis (64,70). For these reasons, development of an injectable polymer that could deliver 5-FU for the desired length of time and at the desired kinetics and rate is of considerable importance.

Figure 28 shows in vitro release of 5-FU from an acetate polymer of five different molecular weights (69). The data show one-day release from the lowest molecular weight polymer and one-week release from the highest molecular weight polymer. Thus, it is possible to control drug delivery times without the use of excipients by simply controlling polymer molecular weight.

Figure 29 shows a comparison between 5-FU release and polymer weight loss (50). These data are consistent

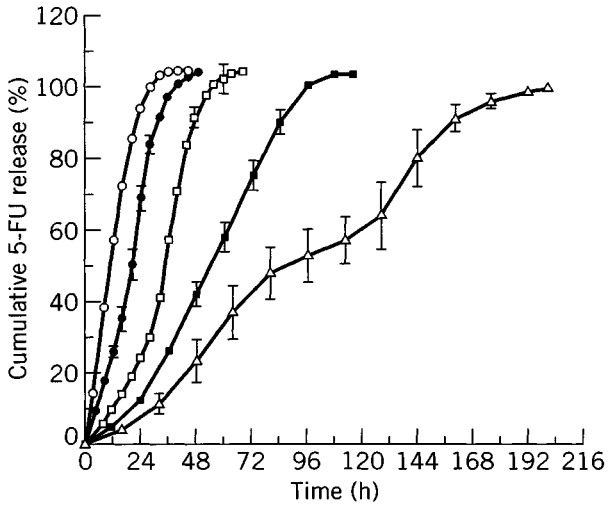

Figure 28. 5-FU release from a polymer prepared from trimethyl orthoacetate and 1,2,6-hexanetriol as a function of polymer molecular weight. Phosphate buffer, pH 7.4 at 37°C. (○) 3.5 kDa, (●) 5.8 kDa, (□) 10.1 kDa (■) 15.2 kDa (△) 33.3 kDa. Mean ± SD (n = 6). *Source:* Reprinted from Ref. 50, p. 109, with permission of Elsevier Science.

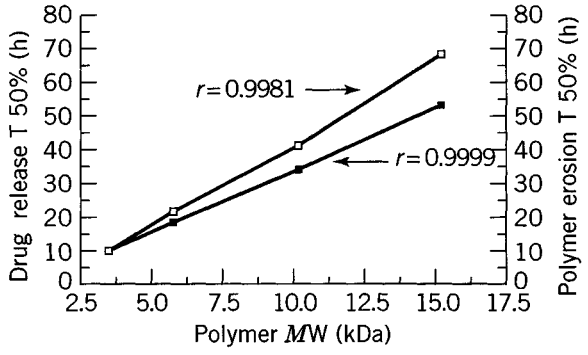

Figure 29. Comparison between 5-FU release (□) and polymer weight loss (■) for a polymer prepared from trimethyl orthoacetate and 1,2,6-hexanetriol as a function of polymer molecular weight using T50% for both parameters. *Source:* Reprinted from Ref. 50, p. 109, with permission from Elsevier Science.

with a combination of erosion-controlled and diffusion-controlled 5-FU release. For a low molecular weight polymer, where erosion is relatively rapid, the diffusional contribution is minimal, but as the erosion times increase, diffusion becomes progressively more important. However, even for the highest molecular weight polymer, total erosion occurs soon after drug depletion. This is highly desirable in glaucoma filtering surgery where lack of encapsulation of residual polymer is important.

Biocompatibility. Initial biocompatibility studies (71) have shown that the subcutaneous injection of a γ-ray sterilized ointment in rats induced a mild local inflammation at 3 days, which could be due to the large injection volume that stretched the tissues. At 7 days, granulation-type tissue was present, with focal zones of more intense inflammation. Mild chronic inflammation remained at 14 days

and was very minimal at 21 days. However, when subconjunctivally injected into rabbits, the same polymer triggered a marked hyperemia at day 3, which confirmed the high sensitivity to irritation of rabbit eyes (72,73).

For this reason, the polymer was further purified and the subconjunctival biocompatibility of a γ-ray sterilized polymer and one prepared under aseptic conditions compared (74). Because local tissue response depends not only on the biocompatibility of the polymer, but with biodegradable polymers, also on its hydrolysis products, an attempt was made to determine which, if any, of the hydrolysis products was responsible for the transient inflammatory reaction.

Figure 30 compares the effect of a 200 μL subconjunctival injections of γ-ray sterilized polymer and one prepared aseptically on hyperemia. Clearly, the significant hyperemia noted with the γ-ray sterilized polymer is markedly reduced.

Because it has been shown (53) that after reprecipitation a very pure polymer with only traces of monomers and oligomers is obtained, the observed transient irritation may be due to the isomeric monoesters of 1,2,6-hexanetriol intermediate hydrolysis products. When these were synthesized and injected subconjunctivally at 50 wt % in phosphate-buffered saline as well as neat, an immediate inflammatory reaction was noted. Because 1,2,6-hexanetriol has been shown to be nontoxic (75) and evoked no reaction when injected subconjunctivally, the irritation is almost certainly due to hydrolysis of the ester, accelerated by esterases, to produce acetic acid that can induce intense local irritation. Although acetic acid is not considered to be systemically toxic because it is eliminated via the Krebbs cycle as CO_2 and H_2O, in large enough amounts it can overwhelm the buffering capacity of the eye.

Attempts to improve biocompatibility by using buffers to neutralize the acetic acid released as a consequence of polymer hydrolysis are currently underway (M. Zignani et al., unpublished data). In this work, salts such as sodium acetate or magnesium hydroxide are incorporated into the polymer. Preliminary results shown in Figure 31 indicate that by using these excipients, it is indeed possible to control pH.

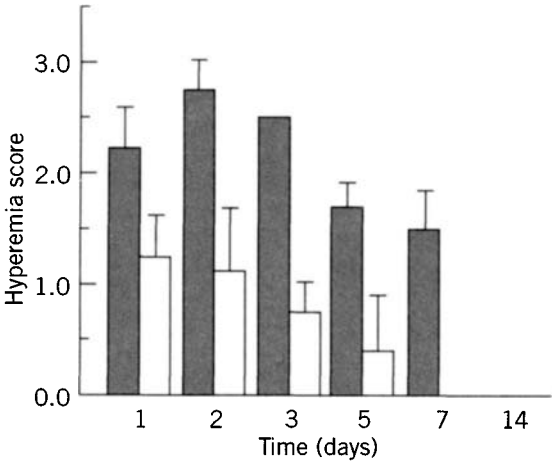

Figure 30. Comparative clinical evaluation of hyperemia induced by subconjunctival injection of a polymer prepared from trimethyl orthoacetate and 1,2,6-hexanetriol. (■) 200 μl of γ-ray sterilized polymer, (□) 200 μl of aseptically prepared polymer. *Source:* Reprinted from Ref. 74, with permission of John Wiley & Sons, Inc.

Typical Experimental Procedures

Semisolid Material. Under anhydrous conditions 48.67 g (0.30 mole) of triethyl orthoacetate, 40.25g (0.30 mole) of 1,2,6-hexanetriol, and 20 mg of *p*-toluenesulfonic acid were weighed into a 500 mL round-bottom flask equipped with a magnetic stirring bar. Next, 300 mL of cyclohexane was added and the flask adapted to a 60 cm spinning band column. The reaction flask was heated to 100°C with vigorous stirring, and the ethanol-cyclohexane azeotrope was rapidly removed at 55°C. Throughout the procedure, strictly anhydrous conditions were maintained. When the boiling point began to climb above 55°C, the take-off ratio of the column was reduced to 1/20 distillation/reflux ratio until the boiling point reached 81°C, where the take-off was set for total reflux. After heating for an additional 4 h, the solution was cooled to room temperature. Five drops of triethylamine were then added to stabilize the product and the solvent removed by distillation. The product was a viscous, ointment-like material with an average molecular weight of 29,000 as determined by gel permeation chromatography using a Waters 150-C instrument with Waters ultrastyrogel 10^3 and 10^4 columns, with tetrahydrofuran solvent at 30°C with a small amount of triethylamine stabilizer. Polystyrene was used for calibration.

Monomer Synthesis.

1. *1,4-Cyclohexanedimethanol monoacetate.* A mixture of *cis* and *trans* 1,4-cyclohexane dimethanol, (930 g, 6.448 moles) was dissolved in 3 L of tetrahydrofuran, and 550 mL of pyridine (7.69 moles) was added. The solution was cooled in an ice bath and stirred under argon. An acetyl chloride solution (506.4 g, 6.45

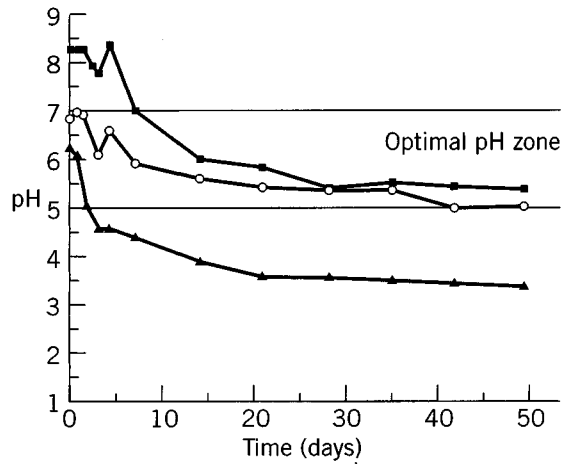

Figure 31. Changes in pH induced by hydrolysis of a polymer prepared from trimethyl orthoacetate and 1,2,6-hexanetriol. 1 g polymer placed in 10 ml 0.9% sodium chloride maintained at 37°C. (▲) neat polymer, (○) 1 wt % sodium acetate, (■) 0.25 wt % magnesium hydroxide.

moles) in 500 mL of tetrahydrofuran was added dropwise over a 2-h period. The ice bath was removed and the reaction mixture stirred for 2 h at room temperature. It was then filtered to remove the pyridine HCl salt and evaporated to remove the tetrahydrofuran. The residue was dissolved in 2 L of ethyl acetate and the solution extracted with diluted aqueous HCl (2 × 300 mL), warm water (2 × 300 mL), and aqueous $NaHCO_3$ solution (2 × 300 mL). The ethyl acetate solution was dried over anhydrous $MgSO_4$, and the ethyl acetate removed on a rotoevaporator. Vacuum distillation of the residue yielded 335 g of product. Gel chromatographic analysis showed that the product contained 59% cyclohexanedimethanol monoacetate and 41% cyclohexanedimethanol diacetate. The overall yield of the monoacetate was 16.5%.

2. *4-Acetoxymethyl-1-cyclohexanecarboxaldehyde.* Under anhydrous conditions, oxalyl chloride (358 g, 2.82 moles) was dissolved in 2.5 L of methylene chloride and the solution cooled to −40°C. Dimethylsulfoxide (407 g, 5.2 moles) dissolved in 200 mL of methylene chloride was then added via a dropping funnel while the reaction mixture was vigorously stirred and the temperature maintained between −40°C and −20°C. Next, a solution of cyclohexanedimethanol monoacetate (600 g, 59% pure, 1.9 moles) in 200 mL of methylene chloride was added dropwise while the reaction temperature was kept below −20°C. After the addition of cyclohexanedimethanol monoacetate solution was completed, the reaction mixture was stirred for an additional 15 min and triethylamine (658 g, 6.5 moles) added. The cooling bath was removed and the reaction mixture stirred for 2 h. It was then extracted successively with diluted aqueous HCl, aqueous $NaHCO_3$, and aqueous NaCl. After drying over anhydrous $MgSO_4$, the methylene chloride solution was distilled under argon to remove the solvent. The residue was distilled at 80°C at 0.4 mm to give the aldehyde (248 g, 70.8% yield).
3. *4-Acetoxymethyl-1,1-cyclohexanedimethanol.* A mixture of 4-acetoxymethyl-1-cyclohexanecarboxaldehyde, (248 g, 1.46 moles), a 37 wt % formaldehyde solution (700 mL, 8.6 moles), and tetrahydrofuran (200 mL) was cooled in an ice water bath. Calcium oxide was then added in small portions while the mixture was vigorously stirred with an overhead mechanical stirrer. After the addition of CaO was completed, the ice bath was removed and the mixture stirred for 2 h. It was then evaporated to dryness and the product extracted into acetone. Evaporation of the acetone solution produced a viscous oil.
4. *1,1,4-cyclohexanetrimethanol.* The crude 4-acetoxymethyl-1,1-cyclohexanedimethanol was added 1 L of an aqueous 2N NaOH solution and the mixture heated at 100°C for 2 h. After cooling to room temperature, the reaction mixture was neutralized with aqueous HCl and extracted with methylene chloride. The aqueous solution was evaporated to dryness, and the residue extracted with acetone. After drying over anhydrous $MgSO_4$, the acetone solution was evaporated to dryness. Distillation of the crude product from the acetone solution at 175°C and 0.1 mm yielded a viscous liquid. Repeated trituration with methylene chloride produced a solid product (150 g, 59% yield, 98.8% purity by gel chromatography).

Polymerization. Under anhydrous conditions, 1,1,4-cyclohexanetrimethanol (3.524 g, 20 mmoles), trimethyl orthoacetate (2.403 g, 20 mmoles), *p*-toluenesulfonic acid (~3 mg), and distilled cyclohexane (80 mL) were added to a predried flask. The flask was fitted with a spinning band column and heated at 100°C under argon. Methanol was removed azeotropically at 56°C at a fast rate, and as the boiling point began to rise, the distillation rate was reduced to 4 drops/min and heating continued for 15 h. The polymer thus prepared precipitated out of cyclohexane. The powdery polymer is crystalline with a melting point (DSC) of 212°C. It is insoluble in the usual organic solvents such as methylene chloride, chloroform, ether, tetrahydrofuran, ethyl acetate, acetone, dimethylformamide, and dimethylsulfoxide.

In a similar manner, 1,1,4-cyclohexanetrimethanol (3.524 g, 20 mmoles) was allowed to react with triethyl orthopropionate (3.634 g, 20 mmoles). This reaction produced a polymer which remained in the cyclohexane solution. Precipitation into methanol yielded a polymer having a M_W of 51,000 (gel permeation chromatography using polystyrene standards) and a T_g of 67.8°C. The polymer was soluble in organic solvents with low or medium polarities such as methylene chloride, chloroform, ether, tetrahydrofuran, and ethyl acetate.

ACKNOWLEDGMENTS

This work was started in 1970, and a great number of individuals have contributed to the development of the three families of poly(ortho esters), both in the United States and in Switzerland. Although they all deserve coauthorship, their sheer number makes this impractical. The following individuals have made major contributions: Dr. Nam Suk Choi, Mr. Donald W. H. Penhale, Mr. Robert F. Helwing, Mr. Bruce K. Fritzinger, Mr. John E. Rose, Dr. Kenneth J. Himmelstein, Dr. Randall V. Sparer, Dr. Gaylen M. Zentner, Dr. Chung Shi, Dr. S. S. Bhosale, Dr. Andrea W. Chow, Dr. Kathleen V. Roskos, Dr. A. C. Chang, Dr. Yu Fu Maa, Dr. Patrick Wuthrich, Dr. Ann France Rime, Dr. Sue S. Rao, Dr. Michelle S. Taylor, Dr. Tierry Vandamme, Dr. Alain Merkli, Dr. Monica Zignani, Dr. Martina B. Sintzel Dr. S. F. Bernatches and Dr. Cyrus Tabatabay.

One of us (JH) wants to especially acknowledge the contributions of Mr. Steven Y. Ng without whose creativity and superb laboratory work this review would have been much shorter. And finally, one of the authors (JH) also wishes to thank Dr. Henry L. Gabelnick, then at the National Institutes of Health, for providing the initial funding for the development of poly(ortho ester) II. Without his patience and understanding of the difficulties in developing a useful monomer and polymer synthesis, this polymer would probably not exist today.

The following funding sources are gratefully acknowledged: NIH Contract N01-HD-7-2826, NIH Contract N01-HD-8-2905, NIH Grant DA 05726, NIH Grant GM 27164, NIH Grant DE 10461, FNSRS Grant 32.35925.92, and FNSRS Grant 32.46795.96. In addition to the government funding, funds were

also provided by ComTech International and by the Finish funding agency TEKES.

The concept of using DNA as a predrug for the prevention, correction, or modulation of genetic and acquired diseases is becoming increasingly promising with the advent of the human genome project and the resulting greater understanding of diseases. By controlling gene expression, it is possible to act on diseases at their genetic origin, thus minimizing nonspecific side effects that conventional therapies often induce. In essence, gene therapy involves the replacement or correction of a defective gene in somatic cells and is not necessarily a permanent means of treatment. For a therapeutic gene to be effective, it must be carefully selected and cloned in a plasmid-based expression system, efficiently delivered to the target cells in sufficient copy numbers, produce sufficient amounts of the required protein over a reasonable time-frame, and furthermore, must not induce any undesirable side effects. The determinants of a gene delivery system can be described by the acronym DART: it must control distribution (D) of the plasmid, access (A) to the cell, or recognition by a cell-surface receptor (R) with intracellular trafficking, and final nuclear translocation (T). The essential components of a plasmid expression system are the gene to be expressed, coupled with necessary control sequences (ART). The protein must be produced in controlled amounts (A) and regulated in a cell- or disease-specific manner (R), with controlled timing (T). Delivery and expression elements have to be rationally designed and assembled together to address the key limiting steps in gaining access from the site of administration to the nucleus of the target cell. The question of delivery is challenging from the fact that a plasmid is a negatively charged hydrophilic macromolecule with a large hydrodynamic size (up to 200 nm); for it to be effective, it must cross a negatively charged surface, the cell membrane. Additionally, after systemic administration, other barriers include opsonization and clearance by the reticuloendothelial system (RES), and rapid degradation by extra- and intracellular nucleases. Because viruses possess sophisticated mechanisms that allow for their effective access to many cells, nonviral gene delivery systems and artificial viruslike structures have been developed using synthetic or semisynthetic materials to mimic some of the viral functions. Nonviral delivery systems have a number of advantages over viral systems. For instance, the plasmid in a nonviral delivery system rarely integrates into the host chromosome, persisting instead as an episome. Few limitations are also placed on the type and size of gene construct. The delivery systems are generally safe, effective in animal models, and can be repeatedly administered. However, it is not yet possible in most cases to meet the high transfection efficiencies demonstrated with viral vectors. Attractive targets for nonviral therapies include directly accessible tissues such as the lungs, skin, solid tumor, and muscle, as well as normal and proliferating endothelia by systemic administration.

Microinjection and calcium phosphate precipitation are well-established techniques for transferring DNA into cells in vitro but are not applicable for in vivo gene therapy. Recent methods shown to enhance transfection include electroporation (1,2), sonoporation (3), and needle-free jet injection (4). Suitable delivery systems include liposomes and cationic lipids (5,6), and cationic (7,8) and uncharged polymers (9), poly(peptides), or lipo(polypeptides) (10). A plasmid is not efficiently encapsulated within liposomes, nonetheless, detectable levels of human α-1 antitrypsin were measured in plasma after intravenous administration in mice (11). Cationic lipids and lipopolyamines were

Bibliography

The concept of using DNA as a predrug for the prevention, correction, or modulation of genetic and acquired diseases is becoming increasingly promising with the advent of the human genome project and the resulting greater understanding of diseases. By controlling gene expression, it is possible to act on diseases at their genetic origin, thus minimizing nonspecific side effects that conventional therapies often induce. In essence, gene therapy involves the replacement or correction of a defective gene in somatic cells and is not necessarily a permanent means of treatment. For a therapeutic gene to be effective, it must be carefully selected and cloned in a plasmid-based expression system, efficiently delivered to the target cells in sufficient copy numbers, produce sufficient amounts of the required protein over a reasonable time-frame, and furthermore, must not induce any undesirable side effects. The determinants of a gene delivery system can be described by the acronym DART: it must control distribution (D) of the plasmid, access (A) to the cell, or recognition by a cell-surface receptor (R) with intracellular trafficking, and final nuclear translocation (T). The essential components of a plasmid expression system are the gene to be expressed, coupled with necessary control sequences (ART). The protein must be produced in controlled amounts (A) and regulated in a cell- or disease-specific manner (R), with controlled timing (T). Delivery and expression elements have to be rationally designed and assembled together to address the key limiting steps in gaining access from the site of administration to the nucleus of the target cell. The question of delivery is challenging from the fact that a plasmid is a negatively charged hydrophilic macromolecule with a large hydrodynamic size (up to 200 nm); for it to be effective, it must cross a negatively charged surface, the cell membrane. Additionally, after systemic administration, other barriers include opsonization and clearance by the reticuloendothelial system (RES), and rapid degradation by extra- and intracellular nucleases. Because viruses possess sophisticated mechanisms that allow for their effective access to many cells, nonviral gene delivery systems and artificial viruslike structures have been developed using synthetic or semisynthetic materials to mimic some of the viral functions. Nonviral delivery systems have a number of advantages over viral systems. For instance, the plasmid in a nonviral delivery system rarely integrates into the host chromosome, persisting instead as an episome. Few limitations are also placed on the type and size of gene construct. The delivery systems are generally safe, effective in animal models, and can be repeatedly administered. However, it is not yet possible in most cases to meet the high transfection efficiencies demonstrated with viral vectors. Attractive targets for nonviral therapies include directly accessible tissues such as the lungs, skin, solid tumor, and muscle, as well as normal and proliferating endothelia by systemic administration.

Microinjection and calcium phosphate precipitation are well-established techniques for transferring DNA into cells in vitro but are not applicable for in vivo gene therapy. Recent methods shown to enhance transfection include electroporation (1,2), sonoporation (3), and needle-free jet injection (4). Suitable delivery systems include liposomes and cationic lipids (5,6), and cationic (7,8) and uncharged polymers (9), poly(peptides), or lipo(polypeptides) (10). A plasmid is not efficiently encapsulated within liposomes, nonetheless, detectable levels of human α-1 antitrypsin were measured in plasma after intravenous administration in mice (11). Cationic lipids and lipopolyamines were

designed to overcome some of the problems associated with liposomal delivery and were shown to condense DNA into small particulates (12–14). Neutral lipids such as dioleoylphosphatidylethanolamine (DOPE) and cholesterol are often included in such complexes, either to stabilize the complex or affect plasmid intracellular trafficking. High levels of cellular uptake and subsequent expression have been measured in vitro (6,15) and in vivo, for example, after aerosol administration into the lung (16). The only nonviral delivery systems currently used in clinical settings are cationic lipids (17,18). Polymers that can be classified as either condensing or noncondensing polymers have been used recently with increasing success, resulting in positive gene expression in vivo (Table 1). Condensing polymers such as poly(vinyl pyridinium), hydroxylated nylons, polybrene, polyethyleneimine, and linear and cascade polyamidoamine dendrimers (Fig. 1) typically compact DNA via electrostatic interaction between the DNA phosphates and the positively charged groups present in the polymer. Polyamidoamine dendrimers are examples of cascade polymers that evolve from a central core by controlled chemical reaction to produce a molecule with a defined number of generations. They possess multiple terminal amine groups that have pK_a's of 6.9 and 3.9, so that at physiological pH these polymers are only partially protonated. The successful use of these polymers was first described by Haensler and Szoka who showed that in vitro transfection using a sixth-generation polymer was 1,000-fold and 100-fold higher than when using poly-L-lysine and a DOTMA-based system, respectively (7). Polyethyleneimine (PEI) was also selected on the basis that it had a large reservoir of cationic charge, because at physiological pH every sixth amine is protonated. PEI was shown to condense DNA into particulates of 0.1–1 μm in size. Boussif et al. injected such complexes into the brains of newborn mice, and luciferase expression was observed in the brain fractions of the mice at 24 h (8). Transfection was also observed in adult brain; the highest expression was measured when formulations of charge ratios closest to neutral, using a 25-kDa molecular weight polymer, had been administered (19). Expression was observed up to 3 months after injection. Kabanov et al. have described the use of polyvinylpyridinium-based polymers for plasmid delivery, and proposed that, upon complexation with plasmid, hydrophobic interpolyelectrolyte complexes form (20). Only complexes with an excess of positive charges were efficiently transfected in NIH3T3 cells. The correlation between complex charge and transfection efficiency was later described (21). One limitation in the use of these complexes is their instability under physiological conditions. Their use in vivo has not been described to date. Such cationic polymer-based systems can also provide the basis for introduction of other agents including endosomolytic molecules and ligands. Ligand-based systems have been synthesized in which transferrin (22–24) and asialoorosomucoid (25–26) have been chemically conjugated to DNA plasmid/poly-L-lysine complexes, and specific uptake in vitro and in vivo has been observed. Endosomolytic agents such as heat-inactivated adenoviruses or synthetic viral peptides have also been conjugated to the complexes and shown to enhance expression (27–29).

This article focuses on the noncondensing PINC™ polymeric systems and the condensing polymer chitosan. The physical characteristics of both polymers are extremely different, and the use of these delivery systems has provided some promising results and an increased understanding of the properties required for enhanced in vivo gene transfer.

PROTECTIVE INTERACTING NONCONDENSING SYSTEMS

In skeletal muscle, the poor bioavailability of unformulated plasmid together with low and highly variable levels of expression are thought to be due to rapid degradation of plasmid by extracellular nucleases, which potentially occurs within minutes (30–33). Typically, less than 0.1% of the injected dose is taken up by muscle cells, and gene expression is limited to the myotubes located in the vicinity of the needle tract (30). By condensing the plasmid with cationic agents, such a stability problem might be overcome. However, in muscle, condensed plasmid does not diffuse easily through the extracellular matrix and gain access to the caveolae and T tubules (33). Protective interactive noncondensing polymers (PINCs), typically polyvinyl derivatives, were first reported for use as gene delivery agents in muscle by Mumper et al. (9,34). They have low toxicity, are biologically and chemically inert, and have the ability to stabilize proteins (35). PINCs are amphiphilic molecules that possess hydrophilic and hydrophobic regions (36–38). Among such PINC polymers, poly(vinylpyrrolidone) (PVP) is an example of a hydrogen-bond acceptor, and poly(vinyl alcohol) (PVA) is a hydrogen-bond donor. Potentially the hydrophilic portion interacts with DNA by Van der Waals or by hydrogen bonding, because DNA can function as either a hydrogen bond donor or acceptor. Such polymers have been shown by isothermal microtitration calorimetry, Fourier transform infrared spectroscopy, and dynamic dialysis to interact with DNA via hydrogen bonding, allowing the DNA to be maintained in a flexible form that can diffuse readily through muscle (39).

Molecular modeling showed that by placing PVP in a minimized conformation at pH 4 in the vicinity of DNA, PVP aligned itself in the major groove of the DNA model, permitting H bonds to form (Fig. 2). The vinyl portion of the PVP forms a hydrophobic shield around the DNA helix that may protect the plasmid from nuclease degradation and render the plasmid surface more hydrophobic (40). Similar hydrophobic regions were proposed by Kabanov et al. to form upon complexing pyridinium-containing polymers with plasmid (20,41). It was suggested that this enhanced hydrophobicity enabled adsorption to the cell membrane and hence facilitated uptake and gene expression. Zeta potential measurements showed that changes in the surface charge properties of the plasmid occurred upon complexation (40). In water, the zeta potential of PVP only decreased from +8.7 mV at pH 4 down to −5.8 mV at pH 7, indicating a small positive charge at lower pH due to the protonation and resonance between carbonyl groups of adjacent pyrrolidone monomers. Despite this slight positive charge, there was no evidence by laser light scattering that PVP condensed plasmid into particulates. The zeta potential of PVP only did not change over the pH range 4.5–7.5 in the presence of salt, supporting the fact that in a

salt-containing medium, hydrophobic bonds potentially contribute to the complexation with plasmid. As increasing quantities of PVP were added to the plasmid in water, the zeta potential became increasingly neutral, indicating that the anionic phosphates were shielded. An ethidium bromide assay also indicated that PVP did not tightly condense plasmid. Upon adding increasing amounts of PVP to preformed or postformed complexes in water, an exponential inhibition of fluorescence was observed, suggesting quenching of the fluorescence rather than inhibition of intercalation of ethidium bromide. The reduction in fluorescence was much less when the complexes were formed in water initially and then made isotonic (150–500 mM) by the addition of 5 M NaCl, and was completely abolished

when the complexes were formed in HEPES buffer at pH 7.3.

As well as protecting the plasmid from nuclease degradation in vitro (39), PINCs have been shown to enhance the extent and levels of gene expression in a reproducible manner in muscle. Comparison of β-galactosidase expression in rat tibialis showed that upon administration of plasmid in saline (so-called naked DNA) (150 μg/50 μL), expression appeared to be low and localized around the needle tract, agreeing with previous studies (42,43). When plasmid was formulated with PVP in 150 mM saline (1:17 w/w), the number of fibers that expressed β-galactosidase was significantly higher (approximately 1 log), as was the distribution of expression. This could be due to increased protection against nuclease degradation as well as to hyperosmotic effects of the formulation. Variables shown to influence the extent of gene expression in muscle include PVP molecular weight and concentration, formulation pH and osmolality, and method of formulation. Maximal gene expression (typically 10-fold higher than with saline) was achieved using a 5% (w/v) polymer concentration (at 3 mg/mL DNA). Expression levels decreased as the polymer concentration increased (39). Formulations containing 5% PVP (50 kDa) produced higher expression than those formulations containing 10-kDa PVP (39). This was thought to be due to the ability of higher molecular weight PVP to bind plasmid more efficiently, as also observed with other drugs. Higher expression was observed using formulations of pH 3.75 rather than pH 5.8 or higher, and similarly with formulations of 500 mM osmolality compared with formulations of 150 mM osmolality.

The use of poly(vinyl pyrrolidone) to deliver a muscle-specific gene medicine for long-term secretion of human growth hormone (hGH) from muscle into the systemic circulation has been reported (44). Skeletal muscle is a convenient and useful site of administration for gene therapy because some proteins expressed in muscle can be secreted into the systemic circulation. In addition, intramuscular administration of gene medicines also provides a useful approach for the treatment of local neuromuscular disorders or, alternatively, for the administration of a genetic vaccine. A plasmid with a muscle-specific promoter encoding human growth hormone was injected into the tibialis muscle of normal rats (150 μg/50 μL). In comparison with naked DNA in saline, the plasmid formulated with PVP (1:17 w/w) produced over a 10-fold increase in the levels of hGH protein detected in muscle. The plasmid expression system was shown to be muscle specific, with no detectable expression after administration in the lung or in the liver. The influence of the same formulation in hypophysectomized rats was also determined after intramuscular administration. In tibialis muscle, mRNA was detectable by RT-PCR 7 days postinjection. The levels of mRNA remained the same for 14 days and then decreased to lower levels at day 21. A statistically significant increase in growth rate was observed in those rats treated with the PVP-formulated plasmid. The inclusion of a chicken skeletal α-actin 3′-UTR in the plasmid further enhanced expression of hGH. The low levels of hGH in serum were difficult to detect, although it was evident that the expressed hGH was biologically active, because elevated levels of endogenous IGF-I and an increase in growth of the animals was observed. Difficulty in detecting levels of hGH protein may have been caused by the rapid clearance of the plasmid, its short half-life in blood, and/or the production of antibodies. For instance, it was evident that the administration of hGH plasmid resulted in production of serum hGH antibodies at day 14 that increased and plateaued at day 21 up to day 35 (Fig. 3a). Cyclosporin A was administered as an immunosuppressant once every other day for 10 days after plasmid administration (Fig. 3b). The antibody response was then totally inhibited, and increased levels of hGH mRNA were correspondingly detected. PINCs have also been used for delivering human

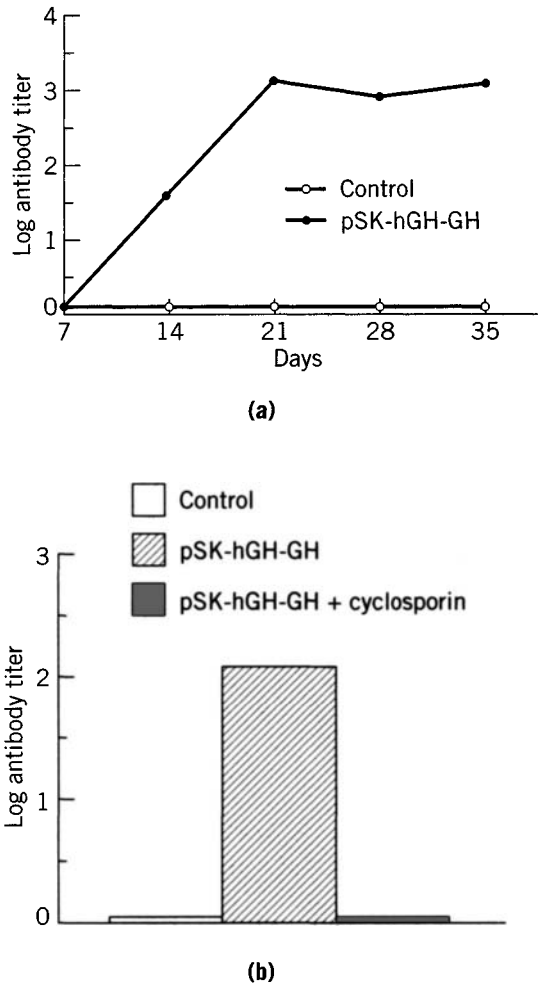

Figure 3. Production of serum anti-hGH antibodies after intramuscular administration of pSK-hGH-GH complexed with PVP. (**a**) Levels of anti–hGH antibodies 0, 7, 14, 21, 28, and 35 days after a single intramuscular injection of pSK-hGH-GH or control plasmid. Values are the average of two separate experiments; in each experiment the antibody titer was determined in pooled sera samples from five individual animals. (**b**) Effect of cyclosporin (5 mg/kg) on antibody response at day 35. Cyclosporin was given intramuscularly once every second day for 10 days (a total of five injections) after plasmid injection. The antibody titer was determined in pooled sera samples from five individual animals in each group.

factor IX gene, whose protein has a longer half-life than hGH. Detectable plasma levels of factor IX were measured at day 21 and increased up to day 29. Expression levels were 10- to 100-fold lower when this plasmid was injected in saline only (45).

An IGF-I gene medicine with reduced systemic toxicity was also developed based on a muscle-specific gene expression system formulated with a PINC polymer (45). The intent was to increase the therapeutic index of IGF-I by restricting local expression. When the human IGF-I plasmid was formulated with PVP, IGF-I protein and mRNA were measured in muscle for at least 28 days. The replacement of the skeletal α-actin 3′-UTR with an hGH 3′-UTR enhanced the secretion of IGF-I, thus improving biological activity. IGF-I plasmid, formulated with PVP, was administered to mice subjected to sciatic nerve crush injury. The formulations were administered intramuscularly every 7 days after nerve crush (E.D. Rabinovsky et al., unpublished data). Treated animals showed an increase and full recovery in gastrocnemius muscle mass, and the nerve conduction velocity in the muscle showed remarkable improvement. Expression of IGF-I plasmid peaked 7–14 days after injection and started to decrease at day 28.

Owing to the success achieved in muscle with PINC systems, such polymers have also been investigated for plasmid delivery to other solid tissues with a dense extracellular matrix, such as solid tumors (46). PINC polymers have been shown to enhance the extent and levels of expression in various mouse solid tumors as compared with naked DNA (Fig. 4).

Renca (murine renal cell carcinoma) and TS/A (differentiated mammary adenocarcinoma) tumors (10 mm^3) implanted in mice were treated using a plasmid encoding IFN-α. The tumors were harvested at 24 h, made into a single-cell suspension, and the supernatants were assayed. Tumors treated with the IFN-α/PVP formulation expressed active IFN-α; however, those that were treated with a control "empty" plasmid did not. The treatment regimen for measuring antitumor activity involved injecting the tumors eight times (four times per week), starting 7 days after challenging Balb/c mice with Renca or TS/A cells. The inhibition of tumor growth increased as the dose of administered plasmid increased (Fig. 5). In those animals implanted with Renca cells, inhibition of tumor growth was observed in 100% of the cases, with a 30% remission of tumors in those animals treated with the IFN-α/PVP formulation. When rechallenged 40–50 days later with the same cell line, all the mice that rejected the primary tumors were protected against this challenge, indicating a systemic immune response. Naïve mice were not protected. These results indicate that PINC systems can also be successfully applied to deliver expression plasmids to other target tissues such as solid tumors.

The uses of PVP as a gene delivery system have been well described, but it is necessary to determine if it is possible to improve its activity by replacing or substituting some of the polymer backbone. By substituting some of the vinyl pyrrolidone units with vinyl acetate groups, a decrease in hydrogen-bonding ability was accompanied by a decrease in gene expression. All formulations were formulated at the same pH and had similar viscosities. The structure–activity relationship (SAR) is shown in Figure 6 as the relationship between polymer structure and expression of β-galactosidase in the tibialis muscle of rats (47). Interestingly, when PVA, a hydrogen bond donor, was formulated with plasmid, higher levels of expression than with PVP were attained in skeletal muscle. A potential "interactive window of opportunity" was defined, such that by enhancing the interaction between the plasmid and the polymer, gene expression would be enhanced, but a point would be reached where the strength of interaction would

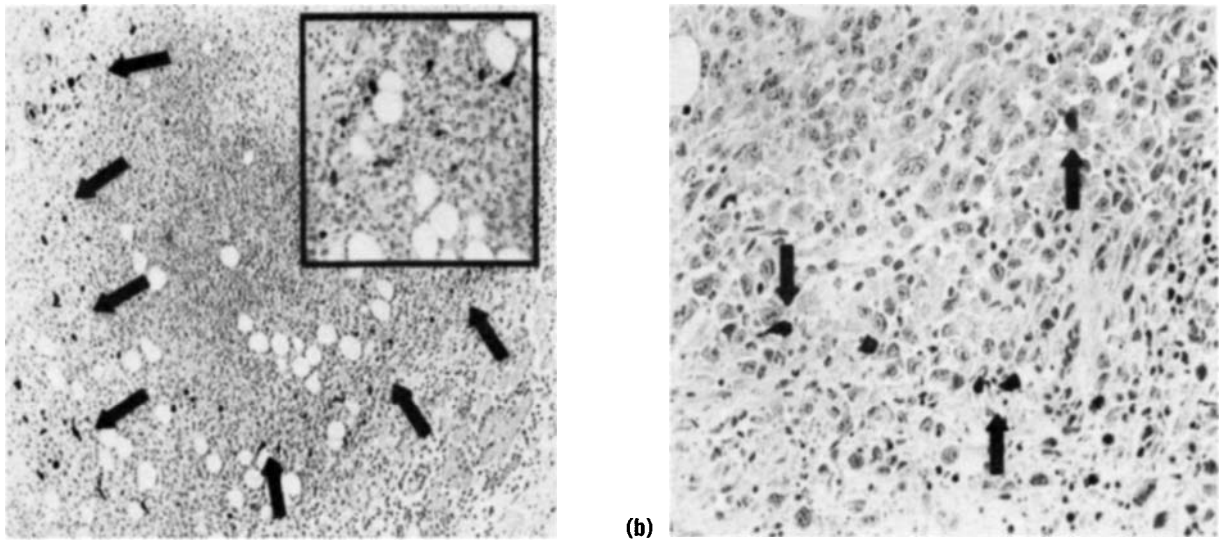

Figure 4. Immunohistochemical staining of paraffin cross sections (4 μm) for CAT in SCCVII tumors in C3HN mice, 24 h after intratumoral injection. (**a**) CMV-CAT (140 μg/50 μL) complexed with 3% PVA in 150 mM NaCl (4× magnification). Insert (40× magnification). (**b**) CMV-CAT (140 μg/50 μL) in saline (20× magnification).

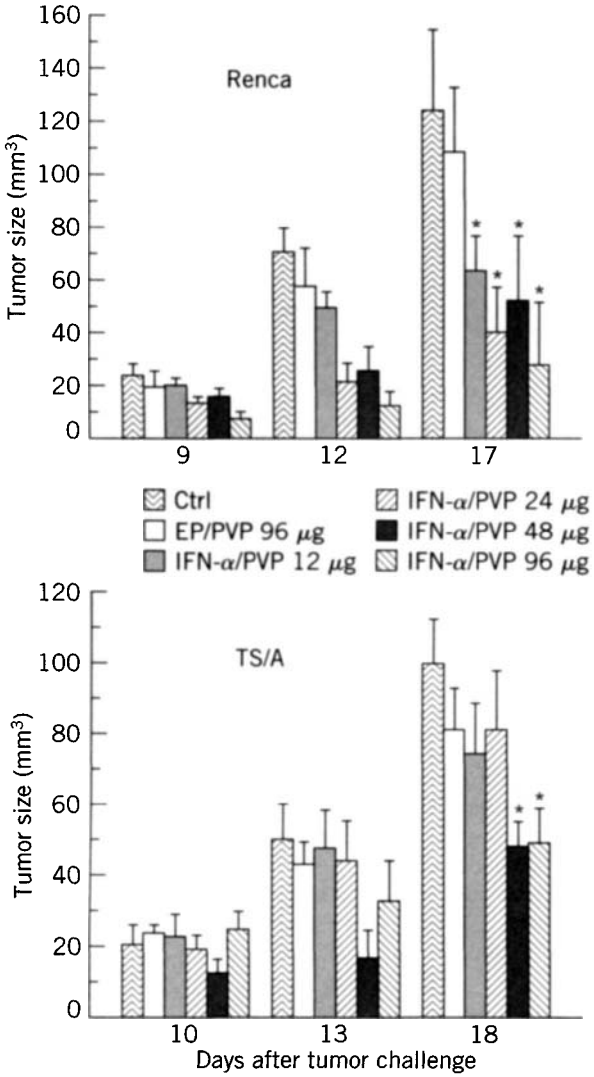

Figure 5. Induction of tumor growth inhibition following intratumoral injection of IFN-α/PVP. Renca and TS/A tumors were initiated by subcutaneous injection of 7×10^5 and 1×10^5, respectively, in BALB/c mice. Tumors were treated with scalar doses of IFN-α/PVP (from 12–96 μg) or empty plasmid (EP)/PVP (96 μg). Treatments started 7–8 days after tumor challenge when tumor size was approximately 10 mm^3, and repeated at 1- 2-day intervals four times per week for 2 weeks (total of eight treatments). Representative experiments are shown (five mice per group). Each experiment has been reproduced twice. ($^*p < 0.05$).

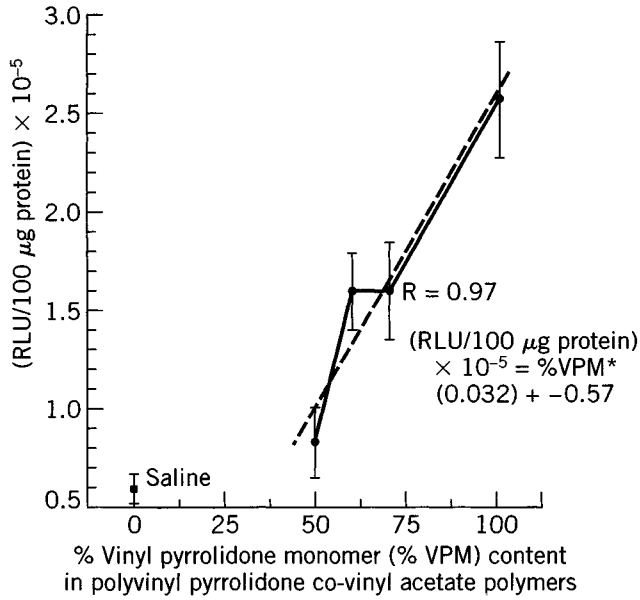

Figure 6. β-Galactosidase expression in rat tibialis muscle at 7 days after intramuscular injection of plasmid (150 μg/50 μL) complexed with copolymers (1:17 w/w) and formulated in 150 mM NaCl. β-Galactosidase expression is plotted as a function of the percentage vinyl pyrrolidone monomer (% VPM) content in the poly(vinyl pyrrolidone-covinyl acetate) polymers (●). The pH values (pH 3.7–4.0) of copolymer formulations and their viscosities were identical. These data are compared to β-galactosidase expression with a saline formulation at pH 6.5 (■). Results reported as mean ± S.E.M. (n = 10 rats).

inhibit gene expression (40,47). This SAR is being used at Valentis, Inc. (The Woodlands, Texas) to further design and synthesize novel PINCs that potentially will enhance gene expression. By enhancing the interaction between the plasmid and the polymer, it is envisaged that plasmid will remain protected from nuclease degradation but will promote more efficient gene transfer in vivo.

CHITOSAN

The concept of using chitosan and its derivatives as DNA delivery systems was introduced by Mumper et al. (9). Chitosan is a polysaccharide composed of two subunits, D-glucosamine and *N*-acetyl-D-glucosamine, linked together by $\beta(1,4)$ glycosidic bonds (Fig. 1). Chitosan is derived from chitin, a constituent of crustacean shells and the second most universally abundant biopolymer, next to cellulose. The potential availability of the raw material chitin therefore does not pose a problem, and over 1 billion tons of chitin is produced annually at low cost. The extraction process of chitin involves crushing the shells and removing proteins and minerals. Chitosan is formed upon deacetylation of chitin by treatment with sodium hydroxide at high temperature (48). Chitin and chitosan are copolymers: chitin is poly-*N*-acetylglucosamine with a small amount of deacetylation. Chitosan is the partially deacetylated derivative that is not polyglucosamine. Chitosan of 10,000–1 million Da can be readily made, with typical degrees of deacetylation in the 70–90% range. It is insoluble in water, alkalis, and organic solvents and requires the aid of select organic acids, such as acetic or formic acids, for solubilization. Other organic acids, for example, sulphuric and phosphoric acids, fail to dissolve chitosan. Due to its high molecular weight and integration of long unbranched chains, chitosan solutions are extremely viscous. Once in solution, chitosan behaves as a linear polyelectrolyte and a weak base; the amino groups present in the N-deacetylated subunits confer a highly positive charge density. A typical polyelectrolyte will exist in an extended conformation in the absence of salts due to the natural repulsion

of like charged groups, in this case the amino groups. Once salt is introduced into the media, the ions neutralize the charged groups and thus reduce repulsion, which allows the polyelectrolyte to exist in a more random coil-type orientation. If too much salt is added, the polymer will precipitate out of solution by a salting-out mechanism.

Chitosan has been used as a drug delivery system (49–51), an excipient in controlled release systems (52–55), a biological membrane (56), and wound dressings (57), and for potential cell targeting (58). Chitosan microspheres have been formulated using different preparation techniques for the controlled release of drugs such as prednisolone sodium phosphate (53) and anticancer agents (52,54). Chitosan has been indicated in preventing and treating peptic ulceration while also acting as a demulcent (57). The gastric mucosa was protected by chitosan after oral administration of ethanol in rats. Also used as a thickening, suspending, and stabilizing agent (59), a chelating agent for removal of harmful metals in industrial and chemical wastes (60), and as a support for ion exchange and affinity chromatography (61), this agent appears to have extreme diversity. By coating liposomes with polymers such as chitosan, their stability can be improved (62–64). Potentially, such liposomes can be used topically for treating wounds and burns (63) and for cell targeting (62). Takeuchi et al. demonstrated that by increasing the presence of chitosan on the surface of liposomes, they became increasingly mucoadhesive in rat intestinal mucosa (62). The liposomes were loaded with insulin and administered orally in rats. Relative to uncoated liposomes, a prolonged reduction in the basal blood glucose levels was achieved (62).

Chitosan is an approved food additive in Japan and in the United States, and it is generally considered to be nontoxic (57,59,65). It is degraded by lysozymes (enzymes present in serum, saliva, and other body fluids) into oligomers, which are further hydrolyzed to *N*-acetyl glucosamine, a common amino acid sugar in the body used in glycoprotein synthesis or else excreted as CO_2 (66,67). Because other drug absorption enhancers have histologically damaged the nasal epithelia (68) it might be assumed that chitosan would induce similar problems. To the contrary, chitosan did not induce any damage when applied to the nasal epithelium of rats (49), and only slight toxicity was observed when administered orally to mice at doses of 18 g/kg for a 19-day period (48). Another study in mice showed a weight loss upon intraperitoneal administration of 5 mg chitosan for 12 weeks (69), but when dosed with 1 mg chitosan, a normal increase in body weight was observed. When orally treated, all mice suffered a weight loss. Richardson et al. administered radiolabeled chitosan systemically and showed accumulation within 5 min in lungs (<10 kDa) and in liver (>10 kDa), and at 60 min, both polymers were found in the liver (70). In the frog palate model, a transient decrease in the mucociliary transport velocity (MTV), measured as the time to clear graphite particles (71), and in human turbinates (51) ex vivo suggested no permanent damage to the nasal surface. Minimal epithelial damage, which may have occurred upon tissue preparation, was observed in turbinates removed from volunteers after treatment with chitosan (51). Aspden et al. used a nasal perfusion technique in vivo to measure release of proteins that act as indicators of damage (50). Chitosan produced only minimal changes in comparison with laureth-9, a surfactant known to induce epithelial damage. In vitro toxicity of chitosan determined in erythrocytes and in a murine melanoma cell line (B16F10) displayed a concentration and salt dependency, the hydrochloride salt being most toxic (72). Chitosan was less toxic than poly-L-lysine but more toxic than DEAE-dextran. Red blood cell lysis was time and molecular weight dependent and occurred within 24 h, but not upon short-term exposure. Richardson et al. showed no toxicity of chitosan in rat red blood cells and L132 cells by the MTT (3-(4,5-dimethylthiazol 2-yl)-2,5-diphenyl tetrazolinium bromide) assay (70). Caco-2 cells were exposed to chitosan solution for 1 h, and discontinuities as well as a reduction in the number of microvilli were observed, but tight junctions appeared to be normal. Intracellular enzyme activity was not as greatly affected as with other absorption enhancers such as bile salts (65). Toxicity appears to be related to the degree of deacetylation and is higher with an increasingly positive charge density.

Chitosan has been used to enhance the absorption of poorly bioavailable drugs such as proteins and peptides across the nasal and intestinal epithelia in vivo (49,73) and in vitro (65,74). Enhanced plasma insulin levels and correspondingly reduced blood glucose levels after intranasal administration of insulin–chitosan solutions have been shown in sheep (49) and in rats (50). Chitosan is an example of a mucoadhesive agent, because at acidic pH, it becomes viscous and adhesive and binds sialic residues in mucus or on cell surfaces, due to its positive charge (49). Two explanations have been given to explain why chitosan works as an enhancing agent: the bioadhesive system is not cleared as efficiently by the mucociliary clearance system in the nose, permitting the drug to maintain a longer contact time with the nasal epithelium, and it is also thought to promote the opening of the tight junctions between cells, allowing larger molecules to pass through the membrane in a paracellular manner. A transient opening in the tight junctions between Caco-2 cells has actually been demonstrated using confocal laser scanning microscopy (75).

The amino groups on the glucosamine subunits have an intrinsic pK_a value of 6.5, and thus chitosan behaves as a polycation at acidic and neutral pH (65). It is these positively charged amino groups that make chitosan readily available for interaction with indomethacin (76), sodium hyaluronate (77), pectin and acacia polysaccharides (78), and polyacrylic acid (79). Such interactions have been well characterized in the literature. Variables shown to influence these electrostatic interactions include molecular weight, molecular size (particularly for controlled release), pH, weight and molecular ratios, and polymer concentration.

It also appears that chitosan possesses some of its own natural targeting ability. Structurally, chitosan resembles glycosaminoglycans, found in many tissues as cell membrane components (67), and is thought to mimic their behavior. It has also been shown to strongly associate with a number of mammalian and bacterial cells (80,81). Werner

and Kissel have also described binding sites on ciliated cells in human nasal epithelium for *N*-acetyl-glucosamine (58). A mannose receptor (a 170-kDa glycoprotein) that has been indicated in receptor-mediated phagocytosis of certain bacteria mediated through a terminal sugar residue such as *N*-acetylglucosamine has reportedly been found on the surface of dendritic cells (82).

Chitosan is commercially available at low cost, is nontoxic, and possesses amino groups for interaction with polyanionic molecules such as plasmid. The concept of allowing DNA to interact with chitosan, in the form of either an oligonucleotide or a plasmid, was thus conceived (9,34). It was demonstrated that condensation occurred upon charge neutralization by electrostatic interaction between the positively charged amino groups present in chitosan and the negatively charged plasmid phosphates. Chitosan has been shown to stabilize calf thymus DNA to melting (83), and prevent nuclease degradation (70). Condensation of DNA plasmid by an 8-kDa chitosan was shown by transmission electron microscopy (TEM) to produce toroids and rod-shaped particles, the size and shape of which suggest a relatively tight interaction (84). Similarly shaped complexes have been observed previously upon interaction of plasmid with condensing peptides or polymers (85,86). The heat of interaction between chitosan and plasmid was measured using isothermal titration microcalorimetry, an extremely sensitive technique used to measure the heat of interaction between two species (84). Aliquots of a ligand are added to a macromolecule, and the heat changes are measured as a series of peaks. Initially, the heat flow is large, as are the number of available sites for binding, but as these sites become bound, heat flow reduces. The initial heat flow was exothermic, representing the electrostatic interaction between the plasmid and chitosan that decreased to an approximate 1:1 (−/+) charge ratio. An endothermic heat flow was then measured, indicating a conformational change in the complexation process, perhaps representative of the condensation phenomenon. No more heat flow changes occurred at higher charge ratios, indicating completion of the interaction. Unfortunately the shape of the heat flow profile is complex, so that information including the binding constant and enthalpy of interaction cannot readily be obtained. In terms of changes to the secondary structure of DNA, circular dichroism has shown that, upon binding chitosan oligomers, a transition from the highly hydrated B-form to the dehydrated A-form of DNA occurred (83).

A number of research groups have now prepared chitosan particulates using different methods for the delivery of DNA, such as plasmid, to endothelial (lung vasculature) or epithelial surfaces (intestine, vagina, nose, and lung) (87,88). Illum proposed that DNA could be adsorbed onto the surface of a chitosan microsphere; however, significant expression was not measured in vitro (87). Particles (10^6) formed by first condensing DNA with chitosan to an ideal size of less than 1 μm, then adsorbing the condensate onto a charged particle, were shown to be embedded deeply in the lungs only 3 h after i.v. administration to rabbits (87). Alternatively, Alexakis et al. have shown the successful encapsulation of calf thymus DNA within cross-linked chitosan membranes or within chitosan-coated alginate microspheres (89). Such microspheres were used for oral delivery in rats. Illum et al. have also described the preparation of chitosan particulates of size less than 1 μm by simple mixing of plasmid and chitosan (88), following the method previously described by Mumper et al. (9,34). The rate of mixing influenced the sizes of the complexes formed at a 1:5 (100–300 nm) or 1:10 (170–470 nm) w/w ratio. Equal in vitro transfection of the macrophage RAW 264 and rat glial tumor cell lines by such formulations (3-μg plasmid dose) was reported; however the error bars were large, and no positive control was included for comparison. Further, a 1:10 w/w complex (100 μg/100 μL) was administered into the nasal cavity of rats, and 72 h later, tissues were harvested and analyzed for chloramphenicol acetyl transferase (CAT) activity. A positive Lipofectin™ control (1:2 w/w) (61.4 μg/100 μL) produced little if any expression in the harvested tissues. In contrast, the chitosan-formulated plasmid was highly expressed in the mandibular lymph nodes, but less so in the nasal mucosa and esophageal and lung tissues.

The complex coacervation of plasmid and chitosan was demonstrated by Mao et al. (90). Complexes were formed upon mixing chitosan (0.2% w/v) with plasmid (100 μg/mL) in acetate buffer, and particulates in the size range 200–500 nm were observed by transmission electron microscopy (TEM). Such complexes demonstrated low toxicity in HEK 293 cells relative to poly-L-lysine and Lipofectin™ complexes, and they produced lower transfection than the positive Lipofectamine™ control in 293, IB3 (bronchial epithelial cells), and THE cells (human tracheal epithelial cells) (91). Such a trend in transfection was also shown in Cos-1 cells (84). In this study, complexes (10 μg/well) made with chitosan with a range of molecular weights at a 1:2 (−/+) charge ratio were formulated in saline and incubated with Cos-1 cells in the presence or absence of serum. Cells were harvested at 72 h. If the affinity of complexation was critical in the transfection procedure, then transfection efficiency would be influenced by complexing plasmid with different molecular weight chitosan oligomers and polymers. The results showed that chitosan molecular weight had little influence on the transfection efficiency. Maximum expression was obtained using the complex containing the 102-kDa chitosan, the level of which was 250-fold less than that achieved using the Lipofectamine™ control. In the presence of serum, the complex formulated with the 540-kDa chitosan was most readily expressed. In contrast, plasmid–chitosan "polyplexes" of charge ratios greater than 1:1.2 (−/+) were transfected in 293 cells with comparable efficiency to a positive control plasmid–PEI (−/+ 1:5) at 6 days (92). CAT expression was observed for 3 weeks. Interestingly, the presence of serum somewhat hindered expression of complexes bearing lower charge ratios compared with higher ratios or even PEI complexes. Köping-Höggård proposed that this occurred because the negatively charged proteins could not neutralize the highly positively charged complexes, which were also more stable to degradation by nucleases (92).

It was conceived that by altering the molecular weight of the chitosan, it might be possible to control the size of the complexes, hence formulating particles of a specific size for targeting. In a method developed by Peniston and John-

son, chitosan was chemically depolymerized by deaminative cleavage to produce chitosan oligomers of reduced chain length (93). The free aliphatic amino groups are deaminated by reaction with nitrous acid formed in situ by the presence of sodium nitrite and 6% acetic acid. A stoichiometric amount of nitrogen is produced, which can be used to measure the extent of reaction, and thus the extent of deamination. Treatment with concentrated acid at high temperature (94) or with dilute acid (95) yields oligomers with low degrees of polymerization. The former method was not particularly selective, but the oligomers made were very pure although difficult to separate and costly to process. Other methods for depolymerization employing enzymes, including chitosanase (96), wheat germ lipase (97), or papain (98), have been described. Dependent on the method of depolymerization, the level of deacetylation will vary, which subsequently influences physical, chemical, and biological properties of the oligomer. Deacetylation can be measured enzymatically (99) or chemically (100). MacLaughlin et al. (84) described the depolymerization of chitosan using the method of Peniston and Johnson (93). As the added amount of sodium nitrite increased, the molecular weight of each oligomer decreased, but the degree of deacetylation and nitrogen content did not change. These observations agreed with those previously made by Peniston and Johnson (93). To efficiently interact with DNA plasmid, it is essential that as many amino groups as possible be available, so that a high positive charge density and the ability to condense DNA can be retained. The amine content was determined using a modified ninhydrin assay (100) but showed differences between the theoretical and experimental amine content (84). This was explained by the fact that the experimental amine content of Seacure 143 (a commercially available medium-grade chitosan, Natural Biopolymer, Inc., Raymond, WA) did not match that stated by the supplier. Once depolymerized, the influence of reduced oligomer molecular weight on the size of the complexes formed with DNA was determined. A proportional decrease in the size of the complexes was observed as the molecular weight of the chitosan decreased (Fig. 7). Although it might be expected that a higher molecular weight chitosan can interact and condense plasmid more efficiently than lower molecular weight chitosan, this is outweighed by the fact that the high molecular weight chitosan has reduced solubility, which may produce an increase in particle diameter or even aggregation. Other factors such as plasmid concentration and charge ratio were also shown to influence complex size. In general, as the plasmid concentration increased, the diameter of the complex increased. Using a 32-kDa chitosan oligomer, the 1:6 (−/+) complexes were only slightly larger than the 1:2 (−/+) complexes at all plasmid concentrations; however, using a 102-kDa oligomer, the 1:6 (−/+) complexes were larger than the 1:2 (−/+) complexes, and this difference became more defined as the plasmid concentration increased.

The stability of complexes in the biological milieu is desired; however, the release of plasmid within the cell is also essential for expression to be achieved. A balance of these two characteristics needs to be maintained. Colloidal stability of the complex to salt and serum challenge was very

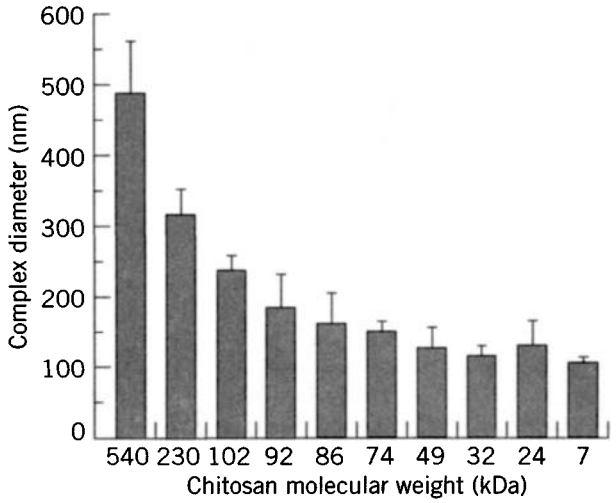

Figure 7. Factors influencing the size of chitosan–plasmid complexes. Complexes were made at 1:6 (−/+) with a plasmid concentration of 100 μg/mL.

much dependent upon the chitosan oligomer molecular weight and the charge ratio of the resultant complex (84). For example, when challenged with normal saline, the 1:0.5 (−/+) and 1:1 (−/+) complex prepared with a 7-kDa oligomer were stable, but the 1:2 (−/+) and 1:6 (−/+) complexes aggregated. The 1:2 (−/+) complex made with a 32-kDa oligomer was unstable, whereas the rest were stable. All complexes made with the 102- and 540-kDa oligomers were stable to salt challenge. The low molecular weight chitosan in positively charged complexes, which is only weakly associated with the plasmid, competes with the salt ions, but as the molecular weight of the oligomer increases, it will associate with plasmid more strongly. When challenged with a solution comprising 10% serum in normal saline, all complexes made with the 7-kDa chitosan dissociated over the 15-min challenge period. With the 32-kDa oligomer complexes, all complexes fell apart except the 1:6 (−/+) complex, which aggregated. Both the 102-kDa (Fig. 8) and the 540-kDa complexes behaved similarly to serum challenge. The 1:0.5 (−/+) and 1:1 (−/+) complexes fell apart, the 1:6 (−/+) complexes aggregated, but interestingly the 1:2 (−/+) complexes remained stable. It would appear that some component of the serum directly competes with the chitosan for association with the plasmid. Such 1:2 (−/+) complexes were also highly stable to challenge with sodium dodecyl sulfate and heparin. Other groups have observed high plasmid–chitosan complex stability. For instance, an insoluble polynucleotide–chitosan complex was formed that was highly stable in solution at 37°C for over 24 h (101). This very high stability may also become a rate-limiting step in the overall transfection process. Cos-1 cells were incubated with complexes containing fluorescently labeled plasmid, and by fluorescence microscopy, the 1:6 (−/+) complexes were observed to adhere to the cell surface in an aggregated manner, and the 1:2 (−/+) complexes adhered in a punctate manner. It was not possible to decipher the exact location of these complexes, and if they were intracellular.

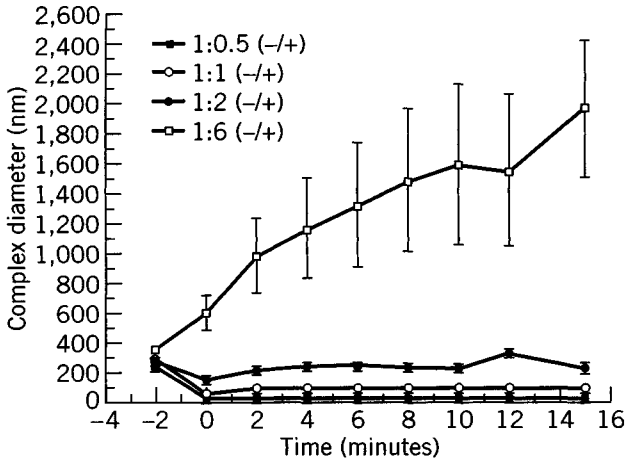

Figure 8. Stability of complexes made at a plasmid concentration of 200 μg/mL to serum challenge (10% v/v fetal bovine serum and 90% v/v normal saline). Complexes made with a 102-kDa chitosan were challenged. The complex diameter measured at −2 min is the diameter of the complex before challenge. The diameter at 0 min refers to the particle diameter measured upon immediate challenge. Where no error bands are shown, the particle distribution is considered to be broad.

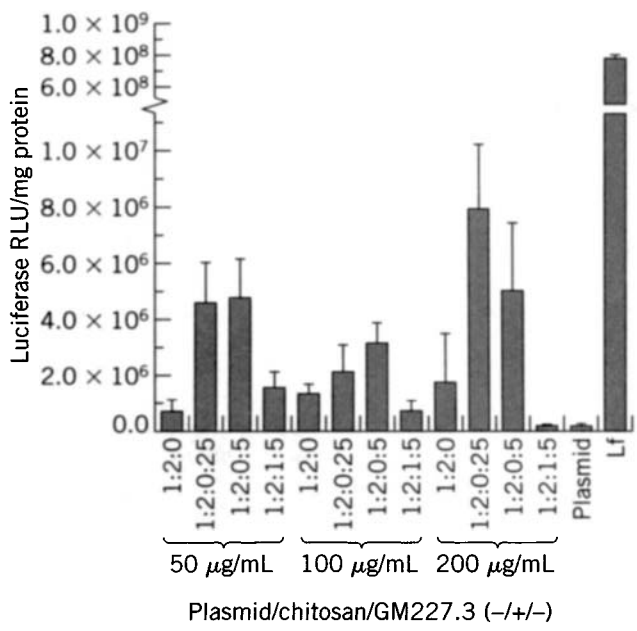

Figure 9. Transfection of Cos-1 cells with complexes containing the lipophilic endosomolytic peptide GM227.3 and chitosan (102 kDa). Complexes were made at a plasmid concentration of either 50, 100, or 200 μg/mL, with charge ratios (−/+/−) of 1:2:0, 1:2:0.25, 1:2:0.5, and 1:2:1.5. A 10-μg dose of plasmid was added to each well. The transfection levels obtained were compared with those obtained with 2.5-μg plasmid–Lipofectamine™ (Lf) (1:6 w/w).

One localization study using confocal microscopy has shown that, 1 h after transfection, particles made with fluorescently labeled plasmid and chitosan were localized in the vicinity of the cell membrane (91). In situ hybridization showed multiple copies of plasmid taken up into cells after 1 h, but after 4 h, some plasmid was observed in the cytoplasm and nucleus, while aggregates had formed outside the cells. At 24 h, most of the plasmid was observed in the nucleus. The researchers postulated that complete degradation or exocytosis of internalized plasmid may be one of the rate-limiting steps in the uptake process. In B16F10 cells, scanning electron microcopy showed that chitosan microspheres were taken into cells. The cell membrane was disrupted as the cell became laden with microspheres (72).

A reduction in the molecular weight of the chitosan did not influence expression, thus it was postulated that endosomal release might be a critical rate-limiting step (84). The influence of incorporating pH-sensitive lytic peptides in the plasmid–chitosan complex by electrostatic interactions was thus investigated. The lytic peptides GM225.1 (GLFEALLELLESLWELLLEA-OH) and GM227.3 (GLFEALEELWEAK(ϵ-G-dipalmitoyl)) were added to preformed plasmid–chitosan complexes and left to incubate at room temperature for 30 min. The presence of the lytic peptide was determined by zeta potential measurement and showed that, as more peptide was added, the zeta potential became electronegative. The presence of GM227.3 was shown to enhance the level of expression fourfold in Cos-1 cells for a 1:2:0.25 (−/+/−) complex formulated at a 200 μg/mL, compared with a complex containing no peptide (Fig. 9). Transfection efficiency was not improved by formulating complexes at different plasmid concentrations and thus different complex diameters. Some plasmid was taken into the cell and expressed, and the presence of the pH-sensitive lytic peptide enhanced the levels of expression slightly. The authors postulated that a small number of DNA plasmid–chitosan complexes were endocytosed and subsequently expressed, whereas the remainder of the complexes stuck to the cell surface (as suggested by fluorescence microscopy), thus explaining the low levels of expression achieved.

A formulation containing GM225.1 in 10% lactose (1:6:0.5 −/+/−) (100 μg/mL) was subsequently administered in the upper small intestines or the colons of female New Zealand white rabbits, and higher levels of expression were measured at 72 h compared with naked DNA or a plasmid–DOTMA:DOPE (1:3 −/+) formulation (84). This is in contrast with the results obtained in vitro where the lipid formulation gave higher levels of expression than the chitosan–lytic peptide formulation. When treated in the upper small intestine with the chitosan–lytic peptide formulation, all animals showed expression in at least two of the four tissues examined (Peyer's patches, enterocytes, colon, and mesenteric lymph nodes). CAT expression in the colon was not observed. When dosed in the colon, only two of the four animals expressed CAT in the colon, but three out of four animals expressed CAT in the mesenteric lymph nodes. Naked DNA was not expressed after administration via either route. MacLaughlin et al. also reported no expression after dosing via the intranasal, intramuscular, or subcutaneous routes (84). Koping-Hoggard et al. administered 1:3 (−/+) complexes via the trachea and lungs (102). Gene expression of formulated plasmids descended

in the following order: PEI > chitosan > naked plasmid. Interestingly, after nasal administration, unformulated plasmid produced the highest expression; however, orally administered plasmid–chitosan complexes were expressed more than unformulated plasmid. This data suggests that along with the fact that chitosan is an immunostimulant, it can be used as a potential carrier for oral nucleic acid–based vaccines. For example, upon rejection of chitosan a humoral response has been demonstrated in mice (103). Upon infection with Sendai virus, interferon levels were enhanced 1 day following infection, after treating with chitosan 1 day prior to infection (57). Chitosan was shown to activate a nonspecific immune response by stimulating the cell-killing abilities of peritoneal macrophages and NK cells. The mode of action for the stimulation of the immune response by chitosan was by enhancing production of lymphokines by NK and T helper cells, in response to stimulation by activated peritoneal macrophages but not spleen cells (57). Shibata et al. showed that intravenously injected chitin particles (1–10 μm) prime alveolar macrophages within 3 days, probably due to the production of interferon γ (IFN-γ), but neither soluble chitin nor chitosan induced an effect (104). Neither T nor B lymphocytes were involved. Chitosan was also shown to stimulate IgM production within 48 h in vitro in human lymphocytes, but did not promote the production of IgA or IgG (105). Deacetylated chitin (30% and 70%) was shown to induce antibody formation as well as cell-mediated immunity in guinea pigs and mice at 28 days (106). Roy et al. described how chitosan could be used as a delivery system for a DNA-based vaccine expressing a peanut antigen (107). The different dosing regimens were not described in detail. IgG (4 and 6 weeks) and IgA (3 and 4 weeks) responses were measured in those mice that were administered the formulations and then boosted. A weak antibody but no cellular immune responses were measured. When sensitized mice were challenged with the antigen, a delay in anaphylaxis and response was apparent. R.J. Mumper et al. (personal communication, 1998) measured the humoral response to expressed β-galactosidase following administration of plasmid/chitosan complexes in mice, 28 days after initial administration. Animals were boosted at day 14. Higher quantities of antigen-specific IgG were determined in sera with the plasmid–chitosan complex than with DNA plasmid alone. No cellular or mucosal effects were determined in this study.

The properties of the plasmid–chitosan complexes are intriguing thus far; however, they still have the potential for improvement. Fortunately, chitosan is an extremely versatile macromolecule possessing amino and hydroxy groups that can readily be modified to produce a molecule with improved properties, yet still retaining basic physical characteristics. For example, a new surface effective in reducing protein adsorption, platelet adherence, and activation was made by permanently immobilizing methoxypoly(ethylene glycol) sulfonate on a chitosan surface by polyelectrolyte interaction (108). Esters of amino acids were conjugated to chitosan via an intermediate glyoxylic acid–substituted chitosan. The removal of heavy metal ions was enhanced independently of the amino acid sequence (109). Krysteva et al. covalently conjugated enzymes by oxidizing the amino group and treating with urea and formaldehyde (110). By derivatizing the amino group with a highly positively charged group, the potential of chitosan for anion exchange was demonstrated. Schatzlein et al. described an interesting new biocompatible delivery system where unilamellar vesicles formed upon mixing acylated glycol chitosan in the presence of cholesterol. These vesicles were loaded with a hydrophilic water-soluble drug such as bleomycin (111). These micelles remained stable for 28 days at room temperature, and over 24 h in plasma. Due to the low solubility of chitosan at neutral intestinal pH values, a soluble derivative, trimethylchitosan chloride, was synthesized and shown to enhance permeability of intestinal layers at neutral pH values relative to chitosan (112) and in vitro in Caco-2 cells (113). A higher degree of substitution results in higher levels of transport. Enhanced uptake of hydrophilic drugs was observed in rats after nasal or rectal administration of the *N*-trimethyl chitosan chloride formulation at pH 7.4 in comparison with chitosan. The chitosan backbone has also been grafted with pluronics (114). Hofmann et al. conjugated Pluronic L122 polyol to chitosan by activating the OH group of the polyol and interacting it with the amino groups of chitosan at different pH values (114). Not surprisingly, the interaction was more efficient at higher pH values, but chitosan is not soluble at pH >7. The reaction still occurred with somewhat reduced efficiency at pH 6. The polymer gelled on increasing the temperature from 4°C to 37°C, probably by physical cross-linking of the hydrophobic polypropylene oxide groups and the chitosan backbone. In the future, it might be possible to evaluate controlled release of plasmid from that type of gel, because plasmid can interact with cationically charged chitosan (115). Chitosan has also been modified with deoxycholic acid to increase its hydrophobicity (116), and the formation of stable complexes with plasmid was indicated by agarose gel electrophoresis. No evidence of colloidal stability was described.

As well as modifying chitosan to improve its properties, a ligand such as transferrin or asialoorosomucoid, or saccharide residues such as galactose can be conjugated to exploit receptor-mediated endocytosis. An *N,N,N,*-trimethyl-chitosan–galactose conjugate was synthesized (117), and the ability to form polyelectrolyte complexes with plasmid was determined. The aminochitosan functionality was protected with a trimethyl group; the CH_2OH group was derivatized with monochloroacetic acid and was mixed with a galactose residue overnight in vitro. Toxicity of the plasmid complexes was similar to DEAE-dextran. Chitosan nanospheres derivatized with transferrin or mannose-6-phosphate using succinimidyl chemistry have also been prepared (118). Interestingly, in HEK293 cells (2-μg plasmid dose) the presence of either targeting ligand did not significantly enhance transfection relative to plain nanospheres, although transfection was still at least 10-fold less than with the positive Lipofectamine™ control. The transferrin conjugates were further derivatized with polyethylene glycol (PEG), and the excess hydrophilicity did not appear to inhibit transfection efficiency in any way. These PEGylated transferrin particles remained stable for 1 month in solution, as did the plain nanospheres and the PEGylated transferrin particles after lyophilization.

So far, the results using chitosan to produce gene medicines or gene-based vaccines appear promising. Many of the ideal characteristics of a gene delivery system are provided. Chitosan is readily available, cost-effective, and relatively nontoxic. Complexes of controllable sizes and high colloidal stability can be readily formulated, that have the potential for further modification for more specific cell targeting. The high stability and low expression achieved in vivo suggest that uptake and/or decomplexation, but to a lesser extent endosomal release, may be critical rate-limiting steps. These issues will have to be addressed to optimize that type of polymeric delivery system.

Potentially, gene therapy offers a useful and efficient option for preventing, correcting, or modulating diseases that typically have no other methods of treatment. In order to design and produce an ideal delivery system, the uptake and fate of the plasmid and barriers to expression need to be further understood. The ideal nonviral delivery system should produce controllable and reliable levels of protein upon in vivo administration and have minimal side effects. The polymers described here offer potential as gene delivery systems, but they still present some limitations. Future goals must involve identifying the location of the gene and controlling levels of expression upon delivery. It is understood that each disease and gene will require a rationally designed delivery and expression system enabling targeting of the gene, yet retaining plasmid functionality.

INTRODUCTION

Defects in bone that result from trauma (e.g., fractures), malformation, or disease processes such as cancer or osteoarthritis can cause significant morbidity. Current therapies for bone replacement rely on the use of allograft transplants from bone banks or autologous bone grafts. Frozen or freeze-dried allografts from human cadavers have been used clinically but are problematic due to potential for disease transmission, rejection, and resorption (1). The autograft involves direct transfer of viable bone-derived cells, inductive factors, and growth factors from the transplanted bone matrix, usually taken from the corticocancellous bone of the anterior iliac crest. Although trabecular autografts have ample osteogenic cells and good revascularization capabilities, it is often difficult to obtain a sufficient quantity of bone from the patient (2). Cortical autografts are more easily obtained and provide greater stability, but they often exhibit poor vascularity, a lower content of osteogenic cells, and a high rate of fatigue fractures occurring 6–8 months following operation (3). Autografts also subject the patient to surgery at a second site, which may lead to additional pain, risk of infection, nerve and vessel damage, and a prolonged hospital stay. Thus, the search for alternatives to autograft and allograft remains an important topic in medical research.

In recent years, considerable research has focused on improving bone repair through the use of various growth (e.g., platelet-derived growth factor [PDGF], transforming growth factor [TGF], fibroblast growth factor [FGF], epidermal growth factor [EGF], insulin-like growth factor [IGF]) and morphogenetic factors (e.g., bone morphogenetic proteins [BMP]). For example, initially isolated from demineralized bone matrix (DBM), partially purified BMP was found to be osteoinductive, inducing bone formation by causing host mesenchymal stem cells (MSCs) to migrate to the repair site and differentiate into bone-forming cells (4,5). The key difference between these two classes of molecules is that growth factors affect cell growth and function (e.g., proliferation and differentiation), whereas morphogenetic factors are involved in cell commitment and induction from an undifferentiated state to a specific cell type. Recombinant techniques are now used to isolate, identify, clone, and express different types of BMPs as well as other growth factors (PDGF, TGF, FGF, IGF) normally present in bone matrix, which may operate in complex synergy. At least two of these proteins, BMP-2 and BMP-7, induce significant bone formation in the absence of other BMPs when implanted into ectopic (non-bony) sites (6,7) as well as orthotopic (bony) sites (8–12), and will likely be the first available therapeutics for bone repair in the clinic. The exact role of other growth factors in the complex cascade of molecules involved in bone formation and maintainance is not well understood.

Many basic research and developmental challenges remain in protein- and gene-based therapeutics for skeletal tissue repair. Perhaps the most basic are the identification and understanding of the complex cascade of genes and proteins that regulate skeletal growth and repair, in both normal and diseased states. Significant progress is being made in this area. With regard to product development, one of the major challenges limiting clinical availability has been the issue of delivery. Traditional systemic delivery of these proteins has not been feasible for a variety of reasons, including short biological half-lives of proteins as well as lack of drug localization to the target injury site. Oral delivery of therapeutic proteins, on the other hand, has been limited by breakdown of proteins by digestive enzymes and challenges with proteins crossing the intestinal wall intact and active. Progress is being made to protect proteins in the digestive tract using encapsulation systems, and this route of drug delivery would be appropriate for certain proteins that have systemic effects. Delivery of proteins and genes for skeletal tissue repair are founded

INTRODUCTION

Defects in bone that result from trauma (e.g., fractures), malformation, or disease processes such as cancer or osteoarthritis can cause significant morbidity. Current therapies for bone replacement rely on the use of allograft transplants from bone banks or autologous bone grafts. Frozen or freeze-dried allografts from human cadavers have been used clinically but are problematic due to potential for disease transmission, rejection, and resorption (1). The autograft involves direct transfer of viable bone-derived cells, inductive factors, and growth factors from the transplanted bone matrix, usually taken from the corticocancellous bone of the anterior iliac crest. Although trabecular autografts have ample osteogenic cells and good revascularization capabilities, it is often difficult to obtain a sufficient quantity of bone from the patient (2). Cortical autografts are more easily obtained and provide greater stability, but they often exhibit poor vascularity, a lower content of osteogenic cells, and a high rate of fatigue fractures occurring 6–8 months following operation (3). Autografts also subject the patient to surgery at a second site, which may lead to additional pain, risk of infection, nerve and vessel damage, and a prolonged hospital stay. Thus, the search for alternatives to autograft and allograft remains an important topic in medical research.

In recent years, considerable research has focused on improving bone repair through the use of various growth (e.g., platelet-derived growth factor [PDGF], transforming growth factor [TGF], fibroblast growth factor [FGF], epidermal growth factor [EGF], insulin-like growth factor [IGF]) and morphogenetic factors (e.g., bone morphogenetic proteins [BMP]). For example, initially isolated from demineralized bone matrix (DBM), partially purified BMP was found to be osteoinductive, inducing bone formation by causing host mesenchymal stem cells (MSCs) to migrate to the repair site and differentiate into bone-forming cells (4,5). The key difference between these two classes of molecules is that growth factors affect cell growth and function (e.g., proliferation and differentiation), whereas morphogenetic factors are involved in cell commitment and induction from an undifferentiated state to a specific cell type. Recombinant techniques are now used to isolate, identify, clone, and express different types of BMPs as well as other growth factors (PDGF, TGF, FGF, IGF) normally present in bone matrix, which may operate in complex synergy. At least two of these proteins, BMP-2 and BMP-7, induce significant bone formation in the absence of other BMPs when implanted into ectopic (non-bony) sites (6,7) as well as orthotopic (bony) sites (8–12), and will likely be the first available therapeutics for bone repair in the clinic. The exact role of other growth factors in the complex cascade of molecules involved in bone formation and maintainance is not well understood.

Many basic research and developmental challenges remain in protein- and gene-based therapeutics for skeletal tissue repair. Perhaps the most basic are the identification and understanding of the complex cascade of genes and proteins that regulate skeletal growth and repair, in both normal and diseased states. Significant progress is being made in this area. With regard to product development, one of the major challenges limiting clinical availability has been the issue of delivery. Traditional systemic delivery of these proteins has not been feasible for a variety of reasons, including short biological half-lives of proteins as well as lack of drug localization to the target injury site. Oral delivery of therapeutic proteins, on the other hand, has been limited by breakdown of proteins by digestive enzymes and challenges with proteins crossing the intestinal wall intact and active. Progress is being made to protect proteins in the digestive tract using encapsulation systems, and this route of drug delivery would be appropriate for certain proteins that have systemic effects. Delivery of proteins and genes for skeletal tissue repair are founded

on local use, and various strategies are being developed to deliver these therapeutics to the local injury site. The emergence of polymeric drug delivery systems and biomaterials has contributed significantly to the challenges of local delivery of proteins and genes. These carriers of therapeutics serve to provide a reservoir that can maintain a local concentration of drugs as well as provide a controlled, sustained release of these drugs for extended therapeutic effect.

Three strategies exist when considering delivery of therapeutics for local skeletal tissue repair. Perhaps the simplest is protein delivery in which the recombinant protein itself is incorporated within a carrier system such as polymer microspheres or biomaterial matrices. Another method is direct gene therapy, whereby the goal is to deliver the naked genes themselves into the target site and have the genes incorporate into the host cells that can produce the gene products. A third option is cell-based delivery, in which the gene of interest is inserted into a specific cell line, usually autogenous or allogeneic, so that the cells become delivery systems for gene products. Active research is being carried out in all three areas with promising results that may become successful therapies in the clinic.

The ideal carrier for bone growth and morphogenetic factors and the genes encoding them is still under investigation. Various bioderived materials such as bone matrix collagen and DBM as well as synthetic materials including ceramics and degradable polymers (e.g., poly(lactic acid) (13), poly(lactide-*co*-glycolide) (PLGA) (10), poly(phosphazene) (14)) have been studied as suitable bone graft substitutes. Allogeneic DBM, which contains a cocktail of osteoinductive proteins, has been shown to form bone in vivo (15), but when the matrix proteins are extracted with guanidinium hydrochloride to yield insoluble collagenous bone matrix (ICBM), bone does not form. When ICBM is combined with this protein extract (containing various BMPs), the osteoinductive activity is restored. However, the use of ICBM or DBM in the clinical setting has serious drawbacks, including potential immunogenicity, potential pathogen transmission, sterility assurance, supply problems, and lack of structural integrity.

Consequently, growth and morphogenetic factors require a suitable matrix or carrier serving as an effective delivery system by localizing and creating a high concentration of protein at the injury site, preventing loss of protein into neighboring sites (i.e., when using scaffolds for local bone formation), providing a sustained release of protein for local or systemic delivery (i.e., when using polymer drug delivery systems), and maximizing the interaction between the protein and the target host cells. Ideally, the bone repair scaffolds should be biocompatible and biodegradable to minimize local tissue response and should resorb as new bone is formed. On the other hand, polymer drug delivery systems should provide a sustained, controlled release of therapeutics for either local or systemic action. Sustained, controlled delivery of growth and morphogenetic factors using polymer delivery systems, scaffolds, or other matrices are advantageous over conventional injection of these therapeutics in solution form due to the clearance or elimination of injected drug by the systemic circulation as well as the inconvenience and necessity for multiple or repeated injections for effective treatment. In this article, proteins and genes involved in skeletal tissue repair as well as novel strategies for delivering them are introduced.

GROWTH AND MORPHOGENETIC FACTORS FOR BONE REPAIR

Serious skeletal defects result from diverse causes including trauma, birth defects, oncologic resections, and disease pathosis (e.g., periodontitis, degenerative osteoarthritis, and osteomyelitis). To restore lost tissue or prevent fracture nonunion, orthopaedic, plastic, and oral surgeons perform more than 250,000 bone grafts annually in the U.S. (8). As currently practiced, bone grafting predominantly uses autogenous corticocancellous bone taken from a donor site such as the anterior iliac crest. Although highly effective, autologous bone grafting is limited by such issues as donor site morbidity and pain, donor site infection, blood loss, and limited supply of donor site material. Allogeneic human cadaver bone graft is the most common alternative to the bone graft, but allografts suffer from the potential for disease transmission, rejection, and resorption.

Urist first observed in 1965 that implanting DBM in extraskeletal sites generated osseous tissue in rats (4). This process has been termed osteoinduction, that is, bone formation from MSCs that have differentiated down the osteoblastic lineage. Osteoconduction, on the other hand, refers to the ability of a material to support bone ingrowth from surrounding bone and depends on the material itself, its biocompatibility, porosity, surface charge, surface texture, and biodegradability. Later studies demonstrated that extracting the DBM with aqueous guanidinium hydrochloride yielded ICBM that is not osteoinductive. Reconstituting ICBM with the aqueous extract, which Urist called BMP, restored the osteoinductive activity as in DBM. However, the use of ICBM or DBM in the clinical setting has serious drawbacks, including potential immunogenicity, potential pathogen transmission, sterility assurance, supply problems, and lack of structural integrity.

More recently, modern biotechnology techniques have been used to isolate, identify, clone, and express more than 15 individual BMPs, which are all members of the transforming growth factor-beta (TGF-β) superfamily. New molecules continue to be identified and cloned. These recombinant human BMPs (rhBMPs) are present in bone extracellular matrix in trace amounts and probably operate in complex synergies. However, at least two of the individual proteins, namely rhBMP-2 and rhOP-1 (osteogenic protein-1, also known as BMP-7), are potential candidates for clinical use because they induce bone formation in the absence of other BMPs when implanted into bony and nonbony sites (6,7). The rhBMP-2, which is expressed in Chinese hamster ovary cells, contains an aminoterminal propeptide of 40–45 kDa, a mature active 30 kDa homodimer consisting of 18 and 22 kDa subunits, and a small amount of uncleaved 60 kDa precursor protein (16).

In vitro, rhBMP-2 induces pluripotent MSCs to differentiate into bone, cartilage, and fat lineages in a dose- and time-dependent manner (17). When combined with ICBM fragments or polyester carriers (e.g., PLGA, PLLA), rhBMP-2 or rhOP-1 regenerates osseous tissue in various species and anatomic sites, including rat muscle (18), rat calvarium (8,11,12), rat subcutaneous tissue (6,7), rat femur (10,19), sheep femur (9), and canine maxillary cleft (20).

TGF-β (25 kD molecular weight) is another factor important in the regulation of cell proliferation and differentiation and has been implicated in bone and cartilage formation and maintenance (21). There are three isoforms (β1, β2, β3), which have the ability to influence the mesenchymal cell differentiation pathway to bone and cartilage in a dose-dependent manner (22). TGF-β is found in macrophages and other inflammatory cells, platelets during degranulation in hematoma formation, and bone matrix, where it is most abundant (23). TGF-β is converted to its active form under acidic conditions, such as those produced by macrophages or osteoclasts during bone resorption (24). There have been a number of studies that suggest that TGF-β is involved in cartilage differentiation and bone repair, although its exact role is not well understood. TGF-β has been shown to induce chondrocytic differentiation from micromass cultures of pluripotent C3H10T1/2 (T1/2) cells (25), chick limb bud mesenchymal cells (26), and periosteal cells (27). TGF-β has also been implicated in the process of endochondral ossification (22,27) (i.e., when TGF-β1 was injected subperiosteally into uninjured bone, it induced a cartilagenous mass that underwent endochondral ossification). Consequently, TGF-β has been shown to have both stimulatory and inhibitory effects on the differentiation of bone cells depending on the maturation stage of the cells used, cell density, and growth factor concentration (25,28).

PDGF is a polypeptide dimer of 30 kDa that is unrelated to the TGF-β superfamily but acts as a mitogen for a variety of cell types. PDGF was found to increase DNA synthesis in cultured rat calvariae and fibroblasts but did not stimulate collagen synthesis or organized bone formation (29). It exists as a homodimer or heterodimer comprising A or B subunits, although the BB homodimer is more effective than AA or AB in stimulating bioactivity in bone cells in vitro (29). Similar to TGF-β, the exact role of PDGF in bone repair is not clearly understood. Marden et al. (30) reported that PDGF inhibited bone regeneration in a rat cranial defect model, whereas Bolander (23) reported that PDGF subperiosteal injections resulted in stimulation of MSC proliferation and subsequent bone mass increase in rat femurs. Other proteins such as FGF and IGF have also been linked to bone cell function (23). In addition, many other types of factors have been identified to influence skeletal tissue development, repair, and maintenance (Fig. 1). Hormones (e.g., parathyroid hormone [PTH], estrogen, calcitonin), vitamins (e.g., vitamin A, C, D, etc.), and glucocorticoids (e.g., dexamethasone, cortisol, etc.) also have specific effects on mesenchymal stem cells, cartilage cells (chondrocytes), and bone cells (osteoblasts) as do growth and morphogenetic factors. The key difference between growth (e.g., PDGF, TGF-β) and morphogenetic (e.g., BMP) factors is that growth factors affect cell growth and function, whereas morphogenetic factors are involved in cell commitment and induction from an undifferentiated state to a specific cell type (Table 1). This will likely influence how they are used in the clinic and suggests that two or more proteins may be necessary for some treatments.

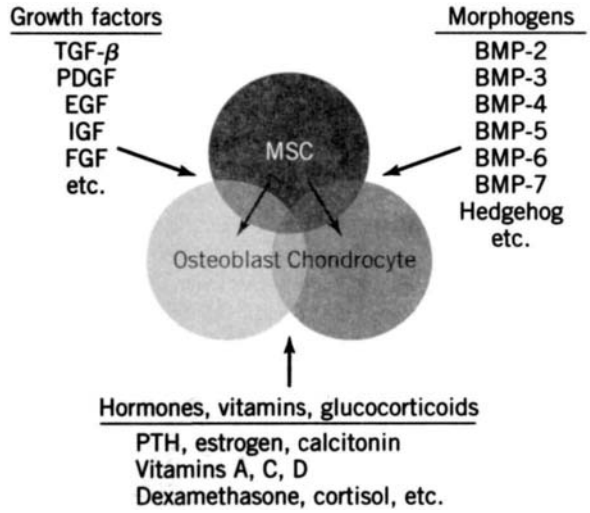

Figure 1. Skeletal tissue development, repair, and maintenance factors that affect MSC, osteoblasts, and chondrocytes.

MESENCHYMAL STEM CELLS

MSCs are undifferentiated, pluripotent cells capable of differentiating into cells that form into various connective tissues such as bone, cartilage, tendon, ligament, muscle, and fat. During development, multipotential stem cells progressively become committed to specific paths. This process, called determination or commitment, irreversibly alters the cells so that the progeny inherits this more limited potential. Once committed or determined, the precursor cell may exist in this state until it differentiates. Differentiation is defined as the expression of one or more markers of the functionally mature cell and may be reversible or terminal. The environment of the progenitor cells (i.e., protein factors, extracellular matrix, cellular contact, and other unknown factors) may influence commitment and differentiation (31). Compared with hematopoietic stem

Table 1. Role of Growth and Morphogenetic Factors on MSCs, Cartilage Cells (Chondrocytes), and Bone Cells (Osteoblasts)

	MSCs	Chondrocyte	Osteoblast
PDGF	Proliferation	Proliferation	Proliferation
TGF-β	Proliferation	Proliferation Differentiation	Differentiation
BMP	Commitment Proliferation Differentiation	Differentiation	Differentiation

cells, much less is known about multipotential progenitor cells of mesodermal origin (also referred to as MSCs). Like hematopoietic factors, BMPs influence the commitment of MSCs.

Bone marrow is a complex tissue comprised of red and white blood cells, their precursors, and a connective tissue network or stroma. Bone marrow stromal cells have a close structural and functional relationship with bone cells, and it is generally believed that osteoblast precursors are derived from the mesenchymal stromal cell lineage. In vitro, typical bone phenotypic markers such as alkaline phosphatase activity, cAMP response to parathyroid hormone, osteocalcin synthesis, collagen I production and gene expression, osteonectin gene expression, and mineralized nodules are expressed by cultured human bone marrow stromal cells (32). The existence of cells in marrow that have osteochondrogenic potential has been demonstrated with whole marrow and cultured marrow stromal cells from a variety of animal species including humans (33). Additional evidence of in vivo osteochondrogenic potential of marrow stroma has been derived from experiments using grafts of whole marrow or cultured marrow stromal cells with calcium phosphate ceramics (34,35).

C3H10T1/2 cells are an established murine MSC line originally isolated as embryonic limb-derived fibroblasts, which differentiate into muscle, fat, and cartilage cells when treated with azacytidine. BMP-2 causes a dose-dependent differentiation of these cells into fat, cartilage, and bone cells; low concentrations favor adipocytes and high concentrations result in chondrocytes and osteoblasts (17). Osteogenic cell markers such as alkaline phosphatase activity have been used to demonstrate stem cell differentiation into osteoblastic cells by BMP-2 (36). Therefore, C3H10T1/2 cells serve as a simple in vitro cell culture system to characterize the osteogenic potential of BMPs and other proteins.

MECHANISMS OF BONE REPAIR

Ectopic bone formation refers to bone formation in a non-bony site, such as in subcutaneous or intramuscular sites. These sites have been mainly used to test the osteoinductive ability of bone morphogenetic proteins in an environment that is surrounded by tissue of mesodermal origin. On the other hand, because bone is a self-repairing tissue (limited by the defect size), a model to test bone formation in a bony site has also been established. A critical size defect is defined as the smallest intraosseous wound that does not heal by bone formation during the lifetime of the animal (37–39). A critical size defect heals by fibrous connective tissue formation and the actual critical size varies in different species, often increasing with animal size. For example, an 8-mm diameter skull defect has been characterized as a critical size defect in a rat, whereas a 4 mm heals eventually. The traditional bony sites involved in testing defects or nonunions (fractures that do not heal) have been the skull and the femur. Calvarial critical defects have been extensively characterized and established as a site to test bone repair materials (37). It is important to note that the calvarium develops and heals by intramembranous ossification (direct formation of bone by osteoblasts) and is a non-weight-bearing bone. In contrast, femoral bone heals by endochondral ossification (bone formation through a cartilage intermediate), which is weight bearing (Fig. 2). BMP-2 has been shown to stimulate endochondral but not intramembranous bone formation.

CARRIERS FOR GROWTH AND MORPHOGENETIC FACTORS

Considerable effort has been dedicated to developing delivery systems for proteins targeted for bone repair. Oral administration presents difficulty for peptide-based drugs, which are rapidly digested by gastric and intestinal enzymes. Intravenous delivery results in alteration and clearance by the liver. Drug delivery vehicles facilitate the sustained, controlled delivery of growth factors and minimize the fluctuating levels achieved with single or multiple doses. A variety of delivery systems or carriers for peptides and proteins have been investigated (40–45) and are illustrated in Figure 3. For example, PDGF (40), basic FGF (46), EGF (47), and TGF-β (48) have been incorporated into various degradable (PLGA films, microspheres, rods, etc.) or nondegradable (mechanical pumps, diffusion

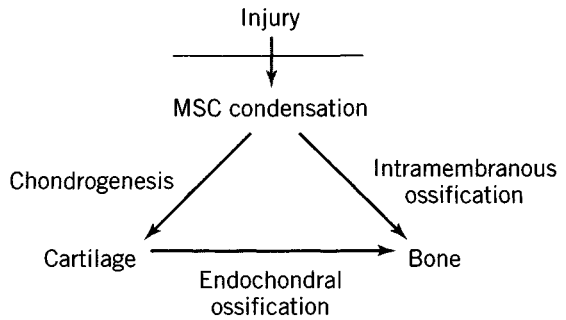

Figure 2. Bone and cartilage development and repair pathways.

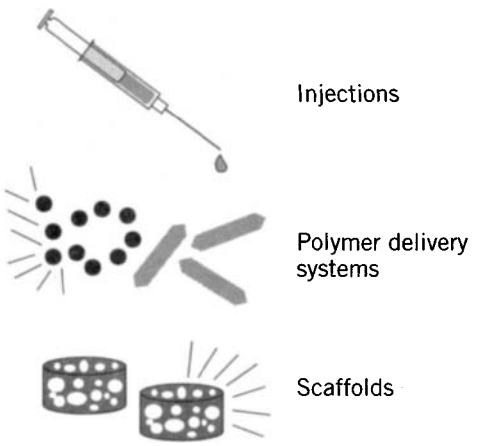

Figure 3. Strategies for delivering protein-, gene-, and cell-based therapeutics for local bone and cartilage repair.

based polymer matrices) delivery systems for controlled release. Ethylene vinyl acetate (EVA) copolymer is a nondegradable elastomer that has been used to deliver a host of small and large molecules (45). Bovine serum albumin (BSA) has been used extensively as carrier for EVA systems and EVA/BSA release has been shown to parallel growth factor release (45). Release kinetics for EVA systems can be controlled by varying drug loading, choice of carrier, device geometry, or by polymer surface coating (45). In one study, controlled, sustained release of bioactive PDGF and TGF-β was demonstrated from EVA polymer rods (40).

New tissue engineering approaches for bone and cartilage repair leverage the ability of growth and morphogenetic factors to control cell growth, differentiation, and new tissue formation at the site of injury or defect. Porous, degradable polymer scaffolds have been identified to be suitable bone or cartilage repair materials because they can be carriers for these tissue-inducing molecules and also allow the seeding of culture-expanded cells (i.e., chondrocytes, osteoblasts, MSCs) in vitro or host cell and tissue ingrowth in vivo. A wide variety of synthetic (e.g., PLGA) or natural polymers (e.g., collagen) have been explored as delivery vehicles for cells or growth/morphogenetic factors. These three-dimensional polymeric scaffolds have been fabricated using a variety of methods and used for a variety of applications such as cartilage repair, nonunion fracture defects, oral and maxillofacial defects, and spinal fusion. Various degradable polymer carriers or scaffolds containing BMPs have been used for local bone and cartilage formation (8,12,20,41,49–51).

Some semisynthetic polymers (e.g., chemically natural polymers) are also being explored. For example, derivatized hyaluronic acid is a class of semisynthetic biopolymer that can be fabricated into porous scaffolds for tissue reconstruction and repair. It is a benzyl ester derivative of the polysaccharide hyaluronic acid, which exists naturally in extracellular matrix and plays an important role in proteoglycan organization, cell hydration, cell differentiation, and wound healing (52). The benzyl esterification of the glucuronic acid residue of hyaluronic acid renders the polymer insoluble in aqueous conditions and significantly decreases the rate of degradation in vivo by hydrolysis and hyaluronidases (53). Hyaluronic acids are attractive choices for tissue repair scaffolds because biocompatibility has been well established (53). In addition, degradation can be controlled by altering the amount of esterification, and complex three-dimensional shapes with various porosities and pore sizes can be achieved (53).

Only a few formulations have been actively pursued for skeletal tissue repair. They include injectable formulations (such as microspheres, depots, and gels) and implantable matrices or scaffolds. Injectables can work as minimally invasive delivery systems by providing sustained release of a protein at the repair site. In open, surgical procedures, implantable scaffolds provide the opportunity for cells to migrate into the carrier, adhere, proliferate, and differentiate while also providing sustained release of protein. Scaffolds for tissue engineering should meet several design criteria: (*1*) the surface should permit cell adhesion and growth, (*2*) neither the polymer nor its degradation products should provoke inflammation or toxicity when implanted in vivo, (*3*) the material should be reproducibly processable into three-dimensional structures, (*4*) porosity should be high in order to provide a large surface area for cell migration, adhesion, and matrix regeneration, and (*5*) the scaffold should resorb in concert with new tissue formation.

Protein Delivery in Orthopedics

New advances are being made in the field of protein-, gene-, and cell-based therapeutics for skeletal tissue repair. Protein drug delivery is the direct delivery of already synthesized proteins using a specific carrier to the local tissue. Proteins are usually encapsulated or admixed within a polymer matrix and are released to the local site in a controlled, sustained fashion in the order of hours up to years (45). The simplicity of drug delivery systems and the ability to control dose and release rate remain the major advantages of this delivery strategy. However, drug stability and bioactivity must be carefully characterized within a particular carrier system.

Of all the growth and differentiation factors discovered to date, only a few have shown significant potential for skeletal tissue repair. These include human recombinant proteins of BMP-2, BMP-7 (or osteogenic protein-1, rhOP-1), basic FGF (bFGF), and TGF-β1. BMP-2 and rhOP-1 are currently in preclinical and clinical studies for a range of bone-specific indications such as fracture healing, oral and maxillofacial defects, spinal fusion, and cartilage repair. bFGF is also in clinical studies for accelerated fracture repair, whereas TGF-β1 is in preclinical studies for cartilage and bone repair. All of these proteins have been delivered in association with an appropriate drug delivery carrier (e.g., collagen), although simple injections of these proteins alone at high doses can still induce some level of efficacy (6). The presence of a matrix or carrier either enhances the volume of new repair tissue formed, decreases the amount of protein needed to induce efficacy, and prolongs residence of protein at the local repair site to allow sufficient time for responsive cells to migrate and react.

In the area of fracture and bone defect repair, BMP-2 and rhOP-1 have shown to be most effective when delivered in association with a carrier, which have mainly been collagen based to date. For example, BMP-2 loaded onto absorbable collagen sponges has shown good efficacy in accelerating healing in a fracture model (54). In another study, rhOP-1 incorporated with another type of implantable collagen matrix was shown to heal large segmental bone defects (55). Both of these devices performed equally or better than the traditional clinical standard of using autogenous bone graft for nonunion defects or immobilization for union fractures. Other carriers such as ceramic-based calcium phosphates containing BMP (56) have been shown to be effective for bone defect repair. More recently, injectable gels such as bFGF-containing hyaluronic acid have shown efficacy for accelerated fracture repair (57). Injectable gels that deliver the protein for the duration of the healing period and contribute to fracture callus formation would be ideal carriers. Polymer, ceramic, or com-

posite matrices that can withstand soft tissue pressure or bear weight may represent the next generation of bone defect repair materials.

Other bone-specific indications for protein delivery include spinal fusion and oral and maxillofacial surgery. In one study, BMP-2 loaded onto absorbable collagen sponges has been shown to enhance fusion in nonhuman primate lumbar interbody spinal fusion models (58). In oral and maxillofacial surgery, collagen matrix/BMP-2 was shown to be successful in repairing mandibular defects in a canine model (59), alveolar ridge augmentation procedures in human clinical trials (60), osseointegration of titanium dental implants in nonhuman primates (61), and maxillary sinus floor augmentation procedures (62).

Cartilage, tendon, and ligament repair are also being using protein therapeutics. Recent studies using BMP-2 in combination with absorbable collagen sponges has shown success in repairing articular cartilage defects in a rabbit model (63). Injection of TGF-β1 encapsulated within liposomes was shown to accelerate the repair of articular cartilage defects in rabbits (64). New members of the TGF-β gene family, the growth and differentiation factors 5, 6, and 7 (GDF-5, 6, 7) have been shown to induce neotendon and ligament when implanted in association with a collagen matrix in rat models (65).

Direct Gene Therapy

An alternative to delivering proteins is to directly deliver the genes encoding these proteins to the host cells as naked plasmid DNA injections, or using nonviral transfection or viral transduction methods. Potential advantages of gene therapy over direct protein delivery include (*1*) no need for manufacturing or purification facilities, (*2*) constant production of fresh protein in bioactive form, and (*3*) lower dose requirements for achieving efficacy. Limits of gene therapy include poor long-term gene expression, inefficient transfection of genes to target cells, and the inability to control or cease expression as needed. Nevertheless, significant progress is being made in orthopedic preclinical studies. In one study, plasmid DNA encoding for either BMP-4 or a fragment of PTH (amino acids 1–34) alone resulted in new bone formation when implanted into segmental bone defects in the rat femur (66). When BMP-4 and the parathyroid fragment were implanted together, acceleration of bone formation was observed compared with either factor alone, suggesting synergy. Adenovirus containing the β-galactosidase reporter gene injected into the synovium of cartilage joints was able to infect the cells lining the synovium and express the marker gene for at least 8 weeks after injection (67). Expression of marker genes using an adenoviral vector injected into segmental defect sites for 6 weeks has also been reported (68).

Cell Based Gene Delivery

An alternative approach for delivering proteins is to use genetically engineered cells as carriers for genes encoding the proteins of interest. This strategy is a novel concept in orthopedic drug delivery and limited literature exists. The basic concept is to generate, in vitro, cells or tissues that are implantable protein factories. The cell-based factories are injected at the local tissue repair site and produce the protein of interest over time. Cells can be injected as a cell suspension or in association with a carrier such as a scaffold or gel. They can also be formed into organized tissue in vitro and subsequently implanted as a discrete structure (69). The advantages of this system are (*1*) the ability to control the dose of protein delivered (by controlling expression levels, cell numbers, etc.), (*2*) the ability to retrieve the cells as needed (if implanted in a defined scaffold such as a cell-occlusive membrane), (*3*) the ability to control transfection or transduction in only the desired cells, and (*4*) the ability to treat acute or chronic conditions. The cells that are transfected or transduced ex vivo can be autologous, allogeneic, or xenogeneic (if protected by a immunoisolatory membrane). Autologous cells are the currently preferred choice as they eliminate any immune response, but they must be harvested from the donor as a separate procedure. Preliminary studies for bone and cartilage repair are encouraging. In one study, a bone marrow stromal cell line infected with an adenovirus expressing recombinant human BMP-2 was able to form ectopic bone when injected into rat muscle (70). In another study, chondrocytes that were infected with adenovirus expressing a marker gene β galactosidase remained in the joint space and expressed the reporter gene for at least 45 days when injected into cartilage explants (71). Additionally, bone marrow cells transfected with a gene encoding for a new osteoinductive protein (LIM mineralization protein-1) and seeded onto a collagen matrix supported successful spinal fusion following implantation into rats (72). Despite promising results, further research is needed to develop cell-based approaches into viable therapies.

SUMMARY

Protein-, gene-, and cell-based systems offer powerful new approaches for skeletal tissue repair. Applications range from fracture healing, bone defect repair, spinal fusion, and oral and maxillofacial surgery to cartilage, tendon, and ligament repair. These approaches require the development of novel delivery systems. Delivery systems have several requirements and must (*1*) serve as effective carriers for therapeutic agents, (*2*) provide localization of the protein to the target repair site, (*3*) maintain bioactivity in vivo, (*4*) provide controlled, sustained release to the surrounding tissue, and (*5*) in some instances, concurrently serve as scaffolds for tissue ingrowth.

Bibliography

Historically, pharmaceutically active agents have been chosen based on biological activity, with absorption, efficacy, and side effect profiles determined by metabolic processes. The effectiveness of the therapeutic agent can be enhanced by sophisticated drug delivery systems that actively control the delivery rate and site of drug action (1–8). Over the past 30 years, drug delivery systems based on the principles of osmosis have shown themselves to be reliable and adaptable to an impressive variety of uses, ranging from oral dosage forms that deliver for less than 24 hours to implantable systems that precisely deliver exquisitely small amounts of potent agents over periods of a year or more.

EARLY OSMOTIC SYSTEMS

The Rose–Nelson osmotic pump is generally recognized as the forerunner of most modern osmotic systems (9). This pump, developed in 1955 for pharmacologic research, consisted of a water compartment, an osmotic agent compartment, and a drug compartment (Fig. 1) (10). The water and osmotic agent compartments were separated by a semipermeable membrane, and the osmotic agent and drug compartments were separated by an elastic diaphragm. In operation, water was drawn into the osmotic agent compartment, resulting in volume displacement of the diaphragm and pumping of the drug solution from the drug compartment. If the osmotic agent compartment was filled with sufficient osmotic agent to maintain a saturated solution, zero-order delivery would be observed.

In 1971, Stolzenberg was issued the first patent for an osmotic pump, which incorporated pistons between the osmotic agent compartment and the drug compartment and between the water compartment and the exterior of the pump (11). Higuchi and Leeper proposed a variation of the Rose–Nelson pump in 1973 in which the internal water compartment was eliminated, placing the membrane in direct contact with the surrounding aqueous environment (12). In the mid-1970s, researchers at ALZA designed a capsular osmotic pump, in which the drug compartment was almost fully surrounded by an osmotic layer and a semipermeable membrane (this design was used in the ALZET® osmotic pump) (13). In 1975, Theeuwes developed the "elementary osmotic pump," which further simplified the design by combining the osmotic agent compartment and drug compartment into one (14). A subsequent variation on this design was the Push-Pull™ osmotic pump, which consisted of an osmotic layer and a separate drug layer (15,16). The development of these systems has been described in numerous articles (14,17–21). This article reviews the ALZET® osmotic pump and several newer applications of osmotic technology.

CHARACTERISTICS OF OSMOTIC SYSTEMS

Osmotic systems exhibit good correlation between in vitro and in vivo release; with proper system design, performance tends to be unaffected by in vivo variables. Therefore, these systems can be engineered to provide a variety of drug-release profiles such as increasing, decreasing, or zero order. The delivery rate can also be biochemically triggered (22) or patterned to mimic a periodic event, such as a circadian rhythm (23–25). Depending on the design, osmotic systems can deliver drug orally into the gastrointestinal tract or parenterally into the systemic circulation. Drug delivery also can be targeted via a catheter into the venous, arterial, or central nervous system or directly to an organ, such as the cerebrum, spleen, or liver. In general, bioavailability issues may be circumvented with osmotic pumps by selection of the optimum delivery site for drug delivery. Dosing is less frequent, and plasma drug concentrations are maintained within the therapeutic window, providing a dose-sparing effect, improved patient compliance, and minimized side effects for extended periods.

The osmotic systems described in this article release a therapeutic agent at a predetermined, typically zero-order, delivery rate based on the principle of osmosis. Osmosis is the natural movement of a solvent through a semiperme-

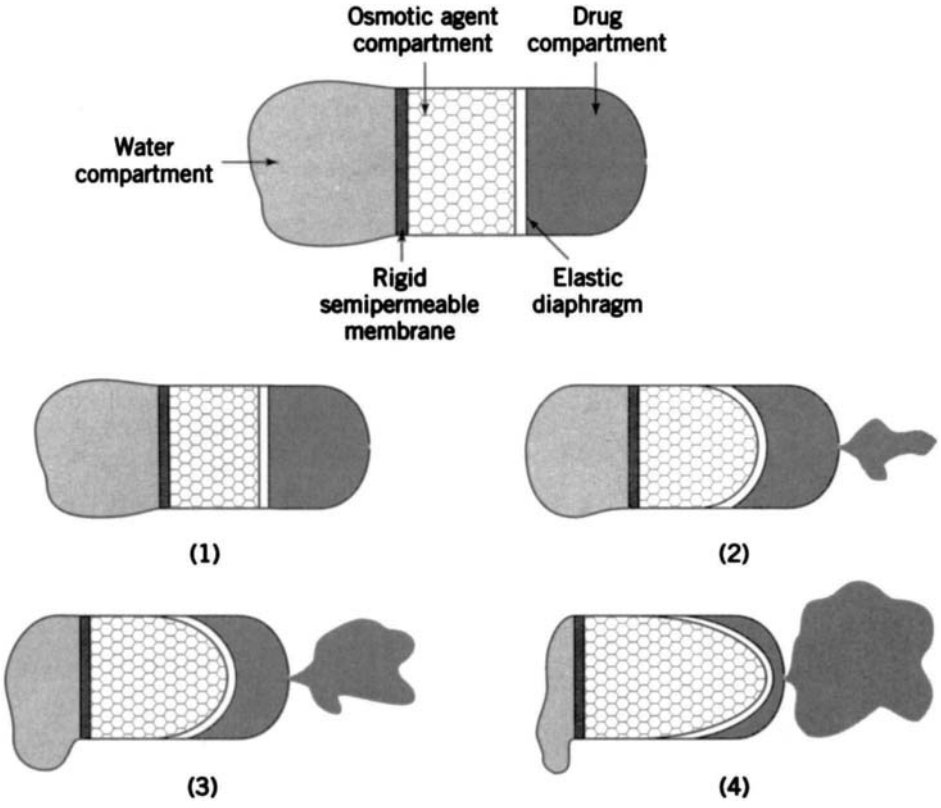

Figure 1. Principle of the Rose–Nelson osmotic pump. *Source:* Ref. 10.

able membrane into a solution of higher solute concentration, leading to equal concentrations of the solute on both sides of the membrane. Osmotic systems imbibe water from the body through a semipermeable membrane into an osmotic material, which swells, resulting in slow and even delivery of drug formulation.

In comparison with drug delivery systems based on diffusion and erosion, osmotic systems tend to be less volume efficient and more complex in design. However, osmotic systems also tend to provide better zero-order delivery and to deliver a greater percentage of the drug loading at a zero-order delivery rate.

OSMOTIC SYSTEM THEORY

Figure 2 illustrates the function of a semipermeable membrane (26). The semipermeable membrane (**a**) is permeable to water (compartment **c**) but impermeable to the solute (osmotic agent, e.g., NaCl) in compartment **b**. When the pressure is equal between compartments **b** and **c** ($P^0 = P$), water (solvent) will permeate through the semipermeable membrane from compartment **c** to compartment **b**, reflecting the gradient in chemical potential of the solvent between the two compartments. As the pressure is increased in compartment **b**, the chemical potential of the solvent increases in this compartment. When the pressure in compartment **b** reaches the osmotic pressure of the solution, the chemical potential of the solvent in the two compartments becomes equalized, and net transport of the solvent through the membrane stops.

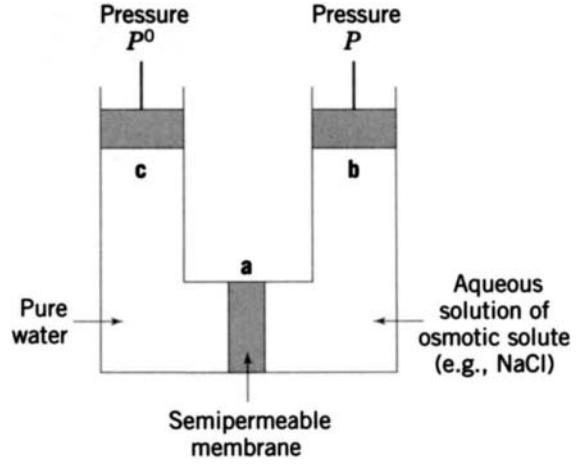

Figure 2. Diagram of a semipermeable membrane (**a**) separating an aqueous solution of an osmotic solute (**b**) from pure water (**c**). *Source:* Ref. 26.

The greater the gradient in chemical potential, the greater will be the rate of transport of solvent through the membrane. Considering the relationship between chemical potential and osmotic pressure, the rate of water transport through the membrane can be written as follows (14):

$$dV/dt = (A/h)L_P(\sigma \Delta\pi - \Delta p) \quad (1)$$

where dV/dt is the volume flow of solvent through the membrane, A is the cross-sectional area for transport, h is

the membrane thickness, L_p is the hydraulic permeability of the membrane, σ is the reflection coefficient, $\Delta\pi$ is the osmotic pressure difference across the membrane, and Δp is the hydrostatic pressure difference across the membrane.

Table 1 presents the osmotic pressures of saturated aqueous solutions of common pharmaceutical solutes (27). Hydrostatic pressure inside most osmotic drug delivery systems is generally less than 1 atm, although some systems may attain pressures as high as several atmospheres. Hence, in comparison with the osmotic pressures reported in Table 1, the hydrostatic pressure differential is negligible:

$$\Delta\pi \gg \Delta p$$

Equation 1 can then be written as follows:

$$dV/dt = (A/h)k\Delta\pi \quad (2)$$

where $k = L_p\,\sigma$. Therefore, k can be taken as the effective permeability of the membrane. (Reflection coefficients for membranes used in osmotic systems are generally quite close to 1.)

A cross-sectional diagram of a generic osmotic pump illustrates the semipermeable membrane and water influx into the pump (Fig. 3) (28). Water permeates through the membrane and enters compartment V_s, causing it to expand; this expansion compresses compartment V_d, pushing drug out through the orifice. In equation 2, dV/dt represents the volume rate of change of the compartment indicated by V_s. If the compartment V_d is filled with a drug solution or suspension at concentration c and if the movable partition readily transmits displacement from compartment V_s to compartment V_d, the rate of drug delivery (dm/dt) from the generic osmotic pump is given by the following equation:

$$dm/dt = (dV/dt)c \quad (3)$$

Substituting in equation 2 for dV/dt, we get the following:

$$dm/dt = (A/h)k\Delta\pi c \quad (4)$$

Depending on the design of the system, A, h, k, $\Delta\pi$, and c may vary with time:

$$dm/dt = [A(t)/h(t)]k(t)\Delta\pi(t)c(t) \quad (5)$$

For some applications, equation 5 can be written in terms of the degree of hydration of the system (H):

$$dm/dt = (A_H/h)k\Delta\pi_H c \quad (6)$$

Consideration of equations 4 through 6 reveals that a variety of delivery rate profiles—increasing over time, decreasing over time, zero order, or some combination of these—are possible depending on the specific design of the osmotic system.

Table 1. Osmotic Pressures of Saturated Aqueous Solutions of Selected Pharmaceutical Solutes

SYSTEM DESIGN CONSIDERATIONS

Osmotic drug delivery technology is based primarily on semipermeable membranes—membranes that are permeable to water but impermeable to ionic compounds and higher-molecular-weight compounds. For example, cellulosic ester membranes are permeable to water but reject sodium chloride. The water content of these membranes varies linearly with acetyl content (Fig. 4), and the hydraulic permeability varies exponentially with acetyl content (Fig. 5) (29). Typical membrane permeabilities range from 10^{-7} to 10^{-6} g/cm/s. Permeabilities can also be altered by incorporating additives into the membrane during processing (30).

For most pharmaceutical applications, the osmotic agent of choice is sodium chloride. Usually the system design provides for sufficient sodium chloride to maintain a saturated solution throughout the delivery period. In some applications, gellants are mixed with the osmotic agent; the resulting osmotic interactions can be complex and difficult to predict from theory.

CURRENT OSMOTIC PUMP APPLICATIONS

The following articles discuss four representative osmotic technologies: the ALZET® osmotic pump, an implant used in preclinical and basic research; the VITS veterinary im-

ALZET® osmotic pumps are miniature, implantable research tools that deliver drug formulations at controlled rates in laboratory animals. Designed for preclinical and basic research, the ALZET® pump offers researchers enhanced control over drug levels in plasma and tissues. The capsule-shaped pumps (ranging from 1.5 to 5.1 cm in length and 0.6 to 1.4 cm in diameter) consist of a cylindrical, elastic reservoir for the drug solution surrounded by an osmotic layer, which is encased in a rigid, semipermeable membrane. Because of the osmotic gradient, water diffuses into the pump through the membrane and swells the osmotic layer, which collapses the reservoir and pushes the drug solution out of the pump at a controlled rate.

Although ALZET® pumps are most commonly implanted subcutaneously or intraperitoneally for systemic administration, they can be used with a catheter for intracerebral, intravenous, or intraarterial infusion. Specific regions can be targeted, such as the spinal cord, spleen, liver, gastrointestinal tract, and tissue transplantation or wound-healing sites. Table 1 lists the major routes of administration as reported in the literature.

Ten models of ALZET® osmotic pumps offer a range of delivery rates (from 0.25 to 10 μL/h) and durations (from 1 day to 4 weeks) (Fig. 1). The pumping rate is fixed at manufacture, but the dosage of drug delivered can be adjusted by varying the concentration of the drug solution placed in the pump. Multiple pumps can be implanted simultaneously to achieve higher delivery rates. For more prolonged delivery, pumps can be serially implanted.

Over 5,200 publications illustrate the use of osmotic pumps to deliver more than 1,600 compounds in 40 animal species, including rats, mice, cats, cattle, chickens, dogs, fish, frogs, guinea pigs, hamsters, iguanas, monkeys, pigs, sheep, and squirrels.

BACKGROUND

The ALZET® osmotic pump was originally developed by ALZA as an in-house research tool. In the mid-1970s, it became available for investigational use, and in 1977, the first commercial product was introduced. Alternatively, animals were connected to heavy infusion pumps, or homemade devices were implanted that were made from Silastic tubes in which a drug, typically a steroid, was packed. Other common administration schemes included dosing in food or water or repeated injection.

With ALZET® osmotic pumps, the typical peak and trough serum profile often seen with repeated injection dosing is replaced with a constant, continuous flat curve,

Intraarterial	

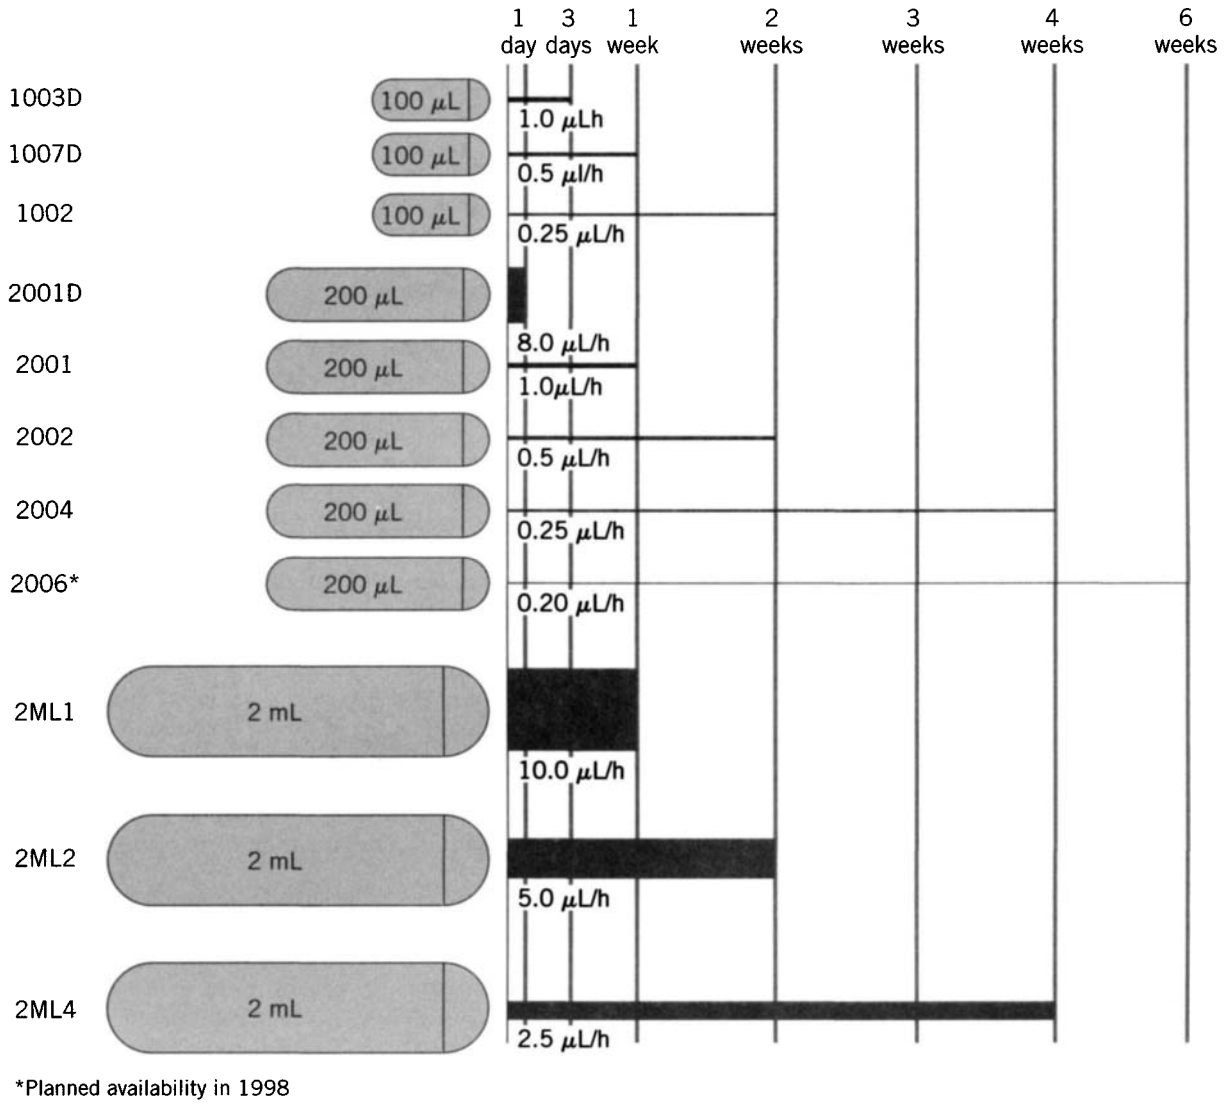

Figure 1. Comparison of delivery rates, durations, and reservoir capacities of ALZET® osmotic pumps.

which can stay in the therapeutic concentration range. This avoids spike concentrations, when adverse effects are more likely, and troughs, when drug effects may dwindle (Fig. 2). ALZET® pump infusion is much more predictable than dosing in food or water. With Silastic tubes, rate control is imprecise because the diffusion rate across the tube wall is not constant and differs by compound (1), whereas with the ALZET® pump, the delivery rate is precise and is not dependent on the physical or chemical properties of the drug. With ALZET® pumps, animal handling and stress are minimized, and repeated nighttime and weekend dosing is not necessary. The ALZET® pump is tamperproof. It does not require any external connections, so animals need no restraint.

SYSTEM DESIGN AND FUNCTION

ALZET® osmotic pumps are composed of three concentric layers: the drug reservoir, the osmotic sleeve, and the rate-controlling, semipermeable membrane (Fig. 3). The drug reservoir is a cylindrical cavity molded from a synthetic elastomer. The reservoir walls are impermeable, blocking any exchange of material between the drug reservoir and the surrounding osmotic sleeve. Outside the reservoir wall is the osmotic sleeve, which contains a concentrated solution of sodium chloride. The difference in osmotic pressure between this solution and the surrounding fluid at the implantation site constitutes the osmotic gradient, which drives the delivery of the drug solution. The outermost layer of the system is a semipermeable membrane made of a cellulose ester blend. An additional component, the flow moderator, is a 21-gauge stainless steel tube that is inserted into the body of the osmotic pump after filling. It minimizes passive diffusion of the drug out of the reservoir, reduces the effect of air bubbles trapped in the drug solution, and prevents accidental spillage. It also provides a convenient attachment point for a catheter.

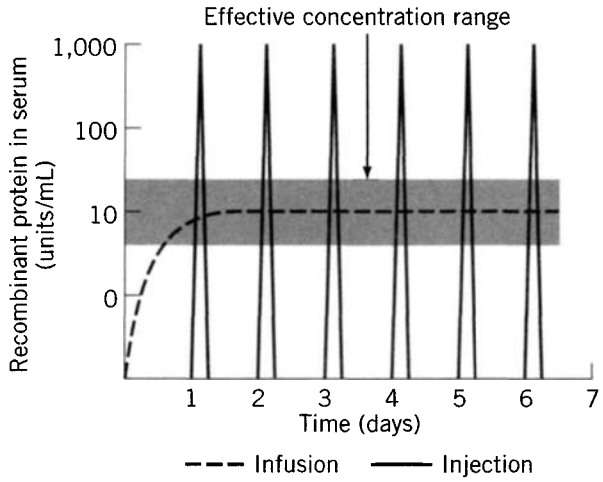

Figure 2. Comparison of serum protein levels over time with infusion versus injection therapy.

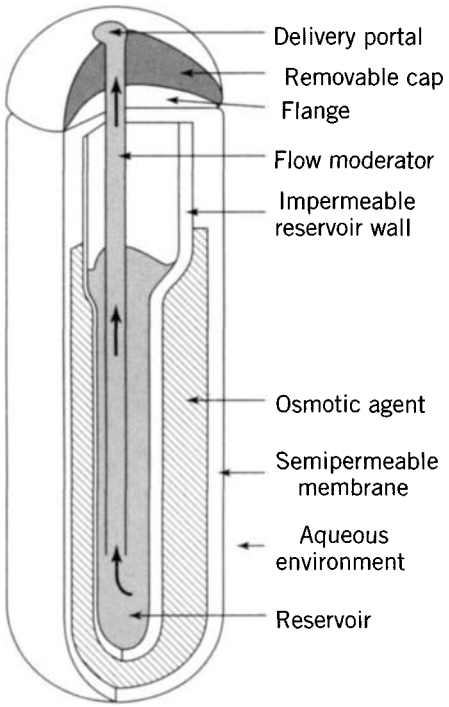

Figure 3. Cross section of a functioning ALZET® osmotic pump.

Before implantation, drug solution is injected into the drug reservoir, and the flow moderator is inserted. Once implanted, the pump imbibes water into the osmotic sleeve along the osmotic gradient. This causes compression of the flexible drug reservoir, which displaces the drug solution through the flow moderator at the same rate that water enters the semipermeable membrane of the pump.

Care is necessary when formulating the drug. The optimal solvent readily dissolves the drug and is compatible with both the interior reservoir of the pump and the tissues or fluids at the site of administration. Using the solvent that best dissolves the drug increases its maximum potential administration rate. ALZET® pump reservoirs are compatible with aqueous solutions, dilute acids and bases, dilute concentrations of dimethyl sulfoxide (DMSO) or ethanol, and up to 100% propylene or poly(ethylene glycol). Table 2 lists the most commonly used solvents.

ALZET® osmotic pumps are not compatible with aliphatic and aromatic hydrocarbons such as heptane, toluene, and natural oils. Standard parenteral fluids such as Ringer's solution (nonlactated form) are ideal for water-soluble drugs given subcutaneously, intraperitoneally, or intravenously. For infusions into the brain, artificial cerebrospinal fluid is recommended. The solution should be at room temperature when the pump is filled and should not generate gases, which would make the pumping rate unpredictable. Solutions with precipitated solute particles should be filtered before use. Homogeneous, viscous solutions of less than 100,000 cP can be administered. Suspensions can be delivered if they do not precipitate and if they remain homogeneous throughout the infusion period. Solvents can be tested for compatibility with the ALZET® pump using a test kit available from ALZA. Tissue compatibility at the implantation site may be an issue with nonaqueous solvents or aqueous solutions that are strongly alkaline or acidic. In addition, care is necessary during preparation and handling of the drug solution to ensure its sterility and isotonicity; microbial contamination can result in local fibrosis and inflammation around the pump and in degradation of some agents, especially peptides.

When filled at room temperature, most ALZET® pumps can reach steady-state delivery in 4 to 6 h (Fig. 4). For immediate in vivo pumping, the prefilled pumps can be placed in sterile saline at 37°C for at least 4 to 6 h (preferably overnight) before implantation. This procedure is mandatory when the pump is to be used with a catheter, when viscous solutions are being delivered, or when the dose of the drug may have acute toxic effects.

After the initial start-up period, the pump operates at a constant rate until 95% of its contents has been delivered; then the pumping rate falls rapidly to zero. The coefficient of variation for the pumping rate of an individual

pump and among a group of ALZET® pumps is less than 10% over the pumping duration. At the end of the infusion period specified for each pump model, the pump becomes an inert object for a period roughly equivalent to half the length of its pumping duration. Then, because of continued osmotic attraction of water into the pump, it may swell and leak a concentrated salt solution, which can cause local tissue irritation. Thus explantation is suggested before this point (1.5 times the system's lifetime).

As expressed in the standard osmotic equation (equation 4 from the PUMPS/OSMOTIC—INTRODUCTION), the delivery rate of an ALZET® pump is determined by the rate at which water enters the osmotic sleeve, which in turn depends primarily on the permeability and dimensions of the semipermeable membrane. The rate is also affected by the osmotic pressure difference across the membrane and the temperature, which become considerations when working with nonmammalian species. The osmotic driving agent is designed to maintain a constant osmotic gradient during the lifetime of the pump. Note that the delivery rate of the pump is independent of the physical and chemical properties of the drug formulation dispensed. Thus, agents of various molecular configurations, including ionized drugs and macromolecules, can be dispensed continuously in a variety of vehicles at a constant rate. Continuous, zero-order release allows the effects of drugs to develop fully and reproducibly, which is particularly useful for compounds with short half-lives, such as recombinant proteins or peptides.

ALZET® pump models are available with fixed delivery rates between 0.25 and 10 μL/h and delivery durations between 1 day and 4 weeks. The exact pumping rate and reservoir volume are measured in 0.9% saline at 37°C (±0.5°C) for each lot of ALZET® osmotic pumps, and this information is provided with the product. This in vitro pumping rate is expected to be within 5% of the pumping rate in homeothermic animals for which 0.9% saline is isotonic. Figure 5 illustrates that the release rate profiles for ALZET® osmotic pumps tested in vivo were within 5% of the analogous systems tested in vitro.

The average duration of pumping can be estimated by dividing 95% of the average reservoir fill volume (μL) by the average pumping rate (μL/h). A 5% residual cannot be displaced from the pump. Although the volume delivery rate of the pump is fixed, different dosages of drug can be achieved by varying the concentration of the drug solution using the following formula:

$$k_0 = Q(C_d)$$

where k_0 is the mass delivery rate (μg/h), Q is the pumping rate (μL/h), and C_d is the concentration of drug solution (μg/μL). Temperature and osmolality affect the rate at which water crosses the semipermeable membrane; thus, they affect the pumping rate. For heterothermic animals or for animals whose body fluids are hypertonic relative to mammals, the following equations can be used to predict the pumping rate:

For models with 100- and 200-μL reservoirs:

$$Q_T = Q_0(0.135e^{(0.054T)} - 0.004\pi + 0.03)$$

For models with 2-mL reservoirs:

$$Q_T = Q_0(0.141e^{(0.051T)} - 0.007\pi + 0.12)$$

where Q_T is the pumping rate at temperature T (μL/h), Q_0 is the specified pumping rate at 37°C (μL/h), T is the temperature (°C), and π is the osmolality of the solution outside the pump (atm). These equations are useful in the range of π = 0–25 atm and T = 4°–42°C, and they are predictive within ±10%. At normal mammalian osmolality of 310 mOsm/L, the osmotic pressure is 7.5 atm. ALZET® pumps have been used at body temperatures up to 42°C (2,3).

Frequently, researchers verify the operation of ALZET® osmotic pumps in their experimental application by monitoring the blood or plasma levels of the infused drug. They can detect when levels reach steady state and whether variables unrelated to pump functionality (e.g., clearance) influence experimental results. When the pump is explanted, the actual pumping rate can be estimated by assaying for the remaining drug in the reservoir. This is done by aspirating the solution from the reservoir using a syringe and a filling tube (provided with each box of pumps) and dividing the calculated volume of drug delivered by the

elapsed time to give the average pumping rate. The weight of an explanted pump cannot be used to determine the quantity of drug delivered because the pump imbibes water during operation.

The component materials of the ALZET® osmotic pump are highly compatible with tissue. When assembled units have been implanted in laboratory animals for the functional lifetime of the system, examination of the implantation site has shown minimal adverse tissue reaction.

ALZET® osmotic pumps are used most extensively in rats and mice. Animals that weigh at least 10 g tolerate subcutaneous implantation of the 100-μL-volume pumps. These pumps can be implanted intraperitoneally in animals weighing at least 20 to 25 g. Animals that weigh at least 20 to 25 g tolerate subcutaneous implantation of the 200-μL-volume pumps without deviation from their normal weight values. However, the same pumps are too large for intraperitoneal implantation in mice. Local tissue damage typically is not seen with subcutaneous, intraperitoneal, intravenous, or intraarterial administration and generally is not seen with local tissue microperfusion. For example, ALZET® osmotic pumps caused no noteworthy hydraulic damage or edema when used to perfuse the renal artery in rats at flow rates of 0.50 to 1.0 μL/h (4).

ALZET® osmotic pumps can be used for systemic or localized delivery. By use of a catheter, a drug can be targeted to discrete locations distant from the pump's implantation site, thereby maximizing local effects of the drug while limiting adverse systemic effects. For example, Ruers and colleagues (5) found that intrarenal infusion of prednisolone via the suprarenal or testicular artery prolonged graft survival time to a median of 26 days. In comparison, intraperitoneal injection, intravenous infusion, and intraperitoneal infusion sustained grafts for only 7, 8.5, and 9 days, respectively.

Direct access to the central nervous system (CNS) via a cannula implanted in the cranium is useful when a drug has effects in the CNS but does not cross the blood–brain barrier appreciably (6). Significant doses can be administered directly to the brain, eliminating the uncertainty of systemic pharmacokinetic variables. Drug can be infused into the cerebrospinal fluid via the cerebral ventricles for delivery to many brain regions or directly microperfused into specific regions of solid brain tissue to target discrete structures.

Although ALZET® pumps are designed to provide zero-order delivery, they can be adapted for pulsatile administration. This is accomplished by thermoforming a coil of polyethylene tubing around the pump (7) and filling the pump's reservoir with an appropriate solvent, such as Ringer's or saline solution. The drug solution is placed in the coiled external tubing in segments alternated with vehicle; each segment is separated with an immiscible barrier such as a small air bubble, mineral oil, or silicone oil. Once implanted, the constant flow of solvent from the pump into one end of the tubing forces the segments of the coil to flow out in sequence. For example, Lynch and colleagues (8) experimentally induced rhythms in plasma melatonin levels in pinealectomized rats using a 6-h-on, 18-h-off periodicity with an ALZET® pump. Additionally, Cronan and colleagues (9) infused nicotine with an 8-h-on, 16-h-off periodicity in rats to mimic drug use in humans.

Detailed descriptions of various techniques for surgically implanting ALZET® osmotic pumps are available from ALZA Corporation (6,10).

APPLICATIONS

Thousands of publications document the use of ALZET® osmotic pumps in over 40 species with more than 1,600 compounds (see Table 3). Key disciplines include neuroscience, cancer and immunology, toxicology, biotechnology, endocrinology, pharmacology, physiology, and cardiology. For a complete bibliography, categorized by drug, route of administration, research discipline, and special interests, see the ALZET website at *http://www.alza.com/alzet*. A bibliography of review articles at the end of this article also provides a good perspective on the literature.

The ALZET® pump has enabled neuroscientists to manipulate the central and peripheral nervous systems of unrestrained animals, permitting simultaneous study of behavioral, motor, and sensory functions. Researchers have administered drugs directly to discrete brain structures, the ventricles, and the spinal cord to bypass the blood–brain barrier. Delivery to peripheral nerves has also been conducted. Using these techniques, ALZET® pumps have contributed to the study of learning and behavior, nerve regeneration, neuronal plasticity, neurodegenerative diseases, drug dependence and tolerance, and neural regulation.

In immunology/cancer research, the ALZET® pump has been used to administer cytokines, target chemotherapeutic agents to a specific organ, and evaluate dosing regimens. Toxicologists have used ALZET® pumps to achieve chronic drug exposure and to conduct teratology research.

Table 3. Classes of Drugs Delivered by ALZET® Osmotic Pumps (As Reported in the Literature)

Anesthetics	Heavy metals
Antibacterials	Hormones
Antibiotics	Immunologic agents
Antibodies	Indicator substances
Anticancer agents	Macromolecules
Anticoagulants	Metabolites
Antiepileptics	Nerve growth factors
Antihypertensives	Neurotransmitters and neuromodulators
Antiparkinson agents	Oligonucleotides

Cholinergics	Renin–angiotensin system components and inhibitors
Cytokines	Steroids
Drugs of abuse	Thyroid and thyroid-related hormones
Enzymes	Toxic substances
Gastrointestinal motility modulators	Vitamins and minerals
Growth factors	
Growth hormones	

ALZET® pumps have proved useful in biotechnology for characterizing novel proteins and peptides, such as growth factors, while also facilitating exciting new research in which antisense oligonucleotides have selectively blocked expression of a specific protein product. In endocrinology, applications have included research on diabetes, growth and development, and hormone replacement. Targeted delivery using ALZET® pumps has proved helpful in pharmacokinetic studies, where it has allowed the characterization of local effects without the obfuscating effects of rapid drug metabolism and clearance. The pump has been used in pharmacologic studies investigating receptor modulation and animal models of human disease. In cardiology, the ALZET® pump has been used to evaluate novel antihypertensive agents and to stimulate angiogenesis in the arterial wall via adventitial delivery of growth factors.

Although ALZET® pumps are frequently used in preclinical research, they are also used in basic research or in other specialized studies. Some notable examples include studies in space, work with endangered species, and oceanographic measurements. ALZET® pumps have been used to dispense fresh medium in a prototype study of a cell cultivation instrument for Spacelab (11), to test the delivery of recombinant human growth hormone (rhGH) in rats on board the space shuttle *Discovery* (11), and to test the effects of rhGH on the atrophic response of the soleus muscle in space (12).

Endangered species have benefited from ALZET® pumps. The green iguana (*Iguana iguana*), native to Central and South America and once abundant in the rain forest, is now threatened throughout most of its natural habitat. Researchers at the Center for Reproduction of Endangered Species (CRES) have bred iguanas in captivity using infused gonadotrophin-releasing hormone (GnRH) to improve the survival potential of this species (13). CRES has also used the ALZET® pump to infuse GnRH in a previously infertile female cheetah at the San Diego Zoo, resulting in the birth of twins. Infertile for nearly 2 years, the cheetah received 10-min pulses of GnRH every 3 h, a regimen calculated to induce ovulation (14).

ALZET® osmotic pumps have also been adapted by oceanographers at the Monterey Bay Aquarium Research Institute and Moss Landing Marine Laboratories to create a self-contained, continuous flow analyzer that measures nitrate concentrations in seawater during long-term, deep-sea deployment (15).

CONCLUSIONS

For more than 20 years, the ALZET® osmotic pump has provided researchers from many scientific disciplines with continuous, zero-order delivery of drugs for basic and preclinical research. Currently these pumps can deliver drugs at volumes of 0.25–10 μL/h, systematically or targeted to specific tissues, for periods up to 1 month. Further work is planned to add additional volumes and durations and to offer a wider range of add-on delivery devices.

The Veterinary Implantable Therapeutic System (VITS) is a small, implantable drug delivery system designed to provide controlled drug delivery in production animals and companion animals for periods of 1 day to 1 year. Typical VITS release is constant and zero order, but declining or pulsatile release profiles are possible by design. A wide spectrum of compounds ranging from small molecules such as steroids to larger, water-labile molecules such as peptides and proteins can be delivered. Because of the VITS pump design and its materials, VITS formulations are completely isolated from potentially damaging in vivo fluids. Because of the small pump size, dosages from μg/day to mg/day are possible, making VITS ideal for the delivery of potent molecules. VITS can be implanted subcutaneously or intraperitoneally. When used in food-production animals, the VITS is removed during slaughter. Possible candidates for VITS delivery include somatotropins, parasiticides, hormones such as estrus suppressants and growth promotion agents, β-agonists, nutritional supplements, and antibiotics.

BACKGROUND

Implants have been used commercially in animals for many years, typically for growth enhancement using steroids. For example, since the 1950s compressed tablets containing estrogenic anabolic steroids have been inserted subcutaneously in and at the base of the ears in cattle,

The Veterinary Implantable Therapeutic System (VITS) is a small, implantable drug delivery system designed to provide controlled drug delivery in production animals and companion animals for periods of 1 day to 1 year. Typical VITS release is constant and zero order, but declining or pulsatile release profiles are possible by design. A wide spectrum of compounds ranging from small molecules such as steroids to larger, water-labile molecules such as peptides and proteins can be delivered. Because of the VITS pump design and its materials, VITS formulations are completely isolated from potentially damaging in vivo fluids. Because of the small pump size, dosages from μg/day to mg/day are possible, making VITS ideal for the delivery of potent molecules. VITS can be implanted subcutaneously or intraperitoneally. When used in food-production animals, the VITS is removed during slaughter. Possible candidates for VITS delivery include somatotropins, parasiticides, hormones such as estrus suppressants and growth promotion agents, β-agonists, nutritional supplements, and antibiotics.

BACKGROUND

Implants have been used commercially in animals for many years, typically for growth enhancement using steroids. For example, since the 1950s compressed tablets containing estrogenic anabolic steroids have been inserted subcutaneously in and at the base of the ears in cattle,

releasing drug through slow erosion or matrix diffusion. These growth enhancers are given for 2- to 3-month periods to improve the rate of weight gain and feed conversion, and their economic benefits have been well documented. Commercial examples of these growth promoters include Compudose® (estradiol-17β), Synovex® (progesterone and others), and Ralgro® (Zeranol) (1). These systems are not explanted. Similar implants have also been evaluated for delivery of parasiticides (2,3).

Although these systems have been suitable for the delivery of steroids and other water-stable agents, adaptation has proved necessary for newer biotechnology products. Larger peptides and proteins are extremely water labile, degrading rapidly in an aqueous environment. They are also very potent agents, given in very small doses. To satisfy these requirements, VITS was developed as a small system in which the active drug is kept isolated from the body's aqueous environment until release.

The VITS implant is much smaller than the Ruminal Therapeutic System (RUTS) ruminal bolus and can be implanted in any ruminant, nonruminant, companion, or production animal. In the VITS implant, drug is isolated from any contact with body fluids in the in vivo environment. Unlike the RUTS ruminal bolus system, in which the semipermeable membrane cup almost fully surrounds the entire system, the VITS absorbs water only at the membrane cup end; hence, the drug formulation is completely isolated from water inside the impermeable drug reservoir.

Compared with repeat-injection dosing, VITS reduces animal stress resulting from restraint, handling, and dosing. With its zero-order delivery, VITS minimizes the adverse effects often associated with the elevated drug serum levels seen shortly after injection dosing. VITS is more convenient to administer than repeat-injection dosing; it eliminates the need for procedures that are often costly, difficult, and labor intensive. With VITS, the amount of drug administered is known, in contrast to the administration of drug in drinking water or food. VITS is efficient in administering therapeutic dosages of potent, expensive compounds that otherwise would have to be given frequently and in large doses because of biological clearance processes. Controlled parenteral administration of therapeutic agents by VITS increases the range of usable veterinary compounds, because many potentially useful products, such as peptides and proteins, cannot be administered by feed or bolus owing to their water lability. Controlled-release dosage forms such as VITS can also reduce human exposure to those veterinary compounds that are unsafe for humans to handle.

SYSTEM DESIGN AND FUNCTION

As shown in Figure 1, the VITS system is a narrow cylinder that consists of an impermeable drug reservoir containing the drug formulation and a rate-controlling semipermeable membrane cup that contains the osmotic engine and a piston. The membrane cup subassembly is tightly coupled with the filled drug reservoir. At the time of implantation, the break-off tab is removed so that drug can be delivered. (An alternative design uses a microcrystalline wax plug, which prevents any backflow of body fluids into the system during start-up.) VITS systems can be designed at various sizes ranging from 2 to 10 mm in diameter, depending on the dosage requirements and the size of the animal.

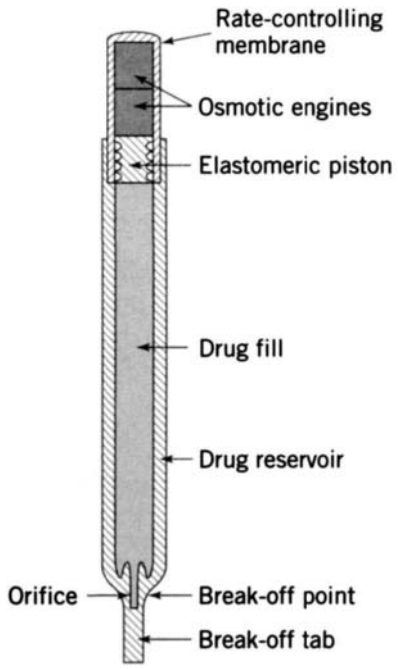

Figure 1. Cross section of VITS.

After implantation, water from the animal's tissues moves across the membrane wall at a constant rate governed by the thickness and composition of the wall. The osmotic material swells, which pushes the piston forward into the drug reservoir. This forces drug formulation through the orifice into the surrounding tissues. The rate of drug delivery is the same as the rate of water influx into the system, based on the basic osmotic equation (equation 4) described in PUMPS/OSMOTIC—INTRODUCTION. System design is described in detail in the patent literature (4–20).

VITS has a predictable start-up profile and a rapid shutdown profile that minimizes drug residues in tissue. At shutdown time, the piston reaches the end of the drug fill area, guaranteeing a complete cutoff of drug delivery at that point.

The dosage, duration, and delivery profile of a VITS system can be adjusted by design within the ranges of 1-week to 1-year duration and μg/day to mg/day dosage. For example, by altering the permeability of the membrane, the resulting dosage and duration of the system can be changed. For a fixed system size and drug reservoir volume, a more permeable membrane results in an increased delivery rate with a shorter delivery lifetime. The inverse holds true as well: A less permeable membrane results in a decreased delivery rate over a longer delivery lifetime. Decreasing the concentration of sodium chloride in the osmotic engine produces a declining release profile (as the osmotic engine solution falls below saturation, the release slows), as shown in Figure 2 (porcine somatotropin [pST]

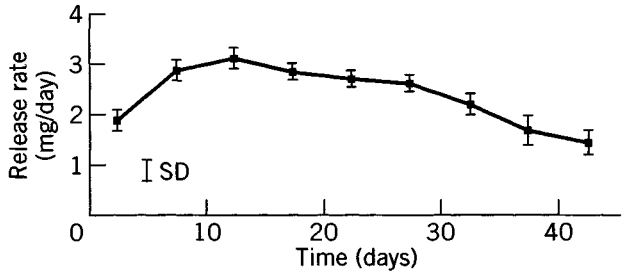

Figure 2. In vitro release profile of pST from a VITS system.

at 37°C). Pulsatile delivery can also be achieved through system design alteration.

In vivo data in finishing hogs show a good dose–response relationship, as demonstrated in Figure 3. For more than 40 days, pST plasma concentrations were maintained for the three dosages (1.2, 3.6, and 4.8 mg/day).

APPLICATIONS

One extensively studied application of VITS technology is the administration of bovine somatotropin (bST) to cattle and pST to pigs. For example, Baile and colleagues showed that administration of a 42-day VITS bST implant (17 mg/day) increased the growth rate by 16% for subcutaneous implantation and 25% for intraperitoneal implantation. Increases in growth rate were sustained with an 84-day VITS intraperitoneal implant when compared with two successive 42-day implants, suggesting that the formulation retains biological efficacy even when the delivery duration is extended to commercially significant time periods (21).

Another study by Kasser and colleagues compared a control group with a group that received bST from two consecutive 42-day intraperitoneal VITS implants at dosages of 6, 12, and 15 mg/day. Body weight and carcass weight were significantly ($P < .05$) higher in treated animals than in controls. Feed conversion was significantly ($P < .05$) better in treated animals than in controls (22).

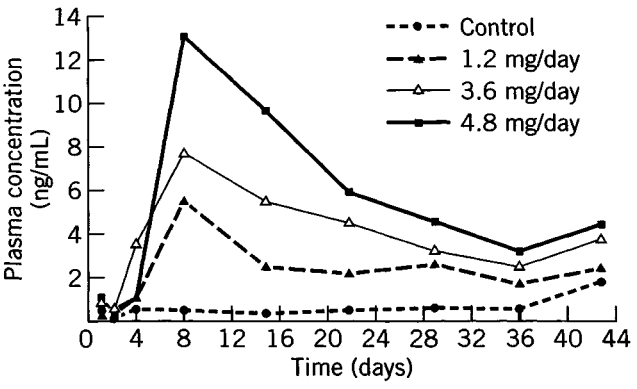

Figure 3. Comparison of plasma concentrations of VITS agent (pST) as a function of its dosage.

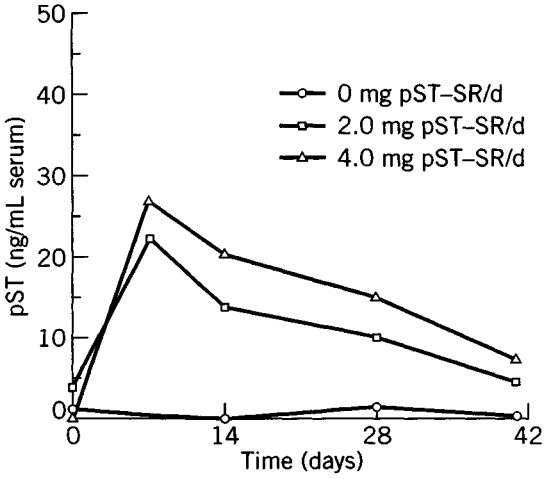

Figure 4. Comparison of serum concentrations of pST in lean gilts as a function of dosage. *Source:* Adapted from Ref. 24.

Armstrong and colleagues found that multiparous beef cows receiving an 84-day subcutaneous VITS bST implant had significantly ($P < .05$) higher milk yields and calf weaning weights than did cows that received vehicle only (23).

Subcutaneous VITS implants containing pST were compared with controls in a 6-week study in genetically lean and obese barrows and gilts (24). Administration of pST by VITS implant significantly increased efficiency of gain and lean deposition while decreasing fat deposition. Serum pST levels, measured each week, remained significantly higher in treated pigs than in controls throughout the study (Fig. 4) (24).

CONCLUSIONS

VITS is an osmotic implant specifically tailored for subcutaneous or intraperitoneal administration of small amounts of potent substances to animals. The drug reservoir completely isolates drug formulations from the surrounding environment, thus protecting proteins and other water-labile compounds for long periods. VITS is typically designed for zero-order release of agents, but other delivery profiles can be obtained through system design alternatives. VITS has been studied extensively in the release of bovine and porcine somatotropins. Demonstration of its feasibility for zero-order delivery of small amounts of potent molecules in animals has led to its adaptation for use in humans—the DUROS™ technology.

Bibliography

The DUROS™ implant is a miniature, osmotically driven drug delivery system designed for the long-term, parenteral, zero-order delivery of potent therapeutic agents to humans. The DUROS™ implant consists of an impermeable titanium alloy cylinder capped on one end by a rate-limiting, semipermeable membrane and on the other end by a plug with an orifice for drug delivery. The interior of the DUROS™ implant contains a polymeric piston that separates the osmotic engine from the drug reservoir (Fig. 1). These single-use DUROS™ implants are sterile, nonpyrogenic, and nonbiodegradable.

The DUROS™ implant functions according to the same osmotic principles as described for other, similar pumps in

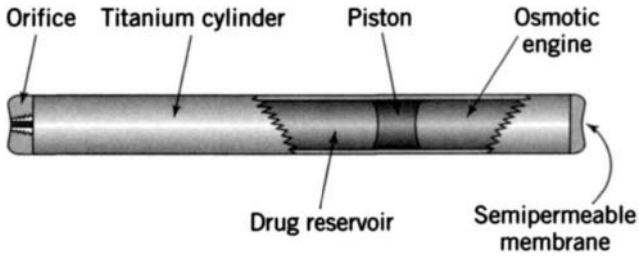

Figure 1. Cross section of a DUROS™ Implant.

this encyclopedia. The osmotic engine, a concentrated salt mixture, establishes a very steep osmotic gradient between the interior of the DUROS™ implant and the surrounding interstitial fluid. In response to this osmotic gradient, water flows into the DUROS™ implant at a rate governed by the permeation characteristics of the semipermeable membrane. As water flows into the DUROS™ implant, drug is delivered from the reservoir via the orifice at the same rate and volume.

A unique feature of the DUROS™ implant, compared with other implantable pumps, is its small size (4 mm × 45 mm), allowing implantation virtually anywhere in the body; the resultant drug reservoir volume is less than 200 μL. (DUROS^{SM} implants with drug reservoir volumes of 50 to 500 μL have been designed.) For systemic administration, the DUROS™ system is implanted under the skin in an outpatient setting with local anesthesia. Explantation at the end of the delivery period is accomplished by a similar, simple surgical procedure. In addition to subcutaneous administration, intravenous, intrathecal, intratumoral, and other forms of targeted drug delivery can be accomplished with the attachment of a catheter.

BACKGROUND

As of 1997, more than 40 biotechnology drug products have been approved, and more than 270 new biotechnology drugs are currently in human clinical trials. Most of these agents are proteins produced by recombinant technology (1). Because of rapid degradation within the stomach and poor absorption from the gastrointestinal tract, proteins and other complex biomolecules cannot be given orally. Drug therapy must therefore rely on parenteral administration via acute injection or preferably through a continuous delivery system. In response to this growing need from the biotechnology sector, researchers designed the DUROS™ implant for the delivery of proteins and peptides.

More than 15 years of research, development, and widespread industry use of osmotic pump technology in animals (the ALZET® osmotic pump, the Push-Melt™ ruminal bolus, and the VITS veterinary implant technology) has demonstrated the potential clinical utility of an implantable osmotic pump suitable for use in humans. In particular, the ALZET® pump has been used in more than 5,200 studies to deliver proteins in nonclinical studies (see PUMPS/OSMOTIC—ALZET® SYSTEM). The widespread use of ALZET® pumps further highlights the need for a human implantable osmotic pump.

The use of a continuous drug delivery system such as the DUROS™ implant offers several pharmacokinetic, pharmacoeconomic, and quality-of-life benefits over traditional bolus dosing methods. Unlike dosing by injection, where blood levels (and clinical efficacy) of the drug vary widely with an initial peak and subsequent trough pattern, the DUROS™ implant delivers drug at a precisely controlled, constant rate within the therapeutic range for long periods. In some therapeutic indications or when using drugs with short half-lives, less drug may be required to achieve the desired effect than with conventional injections, providing substantial dose savings. The DUROS™ implant therapy may offer other pharmacoeconomic advantages in today's health care environment because it requires no maintenance after implantation. The type of "silent therapy" provided by the DUROS™ implant is not only convenient to the patient but also ensures compliance.

SYSTEM DESIGN

The most important design considerations for the DUROS™ implant were biocompatibility; delivery of stable, active drug molecules; and extended zero-order delivery. All tissue-contacting materials were chosen for their biocompatibility and history of use in human implants. Likewise, the components in contact with the drug formulation (e.g. reservoir, orifice, and piston) had to be compatible with a variety of solvents and excipients used to solubilize or suspend the drug. Additionally, the implant components could not adversely affect the drug stability. Design issues based on these considerations will now be discussed for each of the components of the DUROS™ implant.

The rugged titanium reservoir design possesses sufficient mechanical strength to maintain the system configuration despite possible mechanical stresses, such as impact at the implant site. Additionally, the titanium reservoir is impermeable to water, ensuring drug stability and continual zero-order release.

The DUROS™ implant has a polymeric, semipermeable membrane that is permeable to water but essentially impermeable to the osmotic solutes in the osmotic engine. The membrane may include cellulose esters, polyamides, and polyurethanes, depending on the desired characteristics of the membrane, such as system duration. Testing of polyurethane membranes has shown that the membrane material does not change permeability following implantation. Membrane function is not influenced by extracellular fluid, and the membrane remains chemically stable under physiological conditions.

The osmotic engine of the DUROS™ implant can utilize any number of osmotically active solutes but typically contains a combination of sodium chloride (more than 50% by weight) and other excipients, including gelling polymers such as poly(vinylpyrrolidone) (PVP) or sodium carboxymethyl cellulose. The osmotic engine is produced as one or more tablets.

The elastomeric piston seals the drug formulation from the osmotic engine, thus preventing leakage of osmotic solutes into the drug formulation, which could cause significant loss of drug formulation stability and deviations from zero-order delivery. In addition, the piston is compatible with the osmotic engine and moves with relatively little resistance.

The orifice was designed with a small inner diameter and a suitable length to minimize diffusion of drug from the system. Otherwise, diffusion could represent a significant and uncontrolled contribution to the overall rate of delivery at low pumping rates. The drug formulation is not exposed to the surrounding tissue environment until it is released through the orifice. These features also help to prevent back-diffusion of extracellular components when

the system is implanted. Such design features are particularly important for the delivery of biotechnology drugs because proteins, peptides, and other macromolecules are easily rendered inactive by biological processes.

The DUROS™ implant packaging maintains sterility and provides a moisture barrier to prevent premature system start-up. The assembled DUROS™ implant is sterile and nonpyrogenic. Because most peptides and proteins will not withstand conventional sterilization methods (e.g., irradiation or autoclaving), a sterile DUROS™ implant can be produced by irradiating a partially assembled system and performing the remaining filling and assembly steps under aseptic conditions.

SYSTEM PERFORMANCE

When the system is implanted, water is osmotically drawn from the body tissue surrounding the implant (osmotic pressure, π = ~7 atm) through the membrane into the sodium chloride–containing osmotic engine (π = 356 atm). The release rate of the DUROS™ implant is given by equation 4 in PUMPS/OSMOTIC—INTRODUCTION, where A is the membrane cross-sectional area for water transport, h is the membrane thickness, k is the effective permeability of the membrane, and $\Delta\pi$ is the osmotic pressure difference across the membrane.

$$dm/dt = (A/h)k\Delta\pi c \quad (1)$$

If A, h, k, and $\Delta\pi$ are held constant, then a constant rate of drug delivery will result. In the DUROS™ implant, A and h are constant by design and manufacture, and k has been shown to remain constant over time, both in vitro and in vivo. The osmotic engine is manufactured with excess sodium chloride to maintain saturation, ensuring that $\Delta\pi$ will remain constant for the intended duration of drug delivery. Hence, a continuous zero-order release profile is expected for the DUROS™ implant.

The release rate and duration of a DUROS™ implant depend on the overall system size, membrane design, osmotic engine design, drug reservoir size, and concentration of the drug in the reservoir. Figure 2 shows the effect of changing the membrane permeability on release rate and duration while keeping the other parameters constant in the 4 mm × 45 mm device. For a particular reservoir size, the higher the release rate, the shorter the duration of drug delivery.

In vitro studies have demonstrated constant zero-order delivery from DUROS™ implants. DUROS™ implants were placed in test tubes containing phosphate-buffered saline (PBS) and held at 37°C. The implants were placed in fresh PBS weekly, and the remaining PBS was assayed for drug content. In one study with a target duration of 3 months, the delivery rate performance of five systems was measured by sampling at approximately weekly intervals. The systems exhibited zero-order delivery at 1.0 μL/day for 100 days, with coefficients of variation averaging 3% for days 7 to 104 (data not shown). In another study, 30 DUROS™ implants maintained a target of 0.38 μL/day release of blue dye solution for 360 days with a coefficient of variation of less than 9% among the implants (Fig. 3). A zero-order release profile was obtained from the data when assaying on a weekly basis by reversed-phase high-performance liquid chromatography (RP-HPLC). Sampling of cumulative implant output by ultraviolet (UV) spectrophotometry with a flow cell at 6-min intervals for 24 h demonstrated a continuous zero-order release rate (Fig. 4).

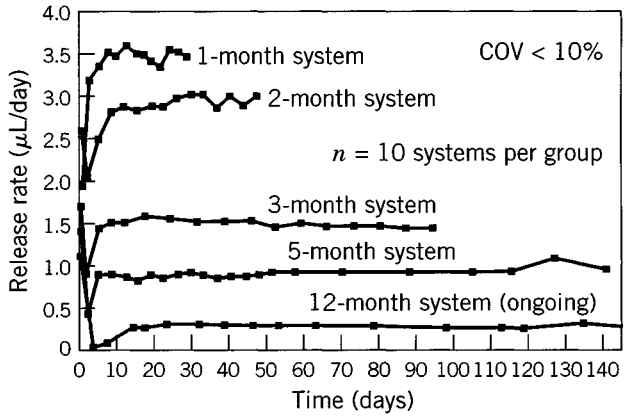

Figure 2. Comparison of release rates in DUROS™ Implants as a function of system duration.

FORMULATION CAPABILITIES

DUROS™ implants with diameters up to 7 mm have been designed, resulting in drug formulation volumes of 50 to 500 mL. The reservoir volume of the 4 mm × 45 mm implant has a total volume of less than 200 μL. Given the limited formulation volume in a single implant, concentrated drug formulations are usually required. Formulation parameters such as saturation solubility and chemical and physical (aggregation) stability are important. For example, in a 150-mL drug reservoir, a 2-month system delivers 2.5 μL/day. Given a 400-mg/mL solution drug formulation, the implant delivers 1.0 mg/day (60 mg/implant). Similarly, a 500-mL drug reservoir (7 mm × 45 mm) lasting 12 months delivers 1.4 mL/day. In this system, a drug formulation at 400 mg/mL delivers 560 mg/day (200 mg/implant).

Important formulation considerations for the DUROS™ implant include stability, solubility, and compatibility. For example, adequate drug stability and potency for a 2-year shelf life plus the implant life are desired. The formulated peptide or protein must be structurally stable and not unfold, gel, or precipitate with loss of activity or production of large particulates capable of clogging the orifice. The formulation must either chemically withstand terminal sterilization or possess sufficient physical stability for sterile filtration, if not aseptically processed. Generation of suspensions in an aseptic environment is often an important factor. The formulation must also be compatible with the pump components in terms of peptide adsorption characteristics and vehicle leachates.

Biotechnology drug moieties can be formulated in aqueous (up to 400 mg/mL) or nonaqueous (up to 500 mg/mL)

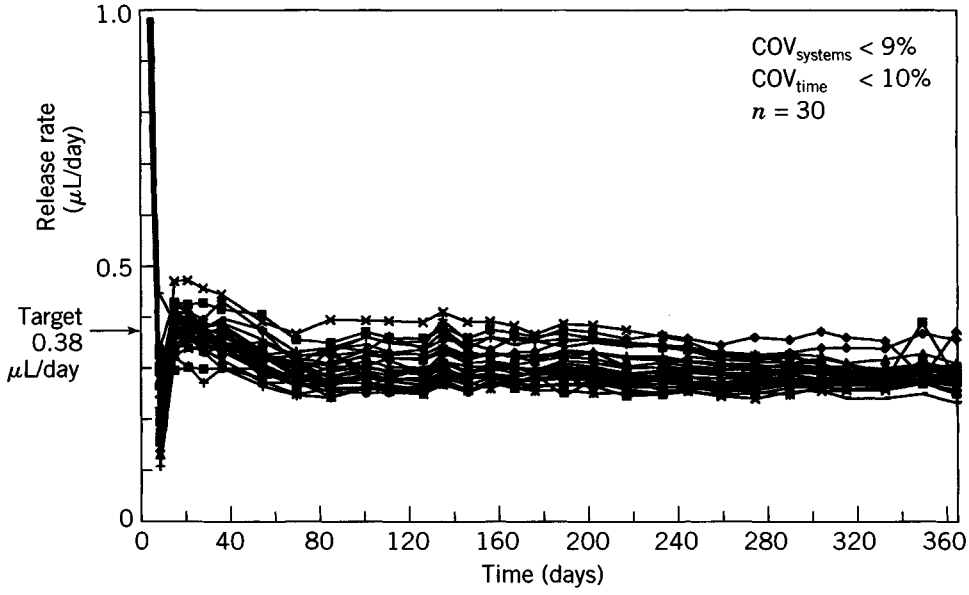

Figure 3. In vitro release rates in the DUROS® Implant as compared with the 0.38-μL/day target.

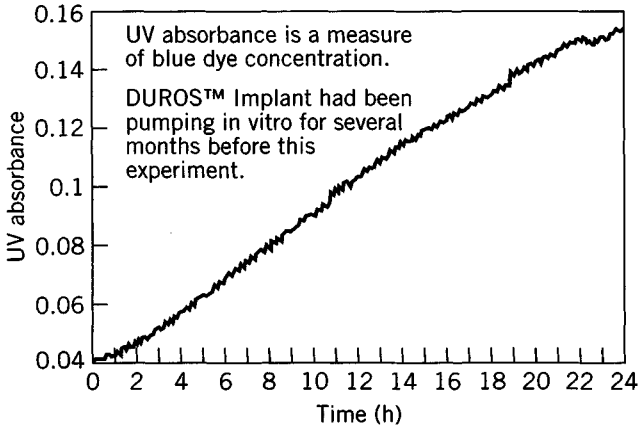

Figure 4. In vitro release rate in the DUROS® Implant, plotted in 6-min intervals.

solutions or in aqueous or nonaqueous suspensions (up to 500 mg/mL), depending on the solubility and stability of the specific molecule. Many times nonaqueous vehicles offer enhanced stability for biomolecules, such as proteins and peptides, by minimizing hydrolytic degradation pathways (2). For drug molecules with solubility or stability limitations, nonaqueous suspensions provide an alternative. For example, stable nonaqueous protein suspensions (e.g., α interferon) in excess of 30% weight in volume (w/v) for 3 to 6 months at 37°C have been reported (3).

DUROS® LEUPROLIDE IMPLANT

The DUROS® Leuprolide Implant is designed to deliver leuprolide continuously at a nominal rate of 125 μg/day over 1 year for the palliative treatment of prostate cancer. It is implanted subcutaneously in the upper arm and explanted after 1 year. The bioactive peptide for the DUROS® Leuprolide Implant is formulated as a stable nonaqueous solution. This implant is designed to provide an alternative to periodic injections of leuprolide, with the goals of long-term patient compliance and improved quality of life.

DISEASE STATE

Because of the dependence of prostate cancer on circulating androgen levels, testicular androgen ablation (i.e., lowering of circulating testosterone levels) has been the standard for primary therapy of advanced prostate cancer for more than 50 years (4). Continuous administration of luteinizing hormone–releasing hormone (LH-RH) agonists, such as leuprolide acetate, results in the decrease of serum testosterone levels to castrate levels. Since the 1980s, LH-RH agonist therapy has been the primary treatment strategy for androgen ablation (5–7). LH-RH therapies are associated with 80% to 90% stabilization of the disease for 10 to 18 months on average, and 2-year survival is approximately 60% (8,9).

Uninterrupted drug administration is essential to the efficacy of LH-RH agonist therapy, so compliance is critical for prostate cancer patients. Unfortunately, compliance is often a problem, where 44% of patients failed to present for one or more monthly Lupron Depot® injections, and 24% of patients were more than 2 weeks late in obtaining a monthly injection in the U.S. Veterans Administration system (10).

FORMULATION STABILITY

Highly concentrated leuprolide solutions have demonstrated good chemical and physical stability when stored in sealed DUROS® implants at 37°C for the functional lifetime of the implant (2,11,12). Excipients used for the early screening of formulations included solution vehicles such

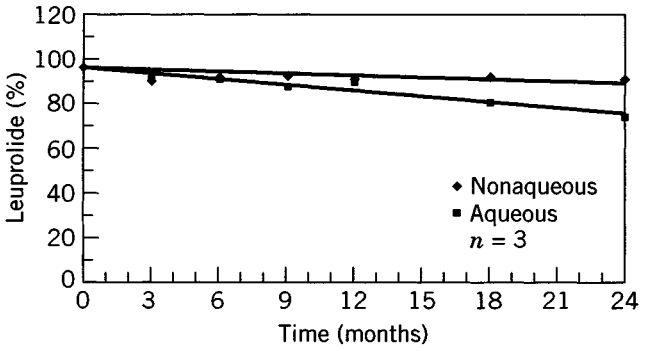

Figure 5. Comparison of the stability of aqueous and nonaqueous formulations in the DUROS® Leuprolide Implant (370 mg/mL at 370°C).

as propylene glycols, poly(ethylene glycols), ethanol, glycofurol, dimethyl sulfoxide, and water. Both aqueous and nonaqueous solution formulations demonstrated 80% to 95% leuprolide remaining after 12 months at 37°C (12). For example, a 370-mg/mL aqueous leuprolide formulation was stable for up to 6 months and then dropped off to slightly below 90% stability, whereas a nonaqueous formulation showed greater than 90% stability for more than 12 months (Fig. 5). The major degradation pathways for the nonaqueous formulation were hydrolysis, racemization, oxidation, and aggregation. Similar degradation pathways were observed for the aqueous formulation. However, in the nonaqueous formulation, the proportion of leuprolide degrading to hydrolytic products decreased while aggregation products increased, resulting in a more stable formulation. In general, no aggregates larger than a trimer were observed. The final formulation used for clinical trials was a 370-mg/mL nonaqueous formulation that provided 92% stability for 2 years at 37°C, which is adequate for a 2-year shelf life (25°C) in addition to a 1-year implant life (37°C).

IN VITRO PERFORMANCE

When in vitro device release rates were measured (n = 6), a zero-order release rate was seen for up to 1 year (Fig. 6). In addition, RP-HPLC analysis revealed greater than 95% in vitro drug stability on average over the test duration.

IN VIVO PERFORMANCE

A 14-month canine study evaluated the DUROS® Leuprolide Implant for serum testosterone concentrations. In the control group, serum testosterone levels fluctuated widely up to 600 ng/dL through the year. Conversely, for every dog that received a DUROS® Leuprolide Implant, testosterone levels were suppressed to castrate levels (below 50 ng/dL) by day 25 and remained completely suppressed (Fig. 7). After 365 days, the first implant was replaced, and blood levels of testosterone remained suppressed to the end of the study (14 months). Histological evaluation of the implantation site did not reveal any unusual changes in the tissue, and neither was any systemic toxicity seen in the study.

Local tissue reactions to the DUROS® Leuprolide Implant were further investigated in rats and Hanford miniature swine. In rats, no unexpected local tissue reactions were observed with the implants over the 38-week study, and in general, tissue reaction scores were equal to or better than those of historical controls receiving control implant material (high-density polyethylene). In miniature swine, no infections or system expulsions occurred over the 12 weeks, and no macroscopic or microscopic evidence of untoward local tissue reactions was seen.

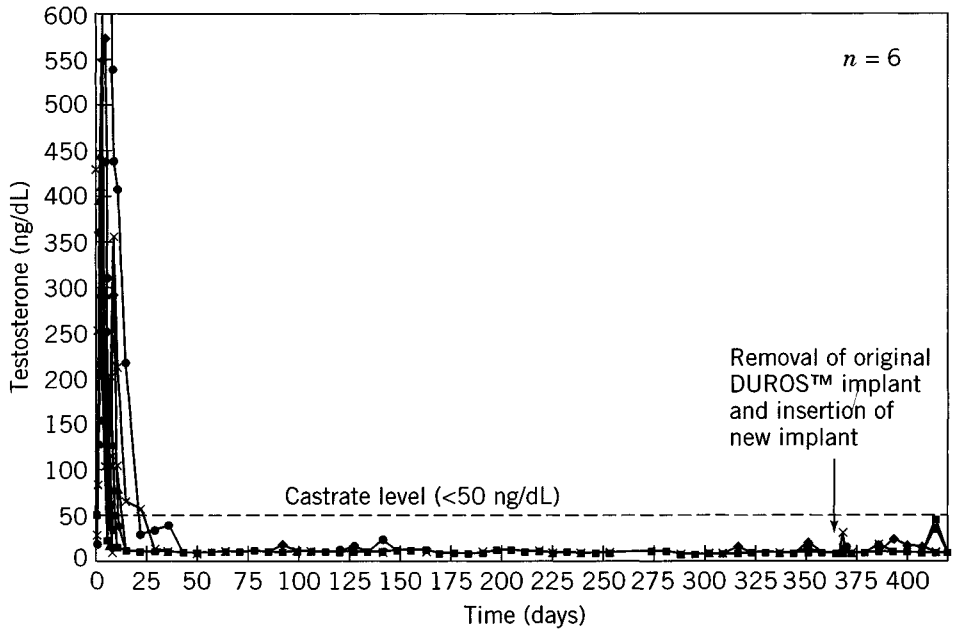

Figure 7. Testosterone concentrations in dogs with the DUROS™ Leuprolide Implant.

IN VIVO–IN VITRO RELEASE RATE AND STABILITY CORRELATION

The in vivo performance of the DUROS™ Leuprolide Implant has been characterized in both dogs and rats, and the results have been compared with the performance of the same batch of implants evaluated in vitro. Cumulative drug delivery was estimated from analysis of residual drug in the reservoir (Table 1). Comparison of in vivo cumulative drug delivery with in vitro cumulative drug delivery shows agreement to within 5%.

Analysis of the residual drug formulation (370 mg/mL) also permitted comparison of in vivo and in vitro stability values using RP-HPLC and SEC (Table 2). Stability was more than 96% for RP-HPLC and SEC measurements, both in vivo and in vitro, at the 6-month timepoint. At the 1-year timepoint, good stability was also observed, both in vitro and in vivo, reflecting the stability of the leuprolide formulation and the design of the orifice in preventing back diffusion of aqueous fluids and extracellular components. Taken together, the close correlation of the in vitro and in vivo release rates and of the in vitro and in vivo stability values for the DUROS™ Leuprolide Implant indicates that these attributes are essentially independent of in vivo conditions and can be predicted from in vitro testing results.

IMPLANTATION AND EXPLANATION

The DUROS™ Leuprolide Implant is implanted subcutaneously in the upper inner aspect of the nondominant arm. The implantation is an outpatient procedure requiring local anesthesia. After normal antiseptic preparation of the site, a local anesthetic is injected along a 5-cm track. A 4- to 5-mm incision is made with a scalpel through the skin at one end of the anesthesized area. The DUROS™ system is inserted through the incision and advanced subcutaneously along the anesthesized track. The incision site is closed with a Steristrip® and a sterile bandage.

Table 1. In Vivo–In Vitro Pumping Rate Comparison (Nonaqueous Formulation)

Species	Time of explant (weeks)	In vivo cumulative delivery (mg leuprolide)	In vitro cumulative delivery (mg leuprolide)	Difference (%)
Rat	24	28.7 ± 5.8 (n = 3)	29.2 ± 2.8 (n = 5)	1.6%
Dog	52	60.5 ± 3.2 (n = 6)	63.5 ± 2.3 (n = 9)	4.8%

Table 2. In Vivo–In Vitro Drug Stability Comparison (Nonaqueous Formulation)

Species	Time of explant (weeks)	Method	In vivo stability	In vitro stability	Difference (%)
Rat	24	RP-HPLC	97.0 ± 0.1% (n = 3)	96.6 ± 0.3% (n = 5)	0.4%
		SEC	97.3 ± 0.1% (n = 3)	97.2 ± 0.7% (n = 5)	0.1%
Dog	52	RP-HPLC	96.5 ± 0.1% (n = 6)	96.0 ± 0.4% (n = 4)	0.5%
		SEC	93.8 ± 2.4% (n = 4)	97.2 ± 0.7% (n = 4)	3.6%

Explanation is accomplished by external palpation and localization of the implant followed by incision and removal. After normal antiseptic preparation of the site, local anesthetic is injected at one end of the implant, and a 4- to 5-mm incision is made, perpendicular to the implant. Finger pressure is applied to the other end of the implant to elevate the removal end. A small slit is then made through any surrounding fibrotic tissue to expose the implant. The implant is then popped out by continued finger pressure on the opposite end, and the incision site is closed with a Steristrip® and a sterile bandage.

CLINICAL EXPERIENCE

A human clinical study (six male volunteers, aged 18–65 years) showed that the DUROS™ implant and explant procedures were well tolerated (13,14). The placebo implant utilized in the study consisted of a sterile titanium alloy DUROS™ reservoir and membrane and orifice components; no drug formulation or internal components were used. No adverse effects were reported during the 8-week study. Additionally no "wearing" sensation was reported by the volunteers. Each implant was explanted in an outpatient surgery area in approximately 3 min.

A 1-year human phase I/II clinical study, begun in March 1997, examines the feasibility, functionality, and efficacy of one versus two DUROS™ Leuprolide Implants (3.75 mg/month with one implant versus 7.5 mg/month with two) in patients with advanced prostate cancer. Preliminary data show that testosterone was suppressed to castrate levels (below 50 ng/dL) by the fourth week of the trial for both the patients who received one implant and the patients who received two implants.

CONCLUSIONS

The DUROS™ implant represents an emerging application of osmotic technology for the delivery of biomolecules for human therapy. The technology reflects recent advances in biotechnology and in stabilization of peptides and proteins formulated as aqueous and nonaqueous solutions and suspensions. The DUROS™ implant design is adaptable for many other compounds and sites of administration. Typically the delivery is systemic, but it can be made site specific by replacing the orifice with a catheter directed to the desired location—for example, into the intrathecal or epidural cerebrospinal fluid. The DUROS™ implant has demonstrated biocompatibility and functionality in animal studies. The first therapeutic application of this technology, currently in clinical trials, is the 1-year DUROS™ Leuprolide Implant for the treatment of prostate cancer.

Bibliography

The Ruminal Therapeutic System (RUTS) Push-Melt™ technology is designed to provide controlled delivery of a drug for up to 1 year in the rumen of cattle and sheep. After oral administration, each capsular system is retained in the rumen, delivering drug for an extended duration. Drug is absorbed through the ruminal or lower intestinal mucosa into the systemic circulation. For cattle, RUTS systems are generally 2 to 3 cm in diameter and up to 10 cm in length. Larger dimensions are possible, depending on the particular application. Up to 10 g of drug can be administered. The RUTS Push-Melt™ technology is applicable to the delivery of parasiticides, insecticides, nutritional supplements, antibiotics, growth promoters, repartitioning agents, and estrus suppressants.

BACKGROUND

In the mid-1980s, the RUTS Push-Melt™ technology was developed to meet the need for drug-dedicated osmotic systems for use in ruminant production animals (1,2). Ruminants such as cattle and sheep have a complex digestive system that includes a large four-chambered stomach; the chambers are the rumen, the reticulum, the omasum, and the abomasum (Fig. 1) (3). In the rumen, ingested cellulose is broken down by microorganisms into simple mono- and disaccharides suitable for digestion. Orally administered, sustained-release delivery systems are typically limited by the target animal's gastrointestinal transit time, but in ruminants (cattle, goats, and sheep) the transit time can be controlled by using a device with sufficient density or a geometrical configuration that keeps it in the rumen for an indefinite period. Objects are retained in the rumen if they are suitably dense (density greater than 2.0 g/cm^3, preferably 2.7 to 3.0 g/cm^3) or large enough to prevent passage to the lower portions of the gastrointestinal tract or upward through the esophagus in regurgitation. In addition to the RUTS system, density-based systems include a system with two semipermeable membranes attached to a stainless steel cylinder that delivers morantel tartrate (4), a system described by Conrad and Skinner that consists of a high-density cylinder containing monensin dispersed in a biodegradable matrix of polylactic acid (5), and a completely degradable corrosion-based Panacur SR bolus that releases 12 g of fenbendazole over 4 to 5 months (6). Geometry-based systems usually have a mechanism for unfolding to a larger size once in the rumen; before administration, the system is secured in a compact configuration by a degradable tape or closure. The Laby device has "wings" (polymeric strips held in place by a water-degradable tape) that expand in the rumen (7,8); this device has been used to deliver albendazole (Captec Proftril™, SmithKline Beecham) by dissolution from tablets in contact with ruminal fluids (9). Another system, consisting of a rolled trilaminate sheet, uncoils in the rumen and releases morantel tartrate (10).

SYSTEM DESIGN AND FUNCTION

The RUTS Push-Melt™ osmotic system consists of an injection-molded semipermeable membrane that encapsulates an osmotic tablet, a partition layer, drug formulation, and an iron densifier. An exit port screen can be included (Fig. 2). Systems can vary in size from 2 to 3 cm in diameter and up to 10 cm in length, with overall drug loading capacity of up to 10 g.

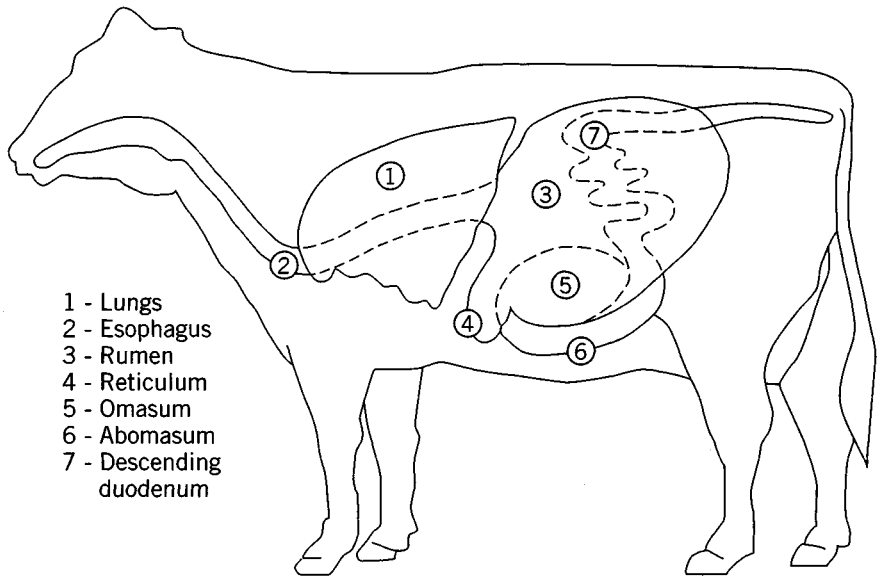

Figure 1. Bovine digestive system. *Source:* Ref. 3.

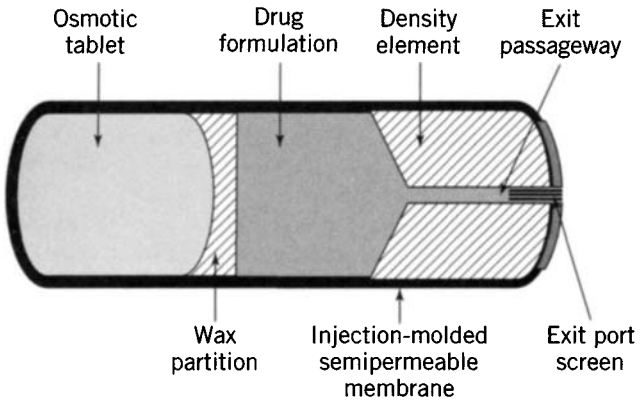

Figure 2. Cross section of the Push-Melt™ Ruminal Therapeutic System (RUTS).

In the aqueous environment of the rumen, water is imbibed through the semipermeable membrane into the osmotic tablet, which swells and pushes against the partition layer. The partition layer forces the thermoresponsive drug formulation through the orifice in the densifier and through the exit port screen if it is present.

The semipermeable membrane controls the rate of water imbibition and therefore the pumping rate of the system. This membrane, composed of cellulosic esters and plasticizers, must be rigid enough to ensure device integrity. The osmotic tablet consists of a swelling hydrogel (e.g., sodium carbomer) and an inorganic, osmotically active salt (e.g., sodium chloride), which provides a high osmotic gradient (more than 300 atm) across the membrane. Between the osmotic tablet and the drug formulation layer is the partition layer, which acts like a plunger in a syringe to ensure a smooth response to the swelling of the osmotic tablet. It consists of a compound with a higher melting point or a higher viscosity than the drug formulation layer. By altering the size of the partition layer, researchers can change the duration of the system while keeping the total dosage constant.

A RUTS Push-Melt™ system can deliver one or more drugs up to 50% by volume in a solution or a suspension. In the drug formulation, drug is suspended or dissolved in a thermoresponsive vehicle that is easily stored as a solid at room temperature. The drug formulation softens to form a viscous, flowable solution or semisolid in the 40°C ruminal environment. Microcrystalline waxes have proved useful as such vehicles (11); drugs can be suspended in these waxes at concentrations in excess of 30% by weight. Because many drugs are essentially insoluble in the wax, such formulations have minimal osmotic activity and high stability. Preparing the drug formulation as a solid improves the stability of compounds with limited solubility and increases the shelf life of the systems. Drugs can be hydrophobic or hydrophilic; if hydrophilic, they are prepared in a hydrophobic vehicle.

The densifier, made of sintered iron, adds sufficient weight to the system so that it will not be regurgitated; the amount of weight required varies with the species. At the end of the exit passageway, the optional exit port screen provides the system with additional protection from ruminal debris.

Although ruminal boluses are typically removed by magnets during slaughter, all system components are designed to be fragmentable and compatible with rendering equipment in the event that they are not completely removed (12).

The basic mathematical expressions that describe drug release from osmotic systems are given in PUMPS/OSMOTIC—INTRODUCTION. The drug delivery rate equation is

$$dm/dt = (A/h)k\Delta\pi c$$

where $\Delta\pi$ is the osmotic pressure gradient between the osmotic engine and the ruminal environment.

For Push-Melt™ systems, the membrane surface area (A) and the osmotic pressure gradient ($\Delta\pi$) change over time as the degree of hydration (H) increases (2). The effective membrane surface area increases over time as the osmotic tablet swells, but the osmotic engine itself is diluted, decreasing the osmotic pressure gradient. To reflect these time dependencies, the equation is modified as follows:

$$dm/dt = (A_H/h)k\Delta\pi_H c$$

where the subscript H represents the dependence of A and $\Delta\pi$ on osmotic engine hydration. The osmotic pressures of the drug formulation and of the partition layer are assumed to be negligible.

The mechanism of RUTS Push-Melt™ drug delivery is independent of in vivo environmental conditions, mainly because of the low osmotic pressures in the in vivo environment. Because of this, in vivo and in vitro system performance are closely correlated, and in vitro assessment is predictive of in vivo performance and therapeutic outcome.

RUTS Push-Melt™ systems can be designed for a variety of drug delivery profiles such as zero-order, pulsatile, ascending, or descending. They are typically designed for zero-order drug delivery of up to 5 g/day for durations ranging from 1 day to 1 year. With zero-order drug delivery, the RUTS Push-Melt™ system prevents drug plasma concentrations from attaining toxic levels or declining to subtherapeutic levels. Drug can be delivered in pulses by alternating the drug and placebo layers in the formulation layer (13). Ascending and descending release profiles can be designed into the system: Creating an increase in the membrane surface area (through choice of appropriate membrane materials and osmotic agents) results in an ascending profile, whereas providing a subsaturated solution in the osmotic tablet gives a descending profile.

PRODUCTS

Two commercial products have been developed and marketed using the RUTS Push-Melt™ technology. Dura SE®, introduced in 1989, delivers sodium selenite to selenium-deficient cattle for up to 4 months. IVOMEC SR® (ivermectin), released in 1992, delivers the parasiticide iver-

mectin to cattle for 135 days, controlling parasitic bronchitis and parasitic gastroenteritis for the entire grazing season when used at turnout. It is also effective in the treatment and control of sucking lice, mange mites, and warbles for 135 days after administration.

IVOMEC SR® Bolus (Ivermectin)

Ivermectin is a unique chemical entity discovered and developed by scientists at Merck Research Laboratories. Its broad-spectrum efficacy and wide margin of safety make it an ideal anthelmintic agent (14). Ivermectin acts by paralyzing parasitic nematodes, arachnids, insects, and warbles; this result is attributed to ivermectin's effect on the central nervous system of these parasites, specifically its effect on the mediation of neurotransmission by γ-aminobutyric acid (GABA) (15). At therapeutic doses, ivermectin has no effect on cattle because it does not readily penetrate the bovine central nervous system. For a discussion of the pharmacokinetics of ivermectin, see Baggot and McKellar (16).

Ivermectin can be given orally, parenterally, or topically. Continuous release is advantageous because animals are susceptible to reinfection when grazed on infected pastures. When ivermectin is given as a continuous-release ruminal bolus, steady-state levels of ivermectin can be ensured with minimal stress to the animal and minimal handling by the producer.

When ivermectin was delivered ruminally by a weighted ALZET® osmotic pump, mean plasma levels of ivermectin were predictable over a 0- to 40-μg/kg/day dosage range; bioavailability was 40% (17). Using the same method of administration, Egerton and colleagues showed that ivermectin was effective in preventing the establishment of nine nematode parasite species in cattle (18). A daily dose of up to 40 μg/kg/day, delivered intraruminally, was effective in protecting grazing calves against these parasites. This work helped establish the target delivery rate for ivermectin in fully grown cattle (300 kg) at 12 mg/day (2).

The IVOMEC SR® Bolus for cattle contains 1.72 g ivermectin as a 22% (w/w) suspension dispersed in a white, microcrystalline wax. The system includes an exit port screen (Fig. 2), which prevents ingress of ruminal matter into the system and increases the internal operating pressure of the system. The IVOMEC SR® Bolus is 9 cm long and 2.5 cm in diameter. Delivering 12 mg/day of ivermectin for 135 days, it is effective for the treatment and season-long control of parasitic bronchitis (lungworm), gastrointestinal nematodes, sucking lice, mange mites, and warbles.

Administration of the IVOMEC SR® Bolus is accomplished by using a balling gun of appropriate size to deliver the bolus into the pharynx just beyond the back of the animal's tongue (Fig. 3) (19). Once administered, the IVOMEC SR® Bolus has sufficient density to be retained in the rumen for an extended duration. Biting or regurgitation of the system occurs infrequently. In the few reported cases of biting, system integrity was not compromised, and the system could be readministered.

Because of the homogeneous nature of the drug formulation (a hydrophobic suspension), ivermectin delivery in an IVOMEC SR® Bolus can be directly calculated from the weight of the pumped drug formulation (2). Hence, when systems were immersed in a fixed volume of water or phosphate-buffered saline maintained at ruminal temperature (40°C), in vitro system performance could be determined from assayed ivermectin delivery or gravimetric measurements of the formulation delivered. For in vivo measurement, ruminants were fistulated so that the system could be removed periodically for analysis, then returned to the ruminal environment. In this case, the IVOMEC SR® Bolus was placed in a metal canister with perforations on one end to permit ruminal fluid access to the osmotic tablet; the other end was not perforated, and entry of water was prevented by means of O-rings. Drug formulation was released into this latter end of the collection vessel and analyzed on periodic removal (2).

IVOMEC SR® Start-up and Shutdown Delivery Profiles. Rapid, reproducible, and predictable drug delivery start-up is important with ruminal boluses for immediate prophylaxis, especially in the spring when animals are sent to fresh pastures, where an increase of parasitic larvae is typical. With prototype IVOMEC SR® boluses, drug delivery was not instantaneous; a time lag was associated with water permeation into the osmotic tablet and pressurization of the drug formulation. To minimize this start-up time, the IVOMEC SR® Bolus is prehydrated by adding a fixed amount of water to the packaged system, causing an increase in the internal hydrostatic pressure as water is imbibed into the osmotic tablet. Once in the 40°C ruminal environment, the thermoresponsive drug formulation softens, with rapid onset of osmotic pumping. Zingerman and colleagues (2) have shown that the onset of drug delivery for hydrated (1.3 g of water added) IVOMEC SR® boluses is rapid (2–3 days). Steady-state delivery is reached in 7 to 10 days. Anhydrous systems took 2 to 3 weeks to reach steady-state delivery (Fig. 4) (2).

Reproducible and predictable delivery termination for the IVOMEC SR® bolus is critical to establish the optimum withdrawal period so that drug residues are minimized to safe levels before slaughter. For the IVOMEC SR® Bolus, the withdrawal period (period since last drug administration in which the animal cannot be slaughtered for human consumption) is 180 days. As shown in Figure 4 (2), termination occurred rapidly at approximately 135 days for both in vivo and in vitro systems; within 14 days, shutdown was complete (2).

IVOMEC SR® In Vivo–In Vitro Release-Rate Correlation. Good agreement has been shown between the in vitro and in vivo release profiles for the IVOMEC SR® Bolus (2). Figure 5 (2) demonstrates this agreement, which has also been verified with seven large, commercial-scale batches. The cumulative coefficient of variation at the time when all the drug formulation was expelled was 4% for in vivo systems and 4.2% for in vitro systems.

IVOMEC SR® Efficacy. In a study by Yazwinski and colleagues, calves treated with the IVOMEC SR® Bolus had significantly fewer fecal egg counts and significantly fewer nematodes at necropsy than did the untreated calves; both

groups were given infective larvae inoculum and grazed on an infected pasture. The ivermectin bolus prevented the establishment of not only actively developing parasitic nematodes but also arrested larvae (e.g., *Ostertagia* EL_4). No adverse reactions were seen, and all IVOMEC SR® boluses remained in the rumen throughout the study (20).

Dura SE® Bolus (selenium)

Selenium deficiency in cattle is a problem in many areas of the world, including parts of the United States. A Push-Melt system, the Dura SE® Bolus has been developed to deliver sodium selenite at the rate of 3 mg of selenium per day to cattle for 120 days. The system does not include the optional exit port screen; otherwise, the design is as shown in Figure 2. The drug formulation consists of sodium selenite dispersed in a microcrystalline wax. Figure 6 shows the in vitro, zero-order release profile obtained for

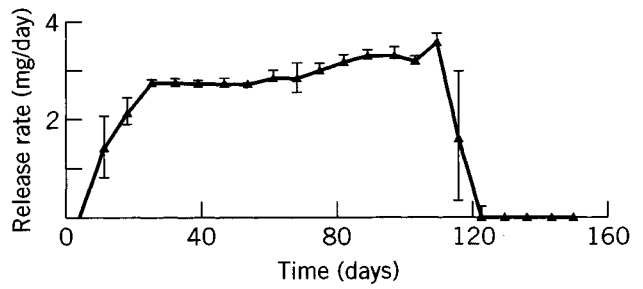

Figure 6. In vitro release profile of selenium delivered from a Dura-SE® bolus.

the Dura SE® Bolus. Adair and colleagues examined the in vivo behavior of Dura SE® Bolus and found that release reached a steady state within 4 weeks, continued at steady-state levels for 16 weeks, and dropped to less than 1% of steady-state levels in the final 2 weeks. Mean in vivo release was 3.1 mg/day, with a range of 2.4 to 4.1 mg/day. Excellent in vivo–in vitro correlation was obtained (21). Figure 7 shows selenium blood levels from selenium-deficient cattle treated with the Dura SE® Bolus. Selenium has a relatively long half-life, which is reflected in the slowly rising selenium levels. Nevertheless, selenium levels were in the normal range (more than 0.08 ppm) by day 35 (22).

In a 220-day study, Campbell and colleagues assigned 150 selenium-deficient, pregnant beef cattle to one of four treatment groups: one Dura SE® Bolus at day 0, two Dura SE® Boluses (one administered on day 0 and the second one on day 119), two selenium pellets at day 0, and control. The Dura SE® Bolus is designed to release 3 mg/day for 120 days; the 30-g pellets contain 10% elemental selenium and are designed to provide selenium supplementation for up to 18 months. At the end of the study, blood levels of selenium were significantly ($P < .01$) higher in the two-Dura SE® Bolus group than in any other group. Calves from cattle in the selenium-supplemented groups had significantly ($P < .001$) higher blood selenium levels, both before and after suckling, than did controls (23).

Maas and colleagues administered the Dura SE® Bolus to selenium-deficient beef heifer calves and found that mean blood selenium was maintained at more than 0.10 μg/mL for 188 days. No untoward effects were seen in the treatment group (24).

CONCLUSIONS

The RUTS Push-Melt™ osmotic system is an innovative adaptation of osmotic technology for the delivery of agents to ruminants. It extends the delivery duration beyond the 28-day lifetime of the ALZET® pump to 4 months or longer. Formulation options include suspensions as well as solutions. Commercialized applications of this technology have been developed for the delivery of ivermectin, a potent parasiticide, and sodium selenite, a nutritional supplement.

Controlled release of drugs, proteins, and other bioactive agents can be achieved by incorporating them either in dissolved or dispersed form in polymers (1,2). During the design stage of these formulations or during experimental verification of their release behavior, it is desirable to develop and use simple and sophisticated mathematical models to describe the release kinetics (3). Although these models are clearly based on transport (diffusion) equations, they are commonly known in the pharmaceutical or drug delivery field as kinetic models or kinetic expressions, because they describe a time-dependent behavior of the drug release.

From a mathematical-modeling point of view, controlled-release systems may be classified according to the controlling physical mechanism(s) of release of the incorporated drug. We have proposed a convenient method (4) based on the mechanism of transport for categorizing them as diffusion-controlled, swelling-controlled, osmotically controlled, and chemically controlled systems.

Mathematical modeling of the release kinetics of specific classes of controlled-release systems may be used to

1. Predict drug release rates from and drug diffusion behavior through polymers, thus avoiding excessive number of experiments
2. Elucidate the physical mechanisms of drug transport by simply comparing the release data to mathematical models

Here we present a critical summary of important mathematical models for the description of drug release from controlled-release systems. In this article we have tried to incorporate only models that accurately depict the physical situation of the problems modeled. Unfortunately, the pharmaceutical literature includes a variety of inappropriately simplified, semiempirical or pseudo–steady-state models. The validity of these models is questionable, and their utility in analysis of drug diffusion data is doubtful. Most of these models have been ignored, except for one (the Higuchi equation), which has been included for historical reasons.

Mechanistic aspects of the diffusion phenomena observed in drug delivery systems are by necessity related to an accurate mathematical model and to the structural characteristics of the polymeric material under consideration. However, very few reviews address these two aspects of controlled-release systems (3–6). Here, we critically evaluate existing mathematical models for drug release from polymeric systems. Unfortunately, lack of a systematic analysis and classification is responsible for the use of inappropriate models, not necessarily describing the experimental conditions of the work of many investigators.

DIFFUSION IN DRUG DELIVERY SYSTEMS

With the exception of a number of swelling-controlled release systems, most polymeric formulations for drug release may be described by the two forms of Fick's law of diffusion, which can be written as equations (1) and (2) for one-dimensional diffusion:

$$j_i = D_{ip} \frac{dc_i}{dx} \tag{1}$$

$$\frac{\partial c_i}{\partial t} = D_{ip} \frac{\partial^2 c_i}{\partial x^2} \tag{2}$$

In these equations, c_i and j_i are the concentration and mass flux of drug I, respectively; x and t are position and time

of release; and D_{ip} is the drug diffusion coefficient through the polymer.

Several assumptions have been made in describing drug diffusion through polymers by equations 1 and 2. First, as one-dimensional diffusion is appropriate for treatment of drug release from thin, planar systems, application of this analysis to thick slabs or short cylinders is incorrect. Then, the drug diffusion coefficient D_{ip} is usually assumed to be independent of drug concentration. Finally, j_i is the drug flux with respect to the mass average velocity v of the system.

Fickian diffusion equations can be solved by standard mathematical techniques (7), provided that sufficient information about initial and boundary conditions of the pharmaceutical experimental situation is provided.

Solution of equations 1 or 2 provides the following information about drug release through polymers:

1. Determination of concentration profiles from the normalized drug concentration, c/c_o, versus dimensionless position, x/δ, as a function of dimensionless Fourier time, $D_{ip}t/\delta^2$. Here, c_o is a reference drug concentration, and δ is the slab thickness.
2. Drug release rates, dM_t/Adt, can be determined by differentiating the previous expressions with respect to position and evaluating the derivative at the water– or dissolution–medium interface. Here, A is the diffusional cross-sectional area.

$$\frac{dM_t}{Adt} = \left[D_{ip}\frac{\partial c_i}{\partial x}\right]_{x=\text{surf}} \tag{3}$$

3. The total amount of drug released per cross-sectional area, M_t/A, can be determined by integrating the previous expression over release time.

$$\frac{M_t}{A} = \int_0^t \frac{dM_t}{Adt}\,dt = \int_0^t \left[D\frac{\partial c_i}{\partial x}\right]_{x=\text{surf}} dt \tag{4}$$

Application of these equations to experimental data of drug release is often conveniently achieved with the use of the semiempirical equations 5 and 6 describing the fractional release, M_t/M_∞, and release rate, dM_t/Adt, as functions of release time, t. Here M_∞ is the amount of drug released at long times, which may or may not be equal to the total drug incorporated in a device (8,9).

$$\frac{M_t}{M_\infty} = kt^n \tag{5}$$

$$\frac{dM_t}{Adt} = nkt^{n-1} \tag{6}$$

The importance of this analysis is easily understood (Fig. 1) because most mathematical solutions of equation 2 for Fickian drug diffusion give release kinetics described by equation 5 with $n = 0.5$. Consequently, the release rate is proportional to $t^{-1/2}$.

A special case of release kinetics with $n = 1$ can be obtained when describing drug release from membrane-type diffusion-controlled systems, some geometrical shapes of matrix systems (e.g., hemispheres), or swelling-controlled release systems. This type of release kinetics is commonly known as zero-order release kinetics because it is characterized by constant drug-release rates (10–13).

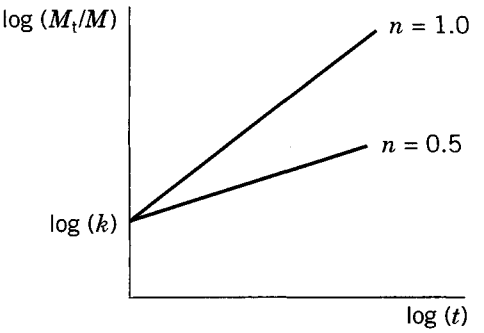

Figure 1. Schematic representation of log (normalized drug released) as a function of log (release time).

RELEASE KINETICS FROM DIFFUSION-CONTROLLED SYSTEMS

In diffusion-controlled release systems, drug diffusion through the polymer is achieved by molecular diffusion due to concentration gradients. Depending on the molecular structure of the polymer, these systems may be classified as porous or nonporous. Porous controlled-release systems contain pores that are large enough that diffusion of the drug is accomplished through water that has filled the pores of the polymer (14). These pores are usually of size greater than 200–500 Å.

Nonporous systems contain meshes of molecular (drug) dimensions. Molecular diffusion occurs effectively through the whole polymer, and the drug diffusion coefficient refers to the polymer phase (14). The macromolecular structure of the polymer affects drug diffusion according to theoretical analyses discussed elsewhere (15). Some of the polymer parameters controlling the drug diffusion coefficient are degree of crystallinity and size of crystallites, degree of cross-linking, degree of swelling, and molecular weight of the polymer. Many swollen, porous polymer systems retain the main characteristics of the porous structure so that drug diffusion occurs simultaneously through water-filled pores and through the swollen polymer per se.

The study of controlled release actually requires the study of diffusion, or transport through a particular medium. There are several types of transport mechanisms that can occur, with the most important being ordinary diffusion. The gradient that produces this diffusional behavior is due to a concentration gradient. It is only one of the forms of gradients that can be responsible for the drug release. In fact, it should be referred to as chemical potential gradient rather than concentration gradient. We are writing here for one dimension, but the actual system will be in three dimensions. The true type of release is a result of a gradient of activity, where the activity has incorporated in it the true nonideal behavior of the drug or solutes that is being released at the same time. The nonideal be-

havior is expressed in terms of the activity coefficient. By multiplying the activity coefficient by the mole fraction, we obtain the activity that leads to the gradient. In addition to this transport mechanism, one should expect to see convection when the pores of the carrier are large. In that case, there will be a flux of drug due to the drug being carried along with the solvent itself.

Another type of transport we may sometimes see is facilitated transport, otherwise known as carrier-mediated transport. It effectively involves one or more components being transported relatively quickly because they have reacted or formed a complex with another chemical agent that has a higher solubility in the phase through which it is diffusing. These are the three main mechanisms of transport, and within these there are unusual transport processes like osmotic transport. There is also relaxation-controlled mechanism, which is a significantly different mechanism. It happens in only one type of controlled-release device, which will be discussed separately. Many of the situations that will be discussed involve transport and reaction at the same time. This may be a reaction into the polymer or into the drug being released, so the equation will have this included in the expression.

The classical equation by which one expresses drug transport through a carrier is Fick's law. Fick's first law describes the flux of the drug, peptide, or protein that is diffusing as a function of a concentration gradient in one direction. This is the simplest form of the equation and can be written in three dimensions or in different coordinate systems. It is important to note that in the simplest possible form that is found in the literature (7), the equation is given in terms of a concentration gradient, not an activity or chemical potential gradient. The equation is modified somewhat if it is in terms of a chemical potential gradient. It must be noted that the concentration units are usually in moles/cm^3, and that gives a flux of moles/cm^2/s. This is the difference between a flux and a rate, where the rate of transport of a drug is expressed in units of mol/s. The flux is expressed per area of release, whereas a rate is expressed simply per time.

For release from a thin film or tablet, the flux per area includes two areas, the upper and lower surface, whereas the rate doesn't have an area at all. As the equation is written here, it is assumed that the diffusion coefficient is constant. Several assumptions are made. The first one is that whether it is a controlled-release device with a large or a small amount of drug in it, the drug exhibits a constant rate. This assumes that the diffusion coefficient does not depend on the concentration of drug, a major hypothesis that is unfortunately incorrect. However, traditionally in the field of controlled release, it has been difficult to express the diffusion coefficient in terms of more sophisticated theories. The diffusion coefficient does not remain constant with concentration. Typical values of the drug diffusion coefficients in polymers range from 10^{-6} to 10^{-7} cm^2/s for diffusion in rubbery polymers and from 10^{-10} to 10^{-12} cm^2/s for diffusion in glassy polymers.

In the Eyring analysis (16), the diffusion coefficient, which is the ease of transport through the polymer carrier system, can be easily calculated as

$$D = \lambda^2 \nu / 6 \tag{7}$$

Here λ is the diffusional jump through the polymer or the specific system being studied. This diffusional jump is related to the polymer and the drug studied. The second parameter, ν, is the frequency of jumping. Thus, in the Eyring theory, diffusion is not a continuous process, and we can distinguish specific jumps. The parameter λ, which is the diffusional jump parameter, is a function of the diffusing species, v_i, the available volume space, V_p, and other characteristics of the system.

Mathematical modeling of such situations has been a major problem in physical chemistry and has been addressed over the last 40 years by many investigators. One of the earliest published studies is that of Ogston (17) involving transport of spheres in stochastic networks.

In 1961, Fujita (18) introduced the idea of free volume in diffusional problems. He defined the free volume, v_f, and came up with a free-volume theory with the drug diffusion coefficient having an exponential dependence on the free volume.

$$D = D_o \exp(-k/v_f) \tag{8}$$

The Fujita theory was modified in the late 1960s by Yasuda and Lamaze (19). This was the first exact free-volume theory in which the diffusion coefficient of the diffusing species through a polymer structure is described in a rather accurate way. This approach is based on the molecular level and tries to explain how diffusion occurs in a controlled-release device. Unfortunately, our field has been marred with improper expressions and incorrect definitions.

Transport through these systems is the classical solute transport in porous media that one would find in any chemical engineering textbook (20). The classical way of describing the diffusion coefficient in such a system is as an effective diffusion coefficient related to the diffusion coefficient of the drug through the pores filled with a solution of drug, D_{iw}.

$$D_{eff} = D_{iw}\varepsilon/\tau \tag{9}$$

In reality, it is not water that occupies these pores but a solution of the drug. As the release occurs, more of the drug is dissolved, and the solution becomes more and more dilute. The porosity is the fraction of pores in the system that are open ($0 < \varepsilon < 1$). The tortuosity, τ, indicates the tortuous path of transport of a drug through this particular porous network structure. For example, in the case of a straight cylindrical pore, the tortuosity is 1 because the diffusion path is straight. If, however, the pores are tilted at 45°, the tortuosity becomes $\sqrt{2}$, or 1.41. As the path becomes more tortuous, τ becomes 3–5. This is the simplest way to describe a situation in a controlled-release system with large pores.

Faxén (21) proposed the following equation for diffusion of spheres through porous media:

$$D/D_b = (1 - \lambda)^2(1 + \alpha\lambda + \beta\lambda^3 + \gamma\lambda^5) \quad (10)$$

Here λ is the ratio of the drug radius, r_s, to the pore average radius, r_p. The diffusion coefficient of the sphere through the pore, D, relative to the diffusion coefficient in bulk solution, D_b, is equal to the semiempirical relation just shown that has been proven for a variety of systems. The diffusion in this porous system is very much dependent on the size of the drug and the size of the pore. We should expect the parameter D/D to attain a limit of one.

A swelling mechanism requires that the water come to the surface and start swelling the polymer itself. In such situations, the diffusion coefficient is very much dependent on the concentration of water that is incorporated into the system. It is interesting that this process takes effectively place in "layers," so that in the case of a controlled-release device in the form of a thin disk or tablet, we expect that the layers on the surface will have swollen first whereas the center will still be a solid. The diffusional behavior of water into the drug-containing system can be described by the following Fujita equation:

$$D_{drug} = D_{do} \exp\{-\alpha(\beta - c_w)\} \quad (11)$$

The diffusion coefficient of the drug is equal to a preexponential term multiplied by an exponential relation, where α and β are two characteristic constants of the polymeric system and c_w is the water concentration of the system. Hence, the higher the concentration of water, the higher the diffusion coefficient of the drug. The terms α and β can be determined by the free-volume theory or the Duda–Ventas theory (22), where several terms appear that are known for specific polymer systems and can be evaluated to give α and β.

Reservoir (Membrane) Systems

In reservoir (membrane) systems, the bioactive agent is usually enclosed at relatively high concentrations between two semipermeable membranes and is placed in contact with a dissolution medium (water or other biological fluid). The bioactive agent may be solvent free or in the form of a concentrated solution.

Equation 1 may be used to describe drug release through reservoir systems. However, because the concentration c_i in this equation refers to drug concentration in the membrane and because this value is difficult to determine experimentally, it is customary to relate drug concentrations in the membrane through the partition (distribution) coefficient, K.

The partition coefficient describes thermodynamic rather than structural characteristics of the drug/polymer/solvent system. It is rather easy to determine experimentally, and it is a measure of drug solubility in a swollen polymer.

When the concentration of the released bioactive agent in the phase external to the system is maintained at a constant low level of concentration, for example, by good agitation and continuous removal of the released drug, equation 1 may be integrated over the thickness of the membrane (for plane sheet geometry) to give equations 12 and 13, where c_{i1}, c_{i2} are drug concentration in the two sides of a membrane:

$$\frac{dM_t}{Adt} = \frac{D_{ip}K}{\delta}(c_{i2} - c_{i1}) \quad (12)$$

$$M_t = \frac{D_{ip}KA(c_{i2} - c_{i1})}{\delta} t \quad (13)$$

Clearly drug release from these systems is zero order, that is, the release rate of drug does not depend on time. The amount of drug released from such a device for the case of two specific drugs as a function of time is shown in Figure 2.

Similarly, for cylindrical devices it is readily shown that

$$\frac{dM_t}{dt} = \frac{D_{ip}KA}{\ln(r_e/r_i)}(c_{i2} - c_{i1}) \quad (14)$$

and

$$M_t = \frac{D_{ip}KA(c_{i2} - c_{i1})}{\ln(r_e/r_i)} t \quad (15)$$

where r_e and r_i are the external and internal radii of the cylinder, respectively, and A is the length of the cylinder. In both situations of slabs and cylinders, one-dimensional diffusion is assumed. This assumption requires that these equations be applied only for analysis of release from thin membranes or long cylindrical systems. Corrections for edge effects due to violation of the one-dimensional diffusion assumption are available (23), if thick membranes are used. However, the preferable method of modeling would be numerical solution of the three-dimensional diffusion problem.

For spherical reservoir systems, the corresponding equations for drug release are

$$\frac{dM_t}{dt} = \frac{4\pi D_{ip}K}{(r_e - r_i)/r_e r_i}(c_{i2} - c_{i1}) \quad (16)$$

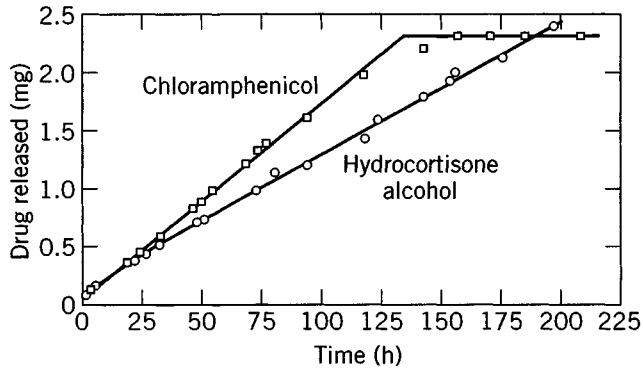

Figure 2. Zero-order release as obtained from a constant-activity reservoir source for chloramphenicol and hydrocortisone alcohol. *Source:* Reproduced with permission from Ref. 1. Copyright 1974 Plenum.

and

$$M_t = \frac{4\pi D_{ip} K(c_{i2} - c_{i1})}{(r_e - r_i)/r_e r_i} t \quad (17)$$

Therefore, drug-release rates from conventional reservoir systems are time independent. However, they depend on the concentration difference, geometry of the device, thermodynamic characteristics of the system (solubility, through the partition coefficient), and structure of the polymer (through the diffusion coefficient).

Situations of drug release from membrane systems at low initial drug concentration or to experimental vessels of finite volumes cannot be modeled with the equations given previously. Instead, equation 18 has been derived (23) for the drug release rate from these systems.

$$\frac{dM_t}{dt} = \frac{M_\infty D_{ip} KA}{V_1 \delta} \exp\left[\frac{-D_{ip} KA(V_1 + V_2)}{\delta V_1 V_2} t\right] \quad (18)$$

Here V_1 and V_2 are the volumes of the device and the vessel, respectively, and M_∞ is the initial loading of the device. The release rate in this situation is an exponential function of release time.

Special release problems observed with reservoir devices include time lag and burst effects. These effects are related to the time history of the device, and they have been mathematically analyzed in previous reviews (1).

The time lag and burst effects alter the initial release kinetics of the expected steady-state release behavior of membrane systems due to accumulation of drug (burst effect) or due to the induction period for drug diffusion (time-lag effect).

It has been previously shown (1) that for membrane devices exhibiting time-lag effects, the steady-state expression (at long times) for fractional drug release is given by equation 19:

$$M_t = \frac{AD_{ip} c_{i1}}{\delta}\left[t - \frac{\delta^2}{6D_{ip}}\right] \quad (19)$$

Here c_{i1} is the initial drug concentration in the membrane.

In a similar manner, one can derive equation 20 for the fractional drug release of membrane devices exhibiting burst effects.

$$M_t = \frac{AD_{ip} c_{i1}}{\delta}\left[t + \frac{\delta^2}{3D_{ip}}\right] \quad (20)$$

The second terms in the parentheses of equations 19 and 20 are known as the characteristic time lag and burst time, θ_l and θ_b, respectively, and they are useful in determining drug-diffusion coefficients in membranes by simple release experiments. More recently, the role of the burst effect in drug-release kinetics from matrix systems has been analyzed, and we discuss this in detail in the section on matrix systems.

Porous Reservoir Systems. Release from porous reservoir systems of hydrophobic polymers may be modeled by equations 9 to 11 where the diffusion coefficient is replaced by the effective diffusion coefficient, D'_{eff}. This parameter describes diffusion through water-filled pores (14,24) and incorporates the porosity (void fraction), ε, and tortuosity, τ, in the drug-diffusion coefficient through water, D_{iw}, according to equation 21:

$$D'_{eff} = D_{iw} \frac{\varepsilon}{\tau} \quad (21)$$

It is sometimes desirable to incorporate into this expression a partition coefficient, K_p, for possible adsorption of the drug on the walls of the pores, and a restriction coefficient, K_r, which accounts for hindered diffusion and is described according to equation 22, where λ is the ratio of the drug radius, r_s, to the pore average radius, r_p:

$$K_r = (1 - \lambda)^2 \text{ with } \lambda = r_s/r_p \quad (22)$$

Then, the effective diffusion coefficient of drug through the pores may be written as

$$D_{eff} = D_{iw} K_p K_r \frac{\varepsilon}{\tau} \quad (23)$$

The well-known theoretical analyses of Anderson and Quinn (25) and Colton et al. (23) are often used to predict the parameters K_p and K_r for drug-release systems with fine pores. Very often, diffusion through porous membranes is accompanied by osmotic effects as a result of which equations 9–11 and 21–23 do not fully describe phenomena occurring in porous reservoir systems.

Matrix (Monolithic) Systems

In matrix (monolithic) systems, the bioactive agent is incorporated in the polymer phase either in dissolved or in dispersed form. Therefore, the solubility of the drug in the polymer becomes a controlling factor in the mathematical modeling of these systems. When the initial drug loading is below the solubility limit, release is achieved by simple molecular diffusion through the polymer. However, when the drug loading is above the solubility limit, dissolution of the drug in the polymer becomes the limiting factor in the release process.

Solutions of the transient diffusion equation 2 can be obtained for a variety of initial and boundary conditions (7), which represent appropriate experimental situations. Some of these solutions are presented here. However, the reader is warned that unusual experimental conditions of release will require solution of equation 2 under the boundary conditions that best describe one's experimental situation.

It is also important to note that most mathematical models for controlled-release kinetics presented in the literature have been derived with the assumption of an experimentally rather unattainable boundary condition of zero (and constant) drug concentration at the interface of the device. This condition requires complete elimination of boundary layer effects, probably by high agitation during the release experiment.

In this section we include, in addition to the conventional solutions of the diffusion equation 2 widely used in

controlled-release technology, new models and mathematical solutions with boundary conditions affected by drug mass transfer from the surface of the polymer to the liquid phase. These models do not require that the concentration at the polymer interface be constant or zero, although previous determination of the mass transfer coefficient is needed. The mass transfer coefficient can be determined by a variety of expressions or experimental techniques discussed in standard mass transfer monographs (26), if the flow characteristics of the release experiment are known.

Dissolved Drug, Nonporous Systems. In these systems the drug is loaded uniformly at initial concentration c_{io}. Several models may be readily developed for plane sheet matrix devices under different boundary conditions (27).

When the surface concentration of the drug in the dissolution medium is kept constant at c_i, we can derive

$$\frac{M_t}{M_\infty} = 1 - \sum_{n=0}^{\infty} \frac{8}{(2n+1)^2\pi^2} \exp\left[\frac{-D_{ip}(2n+1)^2\pi^2}{\delta^2} t\right] \tag{24}$$

Important simplifications of this equation may be used if one is interested in avoiding the lengthy calculations of this series solution. For example, for long release times ($M_t/M_\infty > 0.6$), this equation may be written as

$$\frac{M_t}{M_\infty} = 1 - \frac{8}{\pi^2} \exp\left[-\frac{D_{ip}\pi^2}{\delta^2} t\right] \tag{25}$$

For small release times ($M_t/M_\infty > 0.6$), equation 2 has an alternative solution in the form of equation 26:

$$\frac{M_t}{M_\infty} = 4\left[\frac{D_{ip}t}{\delta^2}\right]^{1/2}\left[\frac{1}{\sqrt{\pi}} + 2\sum_{n=1}^{\infty}(-1)^n \text{ierfc}\,\frac{n\delta}{\sqrt{D_{ip}t}}\right] \tag{26}$$

Equation 26 can be further simplified to give

$$\frac{M_t}{M_\infty} = 4\left[\frac{D_{ip}t}{\pi\delta^2}\right]^{1/2} \tag{27}$$

It is clear that when slabs of monolithic devices are kept at constant external drug concentration, the fractional release is proportional to the square root of release time. However, equation 27 is valid only for the early portion of a release experiment and only under the boundary conditions and assumptions discussed before. By differentiation, we can obtain

$$\frac{dM_t}{dt} = 2M_\infty\left[\frac{D_{ip}}{\pi\delta^2 t}\right]^{1/2} \tag{28}$$

This equation shows that the drug-release rate drops considerably during the release experiment and that it is dependent on $t^{-1/2}$. This observation is important for design of zero-order release systems because it shows that it is not possible to obtain constant drug release rates from "simple" matrix-type devices.

In many experimental studies, the drug concentration at the surface c_i cannot be kept constant. Instead a constant drug concentration, c_o, can be obtained far enough from the surface (28). Therefore a boundary condition for equation 2 can be written as

$$\left[-D\frac{\partial c}{\partial x}\right]_{surf} = k(c_o - c_i) \tag{29}$$

where k is the mass transfer coefficient. Then equation 2 can be solved to give

$$\frac{M_t}{M_\infty} = 1 - \sum_{n=1}^{\infty} \frac{\frac{1}{2}\left[\frac{\delta k}{D_{ip}}\right]^2 \exp\left[-\frac{4\beta_n^2 D_{ip}}{\delta^2} t\right]}{\beta_n^2\left[\beta_n^2 + \left[\frac{\delta k}{2D_{ip}}\right]^2 + \frac{\delta k}{2D_{ip}}\right]} \tag{30}$$

where β_n are the positive roots of equation 31.

$$\beta \tan \beta = \delta k/2D_{ip} \tag{31}$$

Experiments can be also performed with surface concentration c_i of drug varying in a specific way. For example, when

$$c_i = k't \tag{32}$$

the corresponding expression of the released drug is

$$\frac{M_t}{A} = k'\delta t - \frac{k'\delta^3}{12D_{ip}} + \frac{8k'\delta^3}{\pi^4 D_{ip}} \sum_{n=0}^{\infty} \frac{\exp\left[-\frac{D_{ip}(2n+1)^2\pi^2}{\delta^2}\right]}{(2n+1)^4} \tag{33}$$

When the surface concentration increases according to equation 34,

$$c_i' = c_i[1 - \exp(-\gamma t)] \tag{34}$$

the corresponding expression for the released drug is

$$\frac{M_t}{A} = \delta c_i - \exp(-\gamma t)\left[\frac{4D_{ip}}{\gamma\delta^2}\right]^{1/2} \tan\left[\frac{\gamma\delta^2}{4D_{ip}}\right]^{1/2} - \frac{8}{\pi^2}\sum_{n=0}^{\infty} \frac{\exp\left[\frac{-(2n+1)^2\pi^2 D_{ip}}{\delta^2} t\right]}{(2n+1)^2\left[1 - \frac{(2n+1)^2 D_{ip}\pi^2}{\gamma\delta^2}\right]} \tag{35}$$

Models for drug release from devices with other geometries can also be derived by appropriate solution of equation 2 in cylindrical or spherical coordinates (7).

For example, for cylindrical devices of radius r kept at constant surface concentration c_i, the amount released can be calculated by equation 36:

$$\frac{M_t}{M_\infty} = 1 - 4\sum_{n=1}^{\infty} \frac{\exp(-D_{ip}\alpha_n^2 t)}{r^2\alpha_n^2} \tag{36}$$

Here α_n are positive roots of a Bessel function of the first kind of zero order. For long times, only the first term of the

summation of equation 36 is necessary. For short times, this equation can be approximated by equation 37:

$$\frac{M_t}{M_\infty} = 4\left[\frac{D_{ip}t}{\pi r^2}\right]^{1/2} - \left[\frac{D_{ip}t}{r^2}\right] - \frac{1}{3}\left[\frac{D_{ip}t}{\pi^{1/3}r^2}\right]^{3/2} \quad (37)$$

For spherical devices, the early term approximation is going to be again for $M_t/M < 0.4$ and is going to look something like that. Figure 3 shows a comparison of the fractional release and the release rate as a function of release time for slabs, cylinders, and spheres. This equation here is very useful because pharmacists often work with microparticulate systems. The only problem is that it is written for one-size particles. Basically, we have a dependency of $t^{1/2}$ and the first power at the same time. The rate is a function of $t^{-1/2}$. The rate drops with time, and this is why we need to have other particles to keep the rate constant.

Based on this idea, researchers started thinking that perhaps what they could create is a distribution of particle sizes. A design where one particle-size distribution working from the beginning is in contact with the physiological fluid, and a second particle-size distribution, which is much smaller, is brought into contact with the physiological fluid a little bit later, yields approximately zero-order release.

Solutions for other boundary conditions are available in standard references (7). For example, for cylindrical systems with boundary condition described by equation 29, the fractional drug release is

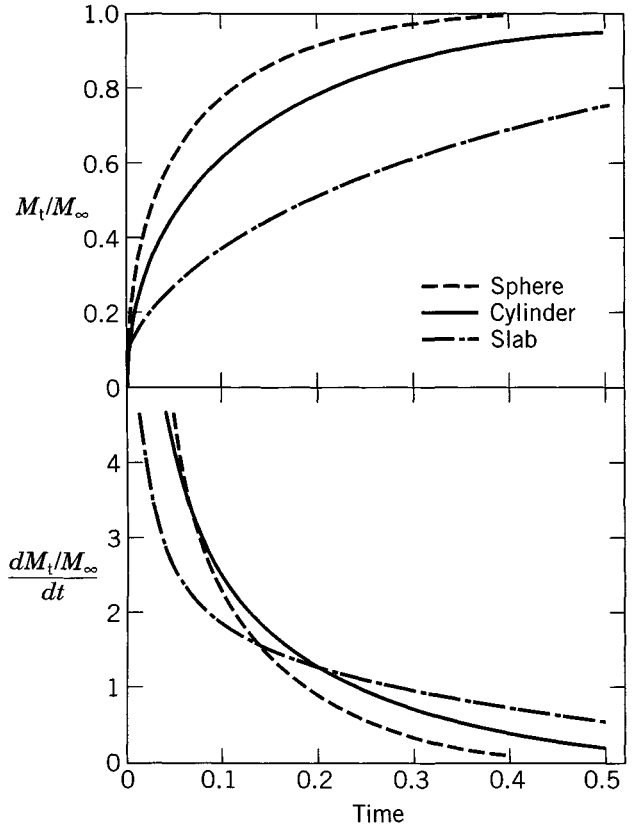

Figure 3. Fractional release and release rate as a function of time for slabs, cylinders, and spheres. *Source:* Reproduced with permission from Ref. 1. Copyright 1974 Plenum.

$$\frac{M_t}{M_\infty} = 1 - \sum_{n=1}^{\infty} \frac{4\left[\frac{kr}{D_{ip}}\right]^2 \exp\left[-\frac{\beta_n^2 D_{ip}}{r^2}t\right]}{\beta_n^2\left[\beta_n^2 + \left[\frac{kr}{D_{ip}}\right]^2\right]} \quad (38)$$

where β_n are the roots of equation 39:

$$\beta D_{ip} J_1(\beta) - krJ_0(\beta) = 0 \quad (39)$$

where $J_0(\beta)$ and $J_1(\beta)$ are Bessel functions of zero and first order, respectively.

An appropriate solution suitable for small times is

$$\frac{M_t}{M_\infty} = \left[\frac{2kt}{r}\right] - \left[\frac{8k^2t^{3/2}}{3D_{ip}^{1/2}\pi^{1/2}r}\right] - k^2\left[\frac{1}{2} - \frac{kr}{D_{ip}}\right]t^2 \quad (40)$$

For spherical matrix devices, equation 2 can be solved with spherical coordinates and constant surface concentration to give

$$\frac{M_t}{M_\infty} = 1 - \frac{6}{\pi^2}\sum_{n=1}^{\infty}\frac{1}{n^2}\exp\left[-\frac{D_{ip}n^2\pi^2}{r^2}t\right] \quad (41)$$

For long times, only the first term in the summation need be retained. For short times of release ($M_t/M_\infty < 0.6$) an approximate solution may be obtained in the form of equation 42:

$$\frac{M_t}{M_\infty} = 6\left[\frac{D_{ip}t}{\pi r^2}\right]^{1/2} - 3\frac{D_{ip}t}{r^2} + 12\left[\frac{D_{ip}t}{r^2}\right]^{1/2}\sum_{n=1}^{\infty}\text{ierfc}\frac{nr}{\sqrt{D_{ip}t}} \quad (42)$$

which may be further simplified for $M_t/M_\infty < 0.4$ by retaining only the first two terms of the right hand side (rhs) of this equation.

Solutions for other boundary conditions are available (27,28). For example, when using spherical devices in conjunction with the boundary condition of equation 29, the fractional drug release is given by equation 43:

$$\frac{M_t}{M_\infty} = 1 - \sum_{n=1}^{\infty}\frac{6\left[\frac{kr}{D_{ip}}\right]^2\exp\left[-\frac{\beta_n^2 D_{ip}}{r}t\right]}{\beta_n^2\left[\beta_n^2 + \frac{kr}{D_{ip}}\left[\frac{kr}{D_{ip}} - 1\right]\right]} \quad (43)$$

where β_n are the roots of equation 44:

$$\beta_n D_{ip}\cot\beta_n + kr - D_{ip} = 0 \quad (44)$$

In general, description of drug-release kinetics from matrix-type systems under different boundary conditions and different geometries can be achieved by selecting an appropriate model from the ones described by Crank (7). Consequently, unnecessary assumptions and gross simplifications, such as unfortunate use of equation 27 where it does not apply, can be avoided.

Dispersed Drug, Nonporous Systems. Monolithic devices may contain drug uniformly distributed at a loading, c_{io}, which is significantly higher than the drug solubility in the polymer, c_{is}. In these systems, dissolution of the drug may be the rate-limiting step of this release process. Therefore, several models have been proposed to describe this phenomenon.

A simple pseudo–steady-state model, the Higuchi model, has attained popularity among researchers working in this area (29). It is based on Fickian diffusion according to equation 1, with zero surface concentration, and it gives the amount of drug released and its release rate according to equations 45 and 46, respectively:

$$M_t = A[D_{ip}c_{is}(2C_{io} - c_{is})t]^{1/2} \tag{45}$$

$$\frac{dM_t}{dt} = \frac{A}{2}[D_{ip}c_{is}(2c_{io} - c_{is})]^{1/2}t^{-1/2} \tag{46}$$

Similar expressions have been developed for cylindrical and spherical devices (1,30). For cylindrical devices and for $c_{io} \gg c_{is}$, one obtains

$$\frac{M_t}{M_\infty} + \left[1 - \frac{M_t}{M_\infty}\right]\left[\ln\left[1 - \frac{M_t}{M_\infty}\right]\right] = \frac{4D_{ip}c_{is}}{r^2c_{io}}t \tag{47}$$

For spherical devices, the corresponding expression for the fractional drug release is

$$\frac{3}{2}\left[1 - \left[1 - \frac{M_t}{M_\infty}\right]^{2/3}\right] - \frac{M_t}{M_\infty} = \frac{3D_{ip}c_{is}}{r^2c_{io}}t \tag{48}$$

Solutions of the Higuchi model with finite external mass transfer resistance according to equation 44 have been presented by Paul and McSpadden (28) using pseudo–steady-state approximation and the boundary condition described by equation 29, with $c_i = 0$. For example, the amount of drug released as a function of release time is expressed by equation 49:

$$M_t = A\left[c_{io} - \frac{c_{is}}{2}\right]\left\{\left[\left[\frac{D_{ip}}{k}\right]^2 + \frac{2D_{ip}c_{is}t}{\left[c_{io} - \frac{c_{is}}{2}\right]}\right]^{1/2} - \frac{D_{ip}}{k}\right\} + \frac{Ac_{is}}{2}\left\{\frac{\left[\frac{D_{ip}}{k}\right]^2}{\left[\left[\frac{D_{ip}}{k}\right]^2 + \frac{2D_{im}c_{is}t}{\left[c_{io} - \frac{c_{is}}{2}\right]}\right]^{1/2}} - \frac{D_{ip}}{k}\right\} \tag{49}$$

Clearly as the mass transfer coefficient increases to infinity (no mass transfer limitations), this equation reduces to the Higuchi model (equation 45). The pseudo–steady-state analysis is the only approximate modeling effort that is included in this contribution because of historical reasons and its wide acceptability by researchers working in this area.

However, exact solutions of this problem are available through the work of Paul and McSpadden (28). The total amount of drug released can be calculated by equation 50, where x^* is the position of the dissolution front of the dissolving drug, which can be determined by solving equation 51 either numerically or using tabulated values from Crank's monograph (7):

$$\frac{M_t}{A} = \frac{2c_{is}}{\operatorname{erf}\left[\frac{x^*}{2\sqrt{D_{ip}t}}\right]}\left[\frac{D_{ip}t}{\pi}\right]^{1/2} \tag{50}$$

$$x^*\left[\frac{\pi}{D_{ip}t}\right]^{1/2}\exp\left[\frac{x^{*2}}{4D_{ip}t}\right]\operatorname{erf}\left[\frac{x^*}{2\sqrt{D_{ip}t}}\right] = \frac{c_{is}}{c_{io} - c_{is}} \tag{51}$$

Equation 50 corresponds to equation 45 for slabs under the boundary conditions of the Higuchi model. If in addition to this model, mass transfer limitations are taken into consideration (equation 29), an asymptotic solution may be obtained in the form of equation 52:

$$\frac{M_t}{A} = \frac{2c_{is}}{\operatorname{erf}\left[\frac{x^*}{2\sqrt{D_{ip}t}}\right]}\left[\frac{D_{ip}t}{\pi}\right]^{1/2} - \frac{D_{ip}c_{io}}{k} \tag{52}$$

Once again, x^* can be estimated from equation 51.

Mathematical problems of drug release from matrix systems initially loaded at concentrations above the solubility limit of the drug in the polymer are problems of moving boundaries, because the front of dissolved drug/undissolved drug clearly moves into the polymer as release proceeds. These problems are known as Stefan or Stefan–Neumann problems (31). Alternative solutions using moving coordinate systems may be obtained by analogy to mathematical solutions discussed by Danckwerts (32).

Certain problems require numerical or approximate solutions. For example, Lee (33) has recently discussed a variety of diffusional release problems for slabs, spheres, and cylinders using Stefan-type analysis, and he has offered some approximate solutions.

Narasimhan and Langer (34) have recently studied the role of the burst effect in an essentially zero-order, controlled-release, coated hemispherical polymeric device containing a single, small orifice in its center face. Asymptotic solutions of their model show that the burst effect is controlled by the solubility of the drug in the release medium and by the drug-diffusion coefficient. The rates of drug release during the burst effect ($t \to 0$) and the steady state ($t \to \infty$) are related by

$$\frac{[dM/dt]_{t\to 0}}{[dM/dt]_{t\to\infty}} = \frac{16}{B(6 + B)} \tag{53}$$

Here B is given by c_s/c_0. The parameter c_0 is the initial drug loading, and c_s is the solubility of the drug in the release medium. From equation 53, it can be concluded that the burst effect is significant for systems where $B \sim O(1)$. It was shown that as drug solubility increased, the drug released faster, and the velocity of the interface between dissolved and dispersed drug is higher. The model solutions established that the burst behavior could be manipulated by using different initial drug distributions. Using the model, conditions under which the burst effect could be

minimized/maximized were established. Figure 4 shows a plot of the fraction of bovine serum albumin released from an inwardly releasing ethylene-vinyl acetate (EVAc) hemisphere as a function of time, where the release as well as the burst period is zero order.

Porous Matrix Systems. Modeling of the drug-release kinetics of porous matrix systems is still at a rather primitive stage, despite significant developments in recent years. Before using existing models, one has to consider several aspects of the physics of this diffusion phenomenon.

1. If the polymer phase is hydrophobic, swelling is negligible, and the problem can be treated as a constant-volume diffusion problem. However, if the polymer phase is hydrophilic, two modeling routes may be considered.
2. If the pores are large enough to be thought of as "channels" for diffusion (pore diameter greater than 150 Å), diffusion occurs predominantly through these water-filled pores and the effective diffusion coefficient, D'_{eff}, of equation 21 must be used. However, if the pores are smaller than 100 Å, then the diffusion coefficient, D_{ip}, through the swollen polymer can be used without corrections for porosity and tortuosity.
3. Phenomena related to drug partition in the pore walls and hindered diffusion due to the relative size of the drug with respect to the pores can be addressed by including the parameters K_{p} and K_{r} in the diffusion coefficient through water and using the effective diffusion coefficient, D_{eff}, described by equation 23.
4. Phenomena related to elastically changing pore walls must be taken into consideration.

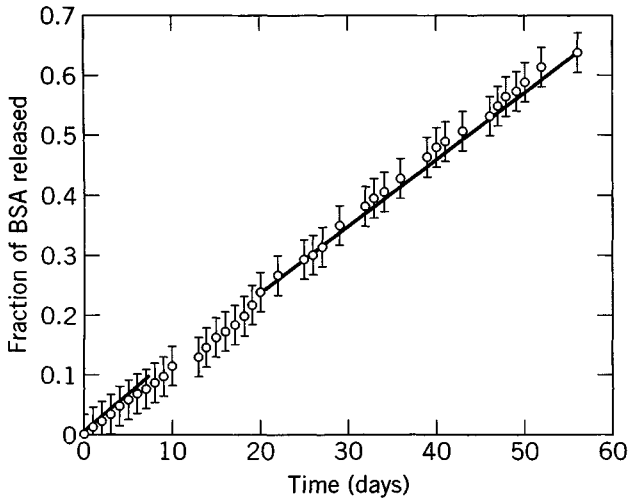

Figure 4. Fraction of bovine serum albumin released as a function of time from coated EVAc hemispheres. The open circles represent experimental data (37) while the line represents model predictions. *Source:* Reproduced with permission from Ref. 34. Copyright 1997 Elsevier.

Therefore, the models developed in "Reservoir (Membrane) Systems" and "Dissolved Drug, Nonporous Systems" may be used for porous systems, with D_{ip} for porous hydrophilic systems of pore size smaller than 100 Å or with D_{eff} for porous hydrophilic systems of pore size larger than 100 Å or with all types of porous hydrophobic systems. Release kinetics for porous systems containing drug at concentrations higher than the solubility limit are somewhat more difficult to model, and equations cannot be written by simple analogy to the models given in "Dispersed Drug, Nonporous Systems."

A traditional pseudo–steady-state model for these systems was developed by Higuchi (35) and predicts drug release according to equation 54, where D_{eff} is given by equations 21 or 23:

$$M_{\text{t}} = A[D_{\text{eff}}c_{\text{is}}(2c_{\text{io}} - \varepsilon c_{\text{is}})t]^{1/2} \tag{54}$$

These models may be unable to describe many experimental results with porous systems loaded with drug above its solubility limit in water.

Two alternatives have been proposed to explain the experimental results. The first model (36) assumes that dissolution of the drug in the pores is the controlling mechanism of release and describes overall diffusion in terms of a modified diffusion equation where the term $k(c_{\text{is}} - c_{\text{i}})$ is a dissolution-dependent contribution to diffusion:

$$\frac{\partial c_{\text{i}}}{\partial t} = D_{\text{eff}}\frac{\partial^2 c_{\text{i}}}{\partial x^2} + k(c_{\text{is}} - c_{\text{i}}) \tag{55}$$

This model can be used under the assumptions of pseudohomogeneous dissolution and of initially unfilled pores in the matrix system, as is the case with tablets and other pharmaceutical systems produced by compression of solids. For finite slabs of thickness δ and zero surface concentration, the amount of drug released is expressed by equation 56, where α_{n} is defined as in equation 57:

$$\frac{M_{\text{t}}}{A} = \left[c_{\text{is}}\sqrt{D_{\text{eff}}k}\tanh\left[\frac{\delta}{2}\sqrt{\frac{k}{D_{\text{eff}}}}\right]\right]t - \frac{c_{\text{is}}D_{\text{eff}}}{\delta}\sum_{n=0}^{\infty}\frac{1 - \exp[-D_{\text{eff}}\alpha_{\text{n}}^2 + k)t]}{(D_{\text{eff}}\alpha_{\text{n}}^2 + k)^2} \tag{56}$$

$$\alpha_{\text{n}} = \frac{(2n + 1)}{\delta}\pi \tag{57}$$

It is interesting to note that at long times, the last term of equation 56 is small, and zero-order release is predicted.

The second modeling effort assumes (11) that solid drug fills completely the pores and dissolution occurs. This phenomenon can be modeled as an unsteady-state, moving-boundary (Stefan-type) problem. For this case, it can be shown that the released drug can be determined by equation 58:

$$\frac{M_{\text{t}}}{A} = \frac{2\varepsilon^{2/3}c_{\text{is}}}{\text{erf}\left[\dfrac{x^*}{2\sqrt{D'_{\text{iw}}t}}\right]}\left[\frac{D'_{\text{iw}}t}{\pi}\right]^{1/2} \tag{58}$$

The position of the front x^* can be determined by equation 59:

$$x^*\left[\frac{\pi}{D'_{iw}t}\right]^{1/2}\exp\left[\frac{x^{*2}}{4D'_{iw}t}\right]\mathrm{erf}\left[\frac{x^*}{2\sqrt{D'_{iw}t}}\right] = \frac{c_{is}}{\rho_i M_i} \quad (59)$$

The diffusion coefficient, D'_{iw}, is defined by equation 60; ϵ is the porosity upon complete dissolution, ρ_i is the density of the drug, and M_i is its molecular weight.

$$D'_{iw} = D_{iw}/\tau \quad (60)$$

Because of the assumptions made, this model can be used to describe the unexpected release behavior of drugs from dense, hydrophobic matrix systems such as those studied by Langer and co-workers (10,37).

SWELLING-CONTROLLED SYSTEMS

Swelling-controlled release systems are rather difficult to model owing to complex macromolecular changes occurring in the polymer during release. These systems consist of water-soluble drugs that are initially dispersed in solvent-free glassy polymers. If a slab is placed in contact with water, diffusion of water into the polymer will be observed depending on the thermodynamic interactions between the polymer and the solvent. This dynamic swelling phenomenon may lead to considerable volume expansion of the original slab. Two fronts (interfaces) are characteristic of the swelling behavior:

1. The swelling interface that separates the rubbery (swollen) state from the glassy state and that moves inward with velocity v
2. The polymer interface that separates the rubbery state from water and moves outward

Swelling of glassy polymers is accompanied by macromolecular relaxation, which become important at the swelling interface (38). This relaxation, in turn, affects the drug diffusion through the polymer, so that Fickian or non-Fickian diffusion may be observed. In these systems, drug release is controlled by the velocity of the water penetration front, v, because drug diffusion through the glassy polymer is negligible.

Mathematical modeling of this type of diffusion behavior clearly belongs to a category of mathematical problems known as Stefan, Stefan–Neumann, or moving-boundary problems. The Fickian diffusion equation 2 is solved with concentration-dependent or concentration-independent drug-diffusion coefficients and moving-boundary conditions (at the two fronts). If, in addition, one imposes problems of non-Fickian diffusion due to macromolecular relaxation, then the mathematical analysis becomes rather complicated (39). Some attempts to describe this behavior have been discussed by Peppas et al. (40), and a more complete literature review is given elsewhere (31).

A common procedure for analyzing experimental data of drug release from swelling-controlled release systems is by fitting them to equation 5 and determining the exponent n. As discussed before (9), the value of this exponent is characteristic of the Fickian or non-Fickian diffusion behavior of swelling-controlled release systems. It is possible to derive sufficient and necessary conditions for obtaining zero-order release from swelling-controlled release systems (41) by examining the dimensionless number, Sw, the so-called swelling interface number, defined according to equation 61:

$$Sw = \frac{v\delta(t)}{D_{ip}} \quad (61)$$

When $Sw \ll 1$, zero-order release should be expected, whereas for values of $Sw \gg 1$, Fickian diffusion is observed.

Kou et al. (42) proposed a model for drug diffusion through swellable cylinders with Fickian equations and concentration-dependent diffusion coefficients. Cohen and Erneux (43,44) presented a treatment of free boundary problems that had fundamental ideas in solving drug delivery problems in swellable systems.

The first detailed model of drug transport with concentration-dependent diffusion coefficients and swelling was proposed by Korsmeyer et al. (45). Lustig and Peppas (46) proposed a free-volume–based model with three-dimensional swelling beyond the point where the fronts meet. Lustig et al. (47) proposed a mathematical model for drug release based on rational thermodynamics, containing a full viscoelastic description of the polymer and concentration-dependent transport of the drug, with three-dimensional swelling.

Drug release from environmentally responsive polymeric systems has also been studied in great detail. Peppas and Brannon-Peppas (48) studied the drug-release rates in a system that responded to changes in temperature. The time-dependent response of the drug was also studied by Brannon-Peppas and Peppas (49) and by Bell and Peppas (50). Models for drug delivery from polymeric systems that responded to changes in the pH and ionic strength of the surrounding medium were proposed by Hariharan and Peppas (51,52).

In addition to these important modeling efforts, researchers have sought to analyze non-Fickian transport with relatively simple equations. One such effort relating the fractional release of the drug to time uses the so-called swelling area number (53). The swelling area number was defined as

$$Sa = \frac{1}{D}\frac{dA}{dt} \quad (62)$$

Here, A is the area available for drug release, and D is the drug-diffusion coefficient. The swelling area number, Sa, has been used to describe systems with varying area (see Fig. 5) due to swelling (specifically the Geomatrix® systems).

CHEMICALLY CONTROLLED SYSTEMS

Chemically controlled release systems include all polymeric formulations where drug diffusion is controlled by the dissolution of the polymer matrix. Modeling of these systems is similar to that followed for swelling-controlled release systems, because mass erosion replaces the phase

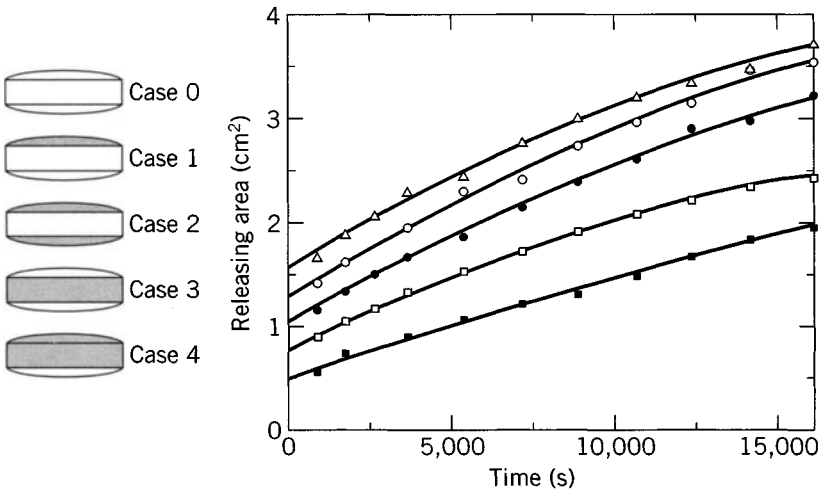

Figure 5. Releasing area as a function of time for the five systems shown. *Source:* Reproduced with permission from Ref. 53. Copyright 1988 Elsevier.

erosion (moving front) observed in swelling-controlled systems. Within this category, there are systems where a chemical reaction triggers the release. That reaction may be induced by hydrolysis, whether enzymatic or biochemical.

The difference between bioerosion and biodegradation is that the latter is the actual degradation, the breaking down of the polymer due to a chemical reaction that is taking place. The polymer will break down into small-molecular-weight materials. A matrix like that would be a polymeric material with the drug molecularly distributed throughout. In the case of biodegradable materials, the drug does not have to be molecularly dispersed; it can also be microscopically dispersed with large particles. The release process is controlled by a surface chemical reaction that will break down the polymer, giving oligomers and small-molecular-weight compounds. As time elapses, the geometry is unchanged but smaller, and the drug that was incorporated in the lost portion is free to dissolve and diffuse. That is why biodegradable systems, with a first-order biodegradation reaction with respect to the area, yield zero-order release for a planar device where the area remains constant.

Bioerosion is a process whereby a phase of the carrier is lost, not by chemical reaction but by dissolution. When bioerodible polymers are brought in contact with physiological fluids, the fluids simply dissolve the polymer rather than break it down. The definition is blurred, and people speak of bioerodible systems when they mean biodegradable systems.

In most chemically controlled systems, the geometric shape of the device controls drug release. The controlling mechanism may be either polymer dissolution or reaction and degradation at the polymer surface. Depending on the type of degradation reaction, these systems may be classified as chemically degradable (e.g., by hydrolysis) or biodegradable (e.g., by enzymatic reaction) controlled-release systems.

Shrinking-core models provide the most accurate description of this release. Cooney (54,55) developed simple expressions for drug release from cylindrical, spherical, and cylindrical devices.

Hopfenberg (56) derived expressions for drug release from erodible slabs, cylinders, and spheres. If one recognizes that the erosion rate is proportional to the continuously changing area of the device, A_e, one may write

$$\frac{dM_t}{dt} = k_e A_e \tag{63}$$

Solution of this equation for various geometries gives the following general expression

$$\frac{M_t}{M_\infty} = 1 - \left[1 - \frac{k_e t}{c_{io} l}\right]^n \tag{64}$$

Here $n = 1$ for a slab of thickness $\delta = 2l$, $n = 2$ for a cylinder of radius $r = l$, and $n = 3$ for a sphere of radius $r = l$.

Mathematical models of erodible systems where drug release from the surface is also important have been recently discussed by Lee (57) and further analyzed elsewhere (58). In order to obtain zero-order release from such erodible devices, the drug distribution was studied (57,58). It was found that a sigmoidal type of initial drug distribution gave almost zero-order release (58). This effect is represented in Figure 6.

Thombre and Himmelstein (59) developed models to describe drug release from poly(orthoester)s. The boundary condition used to solve the transport–reaction problem is given by equation 29, where k_i now represents the reaction constant of species i. The diffusion–reaction model was solved in terms of typical Thiele moduli, φ_i, to describe the reaction–diffusion ratio and Biot numbers, Bi_i, to describe the mass transfer–diffusion ratio. The solutions were reported as fractional amount of each species as a function of time as shown in Figure 7.

$$\varphi_i = a\sqrt{\frac{k_i c_i}{D_i}} \qquad Bi_i = \frac{k_i a}{D_i} \tag{65}$$

where D_i is the diffusion coefficient of the ith species and a is the half thickness of the polymer film.

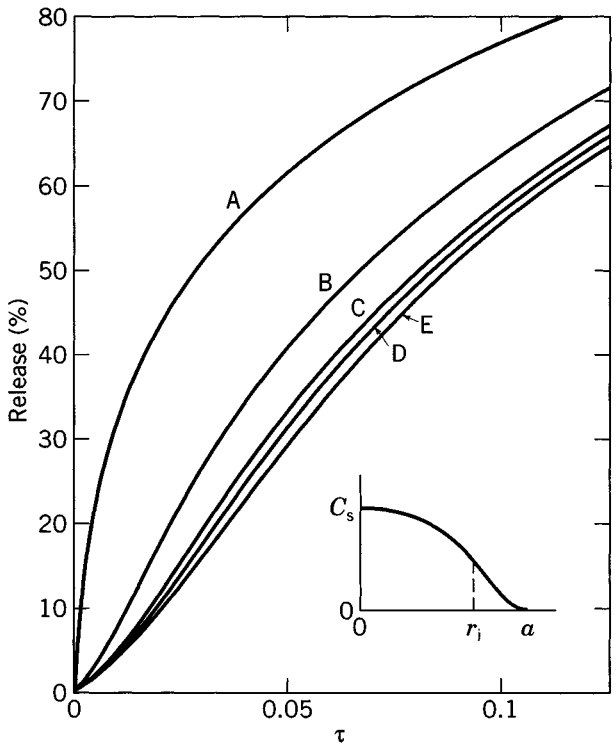

Figure 6. Effect of sigmoidal initial drug concentration distribution on the cumulative release from spherical matrices. Curves A through E represent different values of ξ_i. ξ_i is the initial position of the inflection point in the concentration profile. *Source:* Reproduced with permission from Ref. 58. Copyright 1986 Butterworth. The distribution function is

$$f(\xi) = \frac{1 - \exp\left[-0.5\left(\frac{1-\xi}{1-\xi_i}\right)^2\right]}{1 - \exp\left[-0.5\left(\frac{1}{1-\xi_i}\right)^2\right]}$$

Computer-aided methods (60,61) have also been used to model bioerosion. In these approaches, the polymer matrix is represented as the sum of individual matrix parts, and the erosion of each part is regarded as a random event. Comparisons with experiment yielded good agreement. This analysis was later extended (62) to describe the release of a monomer from an eroding polymer. The model predicts parameters like the porosity of the eroding polymer, the matrix weight, and amount of monomer released. The analysis could be extended to model drug release from such systems (63,64).

Pendent Chain Systems

Models have been proposed by Anderson and his coworkers (65) to describe cortisol hydrolysis from bound PGA systems. The hydrolysis starts at the surface, giving hydrophilic polymer. The rate of water permeation, R_w, in the hydrophobic zone and the rate of hydrolysis, R_h, are important parameters in tuning the release kinetics.

OTHER ASPECTS OF RELEASE KINETICS MODELING

Osmotic Systems

Osmotic systems for drug delivery are designed by applying irreversible thermodynamics and the Kedem–Katchalsky (66) analysis. The total volume flow, J_u, and the total exchange flow, J_D, are respectively given by

$$J_u = L_p \Delta p + L_{pD} \Delta \pi_s \qquad (66)$$
$$J_D = L_{Dp} \Delta p + L_D \Delta \pi_s$$

Here, L_i ($i = p, pD, Dp, D$) represents Onsager coefficients, Δp is the hydrostatic pressure, and $\Delta \pi_s$ is the osmotic pressure of the solvent.

The systems under consideration may also be defined by the reflection coefficient, σ, and the permeability coefficient, L_p. The term σ is defined as

$$\sigma = -\frac{L_{pD}}{L_p} \qquad (67)$$

The osmotic pressure is given by

$$\Delta \pi_s = NRT/V = cRT \qquad (68)$$

where N is the number of moles of the solvent, V is the solvent volume, R is the universal gas constant, and T is the temperature.

The volume flux, dV/dt, for a membrane of thickness δ and cross-sectional area A is given by

$$\frac{dV}{dt} = \frac{A}{\delta}(\sigma \Delta\pi_s - \Delta p) \tag{69}$$

The value $\sigma = 0$ represents a coarse filter, and $\sigma = 1$ represents an impermeable drug. For large orifices,

$$\Delta\pi_s \gg \Delta p \tag{70}$$

Hence,

$$\frac{dV}{dt} = \frac{A}{\delta} L_p \sigma \Delta\pi_s = \frac{A}{\delta} k \Delta\pi_s \tag{71}$$

Using $dM/dt = cdV/dt$, we have

$$\frac{dM}{dt} = \frac{A}{\delta} kc\Delta\pi_s \tag{72}$$

Hence, the drug-release rate in osmotically controlled systems can be tuned to achieve zero-order kinetics.

Dissolution-Controlled Systems

Dissolution-controlled systems have the additional characteristic that in addition to polymer swelling and drug diffusion through the continuously changing phase, they are accompanied by slow disentanglement of the polymer chains, leading to complete dissolution of the carrier. Obviously, this mechanism will occur only in un-cross-linked polymer carriers.

Harland et al. (67) formulated for a model for drug release in a dissolving polymer–solvent system. The transport was assumed to be Fickian, and mass balances were written for the drug and the solvent at the glassy–rubbery interface and at the rubbery–solvent interface. The important parameters identified in the phenomenon were the polymer volume fraction c^* at the glassy–rubbery transition, the polymer volume fraction c_d for disentanglement of the chains, and the dissolution–mass transfer coefficient, k. The expression for drug release as a function of time was obtained as

$$\frac{M_d}{M_{d,\infty}} = \frac{c_b}{ac_{cd}} \cdot \left(\sqrt{\frac{2[-D_s(c^* + c_s - c_d - c_b) + D_d(c_s - c_b) + D_d/c_b]^2(1 - c^* - c_s)t}{D_s(2 - c^* - c_s)(c^* + c_s - c_d - c_b) + D_d(c^* + c_s)(c_s - c_b)}} + kc_b t \right) \tag{73}$$

Here, D_s is the diffusion coefficient of the solvent in the polymer, and D_d is the diffusion coefficient of the drug in the polymer. The parameter c_b is the volume fraction of the drug in the bulk. This model can predict both Fickian as well as non-Fickian behavior. It is to be noted that front synchronization leads to zero-order release in dissolution-controlled systems. The predicted normalized drug release as a function of time is shown in Figure 8.

The previous model was modified by Narasimhan and Peppas (68) by accounting for macromolecular chain disentanglement. An expression for the fraction of the drug released was derived as

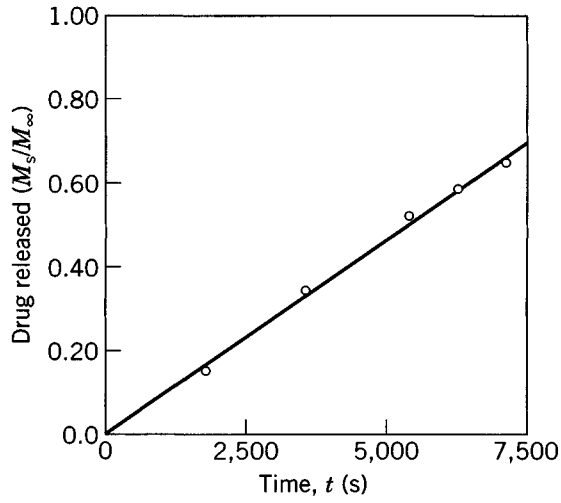

Figure 8. Normalized drug release as a function of time for drug–polymer tablet dissolution system. *Source:* Reproduced with permission from Ref. 67. Copyright 1985 Plenum.

$$\frac{M_d}{M_{d,\infty}} = \frac{v_{d,eq} + v_d^*}{2l}(\sqrt{2At} + Bt) \tag{74}$$

Here, A and B are given as

$$A = D(v_{1,eq} - v_1^*)\left(\frac{v_{1,eq}}{v_{1,eq} + v_{d,eq}} + \frac{1}{v_1^* + v_d^*}\right) + D_d(v_d^* - v_{d,eq})\left(\frac{v_{d,eq}}{v_{1,eq} + v_{d,eq}} + \frac{1}{v_1^* + v_d^*}\right) \tag{75}$$

$$B = \frac{k_d}{v_{1,eq} + v_{d,eq}} \tag{76}$$

Here, l is the half-thickness of the polymer, D is the diffusion coefficient of the solvent, and D_d is the diffusion coefficient of the drug. v_1^* and v_d^* are equilibrium concentrations of solvent and drug, respectively. The parameter k_d is the disentanglement rate of the polymer chains and is calculated using reptation theory (69–71). Figure 9 shows the fraction of drug released as a function of α ($\alpha = A/B$) and dimensionless time τ ($\tau = Bt/l$). It is observed that the model captures Fickian behavior, anomalous transport, as well as zero-order release.

For the drug-release rate to be zero order (see equation (74)), $B^2/A \gg 1$. Hence, choosing a polymer–drug–solvent system such that this inequality is satisfied would result in a zero-order drug release. This model also captures the transition between Fickian and non-Fickian type behavior.

When the polymer carrier is semicrystalline, the process of carrier dissolution is preceded by a process of phase erosion of the crystalline region to an amorphous region. Under certain conditions, this transition may lead to relaxation-controlled conditions of drug transport. Drug release from a new class of such systems—crystal dissolution–controlled-release systems—was modeled by Mallapragada and Peppas (72). In the presence of a thermodynamically compatible solvent, polymer crystals may start dissolving by crystal unfolding and disentanglement. In these dissolving phase-erosion systems, the drug-

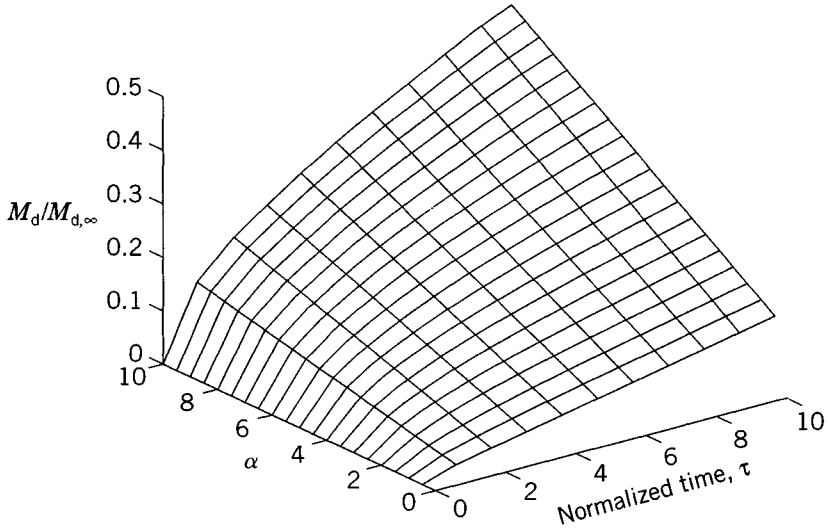

Figure 9. Predicted normalized drug released, M_d/M_d, as a function of normalized time, τ ($\tau = Bt/l$), for different values of α ($\alpha = A/B$). *Source:* Reproduced with permission from Ref. 68. Copyright 1997 ACS.

release rate is controlled by the transformation of the crystalline phase of the polymer to the amorphous phase. The crystalline regions are modeled as impermeable structures that do not permit drug diffusion. Therefore, as the polymer swells and drug is released, the concentration gradient for drug diffusion decreases, but simultaneously, disappearance of part of the crystalline phase causes an increase in the overall drug diffusion coefficient from the polymer. If these two effects compensate for each other, then zero-order drug release can be obtained.

A mathematical model was proposed by coupling crystal-unfolding theories with free-volume–based drug-diffusion theories (18) to predict conditions under which zero-order drug release can be obtained. Expressions were written for changes in the volume fractions of the crystalline polymer, amorphous polymer, and the drug as functions of time. The coupled partial differential equations were solved with the appropriate boundary conditions to yield drug-release profiles as functions of time under various conditions (Fig. 10). Factors affecting the drug-release rate were found to be the polymer degree of crystallinity, crystal size distribution, molecular weight of the polymer, the polymer–water interaction parameter, and the crystal-unfolding rate. The release from these systems was found to be non-Fickian.

CONCLUSIONS

Drug release through controlled-delivery polymeric systems has been modeled predominantly by steady-state and transient description of drug diffusion by use of Fick's law. The correct interpretation of release kinetics from such drug-release models depends on the mechanism of the release itself, the polymer microstructure, and the conditions of the experiment (in other words, the boundary conditions). More accurate mathematical descriptions are necessary in modeling drug release in swellable and porous polymeric systems. Consideration of aspects such as countercurrent solvent diffusion, chain disentanglement, polymer state transitions, degree of crystallinity, and porous structure will enhance understanding and interpretation of release kinetics data from existing models. The advent of codelivery polymeric systems has necessitated the need for models incorporating interacting and noninteracting multicomponent diffusion through polymers.

INTRODUCTION

Inhalation therapies have until now primarily provided fast-acting treatment for respiratory illnesses such as asthma and chronic obstructive pulmonary disease (COPD). Relative to oral delivery, inhalation of bronchodilators, corticosteroids, and other antiinflammatory agents to the airways often produces therapeutic levels in the respiratory tract while maintaining low systemic concentrations and thereby minimizing side effects (1–6). More recently, inhalation therapies for the systemic delivery of proteins and peptides to the body have made important advances in human clinical trials, notably owing to the success with which many macromolecules permeate the alveolar/blood barrier once inhaled (7). For these newer inhalation therapies, inhalation systems are often required that achieve high reproducibility and efficiency; this need has propelled active research and development in the inhalation drug delivery field (8).

The heightened scientific and industrial attention paid to inhaled drug delivery has exposed an unmet need for the controlled release of inhaled drugs (9). Controlled release of drugs in the respiratory system can benefit a variety of existing and future therapies whose success depends critically on multiple daily dosing. Examples include sustained release of bronchodilators and corticosteroids for asthma or drugs such as insulin for diabetes. A logical strategy to achieve sustained release of drugs in the respiratory tract involves encapsulating drugs in slowly degrading particles that can be inhaled. This strategy can, however, be foiled by the relatively rapid (less than a day) natural clearance of insoluble particles from the respiratory system. Efforts are therefore underway to create sustained-release particles that safely avoid respiratory clearance mechanisms, thereby permitting the development of practically useful controlled drug release in the lungs (10–15).

LUNG MORPHOLOGY AND PHYSIOLOGY

The human lung is often conceptually divided into conducting and respiratory zones. The conducting zone serves as the relatively long channel for inhaled air and consists of trachea, bronchus, bronchioles, and terminal bronchioles (Table 1). Insoluble particles deposited in this zone are propelled upward by means of cilia action within the mucus layer residing on the surfaces of the conducting zone. Eventually the insoluble particles reach the pharynx, where they are swallowed. The clearance of insoluble particles from the conducting airways by mucociliary activity is usually complete in 12–24 h (16–19). Respiratory bronchioles are located beyond the terminal bronchioles, followed by alveolar ducts and alveolar sacs; together they comprise the respiratory zone, where primary gas exchange occurs between the air spaces and the blood (Table 1). Insoluble particles deposited in this zone are quickly engulfed by alveolar macrophages, whose ability to chemically break down engulfed material makes them the nemesis of inhaled drugs.

The average alveolar surface area in human lungs (20) is 102 ± 21 m^2, corresponding to 95% of the total surface area in the lungs. The total surface area of alveoli in contact with blood capillaries is approximately 75 m^2 (roughly 40 times greater than the external body surface area) (21). This broad area facilitates the lung's function as the primary gas exchange organ (the lung receives all the blood circulated through each of the peripheral organs and tissues, whereas the abdominal organs receive about 24% of body blood [22]). The epithelial lining of the alveolar spaces, the most significant absorption barrier separating blood from the alveolar lumen (23), has an average thickness of only 0.2 μm—approximately 34 times smaller than the diameter of an average red blood cell (23). The thinness of this barrier and its extensive surface area permits a high accessibility of inhaled drugs to the blood stream. This makes the alveolar region a natural target for inhaled drugs destined for the systemic circulation.

AEROSOL DELIVERY TO THE RESPIRATORY TRACT

To possess a high likelihood of depositing in the alveolar zone of the lungs, inhaled particles must exhibit an aerodynamic diameter in the range of 1–3 μm (25–28). The aerodynamic diameter of a spherical particle (d_a) can be expressed as the product of the geometric diameter (d) and the square root of the particle mass density ρ (R. Vanbever et al., unpublished data) (appropriately normalized to give the proper units). It can be shown that a spherical particle

Table 1. Approximate Dimensions of the Human Lung.

Generation	Length (cm)	Diameter (cm)	Number	Cross-sectional area (cm^3)
Trachea (0)	12.0	1.80	1	2.54
Bronchi (1)	4.8	1.22	2	2.33
Bronchi (2)	1.9	0.83	4	2.13
Bronchi (3)	0.8	0.56	8	2.00
Bronchioles (4–16)	1.3–0.12	0.45–0.06	16–60,000	2.48–180.0
Respiratory bronchioles (17–19)	0.12–0.10	0.06–0.05	60,000–500,000	180–1,000
Alveolar ducts (20–22)	0.10–0.05	0.05–0.04	5×10^5–8×10^6	10^3–10^4
Alveolar sacs (23)	0.05	0.04	8×10^6	10^4

Source: Ref. 24.

of any mass density, in flight, will settle with a velocity that depends only on its aerodynamic diameter (R. Vanbever et al., unpublished data). The concept can thus be used to predict a particle's expected lung deposition performance following inhalation. Numerous experimental (25–28) and theoretical (29–32) studies have shown that particles with aerodynamic diameters in the 1- to 3-μm-range deposit minimally in the mouth and throat and maximally in the lung's alveolar region. Tracheobronchial deposition, generally not desired for inhalation therapy, is maximized for mean d_a between approximately 8–10 μm owing to inertial impaction, whereas central airway deposition by gravity occurs maximally for $3\mu m < d_a < 5\mu m$. Particles possessing d_a less than 1 μm are mostly exhaled, and particles larger than about 10 μm have little chance of making it into the mouth.

For these reasons, inhalation therapies today rely on liquid or dry-powder aerosols comprised of particles with mean diameters in the range of 1–5 μm. Therapeutic particles in this size range are found to produce optimal therapeutic (whether systemic or local) effect.

However, aerosols formed of 1–5 μm particles, in addition to rapidly clearing from the lungs, can aggregate prior to delivery (33). This produces poor efficiency of delivery from standard inhaler devices; hence, devices on the market deliver only about 10% of an inhaled dose into the lungs (34,35). This inefficiency magnifies patient-to-patient variability and can lead to patient discomfort, as manifested in coughing or bronchospasm.

One way to address this problem involves adjusting inhalation procedures. An optimal inhalation maneuver appears to involve a slow, deep inhalation to reduce impaction losses in the orapharynx, with about 10 s of breath hold to allow particles that enter the lung to settle by gravity (36–41). Pulmonary deposition can also be greatly affected by patient inspiratory flow rate, as inertial impaction of particles in the mouth and throat increases sharply with increasing flow rate (42,43).

Greater progress has been achieved by modifications to the inhaler device. Inhalation devices broadly fall into three categories: pressurized metered-dose inhalers (MDIs), nebulizers, and dry-powder inhalers (DPIs). The most commonly used inhalers on the market are MDIs; they contain active ingredient as a solution or as a suspension of fine particles in a liquefied propellant (often a chlorofluorocarbon, CFC) held under high pressure. The drug is emitted through an orifice from a metering valve. Droplets of a MDI tend to exit the orifice at a high velocity, potentially causing extensive orapharyngeal deposition. New breath-activated devices (44,45) now address this problem, and new non-CFC propellants address the CFC concern.

The typical maximum drug dose delivered by a single actuation of a MDI is around 1 mg (46). Nebulizers do not require propellants and can generate large quantities of small droplets capable of penetrating into the lung. As in the case of MDIs, new nebulizer systems avoid the problems of older generation nebulizers (bulk, excessive mouth–throat deposition) though they continue to be considered impractical for daily portable use. Given the concern about CFC's negative effects on the ozone layer, a great deal of work has been done to develop DPI systems. Although DPIs are sold widely in Europe, their use is still limited in other parts of the world, such as the United States. Current developments in the field may change this situation. DPIs have the attraction of storing the inhaled drug in a dry state, which often carries with it advantages of long-term stability and sterility. New generation DPIs modulate flow rate dependence and deaggregate powder, leading to significant improvements in device performance (8). Depending on the device, DPIs deliver either quantities of drug similar to MDIs (1–3 milligrams or less) or in certain cases considerably more.

DPIs may be most useful for controlled-release applications, as they can be maintained on the shelf in a dry state prior to delivery. On the other hand, MDIs might prove useful as well upon appropriate choice of propellant.

FAST-ACTING INHALATION THERAPIES

The mainstay of asthma treatment is the inhalation of a bronchodilator, such as albuterol, for fast-acting relief from bronchoconstriction and a corticosteroid, such as beclamethasone or fluticasone, for antiinflammation protection (1–6). Other bronchodilators and corticosteroids are commonly inhaled, as are anticholinergics. All these inhalation therapies involve fast action and delivery from either a MDI, DPI, or both. Nebulization is the preferred route of delivery in the clinic for a variety of substances, including lung surfactant for surfactant-replacement therapy and DNase for cystic fibrosis (46). DNase is the sole inhaled protein currently on the market, although other proteins are being tested in the clinic, including insulin, salmon cal-

citonin, parathyroid hormone, and LHRH (7). Each of these clinical therapies involves fast delivery of protein to the systemic circulation, with a delivery profile similar to intravenous injection.

SUSTAINED DRUG DELIVERY

Notwithstanding the rapid clearance of inhaled insoluble particles from the lungs, many efforts have been made to achieve sustained drug delivery from an inhalation aerosol. Primarily inhaled drugs have been encapsulated inside liposomes and biodegradable polymers (47,48), though the most successful long-acting inhaled drug (salmeterol, or Serevent) was developed by chemical modification of a fast-acting drug (salbutamol) (49).

Liposomal systems, delivered to the lungs by nebulization, are among the most commonly used methods for sustained pulmonary drug delivery. Liposome-encapsulated drugs have been released over many hours following inhalation in animals and humans; these drugs include, for local delivery, cytotoxic agents, bronchodilators, and antimicrobial agents (50–56); for systemic delivery, drugs such as insulin (57,58) have been released slowly from liposomes as well. Drawbacks to the inhalation of liposomes include (*1*) their relatively short action owing to clearance (they can be eliminated rapidly by alveolar macrophages [59–62]); (*2*) their poor stability during storage and use (63); and (*3*) their apparent need for delivery by nebulization.

Biodegradable polymer microspheres as drug carriers have also been extensively investigated. Albumin (59–62) and polylactide-*co*-glycolide (PLGA) microspheres (64–67) have repeatedly been used to achieve the sustained release of drugs in the lungs (9). Both biodegradable materials appear to be nontoxic and nonimmunogenic, although few if any chronic toxicity studies appear in the literature (9). Another approach to obtaining sustained release from inhaled drug particles involves incorporating macromolecules such as dextran (68,69) or poly(ethylene glycol) (70,71) to reduce particle hydrophilicity. One of the primary drawbacks to this approach for lung delivery is the possibility of accumulation of macromolecular materials within the lung over an extended administration period owing to the relatively slow removal of these materials from the lungs (9).

These techniques, among others, have achieved little success at maintaining therapeutic action following a single inhalation for more than several hours (9) (Fig. 1). To overcome this limitation posed by the lungs' natural clearance mechanisms, a new method to achieve sustained release in the lungs has involved preparing insoluble particles with aerodynamic diameter in the 1- to 5-μm range yet with very low mass density so that particles possess geometric diameters significantly greater than 5 μm (10). This permits the penetration of particles deep into the lungs (owing to small aerodynamic diameter) yet lowers the degree of clearance, because (geometrically) large particles tend to be cleared less by phagocytosis than particles in the size range of 1–5 μm (72–74).

Several studies have now appeared in the literature demonstrating the ability to achieve sustained release of

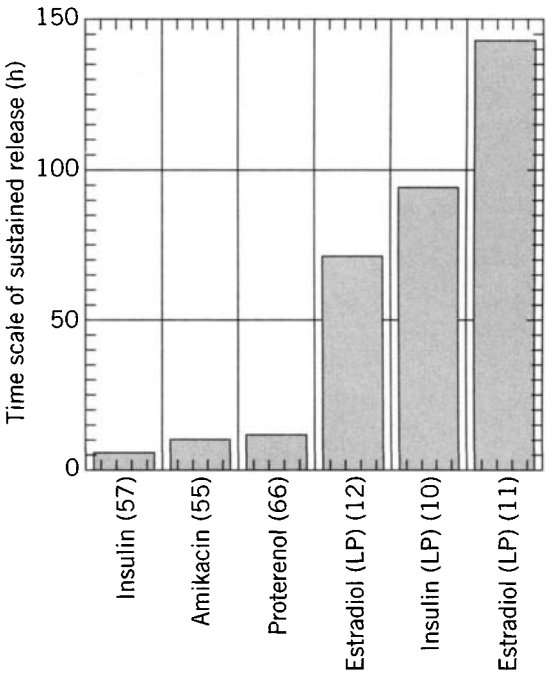

Figure 1. Approximate times of release in vivo from various controlled-release carriers following inhalation. The rightmost columns, indicated by the symbol LP, denote results from large porous particles in humans (12) and animals (10,11).

drugs from the lungs following a single inhalation of large porous particles for up to several days (10–15). In a first study, large, porous particles were prepared using PLGA biodegradable polymers and containing either insulin or testosterone for systemic delivery (10). For comparison purposes, small nonporous particles of similar composition and identical aerodynamic size were prepared. Both types of particles were aerosolized into the lungs of rats. In the case of the insulin aerosols, exogenous insulin appeared in the bloodstream for up to 96 h following inhalation of the porous particles, compared with 4 h for the nonporous particles. Given that the presence of insoluble particles in the lungs beyond 24 h indicates deep lung deposition and that bronchoalveolar lavage demonstrated that the large porous insulin particles were less avidly taken up by alveolar macrophages than the small nonporous insulin particles, the long release (>24 h) of insulin into the systemic circulation appears to owe to lower particle phagocytosis of large porous particles in the deep lungs. In another study, estradiol was formulated in large porous particles comprised of dipalmitoyl phosphatidyl choline (DPPC) as well as particles comprised of other soluble excipients (11). Particles were prepared with large size (approximately 10 μm) and low mass density (approximately 0.1 g/cc) as well as with small size (approximately 3 μm) and standard mass density. Both porous and nonporous powders were aerosolized into the lungs of rats. For two different formulations of the large porous estradiol particles, estradiol released into the systemic circulation following inhalation for 3 days or more. On the other hand, estradiol appeared in the systemic circulation following administration of two

different small nonporous particle formulations for a day or less. As porous and nonporous subcutaneously injected estradiol formulations acted therapeutically for several days, the short action of the small nonporous inhaled estradiol formulation appears again to relate to the more rapid clearance of small nonporous particles from the lungs. Sustained release in the estradiol study (11) was achieved by the use of both a relatively water-insoluble drug (estradiol) and insoluble surfactant (DPPC) rather than by biodegradable polymers.

One of the DPPC/estradiol formulations (Fig. 2) that achieved several-day delivery in rats has recently been inhaled in a human subject study using a simple DPI system (Fig. 3) (12). Inhalation of the porous dry powder at 30 L/min led to systemic estradiol absorption for 72 h, with estimated absolute bioavailability of 47%. The systemic absorption profile obeyed a two-phase model, with an initial fast elimination of estradiol from the body consistent with rapid absorption of estradiol from the lungs and systemic clearance and a secondary slow elimination phase, reflecting slow release from inhaled particles (Fig. 4). This study confirms that inhalation of large porous particles can produce sustained (>24 h) release of drugs into the lungs of humans as previously demonstrated in animals.

An example of sustained release of drugs from large porous particles for the treatment of respiratory disease has recently been described involving albuterol sulfate for asthma therapy (13). Albuterol sulfate particles were prepared using DPPC, human serum albumin, and lactose. Large porous and small nonporous albuterol particles were delivered as inhalation aerosols to the lungs of guinea pigs. To induce bronchoconstriction, immediately prior to measuring airway resistance (at selected intervals following inhalation of albuterol particles), carbachol was intramuscularly delivered. The small nonporous particles provided significant bronchodilatory effect for approximately 5 h following inhalation at a dose of 200 μg. The large porous albuterol particles produced sustained bronchodilation for at least up to 15 h (13).

As the porous-particle and other new sustained-release technologies emerge in the inhalation drug delivery arena, the possibility of several-day, or even several-week, sustained-release inhalation therapies arises. Clearly the desire (and ability) to achieve long drug release times in the lungs will place demands on drug dosing by inhalation. The current limitation of most inhalation systems (other than nebulizers) to inhaled doses of a few milligrams or less will need to be removed so that several tens of milligrams of drug can be inhaled in a single breath, a feat that does not appear too difficult even given currently emerging technologies (75). Another challenge will be to design sustained-release inhalation formulations that comprise materials that are safe for inhalation. Given the slow absorption of very large macromolecules in the lungs, standard sustained-release additives used to achieve oral sustained release (for example, methyl cellulose) may not be

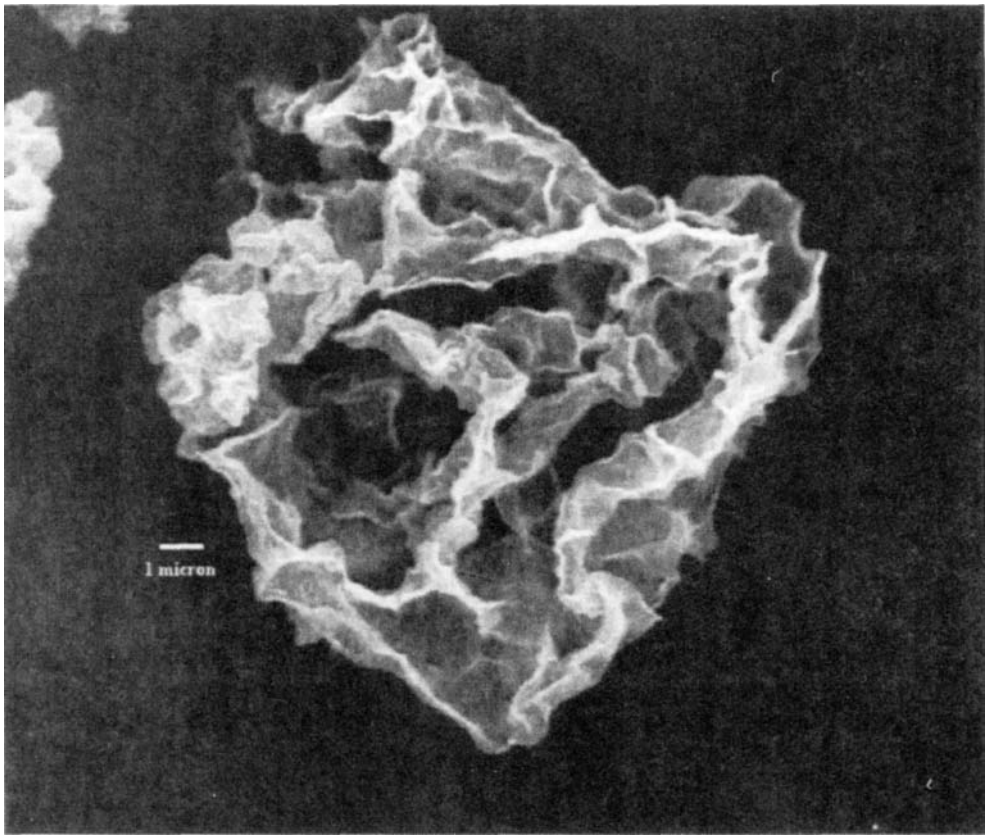

Figure 2. A large porous estradiol particle (12).

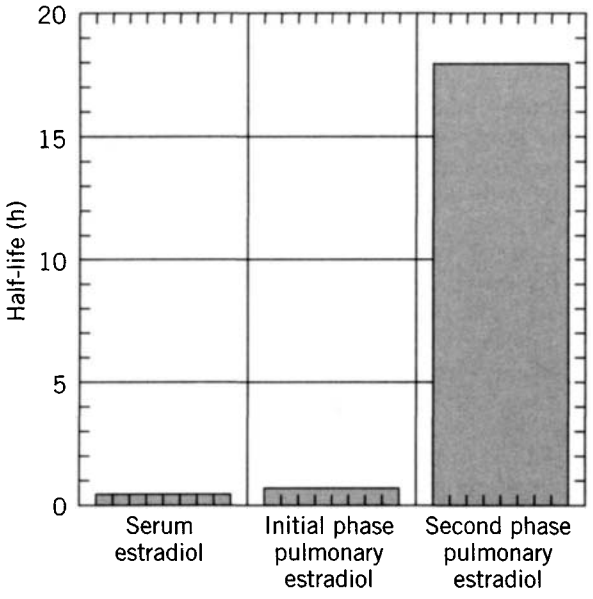

Figure 3. Approximate systemic half-lives of estradiol following intravenous injection and inhalation in humans. The second and third columns refer to clearance of estradiol following inhalation of a large porous particle formulation.

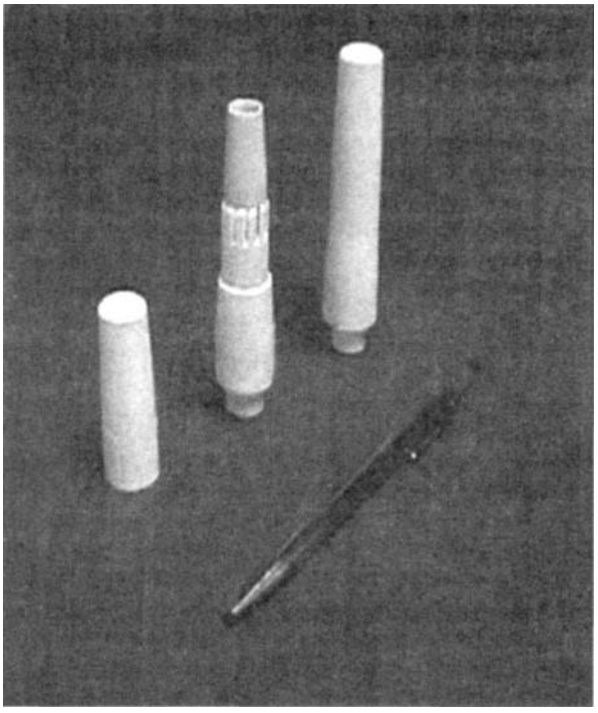

Figure 4. The AIR dry-powder inhaler.

appropriate for inhalation formulations. The search for excipients suitable for frequently dosed inhaled sustained-release formulations will play an important role in the practical success of sustained drug delivery in the respiratory tract.

SUMMARY

Efforts to achieve sustained drug delivery in the respiratory tract have been hindered in the past owing to the rapid clearance of insoluble drug particles in the lungs by mucociliary and phagocytic clearance processes, which remove or engulf particles within approximately 12–24 h after inhalation. Standard size and mass density liposomal and biodegradable polymer sustained-release systems have achieved drug release for modest periods, up to several hours. A new technique involving the production of large porous particles that display an ability to escape lung clearance has led to longer sustained release of drugs in the lungs, up to several days. One of the challenges of this technology will be to formulate sustained-release systems that do not lead to accumulation of materials in the lungs over time.

INTRODUCTION

The design of artificial organ systems typically incorporates those functions necessary for successful organ substitution and, if technology and circumstance permits, those of less critical value. Synthetic vascular grafts are replacements for organs of some chemical and physiologic complexity, but as a vessel substitute, their primary function is to provide a durable, relatively nonthrombogenic conduit for blood. Current larger-diameter vascular grafts accomplish this design goal remarkably well with simple synthetic materials. In smaller-diameter synthetic grafts, where the same synthetic materials perform less well, the absence of complex function may predispose them to failure. The abilities of controlled-release technologies may be able to compensate for the lack of some functions in smaller-diameter synthetic vascular grafts. This article will provide a limited review of the history of vascular grafts, the achievements of synthetic grafts of the past few decades, and some specific applications of controlled-release technology to synthetic grafts.

EARLY INVESTIGATIONS

In 1906 substitutive medicine made its debut into the emerging field of vascular surgery when, during a procedure to remedy a popliteal aneurysm, J. Goyanes replaced the degenerate vessel with a segment of autologous popliteal vein (1). The following year E. Lexer used this approach to repair an axillary artery gap defect with a saphenous vein (2). It could not have been known at the time but this seemingly intuitive resolution, the substitution of an autologous vein for a diseased or damaged artery, would become a preferred and commonplace solution in thousands of annually performed vascular surgeries many decades later. In part, such bold procedures owed their success to the endeavors in vessel repair of many surgeons of the prior three decades (3), but especially to Alexis Carrel, whose defining techniques on vascular anastomoses and philosophies concerning minimal trauma, meticulousness, and asepsis would illuminate the field and win him the Nobel Prize.

The following years witnessed radical and often disastrous attempts at vascular restitution. During World War I, desperate repairs of British soldiers' vascular injuries were sometimes attempted with silver tubes lined with paraffin while, across the battlefield, fresh cadaveric arterial and venous homografts were sutured into wanting German soldiers (2). Though patency of the silver tubes persisted in a few rare instances, the great majority of these and the homografts failed after thrombus formation. The use of paraffin-lined silver tubes as vascular substitutes was not as unconventional as would first appear because "foreign material" implant precedents, such as paraffined and gold-plated aluminum (4), glass (5), and even ivory (3) did exist.

During the following decades, novel vascular surgical concepts and practices were advanced but were concerned more with suture technique and repairing rather than replacing defects. It was not until the post–World War II era that as a result of many factors, vascular substitution again became a popular avenue of investigation. These factors—a growing need for an adequate vascular replacement, the proliferation of surgical research laboratories, the advent of arteriography, the expansion of blood banks, anticoagulant therapy, and the sudden abundance of military surgeons eager to return to career pursuits—invited vascular surgical discovery (3,6).

In 1947, Hufnagel reported on the use of methyl methacrylate (Lucite™) conduits in the "permanent intubation"

of aortas of mongrel dogs, citing the material's strength, smoothness, ready availability, low cost, low tissue response, and its delaying of coagulation times as justifications for its selection (7). These arterial prostheses, 1–3 cm in length, remained patent until the scheduled dates of sacrifice and autopsy, this being from 6 h to 6 months. In 1948, homografts again emerged as though the reasons for past failures were no longer applicable. This time, however, experimental processing was performed on the harvested vessels in hopes of improving the results. After storage in a chilled, isotonic saline solution containing 10% human serum, Gross et al. implanted arterial homografts in humans and dogs in an attempt to correct cardiovascular defects (8,9). In 1952 and 1953, Dubost et al. (10) and Oudot (11), respectively, performed and reported on homograft replacements in human subjects, and others soon followed (12–14).

THE INTRODUCTION OF SYNTHETIC VASCULAR GRAFTS

The replacement of natural vessels with synthetic fabric conduits began somewhat serendipitously in 1947 after Voorhees noted the formation of a "glistening" coat on a silk suture that had remained in the ventricle of the heart of a dog for months (3). From this he reasoned that a fabric mesh formed into a tube and implanted as an arterial replacement would be similarly coated. Shortly thereafter, scraps of a parachute were fashioned into tubes on a home sewing machine and implanted. Following this, tubes fabricated from what was a more biologically preferred material, Vinyon N (vinyl chloride-acrylonitrile), were implanted into 15 mongrel dogs (15). In 1954 18 patients with aneurysms had defective vascular segments replaced with synthetic grafts (2). This experimentation, suggesting a new direction in vascular prosthesis exploration, came a few years prior to reports highlighting the less-than-adequate long-term performance of arterial homografts. Degeneration of the homograft, rather than progression of the patient's disease, was believed responsible for the 70% occlusion rate observed (2). In 1955, Szilagyi had reported on the treatment of arterial occlusion by resection and replacement with arterial homografts (14), but in 1957, after 2 years of experimentation in close to 400 dogs, his group had abandoned such homografts in favor of poly(ethylene terephthalate) (PET), or Dacron®, grafts (16). In a 1957 report on the fate of human arterial homografts, Szilagyi et al. predicted that degenerative changes and diminishing tensile strengths in aortic homografts would begin to endanger patients' lives after 5 years (17). In the following year, Linton noted a 40% failure rate in 38 patients during the first 2–3 postoperative years (2).

Now surgeons, harboring a growing dissatisfaction with long-term biologic graft performance and acknowledging the recent success of the implanted synthetic grafts, began viewing synthetic fabrics as a serious alternative for graft manufacture and implementation. This is not to say that biologic grafts were abandoned, but these factors, combined with the often unsuitable state of potential autograft vessels; advancements in surgical technique; and refinements in anticoagulation, antimicrobial therapy, and angiography, invited exploration.

The early explorations, not surprisingly, focused on the choice of material. However, even in the beginning, other graft characteristics were recognized to influence success or failure. After preliminary investigations, Harrison observed a correlation between graft diameter and occlusion and conducted a comparative study on smaller-diameter grafts (<9 mm) of nylon, Dacron, Orlon® (polyacrylonitrile, PAN), Ivalon® (formalized poly[vinyl alcohol], PVA), and Teflon® (poly[tetrafluoroethylene], PTFE), of varying porosities (18). Following implantation into the abdominal aorta and carotid and femoral artery positions of 133 dogs, he witnessed occlusion rates of up to 92% in periods of 6 weeks. He concluded that because none of the grafts satisfactorily maintained patency, these materials would not serve adequately as small-diameter replacements. However, the contributions of unrefined surgical techniques, crude graft constructions, and harsh preparations (e.g., concentrated acid and base washes, bleaching, and melting of cut ends to prevent unraveling) toward the failure rate should be acknowledged. Also, in retrospect, it is easy to recognize the difficulty of maintaining successful grafts in high-resistance/low-blood-flow positions. Even with modern sterilization techniques and surgical procedures, it is difficult to speculate on whether such poor results would be obtained today with similar graft materials.

In the same month and using the same materials, Harrison published results from a similar comparative study, this time on larger-diameter grafts (>9 mm, with 6–7 cm length) as replacements for thoracic aortas in 84 dogs (19). These results were remarkably different, with only 1 of the 84 grafts failing from occlusion. It was determined that Teflon, Orlon, and Dacron performed equally, well but nylon and Ivalon were not suitable graft materials, as some had extensively degraded during the study period. This study was extended to 2–3 years in 10 of these animals with patent nylon, Dacron, Orlon, and Teflon grafts (20). Of the four nylon grafts observed, only one remained patent at 36 months, though subsequent testing revealed an 80% loss of tensile strength in this graft. Again the Teflon, Orlon and Dacron grafts were viewed as superior, having lost no more than 25% of their tensile strength.

In a report the following year on the fate of human aorta replacements, knitted Dacron grafts were found to be superior to those of nylon and Orlon and to homografts as well (21). In 1964, this emerging trend of positive results was reinforced in an analysis by DeBakey et al. (22) of 67 Dacron grafts removed from 58 patients. After thorough visual, histological, and electron microscopy examinations and demonstrated sustained patency and function for many years, his group was convinced that Dacron could serve as an effective arterial substitute. However, it should be noted that many—if not most or all—of these grafts were in medium- to high-flow positions, primarily serving as aortoiliac and femoropopliteal bypasses. This doesn't lessen the significance of these findings concerning the suitability of Dacron, especially because DeBakey's investigations made this fabric an industry standard, but serves only to place them in perspective. The potential of Dacron as small-diameter replacements in humans was illustrated in a clinical note documenting the patency of a small-diameter Dacron graft (3 mm) as a coronary artery bypass

graft at 17 months (23). But as exemplified in a report by Darling and Linton (24) that showed lower-extremity Dacron graft patency rates of less than 10% at 8 years compared with 65% for reversed saphenous vein, prolonged patency of synthetic grafts of this diameter are the exception, not the rule.

The other synthetic fabric that rose to the status of industry standard for vascular grafts, Teflon, was first used with some success in dogs in the early 1950s by Daniel (25). A few years later, Deterling and Bhonslay (26) obtained satisfactory function with a Teflon graft after some initial blood loss. In 1957 Harrison conducted a 6-month trial of Teflon grafts in the thoracic and abdominal aortas in dogs for which he witnessed an average occlusion rate of 8% (27). He noted that the inner surface layer was thinner and that the grafts healed faster than other grafts. Harrison's 1958 investigations with Teflon as material for larger-diameter grafts gave positive results (19,20), while the smaller-diameter Teflon grafts fared poorly (18).

While these results of Teflon grafts are near those of Dacron, there is one characteristic in the healing of Teflon grafts that sometimes lowers its success. Researchers have noted that the neointima formed on Teflon grafts does not always attach strongly and may be displaced with some ease, even after a year (28). This type of dissection would readily facilitate thrombus and emboli formation, originating not just from the loose intima but possibly from the newly exposed biomaterial surface as well.

In 1969, Robert Gore invented expanded poly(tetrafluoroethylene) (ePTFE) (29), a Teflon that when shaped is simultaneously stretched. The stretching, or expansion, produces a microscopic node–fibril–node pattern throughout the material, the lateral spaces between the fibrils forming the pores. This material, which was introduced in vascular grafts a few years later, can be stretched to varying degrees during fabrication, providing control over the degree of porosity in the graft (30).

The initial results with ePTFE were very favorable. Soyer et al. observed the presence of pannus ingrowth at the anastomoses but also noted its poor attachment (31). The following year Matsumoto et al. obtained extremely positive results of 100% patency in femoral artery replacements in dogs when using high-porosity ePTFE grafts in contrast to the 100% occlusion of ultralightweight woven Teflon grafts in the same study (32). These results were difficult to replicate, and as subsequent investigations indicated, the results were still good, though typically not as good as those of Matsumoto et al. The excitement about ePTFE was soon tempered however, as longer-term results began to be reported. Hobson et al. (33) published 30-month patency results of only 45%, compared with 54% for autogenous saphenous vein, in femoropopliteal, femorotibial, and femoroperoneal replacements. In 250 patients who had ePTFE grafts implanted as femoropopliteal artery reconstructions, a patency rate of 74% at 1 year dropped to 56% at 2 and 3 years (34,35).

The years of experimentation with different fabrics and modifications, by virtue of their poorer performance, reinforced these materials and made them the synthetic graft standards. But along the way, the characteristics to which success was attributed were noted, analyzed, and often integrated into general, but not necessarily universal, acceptance. This resulted in part from varying experimental results and in part from the poor results obtained from small-diameter grafts of fabrics that typically yielded good results when used in a larger-diameter graft. Today, the desired features of successful synthetic vascular grafts are, for the most part, standardized.

SMALL-DIAMETER SYNTHETIC GRAFT SUCCESS OR FAILURE

Synthetic vascular graft characteristics thought to be desirable haven't so much changed over the years as they have been refined. It was apparent early on that porosity, hemocompatibility, biocompatibility, sterility, flexibility, compliance, and durability were vital components of a successful graft (2). Today, little in the fundamental requirements has changed. Abbott et al. have recently published a list of preferable characteristics including optimal biomechanical properties, cosmetic acceptability, handling characteristics, sterility, reasonable cost, production consistency, durability, infection resistance, strength, and a thromboresistant flow surface (36). A comparison of preferred characteristics then and now are outlined and matched in Table 1. It is apparent that the major requirements have changed little and that the later additions reflect contemporary capabilities and realities.

Biology of Small-Diameter Vascular Graft Failure

Before exploring and enumerating the features of synthetic fabric grafts that contribute to success, it is appropriate to highlight and understand the mechanisms of graft failure. Beyond the obvious considerations of vascular graft failure attributable to infections, mechanical degradation, preexisting vascular disease progression, and technical errors are those related to the tissue and blood reactions to the implanted material, specifically the hyperproliferative cellular events occurring in and near the graft.

Upon exposure to a foreign material such as a polymer graft, specific blood components respond as if the integrity of a native vessel has been compromised and the endothelium denuded. These components recognize the material as foreign, become activated, and initiate a series of events

Table 1. Comparison of Preferred Synthetic Vascular Graft Characteristics of the 1950s and 1990s

1950s	1990s
Compliance	Biomechanical properties
Durability	Durability
Flexibility	Handling characteristics
Porosity	Porosity
Proper tissue reactivity	Flow surface, biocompatibility
Sterility	Cleanliness and sterility
	Consistency
	Cost
	Cosmetic attributes
	Infection resistance

in an attempt to repair the perceived damage. The first event is the immediate adsorption of multifarious plasma proteins to the entire graft surface, which may remain attached or desorb under the influence of other proteins or blood flow. It is thought that the graft surface can denature the proteins (37) and that these bound, altered protein configurations may bind platelets and initiate their activation. Additionally, direct contact with a foreign surface alone is sufficient to provoke platelet activation (38). Surface fibrin, platelet debris, and red blood cells (RBCs) comprising the newly formed layer, called *pseudointimal hyperplasia*, can lead to clot and thrombus formation, the progression of which could be the short-term failure of a vascular graft.

Subsequent to platelet coverage and activation upon the graft, specific substances are released from the platelets (e.g., platelet-derived growth factor [PDGF], transforming growth factor β1 [TGF-β1], and thrombin) that are chemoattractants and/or growth factors for smooth muscle cells (39). As a component of the vascular tunica media, the smooth muscle cells begin to migrate from the anastomotic vessel wall and progress into the synthetic graft via chemotaxis. On the graft lumen surface, the sustained proliferation of smooth muscle cells with attendant deposition of cellular matrix, collectively termed *intimal hyperplasia*, can develop substantially and narrow or eventually occlude the graft lumen (40). This mode of graft failure typically occurs more frequently at the anastomoses, reflected in the adjusted designation anastomotic hyperplasia.

In as much as synthetic vascular grafts are viewed as foreign surfaces and can effect compliance mismatches and therefore immediately approximate two components of Virchow's triad (endothelial injury, stasis, and hypercoagulability) (41) with the third not far behind, it would seem appropriate that modifications to the graft that eliminate one or more elements of the triad would improve its potential for success.

Materials

As was discovered very early, an unfortunate choice in graft material will doom the fate of the graft and probably the patient. Thus, in the quest for the best synthetic graft fabric, it was realized that not all implanted graft materials and constructs would behave equally. This opened the door to experimentation, and over the past few decades a variety of different synthetic fabrics (usually polymer derived), constructions, textures, and modifications have been evaluated.

Teflon and Dacron grafts remain the most durable ones available and are fabricated in a variety of sizes and constructions, including weaves and knits (42). Primarily because of their durability and stability and secondarily because of their ease of handling and relative lack of thrombogenicity, they are the only synthetic grafts in clinical use today. Their patency rates are fairly good, but they still suffer higher failure rates in low-flow, small-diameter situations.

Many synthetic graft materials have been investigated over the past few decades, and unfortunately, most either exhibited poorer performance than the available (and well entrenched) grafts or demonstrated success based on difficult-to-reproduce fabrication or preparation techniques. Other synthetic grafts appear in the literature with limited claims of success, typically in small animals, and then disappear after failure in larger animals or after long-term studies reveal failures not foreseen in shorter-term studies.

In 1989, Chaikof et al. examined cross-linked poly(ethylene oxide) (PEO)/polysiloxane as a material for small-diameter vascular grafts (4 mm) based on PEO's low protein and cellular adsorption levels (43). Their results confirmed their predictions of low fibrinogen and platelet deposition, but unfortunately, no grafts were implanted. Subsequent research by this group, again without implantation into animals, alternately confirmed these results with similar-molecular-weight PEO (44) and contradicted the original expectations with low-molecular-weight PEO (45).

A few years later, Greisler et al. implanted 5-cm-long, 4-mm-diameter, woven polypropylene grafts in the aortoiliac position in dogs (46). The selection of polypropylene was based on its physical properties of high tensile strength, degradation resistance, and low platelet adhesion. Excellent results were demonstrated with a one-year patency of 92%, compared with 69% for Dacron and 20% for Teflon, but apparently no subsequent investigations were performed.

The genesis of grafts of bioresorbable materials began in the early 1960s when, as a means to control hemorrhaging at the time of implantation, degradable materials were incorporated into existing grafts (47). In subsequent investigations, significant reductions in hemorrhage with comparable patency rates were obtained for gelatin-treated Dacron and Teflon (48), bovine collagen–impregnated Dacron (49), and gelatin-impregnated Dacron (50). This method of preventing postsurgical graft hemorrhage was superseded by the preclotting of grafts with autogenous blood at the time of surgery.

The goal of bioresorbable grafts was, in principle, to provide a temporary scaffold for the ingrowth and permanent structural establishment of native tissues. In 1985, van der Lei et al. studied partially bioresorbable small-diameter grafts composed of mixtures of polyurethane (PU) and poly(L-lactic acid) (PLLA) in rats (51). Of the four PU/PLLA compositions investigated, the 19:1 PU/PLLA mixture yielded the best results, displaying regeneration of neointima and neomedia similar to the native and no aneurysm formation. However, this was virtually a polyurethane graft, which, if fabricated with porosity introduced by another method, would probably have yielded similar results and obviated the need for the degradable polymer.

Greisler et al. took the idea of bioresorption to the limit in 1985 when they constructed grafts solely of polyglycolic acid (PGA) and implanted these and Dacron controls into rabbit aortas for up to 12 months (52). Inflammatory reactions in each were equal, but the neointima that developed in the PGA grafts was three times thicker than that of the controls. Aneurysmal dilation was also observed in 15% of the PGA grafts, while none was seen in the controls. Two years later, as a means to prevent aneurysmal dila-

tion, Greisler et al. (53) constructed woven grafts from yarns of bioresorbable polyglactin 910 (PG910) and nonresorbable polypropylene in a 69:31 ratio. Forty-two grafts were implanted into the infrarenal aorta position in rabbits and were explanted from 2 weeks to 12 months later. These grafts fared better than the completely bioresorbable grafts, showing 100% patency, no aneurysm formation, and stenosis in only one graft.

In 1988, Galletti et al. (54) experimented with fully bioresorbable Vicryl prostheses that were coated with either of two blends of bioresorbable polymers, which were included to retard the Vicryl fabric degradation time. Eighteen grafts were implanted in the infrarenal aorta position in dogs and were explanted from 3 days to 24 weeks later. Upon explanation, 14 of the 18 grafts were patent, though generally a neointimal thickness of 2–3 times that seen in similarly implanted Dacron grafts was observed. Resembling previous studies of Greisler et al. (52,55) and Bowald et al. (56,57), no elastin was found in the grafts, a consequence thought to be due to the graft rigidity inhibiting elastin expression (54). Aneurysm formation was observed in two of the animals.

Though a completely bioresorbable graft is an ideal, it was an optimistic assumption that the eventual tissue content and arrangement would resemble natural blood vessels in form and function. Unfortunately, these newly formed quasi vessels instead often possessed discordant tissue compositions and failed to maintain the necessary mechanical integrity. Frequent tissue degradation and aneurysm formation were commonly the reason for failure of these grafts.

In the search for an optimal small-diameter graft material, polyurethanes have generated tremendous excitement. These polymers can possess outstanding strength, flexibility, and fatigue resistance (58). Their consideration as a small-diameter graft material arose from concerns of compliance matching and investigations into polymers that preferentially bound albumin instead of fibrinogen, the binding of the latter correlating to thrombogenesis (47). In very early research, Dryer et al. implanted polyurethane foam grafts as aorta replacements in 16 dogs and obtained patency in 13 of the 16 for up to 6 months (59). Using the same polyurethane, Marinescu et al. implanted grafts in canine aortas that lasted for up to 10 years (60). Though minor, this inconsistency in patency results of different researchers could be attributable to surgical experience. In later earliest investigations, Lyman et al. (61) prepared porous, 4-mm-i.d. *co*-polyether-urethane-urea (PEUU) grafts that were implanted in the femoral artery position of 20 dogs. Upon removal, from 10 to 111 days later, 45% of the grafts were patent, comparing favorably with 6-mm-i.d. Dacron and solid-wall, noncompliant PEUU grafts that demonstrated almost zero patency in similar implant situations. These results are appreciably different from those of Dryer et al. and Marinescu et al. and could be due to polyurethane composition, which can vary tremendously between different polyurethanes. Alternately, the smaller graft diameter or the different surface morphology of the grafts could have been the determining factor.

Polyurethane grafts have been fabricated by a variety of unique methods other than the typical weaving or knitting. Annis et al. used an electrostatic spinning method to produce 10-mm-i.d. fibrous, porous poly(ether urethane) grafts, which were implanted in the thoracic aorta position in 42 minipigs (62). Of the 42 grafts, 4 failed due to "faults in the material," and the others remained patent for up to 12 months with no observed aneurysm formation. Hiratzka et al. (63) created polyurethane grafts with a replamineform process whereby machined, microporous, 6-mm-diameter sea urchin spines (tubes) of calcite acted as a templates into which polyurethane was injected. The calcite was dissolved away, leaving a microporous polyurethane tube as a form inversion of the template. These 3-cm-long grafts were implanted in the infrarenal position of dogs and explanted from 1 to 32 weeks later. At the time of removal, all grafts were patent with complete tissue ingrowth and no aneurysmal dilation, though complete endothelial coverage of the lumen was not observed in grafts explanted prior to 16 weeks.

It is believed by many that complete endothelial coverage would render synthetic vascular grafts nonthrombogenic and therefore greatly improve their chances for long-term patency. For unknown reasons, in humans the endothelial pannus ingrowth into the graft from the anastomoses almost always ceases after progressing a few centimeters. Because complete graft endothelialization usually occurs in nonhuman animals but not in humans, incomplete endothelialization of an experimental graft in animals *may* suggest potential failure for this graft in humans.

In 1983, Hess et al. published their results about implanted small-diameter, fibrous polyurethane prosthesis in the abdominal aorta of rats, focusing on the endothelialization process (64). Forty-seven of these 1.6-mm-i.d. grafts were implanted in place of abdominal aorta segments in rats and were explanted after 1 to 25 days and at 6 and 9 months with a patency rate of 91%. Endothelialization began at 5 days and progressed at 0.3 mm per day until day 21, when coverage was complete. In a similar investigation published the same year, Hess et al. (65) described the cells comprising the pannus ingrowth as a combination of layers of smooth muscle cells covered by a continuous endothelium.

The experimental successes of polyurethanes as small-diameter grafts has encouraged their commercial development. Physical and chemical comparisons of a novel microporous polyurethane graft (Vascugraft®) to another microporous polyurethane graft (Mitrathane® prosthesis) and to a microporous ePTFE graft (Gore-tex®) were made by Zhang et al. (66). The resulting favorable analyses and conclusions prompted larger-diameter graft (10 mm i.d.) implantations as thoracoabdominal bypasses in dogs, which yielded mostly positive results (67,68). With awareness of minor concerns raised in the canine studies, 15 femoropopliteal and femoroperoneal Vascugraft bypasses were performed in humans (69). Unfortunately, 8 of the 15 grafts failed during the first year, and the research program was ended by the manufacturer.

Porosity

Even in the first application of synthetic fabric grafts, Voorhees hypothesized on the benefit that porosity would contribute to healing. By 1964, vascular surgeons and researchers believed that the fate of a synthetic graft would be resolved, for better or worse, by its porosity (70). It was and is thought that anchoring of the neointima to the lumen surface would sustain the health of the neointima. Tissue and capillary ingrowth into the external graft surface are believed to stabilize the graft in situ and to supply the tissue ingrowth, and possibly the neointima, with oxygen and nutrients, respectively (71,72). Improved performance of porous synthetic grafts over nonporous grafts was observed early on (73).

In 1964 Fry et al. (74) reviewed case histories of patients who, after having received nonporous Teflon grafts in the aortoiliac position, suffered from complete occlusion of the grafts at 2 months to 3 years postimplantation. At reoperation it was discovered that the neointima of the Teflon grafts had separated from the prosthetic surface and caused thrombosis. Most of the patients then had woven, porous grafts implanted.

Hermansen et al. analyzed two types of Dacron grafts to assess the influence of their markedly different porosities on the viability of the neointima (71). Although dislodged neointima was attributed to the lower porosity in those grafts, no pronounced histological differences were seen. In a study on porosity and healing, White found minimal tissue ingrowth in grafts with pore sizes less than 15 μm, fibrohistiocytic tissue incorporation in grafts with pore sizes of 15–45 μm, and organized fibrous tissue incorporation in grafts with pore sizes greater than 50 μm (75).

Using the graft fabrication technique of Soldani et al. (76), which involves the phase inversion of polyurethane onto a rotating mandrel, Okoshi et al. (77) compared nonporous versus porous graft inner-surface morphologies. After explanation from rat abdominal aortas, the patency rates for the grafts with "skinned" and porous surfaces were 0 and 72% at 2 weeks, respectively, and 0 and 8% at 3 months, respectively. The lower-than-expected patency rate of the porous grafts prompted fabrication of grafts with highly porous inner surfaces, which showed a patency rate of 73% at 3 months.

An interesting and simple way of inducing custom pore sizes during the fabrication of polyurethane grafts was demonstrated by Fujimoto et al. in 1993 (78). Mixtures of polyurethane and monodisperse salt crystals were extruded as 3-mm-i.d. tubes, wrapped with Spandex yarn, and then coated with the same polyurethane/salt mixture. After evaporation of the solvent, the formed tubes were immersed in water to dissolve away the salt. Grafts with average pore sizes from 1.7 to 30 μm were fabricated and implanted into the common carotid arteries of dogs and explanted at 1, 2, and 6 months. All of the grafts with an average pore size of less than 5 μm were occluded by 1 month, while those with a 5- to 30-μm average pore size were patent at 2 months. All of the grafts with average pore size of 30 μm were patent at 6 months as well.

Compliance Matching and Blood Flow Patterns

When anastomotic hyperplasia was observed as a separate phenomenon from general neointimal hyperplasia, it was speculated that host artery/graft differences might have contributed to the failures (79). The difference in compliance between the artery and the graft was one factor thought to affect anastomotic blood flow patterns, which would induce higher shear stresses. This postulate, combined with animal data suggesting a relation between compliance and patency, led to experimentation with more elastic materials in the hope that similar compliances would avert the previously observed hyperplasia. Materials such as latex, Silastic, fluoroelastomers, and hydrocarbon rubbers were investigated, but any benefits derived from similarities in compliance were overshadowed by the thrombogenic effects of the materials, most of which failed (47). It was realized that one desired graft characteristic, however necessary it is thought to be, should not be sought at the expense of others.

Additionally, too often conclusions were drawn after comparisons between less compliant synthetic grafts and more compliant autografts (80). This was the case in a publication by Walden et al. that compared patency rates of various processed and unprocessed natural vessels with Dacron and ePTFE grafts (81). The attribution of an effect to one factor, in a comparison of grafts with multiple differences, is inappropriate. Regardless of the correlations, the conclusions derived from such flawed experimental schemata lack validity.

Lyman et al. examined the patency of otherwise similar small-diameter (4-mm-i.d.) copolyurethane compliant and noncompliant grafts in dogs (82). Although six of the nine compliant grafts were patent upon removal (at up to 77 days), most of the noncompliant grafts failed within 48 hours. In contrast to findings such as these, Annis et al. saw very little patency difference between polyurethane grafts with greater and lesser compliances (83). In this investigation it seems that the compliance of the less compliant grafts was sufficient for equal performance and was not low enough to effect a difference.

In consideration of compliance as a cause of vascular graft deficiency, as with any complex system, there is not always just one well-defined mode of failure. In a statistical investigation of reported vascular graft failures over a 30-year period, Pourdeyhimi et al. (84) concluded that the second leading cause of graft failure was compliance. However, the route to failure was not the expected compliance mismatch, inducing turbulent flow and leading to thrombosis path. Instead, suture line failure due to compliance mismatch, occurring mostly between 30 and 50 months, was the reason for the graft failures.

CELL SEEDING AND OTHER GRAFT MODIFICATIONS

With the incredible numbers of surface-modified vascular grafts and other experimental grafts studied and reported on every year, it may appear as though investigators have acknowledged the limitations of plain polymeric materials in their performance as synthetic vessels. This may be true, or there may be other reasons behind this growing direction in graft research. Possibly some biomaterials searches, now extending past those commonly available and inexpensive and in light of a looming biomaterials lit-

igation crisis, are simply too costly in time and money to pursue. Also, potential elements of a synthetic graft that were once assumed relatively inconsequential may now be thought significantly influential. Or it simply may be that new ideas for grafts appear as technologies progress. Each of these reasons may be the motivation pushing researchers in different directions, or more likely, it is a combination of all of these reasons.

Speculation may have been expressed that because endothelial cells wouldn't completely cover the inner surface of a synthetic vascular graft in a human after implantation, an application of cells prior to graft implantation might improve long-term cell coverage. Cell seeding is the application of endothelial cells in a physiologic medium such as whole blood to a vascular graft and was first attempted on microfiber scaffolds in vitro by Burkel and Kahn in 1977 (85). The popularity of endothelial cell seeding arose from Herring's single-staged method, published in 1978 (86). In his procedure, he scraped endothelial cells from veins of dogs, mixed them with whole blood, and preclotted Dacron prostheses with the mixture before implanting them. In his 1978 report, 12 6-mm-i.d. Dacron grafts were implanted into the infrarenal aortas of dogs, half of which were seeded. Upon explantation at 2, 4, and 8 weeks, the seeded grafts displayed a higher percentage of clot-free surface (76% versus 31%), and Herring concluded that the formed lining was biologically superior to that which developed in the unseeded grafts. As an extension of this technique, Graham used cultured endothelial cells for seeding (87) and in 1982 performed this procedure with 25-cm-long (6- and 10-mm-i.d.) ePTFE grafts in dogs (88). The seeded grafts showed 64 and 91% endothelial cell surface coverage at 2 and 4 weeks, respectively, while the endothelial cell surface coverage of unseeded grafts never exceeded 10%.

In 1987 Emerick et al. determined that up to 90% of the endothelial cells seeded onto a graft are washed away in the first 24 hours (89). Consequently, additional modifications to the cell-seeding procedure, aimed at better endothelial cell retention, have been developed. A few of these are fibronectin (90), Transglutine (a biological glue) (91), and short peptide sequence (92) coatings of grafts prior to seeding. However, these techniques are more modifications of the graft than of the seeding procedure itself.

Other graft modifications focused on changing the graft surface so as to reduce thrombogenicity, prevent infection, induce endothelial cell coverage and retain the cells after coverage, and inhibit specific cell growth. Many of these techniques involve the bonding or application of specific materials or drugs to graft lumen surface to achieve the desired effect, while others employ somewhat unconventional techniques.

Greisler et al. fabricated an interesting small-diameter graft that harnessed the desirable surface properties of Teflon and the bulk properties of Dacron (93). In this study, gaseous tetrafluoroethylene (TFE) monomer was covalently bound to Dacron grafts by radio-frequency plasma discharge, creating a compound graft. Sixty-six grafts, including controls, were implanted into canine aortas (6-mm-i.d. grafts) and carotid arteries (4-mm-i.d. grafts). However, the TFE-coated PET grafts did not demonstrate significantly better performance than the similarly implanted controls.

For a long time it has been thought that capillary ingrowth into the graft wall might be a source of the endothelial coverage on the lumen surface (94). In an effort to induce this ingrowth, Noishiki et al. infiltrated the graft walls with autologous bone marrow cells and implanted these grafts into dogs (95). At all time points past 3 weeks, the marrow-infiltrated grafts showed complete endothelialization and patency, whereas noninfiltrated control grafts demonstrated endothelial coverage only at the anastomoses.

Heparin bonding to the inner surfaces of vascular grafts has been attempted by different researchers hoping to reduce the incidence of thrombogenesis. Esquivel et al. (96) ionically and covalently bonded heparin to polyurethane (PU) and ePTFE grafts (6 cm long and 4 mm i.d.) and implanted these into the carotid arteries of sheep. The results showed reduced early thrombogenicity in both types of grafts with covalently bound heparin and in ionically bound heparin PU grafts though not in ionically bound heparin ePTFE grafts. Unfortunately, this method has shown only sporadic success in humans.

Synthetic graft infection carries far greater risk for the patient than focal infections in other areas of the body (97) and has resulted in limb amputation and patient death (98). The bacteria, which may be otherwise negligible in number at the beginning, can gain a foothold in the fabric interstices of grafts. There, protected from the reach of the immune system, the bacteria multiply virtually unchallenged. Today, infections of vascular grafts almost always necessitate their removal, an invasive procedure with unavoidable risks. Although some infections arise systemically, far past the date of implantation, others result from inadvertent contamination during implantation or the postoperative period. Short-term infection prevention would be welcome and may be possible.

Through methods similar to heparin bonding, antibiotics have been bonded to graft surfaces to prevent graft infections. Moore examined the effectiveness of amikacin bonded to 6-mm-i.d. Dacron grafts in preventing graft infection in dogs (99). After the grafts were implanted in the abdominal aorta, approximately 10^8 *Staphylococcus aureus* bacteria were administered intravenously. Infections were observed in only 8% of the experimental grafts versus 100% in the control grafts.

POLYMERIC CONTROLLED RELEASE

Conventional drug delivery methods are inherently inefficient. Typical bolus administrations often require repeated dosing to sustain drug levels within the therapeutic range, a waste of sometimes costly drugs. To ensure delivery of a sufficient quantity of drug to the intended organ(s), increased dosages can be required. Additionally, specific methods of administration (e.g., injections) can be painful. These combined factors can easily induce stress and avoidance behavior in patients, reducing their compliance and increasing their risk of prolonged illness or worse.

Through drug delivery systems, the controlled release of therapeutics offers significant advantages over conven-

tional delivery methods of drug administration. Controlled-release devices can deliver drugs at a steady rate for extended periods of time, minimizing deviations from the therapeutic range and the need for repeated administrations. Localized controlled-release devices serve to reduce the amount of drug necessary. Oral and topical controlled-release formulations obviate the need for injections. The advantages of controlled-release devices increase patient compliance, reduce drug wasting, and save money for the manufacturer and the patient.

Vascular Grafts and Controlled Release

If synthetic materials are to succeed as small-diameter grafts, then closer approximation to a natural vessel is required. One function of a vessel that could be simulated in a synthetic graft is the controlled release of chemicals that influence the vessel's environment. Cell seeding may loosely be considered a form of controlled drug release from a synthetic graft because the seeded cells invariably secrete specific chemicals. However, the definition, as it is applied here, will include only the release of drugs from nonliving constructs.

Sometimes a sustained presence of antibiotics around an implanted graft is desired. With or without parallel prophylactic systemic administration, localized controlled release of antibiotics to or from the synthetic graft is one option. Ney et al. investigated this method of therapy with grafts that had been intentionally infected with solutions containing *Escherichia coli* and *S. aureus* and then implanted into the infrarenal aorta position in dogs (100). Prior to closure of the surgical wound, low-dose (100 mg antibiotic) or high-dose (300 mg antibiotic) amikacin-loaded biodegradable microspheres were applied topically to the vascular grafts. When the grafts were explanted and analyzed 14 days later, 88% of the control grafts (no administration of antibiotics) manifested clinical infections, while none of the treated grafts demonstrated clinical infection. However, two of the eight grafts treated with the low-dose microspheres did test positive for cultures of *S. aureus*.

Also, growth factors and other drugs have been openly and loosely incorporated into vascular grafts although not specifically engineered as controlled-release devices. In 1991 Soldani et al. fabricated small-diameter polyurethane grafts with an incorporated mixture of nonencapsulated albumin and basic Fibroblast Growth Factor (bFGF) particles (101). After an initial burst, the graft showed fairly constant release for 2 weeks, although the cumulative levels never exceeded 20% of the total amount incorporated.

In an effort to facilitate endothelialization and maintain patency, Lado et al. applied a biodegradable carrier polymer containing platelet-derived angiogenesis fraction (PDAF) to the inner surfaces of 2-mm-i.d. PTFE grafts (102). Twenty-four grafts, 12 experimental and 12 control, were implanted. After a 3-week initial implant period in the retroperitoneum of rats, the grafts were in situ anastomosed, end to side, into the abdominal aorta. Though capillary and tissue ingrowth differences were seen, no significant differences were observed between the treated and untreated grafts. A similar investigation by Greisler et al. (103), with fibrin glue containing fibroblast growth factor (FGF) applied to ePTFE grafts, demonstrated release of the FGF to 30 days. Capillary ingrowth and endothelial cell proliferation promoting endothelialization of the graft was observed. Similar techniques involving the controlled release of therapeutics from tubular structures such as vascular grafts have been patented (104).

Richey and Harris (105) examined the effect on in vitro platelet adherence of controlled-release indomethacin (IM) and aspirin (ASA) from PLA/PLGA-blend microspheres present in the pores of ePTFE discs (1.5 cm diameter). The samples were placed into tissue culture dishes with phosphate-buffered saline for periods of 2 h, 4 days, and 14 days. After these periods of drug release, the samples were exposed to a platelet preparation for 1 h and rinsed, at which time platelet adherence was measured. After 2 h the platelet adherence of the four experimental samples (10 and 20% loaded IM and ASA) was less than that of the controls, though only the two samples with 20% loaded microspheres demonstrated significant differences. The other time points showed similar, though not significant, differences.

Kreitz et al. describe the construction and characterization of controlled-release synthetic vascular grafts without and with incorporated biodegradable polyester microspheres, as shown in Figure 1. Using a modification of the spray–phase inversion technique of Soldani et al. (76), microporous polyurethane grafts were fabricated with heparin-loaded poly(lactic-*co*-glycolic acid) (PLGA) microspheres incorporated into the walls of the grafts (106,107). The controlled release of heparin is intended to inhibit smooth muscle cell (SMC) proliferation in the vascular grafts. Characterizations revealed PLGA degradation over 2–3 months, but with a very rapid heparin release. This was thought to be due to the use of water as a nonsolvent in the graft fabrication process, the extreme water solubility of heparin, and pores in the microsphere coatings of the heparin. Subsequently, an alternate nonbiodegradable controlled-release system was devised for the same graft fabrication technique. Heparin release from these grafts observed over 1–2 months was adequate to effect inhibition of SMC proliferation in vitro.

Therapeutics other than solids have been employed for controlled release to the vascular graft environment. Pulfer et al. (108) used cross-linked polyethyleneimine microspheres to release nitric oxide (NO), a reported inhibitor of thrombus formation, from Gore-tex grafts in vitro. Release from microspheres alone demonstrated nearly linear release of NO over 1 week, whereas the microspheres incorporated into the graft released substantially lower amounts of NO in less time. Because a mixture of microspheres was used, some with lower NO loadings, the results of NO release from the grafts were not unexpected.

TISSUE-ENGINEERED VASCULAR GRAFTS

It is ironic that after so many years of pursuing perfection of small-diameter synthetic vascular grafts, investigation should again turn to natural vessels, albeit in a different way. Researchers may have recognized evolution's power

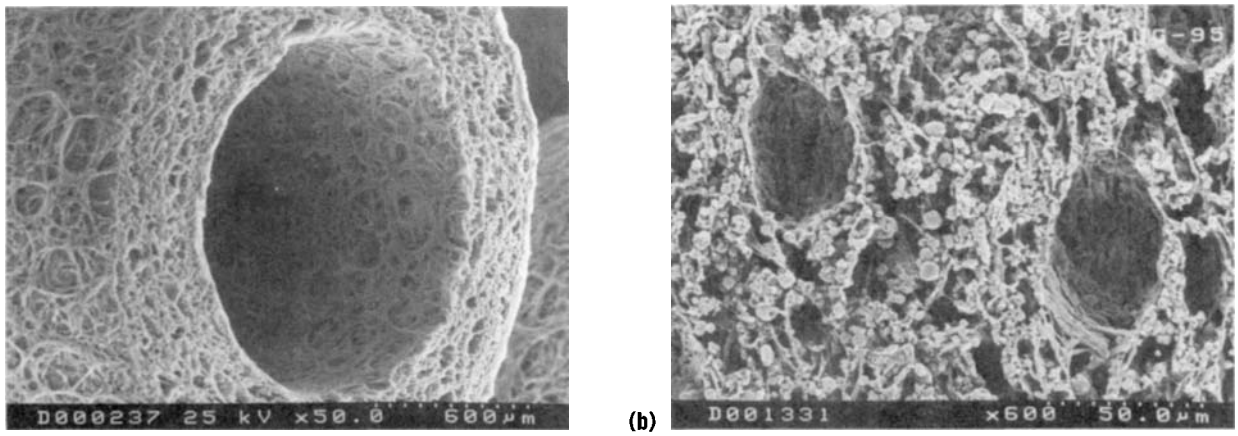

Figure 1. Scanning electron micrographs of vascular grafts produced by the spray–phase inversion process. (**a**) Micrograph shows the microfibrillar structure and porosity of the inner and outer surfaces (magnification 50×). (**b**) Micrograph of a cross section of a composite vascular graft fabricated with spray-dried polyester microspheres. The large quantity of spray-dried polyester microspheres are visible (magnification 150×).

to achieve what they yet cannot, and consequently have begun to focus on recreation instead of simulation. These new vessels are not harvested from animals or humans but rather engineered in the laboratory from human cells. L'Heureux et al. (109) produced tubular structures with three layers of cells, fibroblasts, smooth muscle cells, and endothelial cells, emulating in a natural vessel the adventitia, media, and intima, respectively. Positive indications of comparative function such as expression of von Willebrand factor, incorporation of acetylated low-density lipoprotein, and production of prostacyclin were observed in vitro. The burst strength capacity of this TEBV compared favorably with natural vessels, in contrast to a similar tissue-engineered blood vessel (TEBV) (110) previously constructed by others. In the L'Heureux TEBVs intended for implantation, the endothelial cell component was excluded to lessen the possibility of acute rejection. These human cell–derived TEBVs were implanted into the femoral artery position in dogs and when explanted 7 days later, they xenografts showed a 50% patency rate.

SUMMARY

With refinements in materials, surgical techniques, and related peripheral technologies, the performance of vascular grafts has improved since the initial trials in the 1950s. Though the currently used synthetic materials perform adequately as clinical larger-diameter vascular prostheses, their lack of sufficient antithrombogenicity becomes evident in smaller-diameter grafts. A variety of experimental materials and modifications to existing materials have resulted in limited successes, as have some novel biologically derived grafts. The application of controlled-release technology to smaller-diameter synthetic vascular grafts offers the possibility of emulating some of a natural vessel's functions, which may prove critical for maintaining patency.

INTRODUCTION

The nature of the tissue–implant interface is a critical component in the success or failure of most medical implants. Investigators have sought to improve and control this interface by modifying surface chemistry, surface charge, and surface topography. This article focuses on a subset of approaches that immobilize bioactive peptides on a biomaterial surface to elicit a controlled tissue reaction, particularly for bone-contacting applications. Using small peptides has several practical and experimental advantages over the use of entire proteins:

1. Many extracellular matrix (ECM) proteins are not commercially available, are difficult to purify, and are difficult to work with chemically.
2. Synthetic peptides are widely available and pure, thus minimizing cost and the risk of infection.
3. Linear peptides do not require tertiary or quaternary structure.
4. Small peptides are more resistant than whole proteins to changes in pH and temperature (1) and are less susceptible to proteolysis and hydrolysis.
5. Bioactive peptides allow manipulation at the nuclear level. Specificity in cell stimulation can be gained through the use of sequences known to interact with certain receptors.

Peptides are referred to in this article by their single-letter amino acid sequences (Table 1). Peptides can be protected from proteolytic degradation by modifying the peptide bond, chemically blocking the termini, using NH_2 to COO-terminal cyclization, or using the D-forms of amino acids (which do not occur naturally in proteins) (2).

The Arg-Gly-Asp (RGD) sequence is the archetypal bioactive peptide, and many cells have receptors for it (2,3). Thus, RGD is an ideal model peptide and has been used widely to modify biomaterial surfaces. RGD and other peptides bind to a family of ECM receptors called *integrins* (described later). RGD is a promiscuous sequence that can bind to several integrin receptors. This tripeptide was first found in fibronectin (4). It has since been found to be in the integrin-binding sections of many proteins; of particular relevance to bones are bone sialoprotein (5) and osteopontin (6). Such a ubiquitous sequence may have the disadvantage of attracting undesirable cells such as fibroblasts to a bone implant. The presence of fibroblast-induced soft tissue versus hard tissue could, for example, lead to poor host–implant integration. Several types of bacteria also possess RGD receptors (7), which could lead to implant colonization, although this has not been studied in detail. For bone-contacting implants, the addition of flanking peptide sequences can increase receptor specificity. For example, the RGD-containing peptide CGGNGEPRGDTYRAY from bone sialoprotein has been used by Rezania et al. (5).

Ultimately, favorably controlling cell response is the goal of immobilizing bioactive peptides on biomaterial surfaces. In vitro properties such as cell adhesion, morphology, protein synthesis, and gene expression can be evaluated. In vivo cell and tissue response, cellular makeup, and degree of vascularization can be evaluated. Basic in vitro and in vivo approaches will be discussed, and specific immobilization schemes will be reviewed.

INTEGRINS

Integrins are heterodimeric cell surface receptors for extracellular proteins. The two subunits, designated α and β,

Table 1. Single-Letter Codes for Amino Acids

Amino Acid	Single Letter	Amino Acid	Single Letter	Amino Acid	Single Letter
Alanine (ala)	A	Isoleucine (ile)	I	Arginine (arg)	R
Cysteine (cys)	C	Lysine (lys)	K	Serine (ser)	S
Aspartate (asp)	D	Leucine (leu)	L	Threonine (thr)	T
Glutamate (glu)	E	Methionine (met)	M	Valine (val)	V
Phenylalanine (phe)	F	Asparagine (asn)	N	Tryptophan (trp)	W
Glycine (gly)	G	Proline (pro)	P	Tyrosine (tyr)	Y
Histidine (his)	H	Glutamine (gln)	Q		

are noncovalently associated. Both subunits are compact transmembrane glycoproteins with heavy disulfide binding and a single hydrophobic domain. Under electron microscopy, an integrin presents as a globular head with two stalks (one for each subunit) extending down into the lipid bilayer (8,9). Sixteen α- and nine β-chains have been identified, and they assemble to form the 24 distinct integrins currently identified (10). Each β-subunit can associate with multiple α subunits; however, of the α subunits only α_v can associate with multiple β-subunits (11).

Beyond simply adhering cells to the surrounding extracellular matrix, integrins are key components in many intracellular signaling pathways, and a number of functional changes occur when cells are in contact with ECM proteins. One example of this is mammary epithelial cells, which will not produce milk proteins until after they have attached to extracellular matrix proteins, even when milk-inducing hormones (prolactin and cortisone) are present (12). Synergies exist between integrins and growth factors. Vuori and Ruoslahti showed that insulin receptor substrate -1 (IRS-1) associates with the $\alpha_v\beta_3$-integrin in the presence of insulin. This association appears to increase DNA production in response to insulin, possibly by increasing the phosphorylation of IRS-1 and consequently enhancing intracellular signaling. When exposed to insulin, human pancreatic carcinoma (FG) cells transfected to overexpress $\alpha_v\beta_3$ showed a 250% increase in DNA synthesis versus nontransfected FG cells. When the transfected cells were plated on a non-$\alpha_v\beta_3$-binding substrate (collagen), DNA synthesis was similar to that seen in nontransfected cells (13). A similar association has been found between platelet-derived growth factor (PDGF) and α_v-integrins associating with a 190-kDa protein (14).

ECM–integrin binding can influence cell shape, migration, differentiation, and gene expression (9,15–19). Some integrins may, via cytoskeletal elements, connect directly with the nucleus and serve as mechanotransducers (20). Integrin expression can be regulated by external influences such as growth factors (most notably TGF-β), pharmacologic agents, mechanical stress, and infectious agents. Cells regulate integrin expression by transcriptional or postranscriptional mechanisms, alternative splicing of mRNA, conformation control, and mobilizing intracellular stores (11).

Most immobilized peptides reviewed in this article target integrins (YIGSR-containing sequences are noted exceptions). Integrin receptors recognize specific amino acid sequences within their target proteins, such as the RGD sequence and its variants mentioned earlier. As another example, type I collagen, the major bone protein, contains the DGEA sequence that binds to the $\alpha_2\beta_1$-integrin (21).

APPLICATION TO BONE-CONTACTING PROSTHESES

Limitations of Total Joint Replacement

Total joint replacement is widely used to relieve pain, improve function, and enhance the quality of life for patients with medical conditions caused by osteoarthritis, rheumatoid arthritis, posttraumatic degeneration, avascular necrosis, and other aging-related conditions. Almost 600,000 total joint replacements are performed in the United States alone each year. Current techniques to stabilize the interface between bone and prostheses are physical or geometric in nature. Most orthopedic prostheses are composed of alloys of titanium (Ti6A14V) or cobalt (CoCrMo) and rely on poly(methyl methacrylate) cements for attachment and fixation to bone. Loosening due to cement failure has been implicated in revision of hip, knee, and elbow implants (22–28). Perioperative allergic, hypotensive, and embolic events, although currently unusual, have also been related to the use of cements (29–31). An unacceptably high number of implant failures occur. With cemented total hip arthroplasty, for example, long-term studies indicate a combined (aseptic and radiographic) loosening rate of 20–30% in the acetabulum and 5–10% in the femur, with about a 10% overall revision rate (32). In total knee arthroplasty, for which over 200,000 procedures were performed last year alone, cemented knees also exhibit a 0.5–1% per year loosening rate and approach a 10% revision rate (33–35).

Cementless prostheses are designed to encourage bone ingrowth through the use of porous or sintered coatings (36–38). These implants have the potential advantages of stable long-term fixation, circumventing the issues surrounding the use of cement, and are more easily retrieved should revision become necessary. Tissue ingrowth into porous materials is influenced by several factors, including pore size and implant stability (37,39–41). Experience thus far suggests that using "press-fit" prostheses is problematic for two major reasons (36,38): First, minimal or inadequate ingrowth is observed in a significant number of patients, resulting in loosening and failure, and second, the process of ingrowth occurs over a period of weeks to months, such that weight bearing is necessarily limited early on in an effort to prevent micromotion and allow stable osseointegration. This can potentially increase expense and complication and may become particularly problem-

atic when addressing elderly patients, who comprise the greatest percentage of those needing arthroplasties performed today. Another approach is to coat prostheses with hydroxyapatite and tricalcium phosphate, but such implants have had difficulties with delamination and biodegradation and are still unable to demonstrate optimal bony ingrowth and biomechanical fixation (23,38,42).

Integrin-Mediated Control of Cell Function

The ability to enhance and accelerate ingrowth using biological factors with bone-promoting capabilities would be a significant advancement in implant technology. Bone-implant integration is regulated by numerous factors including extracellular matrix (ECM) elements and growth/morphogenic proteins. The development of orthopaedic devices incorporating bioactive surface molecules may improve our understanding of tissue repair mechanisms and enhance the design of bone-inducing substrates for clinical application. This may be done by stimulating integrin pathways (9,43,44).

Minimal peptide sequences that bind to integrins and mimic the action of much larger and insoluble ECM molecules have recently been identified (Table 2).

Small peptides can be used as agonist or antagonist drugs. In the latter case, soluble peptides can be used to occupy integrin receptors on migrating or blood-borne cells. Receptor occupancy blocks cell–ECM or cell–cell interactions. For example, metastatic melanoma and other tumor cell spreading can be decreased by injection of soluble RGD or laminin (e.g., YIGSR) peptides in animal models (59,74–77). Platelet aggregation has also been reduced by intravascular administration of soluble cyclic RGD peptides or RGD-containing analogs (51,78,79). Finally, osteoclastic resorption has been reduced by innoculation with RGD-containing peptides or analogs (80,81). Osteoclasts are known to express several integrin receptors (49,80). The fact that osteoclasts have RGD-binding integrins is relevant to the present work because activation of osteoclastic resorption at the bone interface is not favorable. Small peptides can be used as agonists to improve cell adhesion if they are immobilized on insoluble substrates (63,64,82,83). For example, endothelial cell and fibroblast adhesion to several biomaterials is enhanced by coatings of peptide ligands from fibronectin and laminin, RGD and YIGSR, respectively (52,63,64,84). YIGSR also supports nerve cell attachment, whereas a second laminin fragment, SIKVAV, supports neurite outgrowth (85). Certain peptides can act synergistically to enhance binding affinity. For example, two nonadjacent peptide sequences from fibronectin, including RGD and PHSRN, a so-called synergy sequence, exhibit such behavior (74,86). The conformation of peptide is important because small chemical changes can have profound effects on cell adhesion (87). Peptides can also effect cell and tissue function beyond cell adhesion.

Osteoblast Adhesion and Integrins

Bone cells are known to attach to tissue culture substrates via fibronectin and vitronectin molecules (88), although the effect of cell attachment peptides has not been widely studied. Osteoblast adhesion, ECM synthesis, and mineralization are influenced by the chemical nature and electrical charge of tissue culture substrates such as modified polystyrene and bioglass (89–93). Osteoblast adhesion on some biomaterials results in the formation of focal adhesion contacts, which entail clustering of integrin receptors (94,95).

Recently, it has been shown that human and rat osteoblasts/osteocytes express a range of integrins (Table 3). There are, however, conflicting data regarding the expression of certain integrins. Most studies report the expression of integrins a5b1, avb3, and a1b1 in rat osteoblasts.

SPECIFIC IMMOBILIZATION CHEMISTRIES

These entries are arranged in roughly chronological order. The level of detail dedicated to each method is not intended to indicate the importance of any particular immobilization chemistry. Rather, it is simply a reflection of the amount of literature available on each technique.

Sepharose

Pierschbacher and Ruoslahti pioneered work in pursuit of active protein sequences and immobilized peptides to sepharose beads using a carbodiimide coupler. Rat kidney fibroblast attachment was assessed by staining the cells with toludine blue and examining with microscopy. They found that only those peptides containing RGD promoted cell attachment, and this sequence is still widely used by investigators today (4).

Further experiments pointed to the importance of immobilization chemistry. Normal rat kidney cells do not rec-

Table 2. Small Peptide Ligands

ECM protein	Peptide ligand	Integrin receptors
Collagen I	cRGD, RGDT, DGEA, GTPGPQGIAGQRGVV	a1b1, a2b1, a3b1
Bone sialoprotein	EPRGDNYR	avb3
Osteopontin	RGD	avb3
Fibronectin	RGDS, EILDV, REDV	a3b1, a4b1, a5b1, avb1, avb3, avb5, avb6, a4b7
Laminin	YIGSR, SIKVAV, RGD	a1b1, a2b1, a3b1, a6b1, a7b1, a6b4
Thrombospondin	RGD	avb3
Vitronectin	RGDV, HRNRKGV	avb1, avb3, avb5
Osteonectin (SPARC)	KKGHK	?

ognize RGDC when it is linked directly to cyanogen bromide–activated sepharose beads, but RGDS was recognized when tethered with a six-carbon spacer (98). Interestingly, RGDC has been found to be active when linked by a gold–thiol bond (see "Gold").

Polyacrylamide

Among the first to covalently link peptides to artificial surfaces were Brandley and Schnaar. The polymer used was a polyacrylamide gel surface to which cells do not adhere in the absence of serum proteins. The N-terminus of the peptide used (YAVTGRGDS) reacted with N-succinimidyl ester groups in the polymer. A linear correlation between the amount of peptide in solution to the amount of peptide immobilized was established, with about 80% of the peptide in solution being bound to the surface (99).

Balb/c 3T3 mouse fibroblasts were used to test these peptide-treated surfaces (5.6 ± 0.3 nmol peptide/cm^2 in the reaction fluid). Cells adhered to the RGD peptide-treated material but not to polyacrylamide with a non-RGD control peptide or plain activated acrylamide. Using a lactate dehydrogenase proliferation assay, they found that the proliferation of cells on the peptide-treated polyacrylamide was about the same as that on tissue culture plastic, but on control surfaces growth was not supported. These effects could be seen with as little as 2 nmol/cm^2 of peptide (99).

Silicone

Another group that first immobilized peptides to artificial substrates was Imanshi et al. Silicone rubber film was exposed to aminoalkylated polydimethylsiloxane followed by oxalic acid, water-soluble carbodiimide, and polyallylamine. This provided a surface amino group density of 0.713 μmol/cm^2. Water-soluble carbodiimide was used again to couple RGDS to these amino groups. Cell attachment increased in a linear manner with peptide surface concentration, from about 11,000 cells/cm^2 with no immobilized peptide to about 26,000 cells/cm^2 with 41 mmol/cm^2 of peptide (1).

Glass

Massia and Hubbell covalently linked the peptides GRGDY, GYIGSRY, GPDSGRY, and GREDVY to glycophase glass (63,100,101). Briefly, glycophase glass is prepared by reacting glass with sodium hydroxide followed by immersion in (3-glycidoxypropyl)-trimethoxysilane. Oxyrane moieties are converted to glycol groups by treatment with acid and heat. Tresyl chloride was used to couple peptides through their N-termini (63).

Peptide surface concentration was measured by radiolabeling the *C*-terminal tyrosine groups on the peptides prior to immobilization. They found that peptide surface concentrations rose linearly with available peptide up to 12.1 ± 0.1 pmol/cm^2. A maximum surface concentration of 12.1 pmol/cm^2 corresponds to a surface spacing of 3.3 nm between peptides (63). 10 fmol/cm^2 was required for complete spreading, focal contact formation, and f-actin cytoskeletal organization in human fibroblasts (102).

Cell proliferation studies were performed with human foreskin fibroblasts by counting cells in 10 fields under a phase-contrast microscope with a 100 × objective. The media used was DMEM + 10% fetal bovine serum. This data showed no differences between the growth rate on surfaces with immobilized RGD and that on nonglycophase glass (63).

Cell spreading was analyzed with image analysis; results are summarized in Table 4. For the sake of comparison, a well-spread cell area on tissue culture plastic in serum-containing media is 2,100 μm^2; a nonspread cell area is about 355 μm^2.

As can be seen from Table 4, cell spreading increased with time on the RGD substrates with and without serum but failed to do so on glycophase glass, especially in the absence of serum (63).

Cell spreading was also noted on YIGSR-treated surfaces with and without serum, but it was not as rapid as RGD, taking over 6 h to occur. At 9 h the median cell area with serum was 2,333 μm^2, without serum it was 1,400 μm^2. Glycophase glass without peptide did not show cell spreading greater than 600 μm^2 at any time point. The effects were due primarily to the immobilized peptide, as cells seeded on an immobilized control peptide, GRGESP, and preincubated with soluble forms of the active peptides did not spread. The fraction of cells that spread on YIGSR or RGD was not effected by the addition of cycloheximide to the media to prevent cellular protein synthesis. Spreading of quiescent or active platelets was absent on all surfaces. Data from several Massia and Hubbell experiments is summarized in Table 5.

As can be seen from Table 5, cell selectivity was demonstrated using this system. Whereas human endothelial cells (HUVECs) showed a high avidity for a GREDVY-treated surface, human foreskin fibroblasts, vascular smooth muscle cells, and platelets did not. In the absence of serum, small focal contacts were present on the RGD-treated surfaces around the outer margins of the cells and at discreet locations on the cell body. Serum promoted the formation of larger, well-defined focal contacts. The YIGSR-treated substrates did not form focal contacts without serum. When serum was added, elongated focal adhesions formed around the periphery of the cells.

Cells on RGD in serum-free conditions showed an extensive actin network. This thickened in the presence of serum. Very few microfilament bundles were seen on the YIGSR in the absence of serum, but in serum thick microfilaments formed (63).

Further in vitro spreading tests were done on this substrate with human umbilical vein endothelial cells (HUVEC). Table 6 summarizes the spreading data obtained. This experiment was done in serum containing medium.

Table 4. Fibroblast Spreading

Time (min)	RGD–glass + serum: median cell area (μm^2)	RGD–glass − serum: median cell area (μm^2)	Glycophase glass + serum: median cell area(μm^2)	Glycophase glass − serum: median cell area (μm^2)

Source: Ref. 100.

As may be inferred from Table 6, there was no statistically significant difference in cell spreading between RGD and YIGSR treated surfaces with this cell type. Focal contacts and large close-contact regions formed on RGD-treated glycophase glass, but focal contacts with minimal close-contact regions were noted on the YIGSR-treated surface. More extensive actin networks formed in cells on the RGD surface than the YIGSR (100).

The type of peptide immobilized affected cell function. HUVECs showed proper antithrombogenic activity on GRGDY, GYIGSRY, GREDVY, and gelatin. However, when these cells were plated on GPDSGR, the antithrombogenic activity was lost even though their morphology was normal (101).

It was also of consequence whether or not the peptide was covalently immobilized or simply adsorbed. Adsorption was done with 20 μg/mL of protein or peptide for 1 h followed by bovine serum albumin for 30 min. Cells were incubated on surfaces in serum-free media for 6 h. Human foreskin fibroblasts incubated with antisera against laminin receptors failed to spread, indicating that these events are receptor specific.

A variety of cells showed consistently that although attachment occurred, cells failed to spread on adsorbed peptide. Two possible explanations for the improved spreading are that covalent immobilization (*1*) helps to stabilize the YIGSR in an active conformation and (*2*) may present the YIGSR to the receptor in a more favorable way (fixed end forward rather than adsorbed on its side) (103).

Polyurethanes

Polyurethanes are currently used as biomaterials in blood-contacting applications. It may be possible to improve the performance of polyurethane implants by developing an endothelial cell layer on the blood-contacting surface. Toward this end, Imanishi began work in 1988 to link a peptide substrate for thrombin, Val-Pro-Arg, to the surface of carboxylated polyurethaneurea (1,104). Three configurations were used. (*1*) immobilizing by the amine terminis of

the peptide (P1), (2) immobilizing the carboxylic terminis at the end of a six-carbon spacer (P2), and (3) repeating P2 with a reversed amino acid sequence (Arg-Pro-Val) (P3).

When the polyurethaneurea samples were placed into solutions containing known amounts of thrombin, both the peptide P1–and nonpeptide-treated surfaces adsorbed the same amount of thrombin. However, the peptide-treated surface did so much more quickly (P1 required less than 30 min for 100% adsorption of 0.22 mg/mL thrombin, while plain polyurethaneurea needed more than 120 min). Thrombin was desorbed from the surfaces and tested for activity. The peptide P1 from the nonpeptide polyurethaneurea retained 73% of its original activity, while that from the peptide polyurethaneurea had only 12%, which would indicate a specific reaction between the thrombin and the immobilized peptide. In experiments using platelet-poor plasma from canine blood, it was found that increasing peptide P1 concentration yielded increasing time to clotting.

The other peptide attachment schemes (P2 and P3) failed to show as much antithrombogenic activity as P1 when incubated with canine platelet-poor plasma in a thromboplastin buffer solution activated with $CaCl_2$. Glass took 930 s; plain polyurethaneurea, 1,079 ± 10s; P1, 1,139 ± 7s; P2, 1,068 ± 11s; and P3, 1,077 ± 7s. It was theorized that the Arg side chain couldn't be blocked (1).

Lin et al. developed a method to carboxylate polyurethanes to facilitate peptide coupling. This was accomplished by grafting β-propiolactone to the polymer backbone using a bimolecular substitution reaction (105). Peptides were then coupled via their free N-termini to the carboxyl groups on the polymer using the coupling agent EDCI. Cold-stage and variable take-off–angle ESCA verified enhanced peptide presence at the surface of the polymer in aqueous environments, presumably due to its hydrophilicity and the ability of polyurethane surfaces to rearrange in response to their environment (106). In vitro tests for human umbilical vein endothelial cell (HUVEC) spreading and adhesion were performed with polyurethane grafted with GRGDSY, GRGDVY, and GRGESY. About 20,000 cells per cm^2 were plated onto glass coverslips coated with the experimental polymer. Four time points were taken for the adhesion experiments: 40 min, 80 min, 120 min, and 240 min. At each of these time points, nonadherent cells were rinsed away, and remaining cells were counted manually with the aid of a phase-contrast microscope. Cell spreading was measured using a combination of scanning electron microscopy and image analysis. These tests were done in both the presence and absence of serum (107). Cell growth on these surfaces was measured in serum with porcine pulmonary aortic endothelial cells. Twelve-millimeter-diameter glass coverslips coated with polymer were inserted into 24-well plates. Cells were seeded at 5,000 cells/well, and growth was quantified using an MTT (3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide; thiazolyl blue) assay (84).

The results of this experiment showed that after 4 h in serum-free conditions, the cell attachments on GRGDVY and GRGDSY were 50 and 23% of the original seeding density, respectively. On the control peptide GRGESY, plain polyurethane, and carboxylated polyurethane, the cell attachment was only 5%. In serum, the cell attachment numbers were higher on all substrates and did not change significantly after the 40-min time point. This is most likely because of the fact that serum contains adhesive proteins that adsorbed onto substrates. The pattern was similar to serum free, however. 65 and 40% attachment was observed on GRGDVY and GRGDSY, respectively. Control peptide, carboxylated, and plain polyurethane all showed a 22% attachment (107).

Cell spreading was not supported in serum-free conditions on control peptide, carboxylated, or plain polymer. Rounded cells on these substrates had an area of 92 ± 15 μm^2. On GRGDVY, cells spread to an area of 532 ± 159 μm^2, and on GRGDSY their mean area was 281 ± 107 μm^2. In serum, spreading occurred on the GRGESP (330 ± 35 μm^2), carboxylated (315 ± 50 μm^2), and plain samples (320 ± 30 μm^2), but not to the degree found on GRGDVY (603 ± 119 μm^2) and GRGDSY (549 ± 138 μm^2) surfaces. It was proposed that the greater effect of the GRGDVY peptide might have been due to a greater affinity for the endothelial cell receptors (107).

Cell growth was relatively poor on noncarboxylated polyurethane, as it had less than half the number of cells on it at 72 h than any other substrate. Unlike the other experiments, the difference between the other controls and the active peptides were not large. This is probably due to the growth factors and adhesive proteins in the serum used in the media (84).

In vivo experiments were performed by Yanagi et al. using modified polyurethane sponges. The polyurethane was carboxylated by graft polymerization with acrylic acids. Proteins and GRGDSP were immobilized via the coupling agent CDI. These sponges were modified with immobilized collagen, fibronectin, GRGDSP, apatite, and a collagen coating. Fibronectin-, GRGDSP-, and apatite-treated rat subcutaneous implants showed lower inflammatory response at 3 days and high or vascularization at 7 days than plain polyurethane or collagen-treated sponges. When these sponges were implanted to fill partial defects in canine tracheas, epithelization on GRGDSP was about the same as that of untreated sponges, which was better than collagen-treated but inferior to fibronectin- and apatite-treated implants (108).

Breuers et al. used plasma polymerization to graft vinylacetate onto bulk polyurethane. After hydrolysing the acetate groups with sodium methoxide glycine and GRGDS, peptide was linked to the film via benzoquinone (109).

Poly(ethylene terephthalate)

Poly(ethylene terephthalate) (PET, commonly called Dacron) is used for vascular grafts and other medical implants. In one study, PET was surface modified with poly(ethylene glycol) (PEG) to make it nonadhesive to cells and proteins. Briefly, the PET surface is partially solubilized in dilute trifluoroacetic acid (TFA). PEG was introduced into this partially solvated surface and then was sterically "locked" into place by removing the PET from the TFA and putting it into water. Peptides were then linked to the hydroxyl groups on the PEG with essentially the same technique used for glycophase glass (101,110).

When compared with data obtained from glycophase glass, two important differences stand out. First, unlike glycophase glass, there is no attachment to the PET + GPDSGR, and second, the HVSMCs failed to adhere on PET. Both may be due to the much lower peptide surface concentrations of the peptide (<20 fmol/cm^2 on the PET, compared with 10 pmol/cm^2 on the glass) (101).

Telios Pharmaceuticals, Inc., developed PepTite (Ac-G(dR)GRSPASSKGGGGS(dR)LLLLLL(dR)-NH_2, which binds via a hydrophobic interaction between its polyleucine domain and the underlying material. This has been shown to attach to a number of materials and promote the integrin-specific attachment of varied cell types (79). Experiments with PET and poly(tetrafluoroethylene) (PTFE) vascular patches modified with PepTite were preformed. Two 2-by-0.5-cm elliptical patches of plain PTFE, plain PET, PTFE + PepTite, and PET + PepTite were implanted into the carotid and femoral arteries of mongrel dogs. The animals were sacrificed at 3 weeks, and the arteries were opened opposite the patches and photographed. Portions of the patch were sectioned for histological analysis, while other parts were used for scanning electron microscopy.

Three of the four PepTite-treated patches showed coverage by endotheliallike cells, and only one of the four plain polymer grafts showed such development, most displaying instead a platelet–fibrin mesh containing macrophages and leukocytes. Foreign-body giant cells were reduced on PET + PepTite fibers compared with plain PET fibers. The neointimal thickness on PET + PepTite was about half of that of on plain PET, while there was little difference between plain PTFE and PTFE + PepTite (both between plain PET and PET + PepTite).

PepTite was also evaluated on the PET sewing cuffs of artificial heart valves in juvenile sheep. After the native mitral valves were removed, artificial valves with plain PET or PepTite + PET sewing rings were implanted and left in place for 3 or 4 weeks. After gross and histologic evaluation, it was found that the tissue growth on the PepTite-treated valves was significantly greater in extent, maturity, and thickness (111).

Poly(ethylene acrylic acid)

RGDS, RGDV, and RGDT are derived from fibronectin, vitronectin, and collagen, respectively. Hirano et al. coupled these peptides plus RGD to the surface of poly(ethylene acrylic acid) (EAA) via carbodiimide-mediated activation of the EAA's carboxylic acid groups.

Adhesion of a mouse epithelial fibroblast cell line (L-929) was evaluated on plain EAA and peptide-treated EAA. Cells were plated at 100,000 cells/cm^2 in serum-free media and allowed to adhere for 1 or 3 h. The peptide-treated surfaces supported two to four times more cell adhesion than plain EAA.

Surprisingly, these investigators found that the peptides solubilized at 2 mg/mL inhibited the attachment of cells to plain polystyrene in serum-free media over 3 h. It is interesting that adhesion to polystyrene is blocked by soluble peptides, and more analysis is required (55).

Polyacrylonitrile

Beer et al. did some investigative work on peptides with varying spacer lengths on polyacrylonitrile and human blood platelets. After rinsing polyacrylonitrile beads in sodium acetate, RGDF peptides with spacers containing 1, 3, 5, 7, 9, 11, 13, 15, 17, and 19 glycine residues in length were reacted with *N*-hydroxysuccinimide groups. Unreacted groups were quenched with glycine ethyl ester. Calculations based on high-performance liquid chromatography (HPLC) data from pre- and postreaction solutions and the surface area of the beads gave a spacing of approximately 4.6 Å.

Platelets were introduced to these beads. When the platelets recognized the immobilized peptides, agglutination would occur. Minimal reaction occurred with a single glycine spacer, but nine-glycine spacers promoted maximal agglutination. Three glycine spacers were most sensitive to outside agents, with no appreciable agglutination occurring with prostaglandin E_1 platelet inhibitor, delayed and incomplete platelet agglutination normally, and extensive agglutination with platelets activated with ADP. Prostaglandin E_1 inhibited but did not eliminate agglutination of surfaces with peptides having nine or more glycine spacers.

Platelet preincubation with soluble forms of the peptides containing one to nine glycine spacers was done to test for inhibition of agglutination. Shorter peptides had a more potent effect than longer peptides, indicating that the glycine spacers were not increasing binding generally. It was hypothesized that a spacer putting the peptide 11 to 32 Å from the surface of the bead is optimal for interaction with its receptor. However, the possibility that this spacer was more important in allowing the peptide to "escape" from the complex molecular geometry of the polymer's surface was also mentioned. Antibody studies indicated that the GPIIb/IIIa receptor is the one targeted by the RGDF peptide (112).

Hydrogels

Hydrogels are hydrophilic cross-linked polymer networks that swell in an aqueous environment. Their mechanical properties are similar to that of some biological tissues and are permeable to tissue metabolites, which makes them potentially useful as scaffolds for cells to grow into during tissue repair. Peptides can be grafted onto these hydrogels to enhance this activity (113,114).

Moghaddam and Matsuda began work on a peptide-modified photocurable hydrogel in 1993. 7-hydroxy coumarin was reacted with potassium carbonate. The excess potassium carbonate is removed, and 2-bromoethyl methacrylate is added. The result is a methacrylic acid-(7-coumaroxy)ethyl ester (MACEE). *N,N*-dimethylacrylamide (DMAAm), MACEE, and *N*-acryloxy succinimide (NASI) were copolymerized and reacted with GGGRGDSP.

Moghaddam and Matsuda mixed 0.5 mL of the polymer solution in phosphate-buffered saline with 0.5 mL of Dulbeco's modified Eagle medium (DMEM) containing 25,000 bovine aortic smooth muscle cells/mL. This mixture was exposed to ultraviolet light, causing the polymer to cross-link and form a hydrogel matrix. Cells entrapped within

this matrix took a few days to spread and proliferated slowly. It was suspected that either the 30 min of UV irradiation required to produce the gel damaged the cells, or the 3-D culture environment effected the proliferation rates (114).

Plant et al. created an *N*-(2-hydroxypropyl)methacrylamide (HPMA)–based hydrogel grafted with RGD. Incorporating glucosamine (NHGlc) or *N*-acetylglucosamine (AcNHGlc) into the polymer backbone enhances the biocompatibility of HPMA (115,116), and so RGD-modified HPMA was compared with these amino sugar–modified implants as well as unmodified HPMA. No control peptide was used.

Optic-tract lesions in 17- to 19-day-old PVG/c and Wistar rats were created and plugged with the experimental hydrogels. Nineteen-week-old PVG/c rats were given circular cortical lesions 500 μm in diameter that were again plugged with the hydrogels (all tested except AcNHGlc). Ten to 12 months after implantation, brains were excised and cryosectioned, and immunohistochemistry was performed. Positive staining for both glial fibrillary acidic protein and S100 marked astrocytes. Oligodendroglia could be identified with a stain against carbonic anhydrase II, and macrophages could be identified with a one against ED1. Antibodies against laminin (for evidence of neovascularization), neurofilaments, and myelin basic protein were also used.

Cortical Implant Results. Two unmodified HPMA plugs are implanted, but only one stayed in place for analysis. This showed no appreciable ingrowth. Macrophages were present outside the polymer, but not within it, and an astrocytic region surrounded the implant. Extensive integration was found around the two NHGlc-containing hydrogels, with 70% of the available hydrogel surface area attached to brain tissue. Laminin staining was evident throughout most of the hydrogel matrices. Astrocytes again surrounded the implant but the staining was only of low to moderate intensity, and unlike the unmodified HPMA a few astrocytes were present within the implant. There was evidence of a few ingrowing axons (average of 6 per section). Macrophage number and location were similar to unmodified HPMA, and here, too, no oligodendroglia could be seen in the implant.

One of the RGD-containing implants had become displaced, but of the remaining three, integration was very good, with about 90% of the available surface area attached to brain tissue. Laminin structures were evident throughout the hydrogels and were often associated with axonal ingrowth. The maximum number of axons found in one section was 78. An extensive matrix of astrocytes was also present within the implant, and there was little evidence of encapsulation by the surrounding tissue. Large numbers of macrophages were present, and no oligodendroglia could be located.

Optic Tract Implant Results. Four unmodified HPMA implants were used in these experiments. Only one of the four was found in the optic-tract lesion site after the brain was removed, and even this one was not attached to the host tissue. The surrounding tissue showed a low astrocytic response, and no astrocytes were found within the polymer matrix. There were no axons, oligodendroglia, or laminin in the polymer. Macrophages were present around the implant but not within.

The two NHGlc-modified implants showed attachment, with a good interface between host tissue and implant; however, a full bridge did not form across the lesion. Laminin staining indicated the presence of new blood vessels. A low number of astrocytes was found within the matrix. No oligodendroglia were present, and macrophages were present inside and outside the matrix. These appeared to be removing debris from the site, which would help explain these implants being a bit smaller than the unmodified HMPA. An average of six axons per section was found.

Three AcNHGlc implants were put into place. Only one of them was attached to host tissue. About 55% of available surface area on the implant was attached to tissue. Very little laminin and few astrocytes were seen in the matrix. No oligodendroglia and very few macrophages were seen in the implant. No axons had grown in.

Six of the seven RGD implants attached to host tissue, with about 75% of the available surface area attached. Laminin was present throughout the matrix and there were an extremely high number of astrocytes within the implant, with relatively little in the surrounding tissue. Many macrophages were present inside and outside of the implant and were in the same areas as astrocytes inside the implant. Five of the six implants showed axonal ingrowth, with an overall average of 36 axons per section. Once again axons were closely associated with laminin structures.

Poly(vinyl alcohol). GRGDSP were all immobilized to poly(vinyl alcohol) (PVA) by Matsuda et al. Hydroxyl groups on the surface of PVA films were activated with CDI, and the peptide in DMF was reacted with the surface. All unreacted active hydroxyl groups were reconverted to surface hydroxyls by treatment with a pH 8.1 solution.

Bovine aortic endothelial cells seeded on plain PVA surfaces in serum did not adhere, but cells seeded on peptide and fibronectin (covalently linked to the surface by the same method) did adhere and proliferate. In the absence of serum, cells on peptide-treated surfaces could be removed by soluble RGDS, indicating specificity for this reaction. The growth of cells at day 3 was greater on immobilized peptide than on fibronectin. Control over peptide density could be achieved by modifying the initial CDI reaction, and it was found that increasing the peptide density slightly enhanced cell growth (117).

Photocoupled Dimethacrylamide and PVA. Others have used coupling agents to covalently link peptides to polymers. Sugawara et al. immobilized an RGD-containing peptide (GGGRGDSP) to PVA and poly(*N*,*N*-dimethacrylamide-*co*-3-azidostyrene) (poly[DMAM]) using 4-azidobenzoyloxysuccimide. The succinimide reacted with the amine terminus of the RGD peptide and the azidobenzoyl bound to the polymer upon exposure to ultraviolet light. Photolysed phenyl-azido groups generate phenyl nitrenes, which are highly reactive (capable of addition to C=C bonds, insertion of C—H bonds, and abstraction of

protons from neighboring compounds). Even though the peptide was successfully immobilized to both polymers, the PVA also supported the nonspecific adsorption of the RGD peptide and was not used for most cell studies (118).

The poly(DMAM) alone did not support the adhesion and spreading of bovine aorta endothelial cells in serum-free medium, but once treated with photoimmobilized peptide, it did. These could be removed from the surface with soluble RGDS peptide, indicating a specific reaction between the cell and the immobilized peptide. A photomask was used to ensure peptide grafting to only specific areas of the polymer in a honeycomb or striped pattern. Cells were plated down in media without serum for a day and then switched to serum-containing media. Over the next few days, cells became confluent only in the peptide-grafted areas (118).

Silicon Dioxide

Rezania used this material to examine the morphology and attachment strength of cells to peptide-immobilized materials. Quartz surfaces were modified with an aminofunctional organosilane. A heterobifunctional cross-linker was used to link the terminal amines to the thiols of peptides with N-terminal cysteines. The experimental peptide was an RGD-containing sequence (CGGNGEPRGDTYRAY) derived from bone sialoprotein. A similar RGE-containing peptide was used as a control. Contact angle, ellipsometry, and ESCA were used to verify peptide attachment.

Cells used were isolated from neonate (6- to 12-day-old) rat calvaria and used at passage 2, 3, and 4. These were plated onto the test surfaces at 5,000 cells/cm^2 in DMEM with 1% bovine serum albumin (to block nonspecific binding).

To measure the strength of adhesion, a radial-flow apparatus (RFA) was used. This device is made of two parallel plates with a fluid jet in the center of one of the plates. The jet produces an axisymmetric flow pattern that in turn puts shear stresses on the surfaces of the plate. The shear stress at which 63.2% of attached cells would be expected to detach (Weibull characteristic strength) was significantly greater ($P < .05$) for RGD-grafted surfaces ($\approx 57 \pm 8$) than that of RGE-grafted surfaces ($\approx 37 \pm 4$).

Morphologically, cells were more spread ($P < .05$) on the RGD-grafted surfaces than on plain or RGE-grafted surfaces at 20 min and 2 h after plating. The spreading on the RGD was also significantly greater at 2 h than at 20 min (5). Fluorescent tagging of vinculin was also used to look at focal adhesion formation. RGE surfaces showed no focal adhesion formation even at 2 h. Though nothing was apparent at 20 min, at 2 h focal adhesions were present on the RGD-grafted surfaces. Focal adhesions were also present at 2 h when the substrate had been exposed to 15% serum-containing media. A major difference between RGD-grafted and serum-adsorbed surfaces was that the cells on the RGD showed many projections, while those on adsorbed serum were pancake shaped (5).

Fluorinated Ethylene Propylene

Vargo et al. developed a technique to immobilize peptides to the surface of a fluoropolymer without the use of coupling agents. Fluorinated ethylene propylene (FEP) was hydroxylated using radio-frequency glow discharge, forming FEP-OH. This material was immersed in DMSO containing YIGSR peptide and K_2CO_3. This was heated to 50°C and allowed to react for 72 h, and the peptide was linked to the surface via its *C*-terminus. Covalent attachment was verified with attenuated total reflection–fourier transform infrared spectrometry, and fluorescent microscopy of rinse solutions indicated against the presence of physisorbed YIGSR. The integrity of the immobilized peptide was verified by time-of-flight secondary-ion mass spectrometry (119).

It was found that increasing the time in the RFGD chamber increased the surface hydroxylation but that the optimal peptide incorporation was achieved between 0.5 to 1 min of plasma treatment (≈2% oxygen at 12-Å sampling depth). This may be due to a decrease in electron density at the surface or surface degradation with longer treatments. As would be expected, Vargo et al. found this technique to be applicable to a number of peptides (119,120).

FEP films were thus modified with the laminin-derived YIGSR and IKVAV sequences (IKVAV in the form of the peptide CSRARKQAASIKVAVSADR). NG108-15 neuroblastoma cell and PC12 pheochromocytoma cell attachment was evaluated.

Cell attachment was performed in serum-free media. All surfaces were preadsorbed with albumin to prevent nonspecific attachment. Quantification was done by randomly selecting a minimum of 300 cells per well under a Zeiss microscope equipped with Hoffman optics at 200× and developing a cells/area plot. To test for the specificity of attachment, soluble IKVAV-containing peptide or CDPYIGSR was used at 1 mg/mL concentration to block cell surface receptors in solution, preventing them from interacting with the immobilized peptide. As a further step, soluble CDPYIGSK was used as a soluble control peptide to ensure that a nonspecific reaction between cell and soluble peptide was not to blame for any decrease in adhesion.

The attachment of the NG108-15 cells to the YIGSR-modified surfaces in the absence of soluble peptide was statistically greater than that with soluble CDPYIGSR ($P < .05$). There was no statistical difference between no peptide and control peptide attachment ($P > .1$). Attachment of PC12 cells to IKVAV-modified surfaces showed a similar pattern, with attachment inhibited by soluble IKVAV peptide ($P < .001$) (120).

FEP surfaces have also been used to immobilize peptides for bone cell applications (121–123). Our lab has shown increased osteocalcin and osteonectin mRNA expression on RGD and RGE surfaces and increased osteocalcin mRNA and protein expression on RGD surfaces and has found that the cells successfully mineralized on all substrates. RAD-treated FEP did not show the same levels of protein and mRNA expression that RGD and RGE treated samples did (123).

Gold

With the exception of silane coupling agents and PepTite, the techniques described earlier, while effective, cannot be

directly applied to skeletal implant metals as they depend on covalent linkages with polymers. The gold–thiol bond has potential in this area.

Sulfur-containing molecules spontaneously form monolayers on gold surfaces. Gold interacts with ligands such as sulfur and phosphorous but remains inert to organic first-row elements (124). This makes this system especially useful for peptides, whose only non-first-row element is sulfur found in the amino acid cysteine.

The bond itself is not completely understood. Some call it covalent (125,126), while others refer to it as chemisorption (127). Basically, gold(I) (gold lacking one electron) thiolates ($RS^- Au^+$) are formed from gold(0) (gold lacking no electrons) and organosulfur species and adsorbed onto the gold(0) surface. This reaction requires the loss of a proton, possibly leaving as water or H_2. The bond energy is high: 40–45 kcal/mol (127).

Monolayers formed by this reaction tend to be close packed, resist the pooling of like molecules in a mixed surface, and require hours or days to exchange with thiols in solution to a significant degree (127,128).

Moodie et al. used cysteine-terminated peptides to evaluate bone cell responses to modified surfaces. Peptides were all solubilized in 50% ethanol at a concentration of 0.22 mM. Gold-coated substrates were exposed to this solution overnight to allow the thiols to react with the surface and the peptides to reach a stable arrangement. The resultant surface is diagrammed in Figure 1.

Cell attachment doubled in the first 20 min on RGDC-treated surfaces, even in the presence of serum (129), and an increased rate of spreading has been recorded over a 2-h time span (130). Alkaline phosphatase, a marker for bone cell maturation, was up-regulated on RGDC-treated gold as shown in Figure 2 (129).

Changes in mRNA expression for integrin subunits were also observed, with increasing α_5 and maintained β_1 expression over 19 days (decreased on plain gold or CG-immobilized surfaces) (129). As mentioned earlier, $\alpha_5\beta_1$ is a known RGD receptor.

Focal adhesions formed on RGDC-treated surfaces, and even after storage for 4 weeks in aqueous media, the percentage of cells showing focal adhesions remained high. This contrasts with adsorbed fibronectin, which lost its ability encourage focal adhesion formations under identical storage conditions during this time, eventually falling to the same level as plain gold surfaces (G. Moodie et al., unpublished data). In vivo bone formation was also increased around RGDC-treated rat femur intramedullary rods as compared to plain gold-coated rods (D. Ferris et al., unpublished data).

INTRODUCTION

Electrically assisted transdermal delivery uses electric fields to enhance transport of active agents across the skin. Iontophoresis and electroporation are the two major methods of electrically assisted transdermal delivery. These methods avoid the gastrointestinal degradation and hepatic first-pass metabolism found in oral administration. Both local delivery (e.g., lidocaine for topical anesthesia) and systemic drug administration (e.g., fentanyl for pain relief) are possible. Both methods can enhance drug flux up to several orders of magnitude above that allowed by passive diffusion (as in conventional skin patches), depending on the nature of the solute. Whereas the effective delivery range for passive diffusion across the skin is con-

strained to small, hydrophobic agents, electrically enhanced delivery can be used for larger, hydrophilic molecules, which is particular advantageous for peptide and oligonucleotide drug administration. Additionally, these methods can be programmed to varied levels for nonconstant delivery patterns, such as for pain management. However, there are practical constraints. The efficiency of transdermal delivery is low, so applications are limited to potent compounds. Irritation, metabolism, and interaction of the agent with the skin can also limit application. The literature on electrically enhanced delivery is extensive, particularly for iontophoresis, and the reader is directed to more complete reviews (1–8).

The skin functions as a physical, chemical, and microbial barrier to transport and is divided into the subcutaneous tissue, the dermis, and the epidermis. The outermost layer of the epidermis is the stratum corneum, which is generally the primary barrier to transport across the skin. In a classic description, the stratum corneum is described as being composed of dense, protein-rich, keratin "bricks" and a more fluid, lipid filled "mortar" (9), which is a multilamellar structure of lipid bilayers that forms a circuitous pathway around the keratinocytes. Additionally, structures such as hair follicles, sebaceous glands, and sweat ducts, collectively known as skin appendages, play a major role in electrically enhanced transport. The skin poses another barrier in that it can metabolize compounds, and the extent of drug loss prior to absorption by the blood stream will adversely affect its effective transport (10). Comprehensive reviews of skin physiology, particularly relating to transdermal delivery, are available (11,12).

IONTOPHORESIS

Iontophoresis involves application of a low-level electrical current across the skin. Iontophoresis uses two electrodes, the anode and the cathode, each of which is in contact with a reservoir containing an electrically conductive medium, which is, in turn, in contact with the skin (Fig. 1). The agent to be delivered is contained in one the reservoirs in an aqueous solution. An electrical potential is applied across the electrodes, causing current to flow across the skin and facilitating delivery of the therapeutic agent. The first well-documented experiments that reported using iontophoresis for delivery of an active agent were performed in 1900 by LeDuc, who demonstrated the delivery of positively charged strychnine sulfate into rabbits, causing convulsions when placed in the anode but no effect when placed in the cathode. Negatively charged cyanide caused poisoning when delivered from the cathode but no effect when delivered from the anode (13).

Transport Pathway

The transport pathway of molecules through skin under the influence of an electric field may be through the skin appendages, across the keratinocytes, or through the multilamellar lipid bilayers. For passive transdermal diffusion, it has been established that diffusion through the lipid layers is the dominant transport mechanism. However, for iontophoresis, substantial evidence indicates that most ion transport occurs through the pathways of lowest electrical resistance, which consist of hair follicles, sweat ducts, and skin imperfections (4). It has been shown in a number of studies that the route of ion transport is elevated in localized areas (14). Evidence includes methylene blue iontophoresis showing a pattern of blue dots on the skin (15), a vibrating-probe study showing locally high areas of current flow (16), and iontophoretic transport of $Fe(CN)_6^4$ coupled with scanning electrochemical microscopy (17) showing that areas of ion transport were associated with hair follicles. However, results also indicate that hair follicles alone do not account for the totality of transdermal flux (18), and some additional route may be present. Confocal microscopy of two dyes with different physicochemical properties indicated that the transport pathways can vary with the properties of the permeant (19). Evidence of transport through the lipid bilayer route has been found in studies of mercuric chloride iontophoresis through porcine skin. Transmission electron microscopy showed evidence of staining by the transported compound within the lipid bilayers (20).

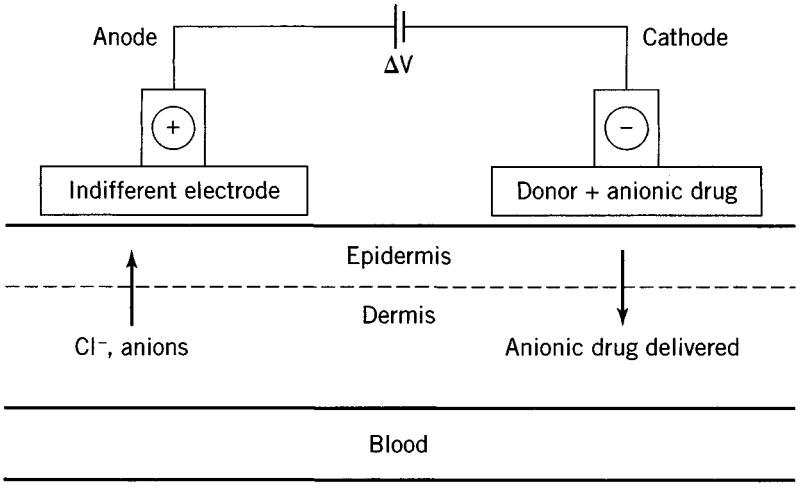

Figure 1. Schematic of iontophoretic drug delivery system. Example shows delivery of an anionic agent from the cathodal reservoir. The agent goes through the nonvascularized epidermis and into the dermis, where it can be transported into the blood through the capillary loops. The counter electrode is sometimes known as the indifferent electrode.

Description and Mechanisms of Transport

Mechanisms of Transport. Drug transport under the influence of iontophoretic current has three main contributions: electrophoretic, passive, and electroosmotic. The electrophoretic transport is caused by the electrical potential gradient applied to the charged species. Anionic (negatively charged) species are driven away from the cathode and towards the anode; cationic (positively) charged species are driven away from the anode and towards the cathode.

The electrophoretic transport for charged species is giving by the following equation:

$$J_{i,\text{electrophoretic}} = D_i C_i \frac{z_i F}{RT} \frac{dE}{dx}$$

where J_i is the flux of the ith species, D_i is its diffusion coefficient, C_i is its concentration, and z_i is its charge. F is Faraday's constant, R is the gas constant, T is absolute temperature, and E is the electric field.

Passive diffusion results from the concentration driving force. The passive diffusion contribution is described by the classic Fick's Law description:

$$J_{i,\text{positive}} = D_i\left(\frac{dC_i}{dx_i}\right)$$

The Nernst–Planck equation is the sum of the electrophoretic and passive diffusive contributions.

Electroosmotic transport is a convective flow of solvent induced by the application of a voltage gradient across a charged, porous medium (14,21). The transport pathways in the stratum corneum generally have a net negative charge. When an electric field is applied across the skin, cations, mostly sodium in the case of a physiological system, are preferentially passed through the skin due to the net negative charge. Volume flow toward the cathode is created by momentum transfer from the cations to the surrounding fluid (22,23). The magnitude of the flow is small, on the order of $\mu L/cm^2/h$, but for large or neutral molecules, it can have a substantial impact on skin flux (24,25). The electroosmotic effect can decrease the transport from the cathode compared with passive diffusion, because the molecule is moving against the direction of electroosmotic flow, impeding its progress (26).

Electroosmotic transport has the following form:

$$J_{i,\text{electroosmotic}} = C_i v$$

where v is the electroosmotic flow rate. In-depth mathematical descriptions and derivations are available (27–29).

Transport Number. An important concept in iontophoretic delivery is the transport, or transference, number. The transport number is a measure of how efficiently the agent of interest is transported relative to the other ions present in the system. It is an indicator of the permselectivity properties of the skin (30). A detailed description of the concept is give by Phipps and Gyory (31). The flux is characterized by

$$J_i = \frac{t_i I_i}{z_i F}$$

where t_i is the ion transport number and I_t is the total current density applied. F is Faraday's constant, and z_i is the charge on the ith ion. For example, for skin at physiological pH the transport numbers of sodium and chloride are approximately 0.66 and 0.33, respectively, indicating that for a given current, more sodium will flow across the skin than chloride and that the skin has a higher permselectivity for sodium than chloride. Therefore, the flux of the molecule of interest is controlled by its mobility *relative* to the other ions that undergo transport. Thus, increasing passive permeability of the skin does not necessarily lead to increased iontophoretic transport of the target molecule. If the mobility of permeants through the skin increases due to an increase in skin permeability, sodium and chloride are also more easily transported, and the applied voltage necessary to generate a current decreases, which may counteract any enhanced mobility of the target permeant.

Factors Controlling Delivery Rate

Experimental Methods. Skin flux of the drug of interest is commonly tested in vitro in diffusion cells with a layer of skin between the two reservoirs. Various configurations of diffusion cells are available (32–35). Common skin sources are cadaver skin; hairless mouse, rat, and guinea pig skin; pig skin; and shed snake skin (36). Animal models, such as hairless rat, mouse, and guinea pig and pigs, are used for in vivo studies, but studies on human subjects are limited to relatively few compounds. In vivo and in vitro results have been shown to correlate well (37,38), although the correlation may vary with the particular compound and drug of interest.

A novel model that is intermediate between a live animal and cadaver or animal skin is the isolated perfused porcine skin flap, developed by Riviere et al. This model uses excised tissue from the belly of the pig, which can be perfused to maintain tissue viability over the course of a 1-day experiment (39–41).

Drug Physicochemical Properties. Generally, smaller and more highly charged molecules will be delivered more effectively by iontophoresis than larger, neutral molecules (42–45). The isoelectric point of the skin is between 4 and 5, so molecules that are charged between the pI of the skin and physiological pH are most suitable (46). Under most conditions, the skin has a net negative charge, so cationic compounds are transported more readily than similar anionic compounds. Hydrophilic compounds transport more readily than similar hydrophobic compounds (47). There is no particular molecular weight cutoff for iontophoretic delivery; however, 1,000 to 3,000 Da is probably the highest molecular weight that could be effectively delivered with present technology. Analysis of a variety of compounds of various molecular weights have been reported (48,49), including an elegant study of various molecular weights of poly(ethylene glycol), an uncharged polymer (50).

Certain compounds can change the electroosmotic transport properties of the skin as they are delivered

(23,51,52). This was discovered from the observation that drug flux for certain peptides did not increase as expected with increasing peptide donor concentration. An investigation of the transport of mannitol, an uncharged compound commonly used to investigate electroosmosis, with the concurrent delivery of the peptides leuprolide and Nafarelin showed a decrease in electroosmotic flow in the presence of the peptide. The mechanism is proposed to be peptide binding to the transport pathway in the skin, with the positive charge of the peptide decreasing the permselectivity of the skin toward sodium and decreasing electroosmotic flow. Electroosmotic flow was increased slightly by using an anionic compound, poly-*l*-lysine, but the effect was less dramatic than the converse decrease for the cationic peptides (53).

The rational design of drug compounds to enhance their iontophoretic mobility, thereby increasing therapeutic efficacy, is an emerging development (54). Systematic modifications of insulin analogs, generated by recombinant DNA technology, have been studied. The delivery of monomeric insulin with two additional negative charges, created by substitute of aspartate and glutamate for uncharged residues, was 100 times more than regular, hexameric human insulin (55).

Current Application Protocol. The current levels used are low, typically in the mA to sub-mA range, with a typical maximum current density of 0.5 mA/cm^2 of skin. The practical current density maximum is primarily limited by the skin irritation that results from the current flow, although sensation associated with the current can be limiting for large application areas. Normally, current is applied across the skin in a constant, direct-current mode. Numerous studies have established the linearity of drug flux with current density for the vast majority of compounds (30,32,44,56,57).

Neutral molecules also show a linear flux relationship to current density because the electroosmotic flow is proportional to sodium transport, which is proportional to current density. The amount of drug delivered is proportional to the amount of delivery time, although there can be an onset period before flux stabilization occurs. However, as iontophoresis duration progresses, accumulation of ions in the reservoir, depletion in drug donor concentration, pH changes, or interaction of the drug with skin can cause a decrease in flux over long-duration experiments (58).

The application of the iontophoretic current has been shown to affect the subsequent passive diffusion of molecules, suggesting that the intrinsic permeability of the skin is increased by the applied current (24,25,27,59–62). Studies of electrical resistance indicate there are changes in the skin following iontophoresis (63,64), but the exact mechanism is unknown. There are no apparent changes in skin permselectivity, as evidenced by the linear relationship of drug flux to current and duration of application.

Constant-voltage, rather than constant-current, iontophoresis has also been used (65). There has also been work using pulsed, rather than constant-current, iontophoresis (5,66) showing enhanced transport from high-frequency pulsing. Interpretation of the effectiveness of these techniques relative to conventional iontophoresis can be complex. Constant-voltage iontophoresis is complicated by the decrease in skin resistance that occurs after application of current (63). From Ohm's Law, as the resistance decreases, current increases, which causes an increase drug transport. However, there is no evidence that the inherent efficiency of transport has been improved. The concept of rapid pulsing developed from the observed decrease in electrical skin impedance as pulse frequency increases. However, it is resistance, not impedance, that is related to ion transport across the skin. Several controlled studies of pulsing showed little or no effect of pulse frequency on ion transport (2,67,68).

Characteristics of the Reservoir Medium. The composition of the reservoir formulation can profoundly affect the delivery rate of the therapeutic agent (69). The concentration of the drug in the donor reservoir is one important parameter. Generally, the drug flux is linear with increasing concentration (47,70), although aggregation, interaction with the skin, and other factors can lead to nonlinear concentration effects (23). Maximum drug concentration is dictated by solubility, although self-aggregation, cost, and other factors affect optimal drug donor concentration.

The pH of the medium affects the drug charge, which, depending on the pK_a, affects its mobility. As stated earlier, charged, especially positively charged, drugs are transported more easily through the skin. A pH gradient between the donor formulation and physiological pH can cause the drug to get "stuck" in the middle of the skin. As the drug moves through different pH environments, it reverses charge and will be driven back in the direction from which it came (41,71). In addition to affecting the charge on the drug, the pH of the medium changes the relative charge on the skin, thus changing its permselectivity (72). As pH of the reservoir is decreased to less than 4.0–5.0, the skin undergoes a transition from being a net negatively charged membrane to a positively charged membrane, and it will become increasingly favorable to anion permeation. Conversely, as pH increases above 4.0–5.0, the skin becomes negatively charged, and cation and electro-osmotic delivery will be favored. The range of physiologically acceptable pH is usually considered to be pH 4.0–9.0.

Another important characteristic of the donor reservoir is the ionic strength and presence of competing ions in the formulation (70,73). Because the total amount of current delivered is constant, a high ionic strength donor and competing ions compete with the drug for the charge transfer and decrease the drug flux. Therefore, it is generally good practice to keep extraneous ions at an absolute minimum. However, the donor must be sufficiently buffered to prevent any side reactions from electrode reactions and to keep the drug in the appropriately ionized state.

Skin Pretreatment. Skin pretreatments have been used with varying effects. Some have reported successful synergistic enhancement over iontophoresis and passive enhancement alone for using oleic acid for AZT (74), ethanol for insulin (55,75,76), and depilatory lotion for insulin (77), whereas others report no enhancement effect (78) or varied enhancement (79). Vasomodulating agents can also alter drug flux. Co-iontophoresis of vasoconstrictors decrease

flux, whereas co-iontophoresis of vasodilators increase delivery (80). The application of proteolytic enzyme inhibitors to prevent the metabolism of peptides in the skin, thereby increasing the absorption efficiency, has been reported (81,82).

Toxicology

The application of the iontophoretic current can cause skin irritation and possibly affect the skin barrier function (83,84). Erythema (redness) and edema (swelling) can result to various degrees depending on formulation, duration, current density, and polarity. Generally, the irritation decreases within hours, although it may take a few days for complete resolution. Additionally, the active agent itself may cause irritation or sensitization of the skin. Studies of prostaglandin E2 (PGE2) release, by sampling using reverse iontophoresis, shows a difference in PGE2 release for several different active agents. PEG2 was correlated with erythema/edema scores (85). The effect of the pK_a of the transported species, among salicylic acid, salicylamide, *m*-nitrobenzoic acid, and *m*-anisic acid (pK_a range from 3.0 to 8.1) showed a sharp increase in irritation as the pK_a of the drug decreased to less than 4 (86). Irritation resulting from lidocaine and luteinizing hormone–releasing hormone (LH-RH) iontophoresis has been examined for gross changes (erythema and edema) and histologically, and the alteration caused by the iontophoresis resolved and had minimal toxicological significance (87,88). Studies using techniques such as measurement of transepidermal water loss, laser Doppler flowmetry, skin capacitance, and skin temperature postiontophoresis showed moderate response and no change in skin permeability or integrity (89,90).

Electrode Design

Electrode design is an important part of an iontophoretic device (33). A number of different types of electrodes have been used in iontophoresis, both for research and commercial applications, including platinum, stainless steel, and carbon. A widely used electrode system is the Ag/AgCl system (91) because it maintains the pH of the iontophoretic medium and has no negative toxicological implications. For Ag/AgCl electrodes, the following reactions occur stoichiometrically:

$$\text{Reaction on the anode: } Ag + Cl^- \rightarrow AgCl + e^-$$

$$\text{Reaction on the cathode: } AgCl + e^- \rightarrow Ag + Cl^-$$

These reactions maintain the pH of the reservoir at a constant level. Platinum and other metal electrodes can have an undesirable hydrolysis reaction, particularly at the cathode:

$$\text{Reaction on the cathode: } H_2O + e^- \rightarrow OH^- + 1/2H_2$$

The resultant high pH is not compatible with living skin tissue. Furthermore, the hydroxide ions formed from the reaction are driven into the skin by the negative charge on the cathode, which can cause a small, but relatively deep, localized skin injury. However, it is possible to circumvent the pH changes caused by water hydrolysis by buffering the medium sufficiently to prevent large pH swings (92).

Another aspect of electrode design is prevention of accumulation of unwanted ions as iontophoresis current accumulates. For example, if the drug is anionic and is being delivered from the cathode, for the Ag/AgCl system, the concentration of chloride ions in the medium will increase over time and will eventually compete with the drug for the available current flow. This would cause a steady decrease in drug transport over the duration of the iontophoresis application period.

Applications of Iontophoresis

Several local and subcutaneous conditions have been treated by iontophoresis. Lidocaine iontophoresis for localized analgesia is a common commercial application (93,94). The Iontocaine® (Iomed, Salt Lake City) is a U.S. FDA–approved combination drug–device system. Topical epinephrine (93), dexamethasone, hydrocortisone (95), and prednisolone has been reported. Antiinflammatory drugs (e.g., diclofenac and ketoprofen) have been given to relieve pain, and steroids and retinoids have been used to treat scarring (46). Other local applications include delivery of antivirals and corticosteroids for herpes infections (96). Irritation reduction by administration of antiflammin 1 peptide has been demonstrated (97). Iomed (Salt Lake City), Iontophor-PM (Life-Tech, Houston, TX), and other companies also produce commercial power supplies with multipurpose electrode reservoirs and electrodes for iontophoresis, which are marketed primarily for localized applications.

Systemic administration of drugs is also possible. Fentanyl is in clinical trials for pain relief (46). Apomorphine, for treatment of idiopathic Parkinson's disease, has been tested in human subjects (37,98). Peptide drugs have been a major target of iontophoresis, and various reviews are available (1,2,4,5,41,99–101). Peptides that have been tested include thyotropin release hormone (56), various series of amino acid derivatives and tripeptides (45,60,62), LH-RH and analogs (23,38,57), vasopressin (5,71,73,75), and calcitonin (102,103). Transdermal delivery of insulin has been reported in vitro and in animal models (41,54,55,77,104–110).

There are applications of iontophoresis in addition to transdermal delivery of a therapeutic agent, and in fact some of these have been the most commercially successful applications (111). Hyperhydrosis, excessive sweating, has been successfully treated with application of iontophoretic current and no additional therapeutic agent (112–116). The Drionic device (General Medical Products, Los Angeles) is a commercial example. Iontophoresis has been applied to the eye to deliver compounds intraocularly (117–121), to the teeth to reduce hypersensitivity (96,122,123), across the nail (124), and to the ear (125). One of the first commercial uses of iontophoresis was for a cystic fibrosis diagnostic test (126): Iontophoresis is used to deliver pilocarpine to the skin to induce sweating, and the sweat is collected and tested for chloride content, which is used as

a diagnostic marker for cystic fibrosis (127,128). This device is available from Wescor, Inc. (Logan, Utah). A newer application of iontophoresis is to extract substances from the body for diagnostic purposes (129–131). Proof of concept of this application for a noninvasive glucose-monitoring system for diabetics has been established. The electroosmotically extracted glucose flux was found to be proportional to the concentration of glucose in the blood (132).

ELECTROPORATION

Basic Principles

Electroporation involves the application of a short, high-voltage pulse across a lipid membrane, which creates transient pores in the lipid bilayers, a phenomenon sometimes known as reversible electrical breakdown (REB) (133). Electroporation has been used for a number of years in cell biology and biophysics, primarily as a method to introduce DNA into isolated cells (134–136). The idea of applying electroporation to whole tissues to increase permeability for drug delivery is a relatively recent development (137). Electropermeabilization of tissue has been used to deliver chemotherapy agents to tumors in vivo, increasing the efficacy of uptake of the agent into the tumors and thus improving effectiveness of the chemotherapy (138–143). Electroporation has also been used to deliver DNA into intact tissue in vivo (144,145). Pioneering work by Prausnitz et al. on transdermal electroporation demonstrated enhanced delivery of molecules through the skin after application of short, high-voltage pulses (146). Electroporation of mammalian skin was shown to increase flux by up to four orders of magnitude over passive delivery for three polar molecules with molecular weights up to slightly more than 1,000 Da. Studies on hairless rats showed similar increases in flux in vivo. After the pulsing was stopped, transdermal flux decreased by more than 99% within 1 or 2 h, indicating significant reversibility of the permeability increase. The transient nature of the permeability change is consistent with the proposal that there is reversible electric breakdown in the skin lipid layers.

There is strong evidence in the literature that in isolated cells, electroporation causes the molecules in the lipid bilayer of the cell membrane to reorient themselves to form a transient hydrophilic pore. After the pulse application is stopped, the pores can reseal over a period of milliseconds to hours, depending on the duration and magnitude of the applied pulse. This allows large molecules, such as DNA, to get into the cell but allows for resealing so that the cell retains viability. The lipid bilayer structure of the skin suggests that it could also be effectively electroporated. However, the skin lipid layers are multilamellar and are composed of different types of lipids than unilamellar cell membranes, so the conditions for skin and cell electroporation may differ. The required transdermal potential to create sufficient transbilayer potentials in the multiple lipid bilayers of the skin for electroporation is in the tens to hundreds of volts. The pulse duration can be a square or an exponentially decaying capacitive discharge, with time constants in the micro- to millisecond range.

Comparison of Tissue Electroporation and Iontophoresis

Although electroporation and iontophoresis both involve application of an electric current across the skin, the mechanism of transport enhancement is generally accepted to be different. Iontophoresis enhances transport through the electric field–gradient driving force. Electroporation enhances the permeability of the skin by altering skin structure. Any driving force—iontophoretic, passive, electroosmotic—can be applied postelectroporation to effect flux enhancement compared with nonelectroporated skin. At this time, the mechanism for electroporation of skin is not as well understood as for cell membranes. Actual visualization of the pores is difficult, owing to their small size and fluctuating nature, so lipid reorientation to form hydrophilic pores must be inferred.

There is mounting evidence that electroporation creates dramatic alterations of the skin structure, as shown from studies of skin permeability changes, skin electrical impedance, microscopic imaging, and mathematical modeling (147). Studies of calcein flux showed that there is a sharp increase in skin flux at a threshold of about 60 V across the skin, followed by linear transport increases and then a plateau. The flux rapidly decreases when pulsing is stopped. The sudden increase in permeability once a voltage threshold has been attained and the reversibility of the permeability increase suggest that the mechanism of enhanced transport in skin lipids may be similar to that of electroporation in individual cells. Studies of the electrical properties of the skin demonstrated that changes in the skin barrier properties from pore formation did occur during high-voltage pulsing and did not occur during low-voltage iontophoresis (148,149). Confocal microscopy, a technique that images fluorescent molecules within the skin, has shown localized transport regions associated with electroporation that are not present under iontophoretic conditions (150,151). These regions may be associated with altered skin structure resulting from electroporation. Modeling of theoretical flux under low- and high-field strengths has led to the hypothesis that electroporation causes a unique form of transport enhancement (152).

Examinations of the transport number to compare efficiency of transport between electroporated and nonelectroporated skin have been reported. The flux of calcein, a highly charged model compound, was compared under a series of high-voltage pulses versus low-voltage iontophoresis. Enhancement of transport efficiency for both small and large ions was demonstrated (153). Electroporation has been used in conjunction with iontophoresis, and studies of the effect of electroporation on iontophoretic transport number were performed. Transdermal skin flux under iontophoresis of LH-RH, vasopressin, and neurotensin were three to eight times greater after the application of a single electroporative pulse than the same iontophoretic current without the pulse. This suggests some modification of the skin transport properties due to the electroporative pulse (154).

Conversely, Higuchi et al. have hypothesized that traditional low-voltage iontophoresis induces pore formation

and that large-voltage pulses are not necessary (26,155,156). It is well documented that regular iontophoresis has been shown to increase passive skin permeability and change the electrical properties of the skin (61). However, it is uncertain whether this is actual electroporation of the lipid bilayers of the skin or some other phenomenon. In a combined theory, it has been proposed that application of voltages in the 1- to 5-V range, levels found in typical iontophoresis, causes electroporation through breakdown of the epithelial cells lining the walls of the skin appendages (sweat ducts and/or hair follicles). Further increases in voltage to tens of volts can cause the stratum corneum lipid lamellae to form pores, but the authors propose that such a pathway is not sufficient to provide a continuous pathway for effective transport. They suggest that a combination of passage through the keratinocytes and lipid bilayers is the transport pathway in high-voltage, pulsed electroporation (157).

Applications of Skin Electroporation

Practical application of electroporation is less advanced than for iontophoresis. A number of researchers have completed initial studies of potential applications of electroporation. Faster response has been suggested as an advantage of electroporation over iontophoresis and passive transdermal delivery, which could be an advantage for pain management applications (158). Vanbever et al. have studied the kinetics of transport of fentanyl, an analgesic therapeutic agent, both in vitro (159) and in vivo (160). Effective analgesia was achieved in hairless rats with rapid onset. Vanbever studied transport of metoprolol (161). Wang et al. have examined topical delivery of cyclosporin A for the treatment of psoriasis (162,163). Jadoul and Preat investigated electroporative and iontophoretic flux of domperidone (164). Delivery of various peptides are discussed by Potts et al. (165). Prausnitz et al. studied transdermal delivery of heparin, an anticoagulant. The anticoagulant activity of the delivered heparin was one-eighth of the donor heparin, indicating preferential transport of the small (less active) heparin molecules (166). The transport of DNA antisense oligonucleotides of 15 mer in length were demonstrated. Zewert et al. have proposed transdermal transport of anticancer nucleotides for treatment of melanomas (167).

Weaver et al. examined a method to increase the lifetime of the pathways created by electroporative pulses (168). It was hypothesized that long, highly charged molecules can act as separators, holding open the pathways in the lipid layers. Molecules such as heparin, dextran sulfate, neutral dextran, and polylysine were shown to enhance electroporation-assisted delivery of mannitol as a model compound. Postpulse skin permeability was higher and skin resistance was lower in the treated skin compared to control. The same molecules did not enhance passive or iontophoretic transport (169). Hofmann (170) and Zhang (171) have proposed enhancing the effect of electroporation of the skin by cocontacting the therapeutic agent with micron-sized particles, followed by the application of pressure. This method was studied for 2- to 20-μm Lupron Depot microspheres and the *lacZ* reporter gene. Additionally, the use of electroporation in conjunction with encapsulation of the agent into vesicles has been proposed (170). Electroporation has also been studied in conjunction with ultrasound to synergistically enhance the effects of both methods (172).

Physiological Effects

Sensation caused by the pulsed current would be expected to be an issue in practical application of the technology. There has not been any significant testing on human subjects under the conditions for transdermal delivery. Studies of transcutaneous electrical neural stimulation (TENS), a technique of applying electrical pulses across the skin to reduce pain, show significant sensation associated with the method (173,174). The applied charge in TENS units are typically less than 25 μC, produced by 30 to 60 V of 200-μs duration or 500 V of 15-μs duration. This is substantially less than those used in in vitro skin electroporation studies (100 to 300 V for millisecond to tens of millisecond duration). The electroporative pulses also cause muscle contraction, which may not be acceptable for some applications. However, there are engineering designs to mitigate the sensation and muscle contracts caused by the pulses. Theoretical work has been done in designing systems to take the electrodes and tissue physiology into account. Closely spaced electrodes could effectively localize the electric field to the stratum corneum, where there are no nerve endings. Such localization would reduce or eliminate sensation, muscle contraction, and damage to underlying viable epidermal tissue

Because the use of electroporation across the skin is a new development, the physiological effects of skin electroporation have not yet been studied extensively. Riviere et al. (88) studied changes in the skin toxicology following electroporation. Vanbever et al. compared the irritation caused by iontophoresis and electroporation (175). In these studies, there was no additional irritation associated with electroporation compared to iontophoresis. On the other hand, tissue injury above that created by thermal burns that occur in accidents involving high-voltage power lines has been related to tissue electroporation causing damage to cell membranes in the injured area (176,177). However, the voltages and currents are at a much higher level than that used in skin electroporation, and the relevance to skin electroporation may be limited. Tissue electropermeabilization has been use in preliminary studies on human subjects to enhance tumor cell permeability for the treatment of squamous cell carcinoma (178). Subjects reported some sensation and muscle contraction associated with the electrical pulses but completed the treatment. The demonstration of human use of tissue electroporation suggests that transdermal electroporation is feasible in human subjects. Ultimately, more work on living skin tissue is needed to assess the viability of electroporation for practical drug delivery.

INTRODUCTION

The use of the skin as a route of drug delivery has a long history; throughout the ages, many types of plasters and poultices have been used to treat various local and systemic complaints. It is only within the last 30 years that increased understanding of the skin and its barrier properties has allowed the development of more reliable and efficacious means of safely delivering therapeutic agents through the skin.

The skin functions as the largest organ in the body and is comprised of several layers that protect the underlying tissues. Absorption of chemicals by the skin may have substantive local and systemic consequences, and a number of factors influence the rate and extent of chemical transport through human skin. A variety of qualitative and quantitative methods are used to determine percutaneous absorption of drugs, and the results of both in vitro and in vivo studies may be used to predict absorption in humans. It has been demonstrated that there are intraindividual and interindividual differences in percutaneous absorption; understanding these differences is key in the design of a reliable transdermal system. The use of predictive models is extremely important in preclinical testing of new transdermal formulations and drug delivery systems. These studies include assessment of transdermal drug permeability and the potential for drug toxicity; skin irritation, immunological responses, and systemic toxicity are also important testing parameters.

The simplest of today's transdermal or topical drug delivery systems incorporate a vehicle such as a liquid, gel, or cream for direct application to skin. Hydrocortisone lotions and acne treatments are prime examples of topical formulations. More recently, transdermal therapeutic systems have been introduced, offering a more sophisticated and more reliable means of administering drug through the skin. Greater understanding of the pharmacokinetics of percutaneously administered drugs has led to the development of rate-controlled systems with optimized delivery profiles, and the use of permeation enhancers has expanded the number of drugs that can be administered transdermally.

In the United States, transdermal systems are now used for analgesics (fentanyl), hormone replacement therapies (estradiol and testosterone), and for the treatment of angina (nitroglycerin), hypertension (clonidine), and motion sickness (scopolamine). Transdermal nicotine replacement therapy for smoking cessation is also available, and a number of other drugs are being studied for possible inclusion in transdermal systems. As compared with other means of drug administration, transdermal systems have been associated with improved bioavailability, sustained therapeutic effect, diminished side effects, and convenient, noninvasive use that allows easy termination of therapy.

In this article, a review of skin biology and permeability is provided, and a discussion of the predictive models and toxicology testing employed in the development of transdermal products is presented. An overview of marketed transdermal systems technology is also presented with an emphasis on product characteristics and the clinical performance measures of safety, efficacy, reliability, and acceptability of drug treatment.

STRUCTURE, COMPOSITION, AND FUNCTION OF SKIN

The skin and other tissues protect internal organs from heat, humidity, pollution, radiation, and other potential insults. Human skin is comprised of the unvascularized epidermis and the highly vascularized dermis just below it (Fig. 1). The external layer of the epidermis is called the stratum corneum, which in Latin means "horny layer." This layer of skin is considerably less permeable than the dermis itself and protects the more permeable skin layers beneath it. The human stratum corneum varies from 10 to 50 μm in thickness and is a heterogeneous structure of dead, flattened, interdigitated keratinocytes that are each 0.5–1.0 μm thick. The constituents of these cells are protein, water, and lipids, the latter are concentrated largely in the extracellular phase and serve to cement the structure together into a coherent membrane (1). The range of stratum corneum thickness varies depending upon anatomic location. On the palms of the hands and soles of the feet, the stratum corneum is adapted for friction and weight bearing, respectively, and is considerably thicker than at other locations. Below the stratum corneum, the living epidermis ranges from 50 to 100 μm and proliferates rapidly by cellular differentiation. Cells migrate from the basal layer toward the skin surface at a rate of one new cell layer per day and undergo keratinization as they approach the external skin surface; the stratum corneum is completely replaced every 15 to 30 days. The epidermis itself is capable of most biotransformation reactions that are seen in the liver; the specific enzyme activity of the skin sometimes surpasses that of the hepatic enzymes. Phase I reactions include oxidation, reduction, and hydrolytic reactions, and Phase II reactions are conjugation reactions such as methylation, glucuronidation, and sulfatation.

The dermis is relatively thick compared with the stratum corneum and epidermis, comprising approximately 2,000 μm and containing a matrix of connective tissue that is penetrated by nerves, blood vessels, and lymphatics. Localized structural features of the skin include the hair follicles, sweat glands, and sebaceous glands, which may serve as permeation pathways to the underlying vascular bed.

PERMEABILITY OF HUMAN SKIN

Although the skin serves as a barrier and was once thought to be virtually impermeable, it is now recognized as a permeable organ capable of local absorption that may have substantive systemic consequences. Many factors influence the rate and extent of drug transport through human skin.

Mechanism of Permeation

It has been clearly demonstrated that the mechanism of permeation through skin is a partition-diffusion process

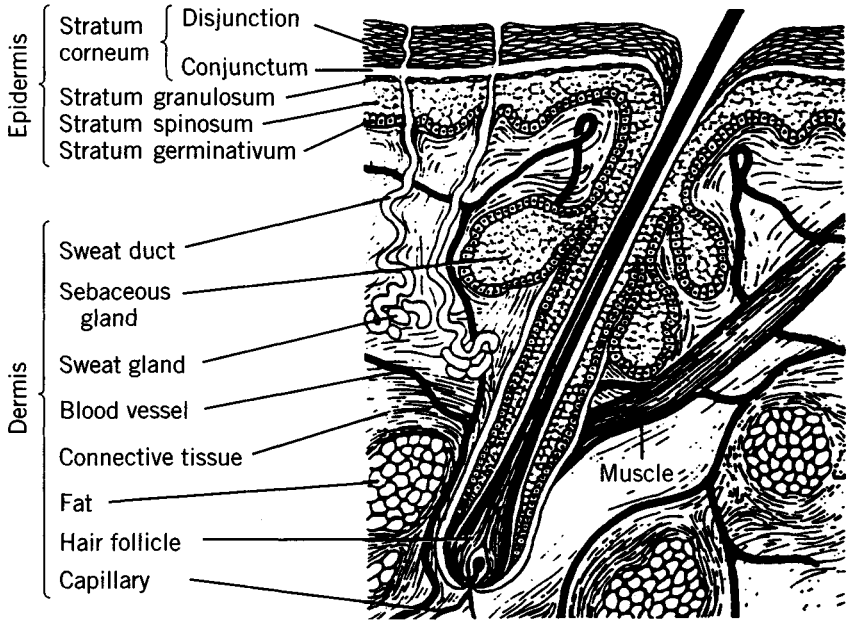

Figure 1. Structure of normal skin. *Source:* From *Casarett and Doull's Toxicology: The Basic Science of Poisons* 3rd C.D. Klaassen, M.O. Amdur, and J. Doull, ed., Macmillan, New York, 1986, p. 414.

rather than an active process (2–5) and, therefore, follows the diffusion principles described by Fick (6). In skin that is intact, the major barrier to drug penetration is the stratum corneum with its bilayer arrays of lipids. These well-organized and repetitive arrangements of lipids form "seals" such that material exchange between the skin surface and the layers beneath it is inefficient. There are various micro routes of drug permeation that have been suggested (Fig. 2) (7).

Techniques for Measuring Skin Permeation

There are a number of methods, both qualitative and quantitative, that may be used to determine the extent and rate of percutaneous absorption of drugs. Results of in vitro and in vivo study may be used to predict absorption in humans (Fig. 3) (8).

In vivo methods. In vivo permeation may be measured by determining what remains of a known amount of a sub-

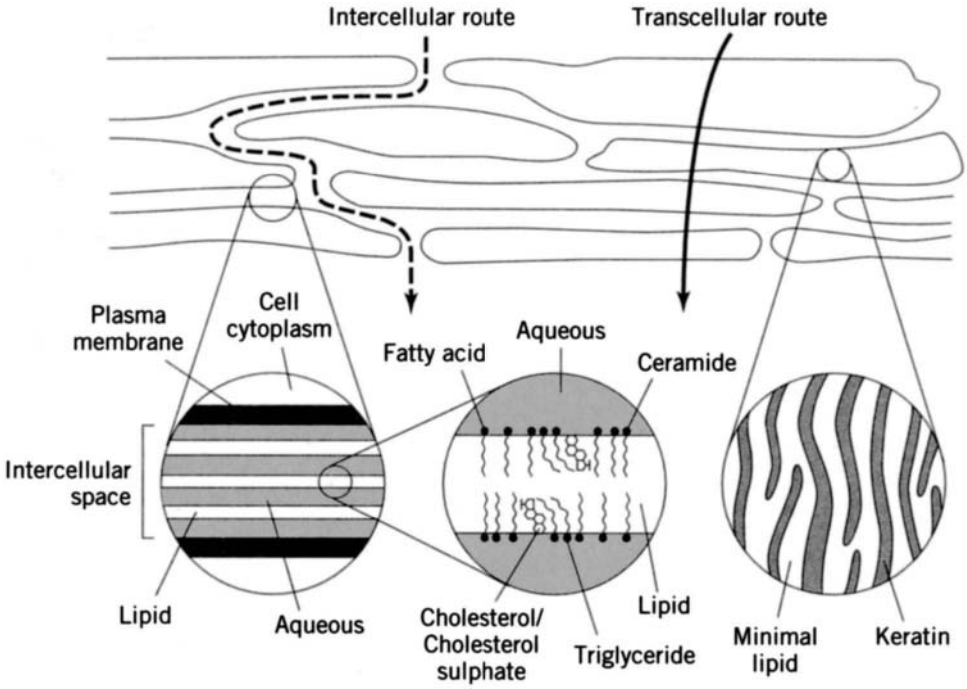

Figure 2. Possible microroutes of drug permeation through human skin—intercellular or transcellular pathways. *Source:* After Ref. 1.

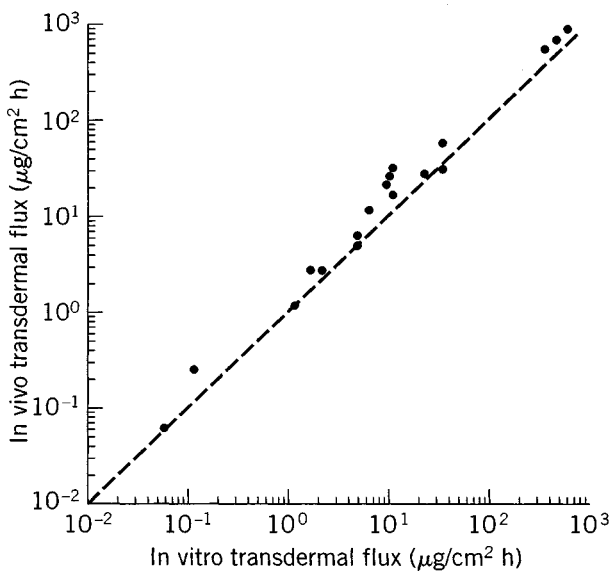

Figure 3. Correlation between in vivo and in vitro transdermal drug flux. Each data point represents a different drug. Dashed line indicates perfect correlation between in vivo and in vitro transdermal drug flux. *Source:* Ref. 8.

stance after it is applied to skin for a given time period. This "residual drug" method of determination is based on the assumption that the difference between the dose initially applied and the residual represents the amount of drug that permeated the skin and has been or will be absorbed by the underlying capillaries. In fact, the drug may have been absorbed in the epidermis or stratum corneum and metabolized in those structures. The "pharmacokinetic method" is an alternative and relies on measured serum or plasma concentrations and the predetermined clearance rate of the compound for calculation of the steady-state permeation rate. Variability in skin permeation between individuals or at different skin sites (Fig. 4) may confound these results.

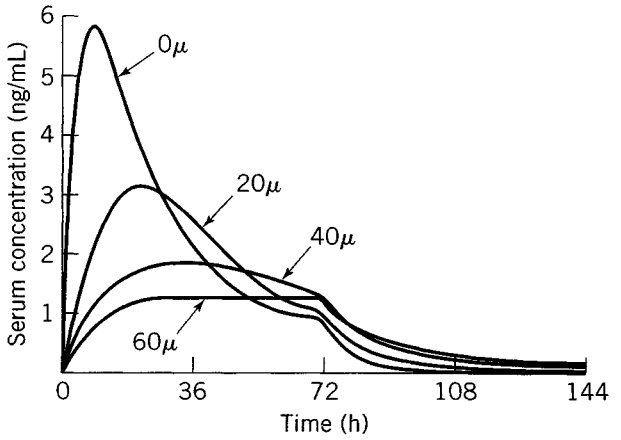

Figure 4. Effect of skin thickness on serum fentanyl concentrations (TTS (fentanyl)-100, 72h).

A number of other methods of determining skin permeation in vivo are also available. Topical application of a radiolabeled compound allows measurement of the amount of radioactivity in excreta, and the final amount of radioactivity is expressed as the percentage of the applied dose that was absorbed. Determination of percutaneous absorption by this method does not account for skin metabolism. Absolute bioavailability of a topically applied compound may be determined by measuring the compound by specific assay in blood or urine after topical and intravenous administration, but this is often difficult because drug plasma concentrations are frequently low after topical administration (9). Estimation of percutaneous absorption may also be determined by substituting a biological assay for a chemical assay and estimating (10); however, this method is only appropriate to use in studying compounds that elicit an easily measurable response.

Skin stripping may be used to determine the concentration of chemical in the stratum corneum after short-term topical exposure. The compound is applied to skin for a period of 30 minutes, and then the stratum corneum is removed by successive application and "stripping" of cellophane tape from the skin. Tape strippings are assayed for chemical content, and linear extrapolation predicts the percutaneous absorption of the chemical for longer application periods (11,12). This method eliminates the use of radiolabeled compounds and the need to measure absorption via excreta. More recently, a number of other methods for in vivo determination of percutaneous absorption have been reported, including infrared spectroscopy (13–15), microdialysis (16), and a laser-photoacoustic method for percutaneous absorptiometry (17).

In vitro methods. In vitro methods of determining the skin permeability of various substances may be more convenient; correlation of in vitro and in vivo flux of a variety of compounds has been described previously (8). In one method, skin specimens may be mounted as a membrane in a diffusion chamber with two compartments. The compound to be tested is placed in contact with the stratum corneum side of the skin at a relatively high concentration or level of activity, and an appropriate receptor vehicle is placed in the other compartment in contact with the dermal side of the skin. The diffusion chambers allow evaluation of mass-transport phenomena through the skin (18). Excised human or animal skin may be used, and the skin can be intact or separated from the epidermis (9). Apparent correlation of any of these data do, however, need to be verified with in vivo pharmacokinetic data. Another in vitro model that employs a partition coefficient of a drug or chemical in vehicle with powdered human stratum corneum has been used to determine the proportion of chemical bound to the skin particles (9).

Regional Differences in Permeation

Research has demonstrated the existence of both intraindividual and interindividual differences in percutaneous absorption. The extent of these differences varies considerably and is affected by the physiochemical nature of the penetrant (19). In evaluations of permeation rates that

have tested skin from the same and different donors, regional intraspecimen variability has been shown to be less than regional interspecimen variability (20). Explanations for these regional differences have been ascribed to a variety of factors, including differences in blood flow, the thickness and lipid content of the stratum corneum, and the number of sweat ducts and hair follicles at the skin site. Percutaneous absorption may also be influenced by other conditions such as temperature, friction, and hydration of the skin (19).

Dermal absorption studies of polycyclic aromatic hydrocarbons demonstrate low but variable regional differences in absorption. Skin at the shoulder is two times more permeable than skin on the forearm; the skin of the ankle and at the palm of the hand is two times less permeable than that on the forearm (19). In vivo permeation of caffeine, benzoic acid, and acetylsalicylic acid have also been demonstrated to be site dependent (12), as has the permeability of scopolamine (Fig. 5) (21). In the latter study, the postauricular epidermis was shown to be about twice as permeable as specimens from the trunk and was even more permeable than epidermis from the forearm and thigh. Scrotal skin has been shown to be considerably more permeable than skin at other anatomic locations; this phenomenon is thought to be the result of its superficial vascularity (22).

Study of in vitro permeation of fentanyl and sufentanil at different skin sites yielded results that contrasted with those of in vivo studies (23). The permeability coefficients obtained on skin from a single cadaver at the upper arm, thigh, abdomen, chest, and sole of the foot were all quite similar. Fentanyl, however, was less permeable at the sole of the foot than at other sites. Both drugs are quite permeable due to high lipophilicity (favoring partitioning in the stratum corneum), and thus their in vitro permeation rates through cadaver skin may not be influenced greatly by skin site. Differences in age and gender did not appear to affect the permeation of these drugs.

Skin permeability frequently differs among patients, leading investigators to study the effects of age, gender, and race on percutaneous absorption using a variety of chemical agents. Advancing age appears to compromise

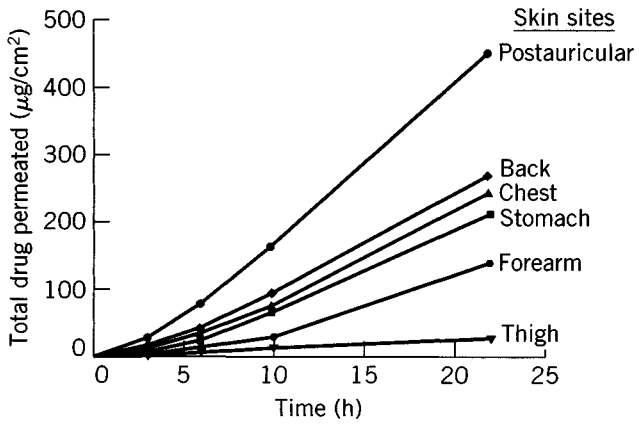

Figure 5. Variation in cumulative scopolamine flux as a function of skin site.

skin, causing the epidermis to atrophy, the dermoepidermal junction to flatten, and the dermis to thin. The majority of published literature indicates that irritant and allergic inflammatory reactions are weaker in older subjects. There is a lack of consensus, however, as to whether there are measurable differences in percutaneous absorption between young and old subjects (24). Gender differences in percutaneous absorption have been postulated, but in general, no significant gender-related differences in barrier integrity or barrier recovery have been found (25). Study of skin structure indicates that the thickness and lipid content of stratum corneum of men and women is similar (26).

The question of whether or not there are racial differences in percutaneous absorption is difficult to answer with complete certainty. Wester and colleagues (27) and Lotte and colleagues (28) studied the percutaneous absorption of benzoic acid, caffeine, and acetylsalicylic acid and found no significant differences in absorption between Asians, Blacks, and Caucasians (Fig. 6). However, a study of nitroglycerin absorption indicates Black subjects had lower systemic drug concentrations than Asians or Caucasians (29). Black skin also showed increased resistance to tape stripping as compared with Caucasian skin and has been thought to resist chemical irritation better than lighter skin. This general assumption, however, may be based primarily on differences in the appearance of erythema, which is far more difficult to detect in Black skin than in light-colored skin (9).

Transepidermal Water Loss and Water Content of the Stratum Corneum

The measurement of transepidermal water loss (TEWL) and the water content of the stratum corneum provide important information about skin function and integrity. The skin loses water as vapor, which evaporates from the skin surface. Occlusion of the surface prevents water loss and increases the water content of the stratum corneum. Healthy skin is characterized by direct proportionality of TEWL and hydration of the skin. Damage to the skin raises TEWL as compared with that of intact skin (30).

In its fully hydrated state, the permeability of the stratum corneum to water can be substantially higher than during its normal state. Occlusion of human skin with vinylidiene polymer film indicated skin was fully saturated with water within 24 hours and reverted to preocclusion values within 18 hours of film removal (31). The increasing permeability of skin under occlusion is attributed to an increasing fluidity of the stratum corneum that is induced by moisture.

Immature, Diseased, or Damaged Skin

Changes in the integrity of skin affect TEWL. The immature skin of infants with a gestational age of less than 36 weeks has significantly greater TEWL than that of a full-term infant (32). In infants over 37 weeks of gestational age, however, TEWL is lower than in adults, suggesting a more efficient stratum corneum. As the skin ages, TEWL and hydration decrease, maintaining their directly proportional relationship. In people over 60 years of age, a number of factors may contribute to decreased TEWL, includ-

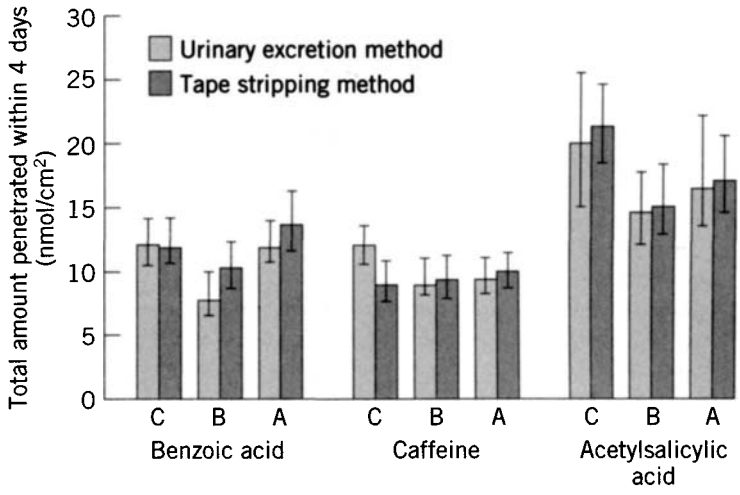

Figure 6. Influence of race on percutaneous absorption of benzoic acid, caffeine, and acetylsalicylic acid in Caucasian (C), Black (B), and Asian (A) subjects. *Source:* After Ref. 28.

ing increases in the size of corneocytes and in the thickness of stratum corneum, the latter is likely related to impaired desquamation of corneocytes (30).

In skin that is damaged or diseased, there is an inverse correlation between TEWL and the stratum corneum water content; the lower the skin hydration, the higher the TEWL (Fig. 7). Alteration of the skin barrier and/or the keratinization of cells are thought to be potential causes of defective stratum corneum water-holding capacity (30). Hyperproliferative diseases, such as psoriasis and exfoliative dermatitis, may lead to significant increases in TEWL due to weakening of the permeation barrier (33). Although this damaged skin is frequently thickened, increased percutaneous absorption is characteristic in patients with inflamed eczematous skin (34,35). Essential fatty acid deficiency or ultraviolet radiation damage may also induce epidermal hyperproliferation and increase TEWL and percutaneous absorption (36–38). TEWL may also be increased by tape stripping or abrading the skin surface; permeability is increased in these settings (36).

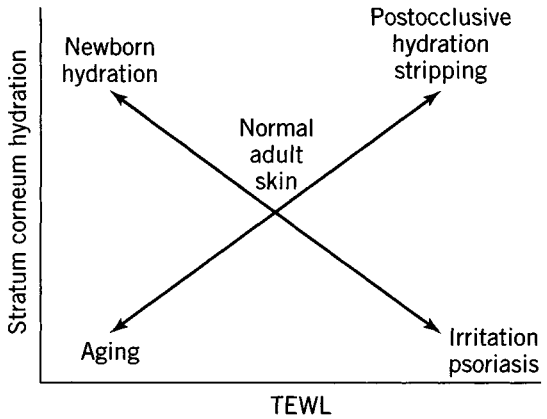

Figure 7. Relationship between TEWL and skin surface hydration. The quantification of hydration and transepidermal water loss may allow the differentiation between physiologic dry skin and pathologic dry skin. In the latter, damage to the water barrier is present. *Source:* After Ref. 30.

PERMEABILITY MODELS FOR STRATUM CORNEUM

The use of a model to predict skin permeability is important in determining the local and systemic characteristics of transdermal drug administration and in providing an understanding of the skin's barrier properties. Several types of models have proven useful in predicting skin permeability to penetrants.

Effects of Stratum Corneum Lipids on Diffusivity

The lipid components of skin appear to play a significant role in the permeability of the stratum corneum. Delipidizing the tissue with a solvent such as a chloroform–methanol mixture removes lipid components without discernible mechanical or morphological alteration of the membrane. The water permeability of the delipidized, hydrated stratum corneum is three to four times greater than that of the normal tissue, and its permeability to larger molecules may be as much as six times greater than that of normal tissue (5).

The importance of lipids as a primary permeability barrier is evidenced by the "brick and mortar" model in which lipids are envisioned as a mortar that holds keratinized stratum corneum cells together (39). Clinical evidence—such as abnormally high TEWL seen in patients with essential fatty acid deficiencies or abnormalities of keratinocytes related to lipid impairment in the stratum corneum—supports the idea that an intact lipid phase is crucial to the integrity of the stratum corneum (1). Permeability of a substance is determined by its solubility and diffusivity in the aqueous protein and lipid phases of the stratum corneum (40). Bearing these principles in mind, low rates of permeability are associated with substances that possess low aqueous or lipid solubility, whereas highly water- or lipid-soluble compounds exhibit relatively high permeation rates (41).

Predictive Models

Several predictive models for skin permeation have been developed. A two-compartment model employs a mineral oil–water partition coefficient and accounts for the water

solubility of penetrant molecules to generate a predicted maximum permeation rate through human epidermis in vitro (39). A stratum corneum diffusion model based on ion–dipole and lipid–lipid interactions resulted in drug flux equations that predicted a linear dependence of flux on the dipole moment of penetrant and on the solubility of penetrant models in a cosolvent system (Fig. 8) (42). The model assumes two separate diffusion pathways for polar and lipid-soluble compounds as follows: (*1*) the skin permeation rate of polar compounds decreases in a linear fashion with interactions between the penetrant dipole and ionized amino acids in the stratum corneum; and (*2*) the nonpolar penetrants interact with the van der Waals and other dispersion forces in tissue. Another skin permeation model, in which the stratum corneum is treated as a homogeneous, passive lipid membrane, indicates the maximum percutaneous absorption rate is a function of molecular weight and melting point. Molecular weight is assumed to affect diffusivity, whereas melting point is assumed to predict the solubility of the penetrant in the stratum corneum lipids (43).

In contrast to the phenomenological approaches used in the predictive models already described, Lien and Gao (44) pioneered a model based on a classic quantitative structure activity relationship. These authors considered as predominant permeability factors the octanol–water partition coefficient, hydrogen bonding characteristics, and the molecular weight of drug molecules. The former two properties are estimated from the structures of drugs. A good log-linear relationship between skin permeability and these three molecular properties was obtained for selected drugs (Fig. 9). Depending on the vehicles used, the optimum octanol–water partition coefficient of drug for a maximum skin permeability changes. However, the hydrogen-bonding has a negative effect on the skin permeability. As in the phenomenological models, the molecular weight always has a negative effect on the permeability.

ANIMAL MODELS FOR PERCUTANEOUS ABSORPTION

The use of animal models is less than ideal in predicting the percutaneous absorption of chemicals in man. However, many compounds are potentially toxic and must be tested first in vitro or in vivo in animals to determine relative safety for experimentation in humans. In general, primates and miniature pigs are thought to be relatively good models for human percutaneous absorption, whereas the smaller laboratory animals (rabbit, rat, mouse) are poor animal models (9). The Rhesus monkey and the marmoset have demonstrated particular usefulness as models for human skin permeability (9,45).

The skin permeability of certain compounds as tested in the guinea pig and hairless mouse were also comparable to that of human skin (36). Hairless animal skin has the advantage of not requiring any shaving prior to testing. Although it has been hypothesized that the hair follicle represents a cutaneous absorption pathway, the skin of hairless guinea pigs has been shown to be much more permeable to some compounds than the skin of haired guinea pigs (46).

Lipids extracted from skin have utility in the preparation of skin models and for study of the effects of various compounds on stratum corneum lipids (47). Simple in vitro skin models have been prepared by air-drying liposomal suspensions containing epidermal ceramides, cholesterol, free fatty acids, and cholesterol sulfate on hydrophilic filter disks (48). Water permeabilities through these filter-supported lipid lamellae were measured using a diffusion cell; the ultrastructure was characterized by scanning and thin-section electron microscopy. Water flux data and the

ultrastructure of the model were shown to be similar to that of the native human stratum corneum.

TOXICOLOGY

The assessment of the potential for drug toxicity is an important consideration in the evaluation of any transdermal drug candidate. Toxic consequences of percutaneous administration may include skin irritation, immunological responses, and systemic toxicity. Many factors influence absorption of and skin response to a compound; the dose, concentration, occlusion, vehicle, mode and site of application, frequency of use, skin physiology, and the nature of the compound are all important variables.

Skin Metabolism

The metabolic activity of the skin can alter the delivery profile and pharmacologic effects of substances that undergo percutaneous absorption. A topically applied drug can be transformed into either active or inactive metabolites that are capable of different levels of toxicity than the parent compound (27). For example, epidermal keratinocytes have the potential to metabolize propranolol via a pathway that includes formation of an aldehyde intermediate (49). Changes in the pharmacologic or toxicologic profile that result from skin metabolism may have local as well as systemic effects.

In Vivo Testing

Irritation. Reliable testing for skin irritation should provide a means for differentiating substances that produce different degrees of skin irritation. In this context, irritation is the local inflammatory response of normal living skin to direct injury by single, repeated, or prolonged contact with a chemical agent. Macroscopic manifestations of such irritation are erythema and edema. Acute and subchronic irritation testing is used to place compounds into general groups according to their irritant properties. The most standardized toxicological procedures are based on the methods described by Draize, Woodard, and Calvery (50). The primary irritation of the skin is measured by the skin patch technique on intact and intentionally abraded skin of albino rabbits. In contrast, the subchronic skin irritation test measures the cumulative irritation on intact skin that has been exposed to the chemical agent for an extended amount of time. The Draize rabbit skin irritancy test is valuable for its ability to distinguish between chemical agents that are moderate to severe irritants. This method of testing, however, does not allow accurate distinctions between mild and moderate irritants.

Sensitization. Toxicological study also includes evaluation of hypersensitivity. The guinea pig and, more recently, the hairless guinea pig strain, have been widely accepted as the animals of choice for studying this phenomenon because of their genetically based proclivities to sensitization (51). These animals may be used as predictive models to study mechanisms involved in contact sensitization to therapeutic agents. Compounds intended for cutaneous application that are capable of producing sensitization are readily identified by predictive testing (51). The hairless guinea pig has all the humoral and cellular components necessary for sensitization and is responsive to known sensitizers (52,53). A parallel does exist in the sense that the strong and weak sensitizers in man are, respectively, the strong and weak sensitizers of the guinea pig (54–56).

Contact sensitivity is characterized by cellular mediated (thymocyte) allergic reactions of the skin that may be induced by a single contact or may require repeated contacts with the sensitizer, with or without potentiation (57). Potentiation may be provided by physical or chemical irritants such as sodium lauryl sulfate (used in the Kligman Maximization Test) (58) or by immunopotentiators such as Freund's complete adjuvant. The ensuing sensitization response develops slowly on challenge and may require from 8 to 35 hours to appear; it generally persists for 24 hours or more.

Freund's complete adjuvant test is an appropriate method for screening single chemical substances for their immunogenic properties. It is a semiquantitative method for measuring the minimal concentration needed to elicit a response in sensitized animals. The test can establish the allergenicity of a chemical substance, but it cannot establish the actual risk of contact sensitization under conditions of use (51).

In Vitro Testing

Irritation. Organ and cell cultures can help predict whether or not application of some agents results in damage to keratinocytes or to other types of cells. Endpoints used to assess cytotoxicity include cell growth, which may be determined by protein analysis and cell counts. In addition, characteristics such as enzyme release, release of radioactive markers, exclusion of dyes, metabolism, and plating efficiency are all measurable endpoints of cell function. Because these endpoints involve active cellular processes, false-negative results are infrequent. In contrast, tests that interfere with passive structures such as the cell membrane may yield false negatives because testing agents that kill by fixation preserve structural components of the membrane (59). Other types of assays measure sublethal and lethal endpoints.

In vitro testing includes direct and indirect test methods. The latter involve testing individual components or combinations of chemicals as extracts. The types of characteristics not measured by in vitro assays are those that are time dependent or reversible; likewise, complex in vivo interactions are not measured by in vitro assays. The atypical pharmacokinetic profile seen with some compounds may produce changes in vitro that are normally not seen in vivo. It has been reported that the high in vitro toxicity associated with some agents is not representative of local irritation in vivo. When choosing a testing strategy, investigators are wise to select a battery of in vitro assays that assess both active and passive cellular processes.

The use of standard in vitro testing may link the study of toxicity and its mechanism (60). In vitro testing that employs standardized methods can determine a maximum tolerated concentration and the concentration that reduces

a study parameter by 50% of the control value. The neutral red uptake assay, for example, is a test in which the drug effects on the membrane or its ability to alter lysosomes then influences binding of the cationic dye to anionic sites in the lysosome matrix (61). In another similar assay, the metabolic reduction of 3-(4,5-dimethylthiozol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) by cells results in formation of a blue formazon dye (62). Modification of this MTT assay has allowed its use for screening of compounds for their in vitro cytotoxicity in human keratinocytes (63). Inhibitory concentration values, such as the IC_{50}, represent the molar concentration of the drug compound required to kill 50% of fibroblast cells and are also used in screening of compounds for in vitro toxicity (64).

Sensitization. Evaluating the potential for sensitization may include assay of the lymphokines released by antigens from sensitized lymphocytes and lymphocyte proliferation assays (60). Another assay is the murine lymph node assay that studies lymphocyte proliferation and provides both objective and quantitative results. A modification of this procedure involves occluded application of the compound on the shaved abdomen of the animal for 24 hours. Another application is repeated on day 5 and on day 6; the animals are sacrificed, and the brachial and inguinal lymph nodes are removed. Measurement of the spontaneous proliferation capacity of cells seeded in the microtiter well is measured by incorporation of [^{3}H]thymidine. A percent stimulation index is calculated by dividing test-cell incorporation by control-cell incorporation. Results may be correlated with those obtained from in vivo guinea pig sensitization assays. The murine node lymph assay provides a relatively simple, rapid, and inexpensive way to identify agents that exhibit moderate to strong sensitizing potential.

Other Preclinical Testing Requirements

In addition to the determination of irritation and sensitization potential, drugs that are to be used in pharmaceutical products must undergo standardized preclinical testing as part of the requirements for marketing approval. The U.S. FDA considers transdermal drugs as if they were new drugs. Transdermal products that include approved drugs are likely to be approved more readily, however. It is widely accepted that transdermal systems generally produce plasma levels of drug that are considerably lower than those resulting from other administration methods; systemic safety may be less of a concern in such cases.

TRANSDERMAL DRUG DELIVERY

Since the introduction of the first transdermal therapeutic system, the field of transdermal drug delivery has advanced rapidly through greater understanding of the mechanisms, variables, and measurement of percutaneous absorption. Greater understanding of the pharmacokinetics of percutaneously administered drugs has led to the development of systems with optimized delivery profiles. Use of permeation enhancers has increased the number of drugs available for transdermal therapy. The potential advantages of rate-controlled transdermal therapy include the following:

- Improved bioavailability for many drugs
- Reliable blood levels of drug
- Sustained therapeutic effect, allowing use of drugs with short half-lives
- Diminished side effects
- Daily, multiday, or weekly dosing to improve patient compliance
- Simple, noninvasive administration, particularly important for patients who are unable to take medication orally
- Reduced overall treatment costs in many instances

These advantages of transdermal therapy may yield enhanced safety, efficacy, reliability, and acceptability of drug treatment.

Permeation Enhancement

Chemical Enhancers. The skin's physical structure provides a barrier that may limit the permeation of some agents. Skin permeation enhancers broaden the range of drugs that can be delivered transdermally by increasing the penetration of permeants through enhanced diffusion of the stratum corneum and/or by increasing the solubility of the penetrant. Protein denaturation may disrupt the barrier as may fluidization and randomization of intercellular lipids or intercellular delamination and expansion (65).

Ideally, a permeation enhancer functions only to reduce the barrier resistance of the stratum corneum and does not damage any viable cells. The necessary attributes of an enhancer have been reviewed by Barry (7); the ideal enhancer is:

- Pharmacologically inert
- Nontoxic
- Nonirritating
- Nonallergenic
- Rapid-acting with a duration of activity that is predictable and suited to its use
- Chemically compatible and easily formulated into a variety of systems
- Inexpensive
- Odorless
- Tasteless
- Colorless

The enhancer should not extract endogenous material out of the skin but should spread well on skin and have a suitable skin feel. If the substance is a liquid and is to be used at high volume fractions, it should be a suitable solvent for drugs (7).

There are numerous chemical permeation enhancers now being used to facilitate transdermal drug administration. Solvents are frequently used and include alcohol, di-

methyl sulfoxide, dimethylformamide, dimethylacetamide, propylene glycol, pyrrolidones, and water. Other enhancers include Azone® and its derivatives, surfactants, fatty acids, terpenes and their derivatives, alkyl sulfoxides, phosphine oxides, sugar esters, urea and its long chain analogues, *N,N*-diethyl-*m*-toluamide, calcium thioglycolate, and anticholinergic agents (7).

Ethanol has been used very successfully as a permeation enhancer in a variety of commercial transdermal systems (66), including those that deliver estradiol and fentanyl. Pure ethanol-enhanced permeation of solutes across the skin in vitro is thought to be a result of the extraction of skin lipids by ethanol, but apparent diffusivity has not been significantly altered in in vivo studies (67). For example, the flux of estradiol across viable human skin was shown to be increased in vivo only with saturated solutions of estradiol, indicating the increased solubility of estradiol in ethanol and an increased concentration gradient of estradiol across the skin. Knowledge of the apparent partitioning of the solute into the stratum corneum and the solute concentration in the vehicle allow prediction of the flux of estradiol across human skin in vivo.

More recently, use of composite lipidic agent-carriers such as liposomes and niosomes has been tried. These agents have been less successful than conventional enhancers because of their inability to pass through the narrow intracellular passages in the outer skin layers. A more deformable supramolecular aggregate known as the transfersome has been described and is thought to use the transepidermal gradient as a means of permeation enhancement. Successful use of transfersomes to achieve transcutaneous peptide and protein delivery in animals and in humans has been reported (Fig. 10) (47).

Epidermal enzymes have also been identified as potentially valuable permeation enhancers in transdermal drug delivery (68). It has been demonstrated that epidermal enzymes play an important role in the differentiation of keratinocytes, and that epidermal phospholipids undergo enzymatic conversion to nonpolar species and contribute to the barrier function of the stratum corneum. In vitro study of the role of these enzymes on the permeation of benzoic acid, mannitol, and testosterone in an excised human skin model reveal that enzymes may have remarkable effects on the permeation of topically applied compounds. Of the enzymes studies (phospholipase C, triacylglycerol hydrolase, acid phosphatase, phospholipase A_2), phopholipase C was the most effective in facilitating the transport of all solutes. The effects of these topical enzymes appear to be mediated through their influence on skin lipids.

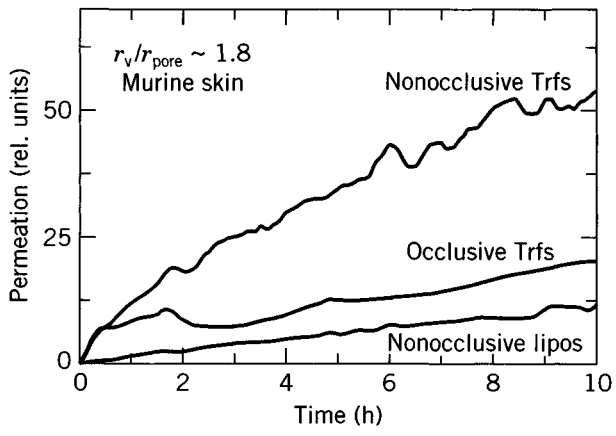

Figure 10. The penetration of standard liposomes (dotted curve) and of the highly deformable transfersomes (full curve) through the murine skin after an occlusive or nonocclusive application. Only an open suspension of transfersomes results in significant transfer of the fluorescently labeled lipids incorporated into the lipid vesicles through the intact murine skin. The small signals observed in the other cases are largely due to the permeation of the free label. *Source:* From Ref. 47.

Pharmacokinetics

The successful delivery of drugs through skin and into the systemic circulation may require four to five biological half-lives of a compound to transpire before steady-state blood levels are reached (41). Thus, the plasma half-life of a drug is a major consideration when selecting a drug for transdermal administration. Drugs with shorter half-lives are ideal, whereas agents with longer half-lives may interfere with the ability to achieve and maintain close control over drug levels in plasma. However, modifications in transdermal system design may allow the use of drugs with a less than ideal pharmacokinetic profile. Examples of two transdermal drugs, nicotine and fentanyl, are presented to illustrate differences in pharmacokinetic properties and, thus, system requirements.

Nicotine is an example of an agent that is highly soluble, readily penetrates the skin, and possesses a relatively short half-life. It is administered transdermally to aid in smoking cessation. Following intravenous (IV) administration of nicotine, the volume of distribution is approximately 2–3 L/kg and its half-life ranges from 1 to 2 hours. In one nicotine transdermal system (Nicoderm® CQ, SmithKline Beecham Consumer Healthcare, Pittsburgh, PA), approximately 68% of the nicotine released from the system enters the systemic circulation (69). Plasma nicotine concentrations rise rapidly when the system is applied, plateau within 2–4 hours, and slowly decline until the system is removed (Fig. 11) (69,70). Plasma nicotine concentrations achieved are proportional to system size (dose); linear kinetics are observed (70). Nicotine kinetics are similar for all sites of application on the upper body and upper outer arm, and no gender-related differences in nicotine kinetics have been observed. Removal of the nicotine transdermal system results in an exponential decline in plasma nicotine levels with an apparent mean half-life of 3–4 hours. The half-life of transdermally administered nicotine is longer than that seen with IV administration because of continued absorption from the skin depot (70).

Fentanyl is an opioid analgesic that has a longer IV half-life (3–12 hours) than nicotine and penetrates the skin slowly, requiring a permeation enhancer (ethanol) for adequate delivery (71,72). The drug's average volume of distribution is 6 L/kg, and the variability in reported ranges of distribution volumes is large (73). Transdermal absorption of fentanyl is generally characterized by a zero-order process. In the fentanyl transdermal system, a permeation

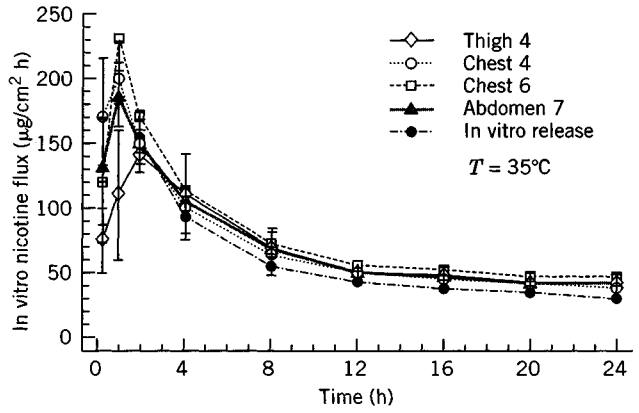

Figure 11. Mean (SD) in vitro nicotine flux for the Nicoderm® system.

enhancer increases the rate of drug flux through skin, resulting in effective blood concentrations for a prolonged period. Transdermal fentanyl is 92% bioavailable and, thus, does not appear to be metabolized by skin nor significantly degraded by the skin's bacterial flora (71). Following application of Duragesic® [fentanyl transdermal system] CII (ALZA Corporation, Palo Alto, CA, and Janssen Pharmaceutica, Titusville, NJ), the skin absorbs fentanyl and dissipates it into the systemic circulation (71,72). Absorption continues throughout the 72-hour dosing interval (Fig. 12). Low enhancer flux minimizes the skin drug depot (74). Serum fentanyl concentrations increase gradually following initial application of the system, generally leveling off between 12 and 24 hours and remaining relatively constant for the remainder of the 72-hour dosing period. Peak serum levels of fentanyl generally occur between 24 and 72 hours after initial application. Serum fentanyl concentrations are proportional to the delivery rate, and after several sequential 72-hour applications, patients reach and maintain a steady-state serum concentration that is determined by individual variation in skin permeability and body clearance of fentanyl (71,72).

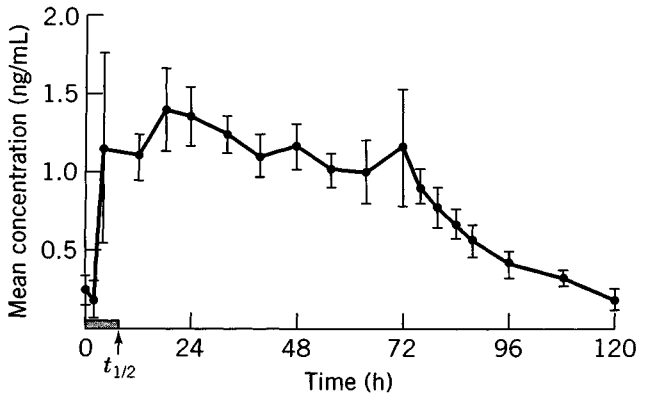

Figure 12. Fentanyl concentrations from TTS (fentanyl)-75 (72 h application).

MARKETED TRANSDERMAL SYSTEMS

There are a number of transdermal systems now available. Generally speaking, however, system design can be classified based on the type of rate control employed (skin-controlled vs. system-controlled drug delivery) and by the presence or absence of permeation enhancers in the delivery system. Skin-controlled drug delivery devices rely on the skin's barrier properties to control the rate of drug input to the body. These devices may include a matrix or multilaminate design to act as a carrier that maintains drug in contact with the surface of the skin. Drug diffuses through the skin at a rate dictated by the concentration of drug on the skin and by the permeability of the skin to the drug. Because rate control relies completely on the skin's diffusive properties, variations in skin permeability (e.g., at different sites) may have variable effects on the delivery rate of systems without built-in control mechanisms (75).

System-controlled drug delivery requires a rate-controlling element such as a polymeric membrane (Fig. 13). The membrane allows measured release of drug throughout the wearing period and provides more protection from potential drug overdose than skin-controlled delivery. Drug delivery with a system that incorporates a rate-controlling membrane produces less variability in drug input, yielding a more predictable and reproducible pharmacokinetic profile (75).

The need for permeation enhancers is determined by the nature of the drug intended for use in the transdermal delivery system. Highly skin-permeable drugs agents, such as nicotine, do not require a permeation enhancer. The transcutaneous flux of most hormones, however, is low, requiring the use of a permeation enhancer such as ethanol or triethanloamine. These solvents permeate the skin but without rate control or occlusion, their effectiveness is brief and limited. The use of certain types of permeation enhancers has been associated with skin irritation.

Types of Transdermal Systems

Worldwide, a variety of transdermal systems are available. In the United States, transdermal systems are used for delivery of analgesics (fentanyl), hormone replacement therapies (estradiol and testosterone) and medications for angina (nitroglycerin), hypertension (clonidine), and motion sickness (scopolamine) (Table 1). Transdermal systems that deliver nicotine for use in smoking cessation are also available. In Japan and in parts of Europe, systems that incorporate antiinflammatory drugs (flurbiprofen and

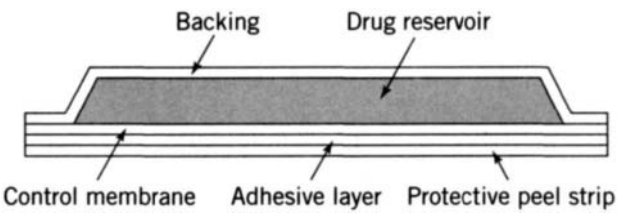

Figure 13. System-controlled drug delivery system.

Table 1. Advantages of Rate-Controlled Transdermal Drugs: Three Examples

Drug	Use	Dosing frequency via transdermal delivery	Dosing frequency via other means	Improved selectivity of action with transdermal delivery	Other advantages of transdermal delivery
Scopolamine	Motion sickness	Once every 3 days	4–6 times per day	CNS effects diminished or absent	May be used in the presence of nausea/ vomiting
Nitroglycerin	Prophylaxis of angina	Once daily	2–3 times per day		Prevents massive drug degradation in the liver
Clonidine	Treatment of hypertension	Once daily	2–3 times per day	Dry mouth, drowsiness, sexual dysfunction lessened or absent	

ketaprofen) and monoamine oxidase inhibitors such as selegiline have also been introduced. In this section, a review of a selected group of systems is provided with an emphasis on product characteristics and the clinical performance measures of safety, efficacy, reliability, and acceptability of drug treatment.

Fentanyl. The successful management of chronic pain frequently requires long-term administration of opioids such as fentanyl. Fentanyl is an opioid analgesic that has been used parenterally to treat chronic pain for more than 20 years and has been available in a transdermal delivery system (Fig. 14) (Duragesic® [fentanyl transdermal system] CII, ALZA Corporation, Palo Alto, CA, and Janssen Pharmaceutical, Titusville, NJ) since 1990. For patients who require continuous opioid analgesia for pain that cannot be managed by lesser means, the development of a transdermal system that delivers fentanyl over 72 hours confers a number of advantages over traditional IV administration, including prolonged dosing that does not require an indwelling catheter and maintenance of drug presence that may prevent breakthrough pain. The system comprises a peel-off protective liner and four functional layers: a backing of polyester film, a drug reservoir containing fentanyl base and alcohol, an ethylene–vinyl acetate copolymer membrane that controls the rate of drug delivery to the skin, and a fentanyl-containing adhesive layer. The impermeable outer layer prevents loss of drug from the system and entry of water into the drug reservoir. The inclusion of alcohol in the reservoir enhances drug flux through the rate-limiting membrane and increases the skin's permeability to fentanyl (Fig. 15); the amount of alcohol released during the 72-hour application period is small (<0.1 mL/10 cm^2). The adhesive layer, which contains a bolus of drug, allows initial administration of fentanyl with system application. The system is available in four strengths that deliver fentanyl at rates of 25, 50, 75, or 100 μg per hour. The amount of fentanyl released from each system is proportional to its surface area (2.5 $\mu g/h/cm^2$).

The analgesic activity of transdermal fentanyl has been demonstrated in a number of clinical trials (72,76–78). System functionality and a pharmacokinetic model have also been studied, and these results indicate the serum fentanyl profile for the transdermal system is a net result of system performance and drug absorption and elimination (79).

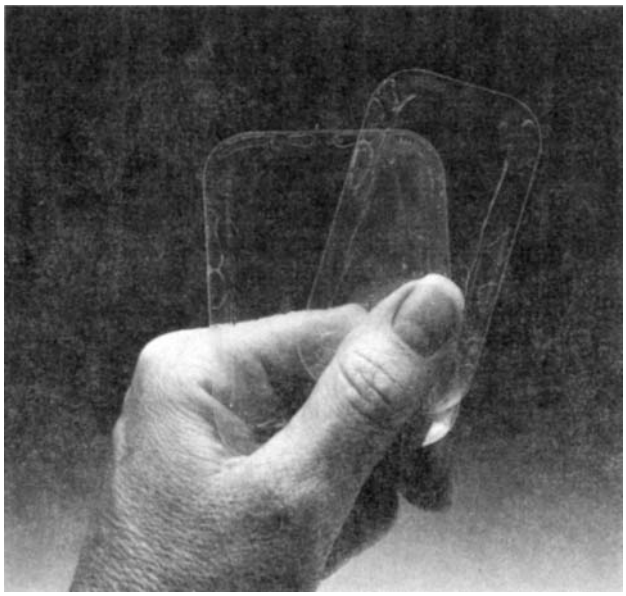

Figure 14. The Duragesic® (fentanyl transdermal system).

Estradiol. A variety of transdermal systems are available for use in hormone replacement therapy. Estraderm® (Ciba-Geneva Pharmaceuticals, Summit, NJ) is available in 0.05 mg and 0.1 mg dosage forms and incorporates a

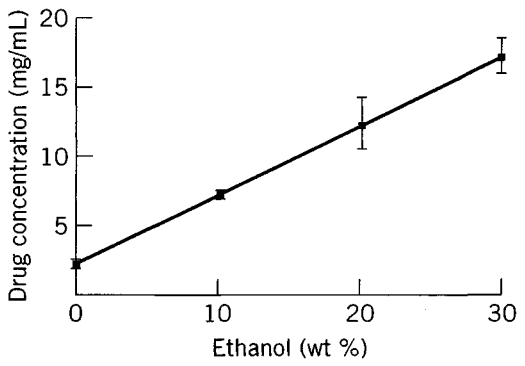

Figure 15. Fentanyl Concentration in Human Epidermis (room temperature).

rate-controlling membrane that allows controlled release of estradiol from a drug reservoir. Climara® estradiol transdermal system (Berlex Laboratories, Wayne, NJ), uses an acrylate adhesive matrix that contains estradiol in a 0.05 mg or 0.1 mg strength. The Vivelle® estradiol transdermal system (Ciba-Geneva Pharmaceuticals, Summit, NJ) is available in the following strengths: 0.0375 mg, 0.05 mg, 0.075 mg, and 0.1 mg of estradiol. The system contains estradiol in a multipolymeric adhesive and releases the hormone continuously upon application to the skin. FemPatch® (Parke-Davis, Morris Plains, NJ) is a self-adhesive matrix system that delivers estradiol at a rate of 0.025 mg/day for 7 days and contains a silicone-based contact adhesive. Alora® (Proctor and Gamble Pharmaceuticals, Cincinnati, OH) is another self-adhesive matrix system that incorporates an acrylate contact adhesive and delivers estradiol at rates of 0.05, 0.075, and 0.1 mg/day for 3–4 days.

Transdermal administration of estradiol has proven to be a very successful means of hormone replacement therapy, alleviating the vasomotor and other estrogen deficiency symptoms among postmenopausal women. These symptoms include hot flushes and other discomforts such as vaginal atrophy, vaginitis, and atrophic changes of the lower urinary tract. Hormone replacement therapy is also given to prevent osteoporosis. The transdermal route is associated with fewer adverse effects than oral regimens and allows serum estrogen levels of remain quite steady over the 3–4-day application period; daily peaks and troughs are minimized (Table 2). The direct absorption of estradiol into the circulation allows peripheral metabolization to estrone and achieves a premenopausal pattern of estrogen as well as premenopausal levels of the hormone (80).

Testosterone. Currently, two transdermal products are available for testosterone replacement therapy: a scrotal system (Testoderm® Testosterone Transdermal System, ALZA Pharmaceuticals, Palo Alto, CA) and a nonscrotal system (Androderm® Testosterone Transdermal System, SmithKline Beecham Pharmaceuticals, Philadelphia, PA) that may be applied to the torso or appendages. The efficacy of both products in establishing optimal levels of testosterone in hypogonadal males was demonstrated in clinical trials (22). Transdermal administration has several benefits over other routes of testosterone administration. It minimizes the nonphysiologic peaks and troughs associated with intramuscular (IM) or oral dosing, and avoids the inconvenience of frequent injections. Unlike absorption via the oral route, transdermal absorption is not affected by food intake or hepatic first-pass metabolism, which may increase dosage requirements, produce unusual metabolites, or possibly result in liver toxicity (81–84). Testosterone transdermal systems have demonstrated an ability to approximate the natural endogenous pattern of serum testosterone levels in normal males and have been shown to produce positive effects on fatigue, mood, and sexual function, as well as significant increases in sexual activity (85–88).

Table 2. Benefits of Transdermal Estradiol

Use of natural hormone
Effective treatment of hot flushes
Therapeutic hormone levels with low daily dose
Restoration of premenopausal ratio of estradiol to estrone
Avoidance of dose-related hepatic effects
Rapid initiation and termination of therapy

The Testoderm® testosterone transdermal system is designed for scrotal application to take advantage of the unique superficial vascularity and highly permeable nature of the scrotal skin. Application of the Testoderm® system at this site allows a high transfer rate of the hormone without the use of a permeation enhancer, adhesives, or preservatives. The scrotal system is designed to release controlled amounts of testosterone continuously upon application to dry-shaved scrotal skin. A single scrotal system delivers either 4 mg or 6 mg of testosterone over a 24-hour period in a pattern that approximates normal circadian rhythms of testosterone secretion. Data suggest testosterone delivery is negligible when the scrotal system is applied to nonscrotal skin (unpublished data, ALZA Corporation, 1991).

The Androderm® testosterone transdermal system is designed to deliver testosterone through intact nonscrotal skin—for example, on the back, abdomen, thighs, and upper arms. The system contains a drug reservoir gel that is surrounded by a peripheral adhesive area and relies on the barrier properties of the skin to control permeation. Testosterone flux is facilitated by permeation enhancers in the system that assist the transport of drug across the skin. Originally, two Androderm® systems (each 2.5 mg) were applied nightly to deliver approximately 5 mg of testosterone over a 24-hour period. Recently, however, a 5 mg Androderm® system has been developed to allow nightly application of a single system. Both the 2.5 and 5 mg systems produce hormone levels that mimic the daily pattern of testosterone release in healthy men.

In one study comparing the two marketed testosterone transdermal systems (89), the scrotal system was shown to be better tolerated. In those using the permeation-enhanced Androderm® system, allergic contact dermatitis and spontaneous flaring of prior application sites occurred in 7 (12%) subjects using Androderm® systems on day 12. In contrast, use of the Testoderm® testosterone transdermal system resulted in no confirmed cases of allergy ($P < 0.001$). For Testoderm® and Androderm® systems, respectively, moderately intense irritation was noted in 5% and 32% of subjects ($P < 0.001$) and in 1% and 7% of application sites ($P < 0.001$). The Testoderm® system produced no confirmed contact allergy and less topical irritation than the Androderm® system, and patients with contact allergy to Androderm® used the Testoderm® system without a reaction, suggesting testosterone was not the allergen.

Nitroglycerin. Nitroglycerin has been used in the treatment of angina pectoris for more than a century. Nitroglycerin ointment preceded the development of nitroglycerin patch systems and is still available (Nitro-Bid® Ointment 2%, Hoechst Marion Roussel, Kansas City, MO). Plasma concentrations of nitroglycerin with ointment treatment, however, are subject to a rapid rise following

application and a sharp decline after approximately 8 hours (90). There have been a number of nitroglycerin systems that have come to market, including Deponit® (Schwarz-Pharma, Milwaukee, WI) Nitrodisc® (Roberts Pharmaceutical Corp., Eatontown, NJ), Nitro-Dur® (Key Pharmaceuticals, Inc., Kenilworth, NJ), Minitran® (3M Pharmaceuticals, Northridge, CA) and Transderm-Nitro® (Ciba-Geneva). The rate of delivery of the drug from the inner surface of the patches is controlled either by dispersing it in a solid-nitroglycerin-impregnated polymer (Nitrodisc®), incorporating it in a gel-like matrix (Nitro-Dur®) or adhesive matrix (Deponit®, Minitran®), or by placing a permeability-modulating membrane between the drug and the skin (Transderm-Nitro®).

Studies have demonstrated clinical efficacy, indicating effectiveness over 24 hours or longer and decreased frequency, severity, and duration of anginal attacks and S-T segment depression during treadmill tests (91). A number of studies have also investigated patient preference, including factors such adhesion, incidence of local skin reactions, and cosmetic properties. In a comparison of Transderm-Nitro® and Nitro-Dur® systems, the former was associated with superior adhesive properties and a lower incidence of local reactions such that the patient preference was nearly 10 to 1 in favor of Transderm-Nitro® (92). In another comparison of the two systems, a preference for Transderm-Nitro® was also cited based on adhesion, a lower rate of local reactions, and better cosmetic properties (93). Comparison of Transderm-Nitro®, Nitrodisc®, and Nitro-Dur® revealed that patient preferences varied considerably and that use of Transderm-Nitro® was associated with significantly fewer intolerable skin reactions than Nitro-Dur® and caused less discomfort upon removal as compared with Nitrodisc® (94). Results of a later study by Chinoy and colleagues (95) indicate the Tranderm-Nitro® system showed better adhesion than Deponit® ($P < 0.0001$) and improved tolerability at the site of application ($P < 0.0588$).

Clonidine. Clonidine is a potent, central-acting hypotensive agent. The drug is widely used and normally administered orally two to three times daily. A transdermal therapeutic system with a rate-controlling membrane (Catapres®-TTS, Boehringer Ingelheim Pharmaceuticals, Inc., Ridgefield, CT) administers this drug over 7 days after a single application (Fig. 16). Following system application to intact skin, clonidine in the adhesive layer saturates the skin site below the system; clonidine from the drug reservoir then begins to diffuse through the rate-controlling membrane and through the skin for absorption by the capillaries beneath the skin. Therapeutic clonidine levels are achieved 2–3 days after application of the first system; application of a new system at weekly intervals maintains therapeutic drug levels. To ensure constant release over 7 days, the total drug content of the system is maintained at or above saturation. The mean plasma concentration of clonidine is proportional to the surface area of the system, demonstrating the linearity between the system size (dose) applied and associated plasma levels. A comparison of oral clonidine (three times daily) with once-weekly transdermal administration revealed that the former resulted in a seesaw pattern of drug concentration in plasma. Virtually steady plasma concentrations of clonidine are produced by transdermal dosing over 7 days (8). In a clinical trial of patients suffering from mild hypertension, 48 of the 69 subjects achieved long-term control of blood pressure with Catapres®-TTS. Side effects associated with orally administered clonidine, such as drowsiness and dry mouth were reduced by rate-controlled transdermal administration (41).

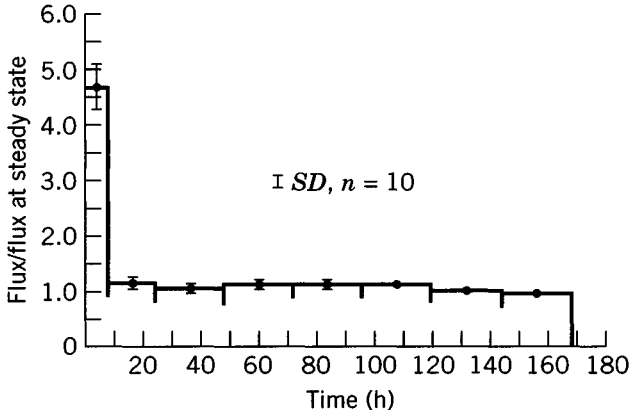

Figure 16. Mean in vitro drug release rate from Catapres-TTS® (Water receptor, $T = 32°C$).

Scopolamine. The first controlled-release transdermal dosage form was Transderm-Scop® (Ciba Self-Medication, Inc., Woodbridge, NJ). One application of the system, which incorporates a rate-controlling membrane, delivers 0.5 mg scopolamine over 3 days to prevent motion sickness. Transdermal administration allows reduction in the total dose required and is a clear improvement over the usual intramuscular injections that require four to six daily doses. A loading dose is released from the transdermal system in the first two hours of application, and then drug release declines rapidly to a constant rate designed to maintain steady-state levels. It has been demonstrated that when scopolamine is administered transdermally or intravenously at similar constant rates over 24 to 72 hours, the rates of urinary excretion of the drug are also similar (96). These results suggest blood levels via the two different administration methods are also similar. Rate-controlled transdermal delivery under steady-state conditions can be compared with continuous, controlled, IV infusion.

Clinical results with the Transderm-Scop® system indicate considerable success in the treatment of motion sickness. In one controlled trial, the system prevented motion sickness in 75% of the susceptible subjects and yielded a low incidence of side effects (Fig. 17) (97). Although the drug has a narrow therapeutic index, study of the general use of Transderm-Scop® indicates that the efficacy of the transdermal dosage form has been excellent and that the incidence of side effects of a parasympatholytic nature have been low (98). Clearly, the clinical performance of this dosage form is related to the rate-controlled delivery of the

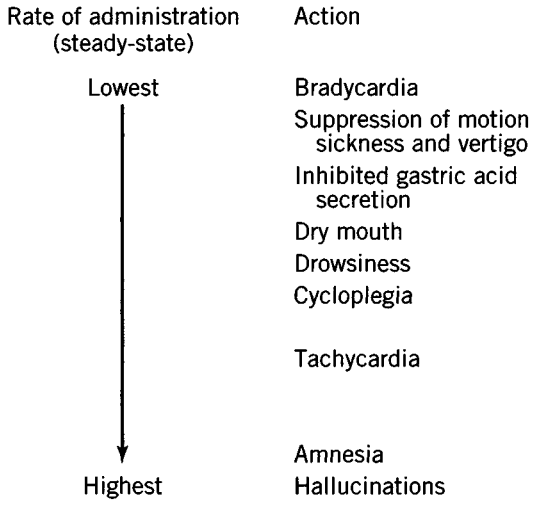

Figure 17. Zero-order pharmacology of scopolamine.

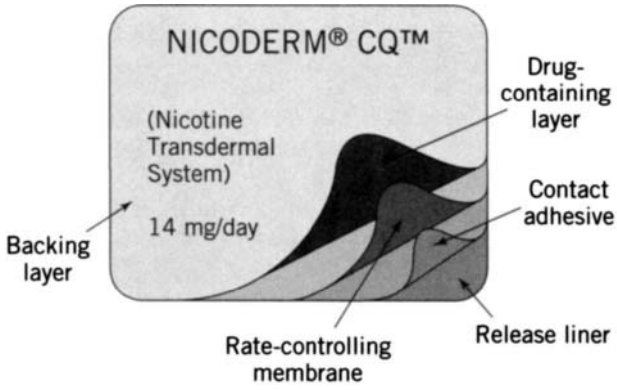

Figure 18. NicoDerm® CQ™ nicotine transdermal system.

Table 3. Nicotine Transdermal Systems: Comparative Functionality

Parameter	Nicoderm®	Habitrol®	Prostep®
Dose (mg/day)	21	21	22
C_{max} (ng/mL)	23	17	16
C_{avg} (ng/mL)	17	13	11
C_{min} (ng/mL)	11	9	5
T_{max} (hours)	4	6	9

system, which regulates systemic drug input in the therapeutic range.

Nicotine. The addictive properties of nicotine are well known, and its potential for abuse is well established (99). Withdrawal from nicotine causes physical complaints that are abated by smoking, and thus, smoking behavior is reinforced by the disappearance of these symptoms. The administration of nicotine to nicotine-dependent individuals is the most successful pharmacologic approach to smoking cessation (75), significantly decreasing the severity of nicotine withdrawal symptoms (100,101).

There are a number of nicotine transdermal systems now available worldwide, including Habitrol® (Ciba Self-Medication, Woodbridge NJ), Nicoderm® CQ (SmithKline Beecham Consumer Healthcare, Pittsburgh PA), Nicotrol® (McNeil Consumer Products Company, Fort Washington, PA), and Prostep® (Lederle Laboratories, Wayne, NJ). These systems have several features in common: they are self-adhesive, multilayered, and possess a removable protective liner. The patches vary in their methods of nicotine storage, mode of drug release, and degree of rate control. Habitrol® and Nicotrol® have a drug reservoir that equilibrates within the system after manufacture; neither possess any rate control features. Prostep® contains a nonadhesive drug gel, and the system is not self-adhesive,

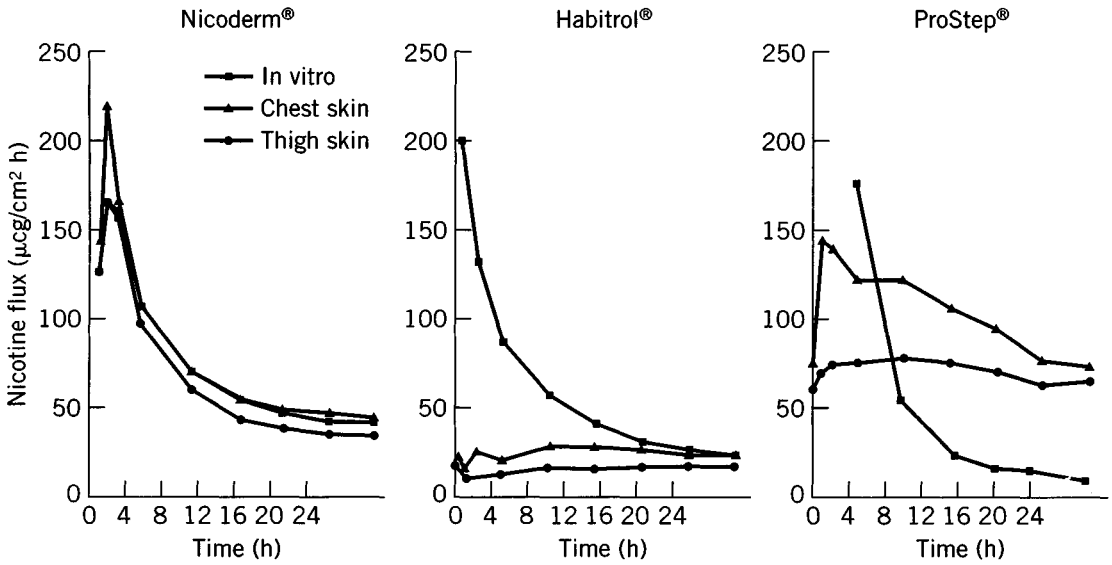

Figure 19. In vitro release of three transdermal nicotine products.

requiring a peripheral adhesive to adhere the product to the skin.

Habitrol®, Nicotrol®, and Prostep® are examples of products that depend on the rate-controlling properties of the skin to modulate nicotine input. In contrast, Nicoderm® (Fig. 18) possesses a membrane that controls the rate of drug input through the skin. This system provides several advantages over its non-rate-controlled counterparts, including rapid onset of therapeutic levels of nicotine in plasma, more consistent drug input among application sites (Fig. 19), greater control over absorption and drug-blood levels (Table 3), and improved protection from abuse and drug overdose (75,102,103).

Treatment with nicotine transdermal systems should be used as part of a comprehensive behavioral smoking-cessation program and has been shown to result in significantly higher "quit rates" than placebos (104).

SUMMARY

Transdermal therapy has advanced rapidly amid greater understanding of the skin's permeability characteristics. Techniques for measuring permeation of chemical agents and the development of appropriate predictive models have been extremely important in the design of safe and effective transdermal systems. A number of pharmacotherapeutic and pharmacoeconomic benefits have been realized with transdermal therapy, and research and development programs will undoubtedly reveal additional merits of this important technology.

Immunization against infectious diseases is arguably the most effective intervention to improve public health. There are over 50 vaccine formulations currently available in the United States (1), but a great worldwide need for effective vaccines remains as this represents only a small minority of all infectious diseases. Also, there is still need for improvement among the existing vaccines. These needs are particularly evident in the developing world, where infectious diseases continue to be one of the leading causes of morbidity and mortality despite widescale vaccination programs (2). In addition, the emergence of a number of drug-resistant organisms, such as multidrug-resistant *Mycobacterium tuberculosis*, and pathogens for which a totally effective treatment has yet to be developed, most notably HIV, have also highlighted the need for improved preventative measures.

A number of authors have described the ideal vaccine and the various properties that it would have to possess. Most importantly, an ideal vaccine would have the ability to elicit the appropriate immune response for the pathogen under consideration. Many bacterial and viral infections can be successfully stopped by serum antibodies that confer immunity while intracellular microbes, like *M. tuberculosis*, require a cell-mediated response. Some pathogens, such as HIV, might be best controlled by a combination of both types of immunity. Ideally, the immune response would be long term, preferably for life. It should under no circumstances cause the disease that it is supposed to prevent and possess minimal side effects. To make the widespread use of the vaccine economically feasible, the vaccine should be easily administered in a single dose, preferably close to birth to initiate protection when people are most vulnerable, and production conditions should be well defined and reproducible. Finally, the vaccine itself must be stable enough to maintain immunogenicity before administration without the use of an expensive cold chain (3). None of the existing vaccines meet all of the requirements for being ideal. However, the use of controlled-release technology may allow for the development of vaccines that better approach all these criteria, which are summarized in Table 1.

This article concentrates on describing some of the work being conducted toward the development of controlled-release vaccines. After a brief description of some of the relevant concepts in immunology and current vaccines, descriptions of some of the existing research follow. The types of vaccines considered have been broken down into two types, either liposome- or polymer microsphere–based, as these have received the most attention. Special emphasis will be placed on mucosal immunology and the development of oral controlled-release formulations. This article is not meant to be exhaustive in its coverage of the work conducted so far but should serve as a good starting point in describing some of the key concepts and developments in controlled-release vaccine technology, with emphasis on liposome- and thermoplastic polymer–based systems.

Table 1. Properties of the Ideal Vaccine

Biologic considerations	Economic considerations
Confers lifelong immunity	Administered in a single dose
Never causes disease	Reproducible production conditions
Minimal side effects	Stable without a cold chain
Administered perinatally	Medically trained individuals not required for administration

VACCINE IMMUNOLOGY

The immune response to natural infection is generally characterized by an initial antibody response to the pathogen followed by a prolonged memory response with continued exposure. Upon first exposure to an antigen, the immune system responds by an increase in serum antibody levels (within 2–4 weeks), followed by a relatively rapid drop-off of antibody levels. However, this initial exposure to the antigen enhances the body's ability to respond because of the proliferation of those lymphocytes specific for that particular antigen. The immune system becomes primed, and any further exposures to the same antigen are usually larger, more rapid, and longer lasting than the first (4). To take advantage of these natural immune responses, vaccines need to be presented once in an initial dose and then in booster shots to achieve long-lasting immunity. It is this natural limitation that presents one of the most difficult challenges in the development of an effective, widespread vaccination program. In fact, the World Health Organization (WHO) estimates that only 70% of people in developing countries receiving the initial dose of a vaccine return for the booster, leading to an extraordinary waste of limited resources and an undervaccinated population. Considering this, controlled-release technology has great promise in improving these numbers with the development of vaccines that would combine an initial immunization and boosters in a single shot or dose, thus hurdling this obstacle presented by the body's immune system.

Types of Vaccines

By definition, a *vaccine* is a material that induces an immunologically mediated resistance to a disease but not necessarily infection. It is important to understand this distinction when developing new vaccines as colonization by a pathologic organism would be acceptable if disease could still be controlled. The different types of vaccines include live or inactivated organisms as well as subunits or DNA. All of these forms of vaccines can potentially be delivered by controlled release.

Live Vaccines. Edward Jenner's smallpox vaccine of 1798 was based on the coxpox virus (bovine vaccinia virus), which was unable to produce clinical disease in humans but homologous enough to the human vaccinia virus to produce immunity. With this type of vaccine, a closely related organism of lesser virulence is administered, and the resulting immune response is sufficient to stop the virulent organism. This was certainly fortuitous in the case of smallpox, but even in cases where a naturally occurring attenuated organism does not exist, one can be produced in vitro by culturing under adverse conditions. This results in the selection of certain mutants that have adapted to grow well under these conditions but poorly in the human host. The BCG (for tuberculosis), oral polio (OPV), yellow fever, measles, and pertussis vaccines are all based on attenuated organisms produced in the laboratory. The immune response is usually good, producing both humoral and cell-mediated responses. Lifelong immunity is often achieved with a single dose. However, although much success has been achieved with attenuated organisms, they do possess major problems. These include the potential reversion of the vaccine to virulence especially in the immunodeficient, a huge group considering the world's aging population, the spread of HIV infection and the prevalence of diabetes mellitus and cancer. In fact, OPV, which has long been the preferred vaccine for the prevention of polio in the United States, is currently being replaced by the inactivated polio vaccine (IPV) for this reason because the chance of obtaining polio from the vaccine is actually becoming more likely than obtaining it from the general population! In addition to this, live vaccines need to be stored frozen, which is often prohibitively expensive.

Live recombinant vaccines have also been explored. Bacterial or viral vectors are genetically engineered to express an immunogenic protein of another organism. After administration, this recombinant would replicate and express the foreign antigen to induce an immune response to that protein. These systems are currently still only in the experimental phase.

Killed Vaccines. Entire viruses or bacteria can be killed and delivered as vaccines. These vaccines are not infectious, assuming that all the pathogens are actually killed in the fabrication process, and are therefore generally safe. Of course, they must be carefully monitored to ensure that all the infective organisms are indeed inactivated. This type of vaccine has the advantage of possessing all the necessary antigens, but immunogenicity is often reduced, leading to the need for repeated boosters. The inactivated polio vaccine is an example of this type and, as mentioned earlier, is regaining popularity.

Subunit Vaccines. In cases where protective immunity is known to be directed against one or two proteins of an organism, often surface proteins, purified antigens can be used as an effective, well-defined vaccine. For diseases that are caused by toxins produced by the infectious agent (such as diphtheria, tetanus, and cholera), the subunit can be inactivated toxoids of the bacteria. The subunits can also be surface polysaccharides (as used for the *Hemophilus influenzae* vaccine) or specific viral proteins (as in the hepatitis B vaccine.) There is great potential in this type of vaccine because the development of recombinant DNA technology can allow for the synthesis of desired antigenic epitopes in large and well-defined quantities. However, the greatest problem in the development of this type of vaccine lies in identifying the epitopes that possess sufficient antigenicity to produce long-term immunity. DNA vaccines, vaccines in which cells of the recipient are transfected to produce an immunogenic protein (often a subunit), have been proposed and are being worked on by many investigators.

Mucosal Immunology

Much of the early work on vaccine development has concentrated on the induction of antibody-based humoral immunity toward specific pathogens. This type of immunity is conferred within the bloodstream and is most effective against organisms that have a significant presence or portion of its life cycle within the bloodstream. However, a great deal of the recent work has focused on the develop-

ment of new vaccines that induce mucosal immunity. Mucosally delivered, most often by the oral route, controlled-release vaccines have been shown to be effective in inducing this type of immunity. An immune response focused at the mucosal surfaces may be sufficient to prevent the colonization of these surfaces and therefore help prevent the spread of the pathogen even before it enters the bloodstream. This mucosal immune response is characterized by a secretory immunoglobulin A (sIgA) response towards the antigen at mucosal surfaces (gastrointestinal, respiratory, rectal, vaginal, etc.). There is evidence that all these sites are linked so that vaccination at any mucosal surface, such as the gut wall after oral dosing, will induce secretory IgA responses at not only that specific mucosal site but also at the other mucosal sites (McGhee, 1993 #3). This property of the mucosal immune system, although somewhat oversimplified as stated, has great implications for the development of effective mucosal vaccines. More than 70% of the body's antibody-producing lymphocytes are part of this mucosal immune system and are located in the intestinal tract (5). Considering its size and pervasiveness and the fact that all vaccines currently available (except the oral polio virus) are given systemically and do not elicit a meaningful mucosal immune response, it is safe to say that mucosal immunology has yet to be exploited to its full potential. The greatest promise of controlled-release vaccine development lies in its potential of harnessing this powerful natural barrier to infection.

The mucosal immune system has evolved into a complex system to deal with the many foreign antigens presented at the mucosal surfaces. There are two areas of antigen processing where mucosal immune responses can be induced: the gut-associated lymphoreticular tissue (GALT) and the nasal-associated lymphoreticular tissue (NALT), both of which possess similar cell architecture. The GALT is made up of the Peyer's patches (collections of lymphoid tissue located in the small intestines, mostly in the terminal ileum), isolated lymphoid follicles of the appendix, and the mesenteric lymph nodes. The GALT is covered by a special epithelium, the follicle-associated epithelium (FAE), which is lined by M cells, which sample intestinal antigens and particulates and deliver them to the underlying lymphoid tissue (6). Here, antigen-presenting cells present the antigens to Th2 and B lymphocytes, which can then travel systemically to the mucosal effector sites. These effector sites include, but are not limited to, the lamina propria of gastrointestinal (GI), respiratory, and genitourinary tracts. At these sites, B cells are then stimulated to secrete IgA.

Most work on mucosal controlled-release vaccines has been focused on trying to immunize the GALT by delivering the antigen in either liposomes or thermoplastic microspheres directly to the M cells of the Peyer's patch following oral administration. Therefore, understanding the interactions between luminal particulates and the cells lining the FAE is critical to the design of vaccines meant to illicit a mucosal immune response. Some of the work at quantifying the uptake of liposomes and microspheres by the GALT is reviewed in this section and followed by a description of some of the controlled-release vaccines described in the literature.

PARTICLE UPTAKE BY INTESTINAL M CELLS

As early as 1961, it was known that the intestine is an imperfect barrier to small particulates. Polystyrene beads of 220-Å diameter were shown to cross gastrointestinal epithelial cells and appeared in the liver following oral administration to rats (7). Other work, 17 years later, showed that commercially available 2-μm polyvinyltoluene particles chronically fed to mice would accumulate in the Peyer's patches, intestinal villi, and mesenteric lymph nodes (8). However, the connection of this phenomenon to the potential development of oral vaccine delivery systems was yet to be made. A large body of work now exists in which investigators attempt to document the uptake of orally fed particulates, specifically by M cells lining the Peyer's patches, to establish the feasibility of an oral controlled-release vaccine. Such particles with an affinity for uptake by the Peyer's patch could be used to encapsulate an antigen and elicit a mucosal immune response.

Microscopy has been the most common method used to follow the uptake of microspheres or other particulates by the GI epithelium. In particular, light microscopy has been used extensively. Rabbits have been used frequently as the animal model in this type of research as they possess a relatively large number of Peyer's patches in their GI tracts when compared to other mammals. In one specific study, light microscopy was used to show the translocation of fluorescent, polystyrene microparticles through the intestinal wall of rabbits. The temporal movement of these 600- to 700-nm beads across the epithelial surface of the FAE was followed after intraluminal instillation. Translocation occurred within 10 min, approximately the same amount of time that soluble tracers needed to cross the epithelium. The authors estimated that 5% of the intraluminal dose entered the FAE. These results implied that translocation of thermoplastic microparticles did indeed quickly occur into the Peyer's patch and could potentially be utilized for vaccine delivery (9).

In another study, chronically fed polystyrene microspheres of different sizes (50 nm to 3 μm) were also shown to appear in rat Peyer's patches, villi, liver, spleen, and mesenteric lymph nodes. No spheres were seen in the heart, kidney, or lungs. Radiolabelling of the spheres with ^{125}I allowed quantification of spheres in tissues and demonstrated that, in general, smaller spheres had greater uptake than larger particles (Table 2). However, a few interesting observations, were made. In particular, the largest spheres examined (3 μm) appeared to show greater uptake

Table 2. Total Uptake of Various Sized Polystyrene Beads following Oral Administration

Polystyrene microsphere size	uptake (%)
50 nm	33.7 ± 3.7
100 nm	25.9 ± 3.2
300 nm	9.5 ± 1.25
500 nm	13.7 ± 1.2
1 μm	4.6 ± 0.7
3 μm	≈12

Source: Data from Ref. 10.

than the 1-μm spheres, but they were not observed in the bloodstream or in the liver as the smaller spheres were. This was explained by the authors as being due to a large number of 3-μm spheres that were adsorbed and immobile within the submucosal layer of the Peyer's patch and therefore not allowed into the circulation. The smaller spheres were quickly translocated into the serosal layer and appeared in the circulation (11). Histological work by the same group indicated that most of the uptake of these spheres did occur through the Peyer's patch and that particles in the liver were mainly in the Kupffer cells (macrophages) or endothelial cells lining the sinusoids, not the hepatocytes themselves.

Other methods of microsphere identification and/or quantification have also been used, including confocal microscopy (12), electron microscopy (13–15), extraction of the polymer from tissue followed by quantification by gel permeation chromatography (11), and flow cytometry (16). All of these studies came to similar conclusions: Polymer microparticulates of <10 μm in diameter indeed can enter the GALT, often within 1 h of oral administration, and have promise as antigen carriers for controlled-release vaccine applications.

Although particle uptake has been demonstrated using hard, nonbiodegradable microspheres, it is clear that biodegradable polymers would be more useful for the development of a controlled release system. Such a polymer, poly (D, L-lactic-*co*-glycolic acid) (PLGA), in the form of 1- to 10-μm microspheres, has also been shown to be transported into rabbit Peyer's patches following intraluminal instillation. This system has advantages over the other mentioned in that the PLGA is biodegradable and has already been studied and used extensively as the carrier in a number of controlled-release devices. Electron microscopy shows that microspheres of this copolymer are taken up by M cells and translocated toward the underlying lymphatic tissue within 1 h (17). This rapid uptake of PLGA microspheres and its biodegradative properties has led to extensive work with this polymer in vaccine applications. Many of these are discussed later in this section. Other degradable polymers, most notably polyanhydrides, have also been shown to exhibit uptake properties. Light and transmission electron microscopy studies with poly(fumaric-*co*-sebacic) anhydride fabricated into microspheres of 0.5–5 μm in diameter show translocation across the epithelium of the GI tract. The spheres were seen as early as 1 h postfeeding and were observed in the Peyer's patch at 3, 6, 12, and 24 h following oral administration (18).

LIPOSOME UPTAKE

In addition to thermoplastic microspheres, studies have also been conducted to determine the extent of uptake of orally administered liposomes. Significant uptake after intraluminal administration of a fluorescent marker, 6-carboxyfluorescein, was seen only when enclosed in negatively charged liposomes greater than 374 nm and made up of at least 25 mol % phosphatidylserine. The uptake was seen predominantly by the ileal Peyer's patches in rats as compared to those in the more proximal small intestine. The authors suggested that these findings indicate that these liposomes could therefore be used to specifically target the Peyer's patch (19). To address the issue of the stability of these liposomes in the harsh conditions of the GI tract, the same investigators demonstrated that liposomes made of distearoylphasphatidylcholine or dipalmatidyldiphosphaidylcholine, phosphatidylserine, and cholesterol were stable in simulated gastric, bile, and pancreatic fluids. These findings lend greater support to the belief that such liposomes could successfully deliver antigens to the Peyer's patch and indeed were seen to enter the Peyer's patch after oral administration (20). Further support to this hypothesis was provided by a study in which gold-labeled liposomes intraluminally administered to isolated intestinal loops of rats were seen within endocytic vesicles in M cells of the Peyer's patch with transmission electron microscopy (TEM) (21). Many other investigators, both before and after these findings, have used antigen-loaded liposomes to elicit immune responses. These will be addressed later in this section.

LIPOSOME-BASED VACCINES

As mentioned earlier, the greatest problem with subunit vaccines is their decreased immunogenicity. A large number of materials, known as adjuvants, can potentiate immune responses to weak antigens. These include Freund's incomplete antigen, a water-in-oil emulsion containing the antigen, Freund's complete adjuvant (FCA), the same water-in-oil emulsion including killed tubercule bacilli, aluminum hydroxide (alum), and others. However, alum is the only material approved for human use as the others are quite toxic; FCA causes undesirable granulomas at the site if injected. Alum has been shown to be inadequate in many situations because of variations in its adjuvant effect with different antigens and formulations. Despite their differences in structure, most adjuvants are believed to derive their ability to increase immune responses by forming emulsions or depots with the antigen and by slowly releasing it over a period of time. Controlled-release systems behave similarly and, in fact, it has been known for many years that liposomes act as immunological adjuvants.

Liposomes loaded with proteins or other antigens have been shown to slow the release of these antigens and act as immunological adjuvants. In the seminal work on liposome-based antigen presentation, mice immunized with diphtheria toxoid (DT) loaded in multilayered, negatively charged liposomes made of egg lecithin, cholesterol, and phosphatidic acid showed greater primary and secondary immune responses than mice administered free DT (22). These results were observed with all three different routes of administration tested, intravenous, subcutaneous, and intramuscular. Unlike the other types of adjuvants, the liposomes caused no granulomas or other undesired immune reactions at the site of injection.

This work was followed by many others exploring the possibility of taking advantage of this adjuvant property and the apparent safety of liposomes to produce liposome-based vaccines. There are certainly a great number of var-

iations possible when designing liposome-based vaccines. Vesicle size, lipid composition, antigen loading (including how much and where the antigen is loaded), lamellarity, and surface composition of the liposomes can all be modified to try to optimize the adjuvant effect on the desired antigen. However, a wide variety of liposomal formulations have shown increased immunogenicity, suggesting that specific liposomal properties such as size, composition, lamellarity, and charge may be less important to the systems adjuvanticity than the simple act of the antigen's release being slowed by its interaction with the lipids (23). Liposome technology has been applied to many different types of antigens—bacterial, protozoal, viral, protein, and others. In fact, there have been over 100 (and counting) international patents issued for variations on this type of technology (24). It would be impossible to describe all of the systems that have been explored, so only a few representative ones are discussed here. Table 3 shows just a few of the recent papers based on liposome-encapsulated vaccines and demonstrates the wide variety of antigens that have been attempted, including a description of some of these liposome-based vaccines.

Model Vaccines Delivered in Liposomes

Bovine Serum Albumin. In a search for easier routes of vaccine delivery, the intranasal route has received a large share of interest, especially when dealing with infectious agents that gain entry through the respiratory tract. In these cases, a local sIgA response on the nasopharyngeal mucosa would be extremely beneficial. This route of delivery targets the nasal-associated lymphoreticular tissue and thus may also induce a disseminated mucosal immune responses. Work with a model protein antigen, bovine serum albumin (BSA), showed that serum IgG and salivary IgA were significantly elevated after nasal administration of BSA-loaded liposomes (26). Antigen localization, whether within aqueous spaces in the liposomes or attached to the outer surfaces, did not seem to influence the systemic IgG response. However, salivary sIgA responses were noted to be significantly higher with antigen linked to the outer surface of the liposomes, hinting that the immune processing of the two types of liposomes may be different.

T-Independent Antigens. As is discussed in the following section on *Streptococcus mutans* vaccines, conjugated polysaccharide and protein antigens can be delivered by liposomes to elicit a long-term immune response to polysaccharide antigens. This conjugation of polysaccharide and protein antigens is a common immunological method used to induce T cell–dependent response (normal for protein antigens) to antigens that normally induce T cell–independent responses (polysaccharides). However, it has been shown that the conjugation of polysaccharide and protein

Table 3. Examples of Liposome-Based Vaccines

Antigen	Comments
Ascaris suum crude antigen	Slightly increased protection from nematode infection, especially when combined with levamisole (25)
BSA as a model antigen	Increased IgG and sIgA after nasal administration of liposomes in mice (26)
Conalbumin as model antigen	In vivo to in vitro comparing encapsulated antigen to surface-linked antigen (27)
Diptheria, tetanus, HAV, HBV, and influenza	Shows good immunogenicity and tolerance in humans; may lead to development of new combined vaccines (28).
Ferritin as a model antigen	Increased IgA responses to rectally administered vaccine, especially when combined with cholera toxoid and LPS (29)
Hepatitis A virus, formalin-inactivated	Protective antibody levels in clinical trials; currently marketed in Europe (30)
HIV-1, subunit from gp120	Antigen in "protein cochleates" induces humoral and cellular immunity after both oral and intramuscular administration (31).
HIV-1, subunit from gp120	Increased antibody and cytotoxic T cell lymphocyte responses in vaccinated mice (32)
Influenza virus, HA and NA	Phase 1 clinical trials showing slightly more adverse reactions than those receiving standard HA vaccine (33)
Influenza virus, HA3/NA2	Increased primary and secondary immune responses to HA3/NA2 in hamsters (34)
Influenza virus, LPS and HA2	Liposomes induce a T cell–dependent response to loaded LPS in mice (35).
Measles virus inactivated	Increased serum IgG and sIgA in respiratory tract in mice after intranasl administration (36)
Plasmodium falciparum circumsporozoite protein (Malaria)	The protein loaded into liposomes, but not unencapsulated protein, resulted in cytolytic T cell–lymphocytes and an antibody response. This reactant serum inhibited sporozoite invasion of hepatoma cells in vitro. [White, 1993 #259]
Streptoccocus mutans glucosyltransferase	Increased salivary IgA in humans after oral dosing; serum IgG not greatly increased (37)
Streptoccocus mutans, purified antigens	Oral liposomes induce salivary IgA and result in increased protection from dental caries (38).
Streptoccocus sobrinus ribosomal antigen	Orally immunized rats showed greater salivary IgA and were more protected from dental caries (39).
Vibrio cholerae cell-free lysate	Liposome vaccines were effective orally and parenterally. Polyester-loaded antigens were only effective parenterally (40).

is not actually necessary when delivering the antigens in a liposome formulation. Liposomes have been shown to provide T cell–dependent help to T cell–independent antigens by simply loading both polysaccharide and protein in the same liposome. DNP-aminocaproyl phosphatidylethanolamine (DNP-CapPE), a well-characterized T cell–independent antigen and influenza hemagluttinin A2 (HA2), a well-known T cell–dependent antigen, were loaded into phosphatidylcholine liposomes by the dehydration–rehydration technique. These liposomes elicited a memory response made up of all the IgG subclasses to DNP-CapPE after injection in mice. When liposomes containing just DNP-CapPE were used, an IgM response was observed. These results are very interesting in that one of the tenets of immunology, T cell–independent antigens can only elicit a T cell–dependent response when conjugated to a T cell–dependent antigen, can be circumvented by the delivery of both antigens, unconjugated to one another, in liposomes (41).

This work also illustrates another important concept: In addition to the desired antigen, other potentially helpful compounds or adjuvants can be encapsulated in or conjugated to the liposome formulation. For example, cholera toxin (CT) or the cholera toxin B (CTB) subunit, known mucosal adjuvants, can be incorporated to the liposome vaccine to produce a greater response after oral vaccination. The adjuvant effect of the CT and CTB may be due to its targeting of intestinal ganglioside on the epithelial cell surface or increasing cell permeability of the antigen. The coupling of biologically active CT or CTB to small unilamellar liposomes by a thioether bond retains their immunogenicity (42). The authors suggest that these formulations may be helpful in specifically targeting the liposomes to the Gm1 ganglioside receptors on the Peyer's patch M cells, resulting in greater uptake after oral delivery of the vaccine. These last two studies illustrate an important point about controlled-release formulations that deserves emphasis: In addition to the specific antigen, other desired agents (such as adjuvants, targeting molecules, or even other antigens) can be coadministered in the controlled-release system and potentially improve the response.

Effect of Antigen Association. Liposomal antigens have been shown to influence different immune responses depending on how the antigen is associated to the liposome and whether it is encapsulated within the aqueous portion inside the liposome or surface linked within the lipid bilayer (27). Encapsulation was performed by using a dehydration–rehydration technique, and surface linkage was accomplished by covalently attaching lipid to protein by using a heterobifunctional reagent. Mice intraperitoneally immunized with encapsulated antigen showed only a short-lived antibody response, while those immunized with surface-linked microspheres showed a longer-lasting effect. However, as stated earlier, a multitude of different liposome formulations have proven effective in the induction of long-lasting immune responses implying that generalizations about optimal liposome formulations for different antigens may not be possible to make. Further study is needed into how different liposome structure, size, lamellarity, and other properties lead to the activation of different immune pathways. The examples of just a few of the current vaccines under development for specific diseases shown in Table 3 demonstrate the diversity of liposomal formulations that can be used.

Specific Liposome Vaccines under Development

Dental Caries. The bacterium *Streptococcus mutans* has been identified as the major causative agent of human dental caries. The bacteria colonize the mouth, adhere to teeth, and, with sugar as a food source, produce acids that cause cavities. Increased salivary IgA responses to antigens from this bacteria are expected to control this colonization and potentially offer protection from dental cavities. As a result, a number of studies have attempted to present streptococcal antigens in a liposome vaccine. Purified surface polysaccharide and proteins (43), ribosomal proteins (38), and bacterial glucosyltransferase (37,38,44) have all been explored as potential antigens.

The adherence of *S. mutans* to teeth was found to be dependent on a complex mechanism that involves many of the bacteria's cell wall components, including certain polysaccharides, proteins, and lipoteichoic acids. Secretory IgA responses to any or all of these components would be expected to inhibit bacterial attachment. In general, polysaccharides are thymus-independent (TI) antigens that can induce short-term IgM responses but can not induce immunological memory. This problem can be overcome by conjugating the polysaccharide to a protein, a thymus-dependent (TD) antigen. This conjugate can then be used to elicit a long-term immunological response, as is done in the current *H. influenzae* vaccine. Such a protein–polysaccharide conjugate was associated with liposomes to produce both serum and salivary immune responses following oral administration (43). Briefly, conjugates were formed from polysaccharide and protein obtained from bacterial cell cultures and loaded into liposomes that were then administered orally to rats. Salivary IgA to the polysaccharide were evident in rats fed the conjugate liposome vaccine but not in rats fed vaccines containing only polysaccharide or protein. Salivary IgA responses to the more immunogenic protein occurred with both unconjugated and conjugated antigens. As demonstrated by some of the work with model antigens described earlier, this experiment demonstrated that although it is not able to produce an immune response to unconjugated polysaccharide, a liposome formulation could deliver a thymus-independent antigen when conjugated to a protein and produce an extended response.

It is well known that certain surface antigens of *S. mutans* can induce antibodies cross-reactive to the patient's own heart. The perceived danger of this cross-reactivity led to work on developing a vaccine based on a ribosomal preparation. These ribosomal vaccines have been shown to react to many strains of *S. mutans*, inhibiting adherence, acid production, and growth. Encapsulation of the ribosomal antigen into dipalmitoyl phosphatidylcholine, cholesterol, and dicetylphosphate was accomplished by a modified dehydration–rehydration procedure. All rats vaccinated with these liposomes elicited salivary IgA responses, but so did all rats fed just the ribosomal antigen.

No or low levels of salivary IgG, serum IgA, and IgG were seen in all cases. In bacterial challenge experiments, fewer adherent bacteria were found in rats given the liposome vaccine than in unvaccinated animals. In addition, there were significantly fewer carious lesions in liposome-vaccinated rats than in those that received only free ribosomes or no vaccine (39).

The final antigen to be discussed here that has been studied for the induction of sIgA to *S. mutans* after incorporation in a liposomal vaccine is the bacterial glucosyltransferase. This protein has been loaded into well-characterized dipalmitoyl phosphatidylcholine, cholesterol, and dicetylphosphate (16:7:1) unilamellar liposomes of uniform size (~100 nm) and loading. Administration of these liposomes to rats showed a 25–38% reduction in *S. mutans* colonization and a 30–40% reduction in caries (38). Human studies using similar liposomes that were dehydrated and loaded into gelatin capsules also showed increased levels of salivary IgA lasting for 56 days and minimal plasma immune responses. This was the first evidence that a dehydrated liposome preparation could rehydrate after oral dosing and still successfully elicit an immune response in humans (37,44).

Hemophilus influenza. The currently available *H. influenza* type B vaccine consists of a purified surface lipopolysaccharide (LPS) from the bacteria surface conjugated with a protein carrier, which allows the polysaccharide to achieve a T cell response. The necessity for a "carrier" protein has also been shown to be required when LPS is loaded into liposomes for vaccine applications. Incorporation of LPS and HA2 peptide from the influenza virus in liposomes resulted in anti-LPS-specific IgG responses following subcutaneous immunization (35). This response was characterized by IgG1, IgG2, and IgG3 subclasses, indicating that the normally T cell–independent antigen had been given a T cell–dependent quality, allowing for immune recognition by both T cell–helper and T cell–cytotoxic lymphocytes. Liposomes loaded with only LPS maintained their T cell–independent status and elicited only low levels of IgG3 responses.

Hepatitis A. A commercially available and very effective liposome-based hepatitis A vaccine is currently licensed and available in Europe. This vaccine is based on a specific type of liposome dubbed an immunostimulating reconstituted influenza virosome (IRIV); these are described as spherical, unilamellar vesicles of approximately 150 nm in size. The IRIVs are made of 70% egg yolk phosphatidylcholine, 20% phosphatidylethanolamine, and 10% envelope phospholipids from the H1N1 influenza virus. In addition, biologically active neuraminidase (NA) and hemagluttin (HA) glycoproteins from the influenza virus are located in the lipid bilayer of the virosome, forming short surface projections of 10–15 nm in size. These surface glycoproteins are meant to contribute to the effect of encapsulation within the virosome. HA is a major antigen of the influenza virus and thus a major constituent of its vaccine, and it is responsible for the fusion of the influenza virus with cell membranes. The presence of HA on the surface of the virosome is expected to lead to greater uptake and immune processing of the antigen by macrophages (30).

A number of variations have been made on the successful IRIV hepatitis A vaccine. As stated earlier, one of the properties of an ideal vaccine is the ability to confer immunity after a single dose, yet this vaccine is given as part of a recommended vaccination schedule of three doses of 0, 1, and 6 or 0, 1, and 12 months apart. In a human trial, three vaccine formulations were compared to determine the efficacy of a single-dose vaccine. One group received intramuscular injections of purified inactivated hepatitis A vaccine (HAV) in IRIVs, one received (HAV) absorbed to alum, and the other received soluble HAV. Although 100% of all the subjects showed responses to each of the formulations at 6 months, the mean antibody levels for the virosome vaccines were greater than the alum-associated and soluble vaccines at 14 days, 28, days and 6 months. However, owing to individual variability among the immune responses, the differences among antibody titers were only significant at 14 days (45). Work continued with this system until a safe and effective IRIV-based hepatitis A vaccine was produced (46). The IRIV system has also been used in an attempt to create a combination vaccine containing five commonly used inactivated vaccines that are usually delivered as alum-associated products: hepatitis A and B, diphtheria toxoid, tetanus toxoid, and two different strains of influenza. For diphtheria, tetanus, and influenza, the combined vaccine showed greater immune responses than single vaccines at almost all times tested (28, 90 and 180 days). The immune response at 28 days for the hepatitis A vaccine in the combined vaccine was statistically less than the response to a single vaccine; however, this difference disappeared at the other two time points. This work showed that a number of different antigenic could successfully be incorporated into the same IRIVs and that showed promise as combined vaccines (28).

Human Immunodeficiency Virus. Most of the examples considered thus far have concentrated on vaccination strategies designed to elicit a predominantly humoral immune response. However, both humoral immunity and cellular immunity are required for the effective prevention of a number of diseases, most notably AIDS. The human immunodeficiency virus (HIV) is blood borne, and thus potentially stoppable by serum antibodies, and takes up residence in T lymphocytes, thus requiring the presence of cell-mediated immunity. In addition, because HIV infects across mucosal membranes, a mucosal immune response is thought to also be beneficial. A vaccine that results in cellular, humoral, and mucosal immune responses to HIV has the potential to protect HIV-negative individuals and help stop the spread of the current pandemic of HIV infection.

A lipid-based HIV vaccine has been developed that successfully induces each of the three branches of the immune response. It possesses original structures called protein cochleates that are stable protein and phospholipid bilayers rolled up into a "jellyroll" shape. This rolled-up lipid structure is stabilized by the presence of calcium ions that cross-link successive layers. In a low-calcium environment or in the presence of chelating agents, the calcium is re-

moved, and the cochleates unroll and form unilamellar liposomes with the antigenic proteins incorporated in the lipid bilayers (31). When the envelope protein gp160 from HIV-1 is incorporated into protein cochleates and administered intramuscularly to mice, a strong anti-gp160 antibody response at 8 weeks was measured as well as a strong response (60–70% specific kill at 17 weeks) was observed (47). Following two oral administrations, this type of liposome has proven to induce both high sIgA and systemic antibodies. In addition to HIV, protein cochleate vaccines for influenza and parainfluenza viruses have been studied in experimental animals (47).

Influenza Virus. The vaccine for influenza changes from one year to the next. Based on epidemiological studies around the world, the strain of influenza virus most expected to spread the following year is identified, and the appropriate HA and NA proteins are incorporated into that year's vaccine. As a result, a great deal of work goes into the production of the influenza vaccine each year. In addition, a number of liposome-based strategies have been explored to improve on this current method. In one example, influenza (A/PR/8 strain) envelopes and influenza (A/Sichuan/87 [H3N2] strain) surface antigens were encapulsulated in phospholipid/cholesterol liposomes using a dehydration–rehydration technique. The liposomes produced had encapusulation efficiencies of approximately 40%, which is very good for liposome fabrication. These liposomes were administered to mice intramuscularly in a primary dose and booster dose after 4 weeks, which resulted in increased antibody responses to both HA and NA. This was compared with no response toward unencapsulated HA and NA, which are normally not very immunogenic. The authors concluded that such a system could be used to improve the efficacy of the influenza vaccine and could quite possibly be used for combination vaccines (34). Another liposome-based influenza vaccine has gone through phase I clinical trials in human volunteers showing that it was safe and did indeed produce greater anti-HA antibodies than the standard vaccine. The liposomes were made from B30-MDP, cholesterol, and octyl glucoside. As this was a phase I study, it concentrated on safety of the vaccine and not efficacy. Unfortunately, it was found to have slightly greater side effects than the standard vaccine (reddening at the injection site and deviations from the norm on blood and urine tests). Clearly, more work on this vaccine needs to be done (33).

Measles Virus. The current measles vaccine generally consists of a live, attenuated organism given parenterally, most often intramuscularly. Although these vaccines have been shown to be very effective, they do not induce a secretory IgA response, which may be of great importance in protecting from airborne virus particles. In addition, as discussed earlier, there are other advantages in developing inactivated whole virus or subunit vaccines. In work to this end, an inactivated whole virus vaccine mixed with phosphatidylcholine, dicetyl phosphate, and cholesterol (4:1:5) liposomes showed a significant increase in serum IgG and sIgA in the lungs and nasal cavity. Free inactivated virus was unable to induce an sIgA response. In addition, intramuscularly administered virus-containing liposomes elicited an IgG response but not an sIgA response. This is important as it shows that the route of administration is crucial in obtaining the desired immune response and that nasally administered liposomes can indeed present antigens to the nasopharyngeal lymphoid tissue (48).

POLYMER-BASED DEVICES

A great deal of work has also been conducted with polymer-based, controlled-release vaccine formulations. In the earliest application of this technology, an antigen released from a polymeric device made of nonbiodegradable ethylene-vinyl acetate copolymer (EVAc) enhanced antibody formation for more than 6 months in mice (49). In this work, a 1-mm EVAc pellet loaded with model antigens (albumin, gamma globulin, and ribonuclease) was implanted subcutaneously in mice; the immune response was comparable to antigen emulsified in FCA. The three different proteins used resulted in different antibody responses, which was considered to be due to the fact that larger proteins resulted in slower release, thus resulting in a greater adjuvant effect and immune response. These results were very encouraging and began a new field of inquiry into this type of antigen-loaded polymers.

Adjuvant Effect of Degradation Products

In addition to the adjuvant effect gained by the slow release of an antigen, a number of individuals have theorized that beyond the intrinsic adjuvant effects of controlled-release systems, other biodegradable systems can be engineered that possess added adjuvancy in the form of degradation products. A biodegradable polymer based on poly(CTTH-iminocarbonate) degrades into *N*-benzyloxycarbonyl-L-tyrosyl-L-tyrosine hexyl ester (CTTH), which is as potent an immunological adjuvant as FCA. It was hypothesized that an antigen delivered in a matrix of such a material would benefit by the adjuvant effects of the degradation products. BSA loaded into this polymer and delivered subcutaneously in mice did elicit a much greater immune response than BSA loaded into a comparable control polymer made of EVAc (50). This provides evidence for the idea that there is indeed difference between the adjuvancy of different polymers and that the effect can not solely be attributed to the slow release of antigen from these devices. Although this is a very interesting concept and one that should certainly be considered when selecting specific polymers for use in a vaccine formulation, not much more specific research along these lines has been published since this work.

Model Vaccines

Many of the early experiments conducted on controlled-release vaccines concentrated on illicting immune responses to model antigens loaded into thermoplastic matrices. The purpose of these studies was not to develop a specific protective immunity to a pathogen but to prove that antigens could successfully be included in a controlled-release device and retain immunogenicity. The

most popular of these model controlled-release vaccines incorporate ovalbumin (51–56) or BSA (49,57) as an antigen. Table 4 offers a brief description of some of these model controlled release vaccines.

Many of the important general characteristics of controlled-release vaccine systems were elucidated in these studies. However, only a few of these are discussed further, and the remainder of this section concentrates mainly on vaccines potentially effective for specific pathogens. Most work on controlled-release vaccines from biodegradable microspheres has been based on poly(lactide-*co*-glycolide) (PLGA), which is approved by the U.S. FDA for specific applications and is widely used in biodegradable sutures. The literature contains many examples of controlled-release formulations based on this system.

By far, the most common polymer used for the development of controlled release vaccines has been PLGA. Ovalbumin (OVA), a poorly immunogenic model antigen, when loaded into PLGA, is able to elicit a strong immune response after intraperitoneal or subcutaneous administration (61). Microspheres were prepared by solvent evaporation from an oil-in-water emulsion and had an average size of 5.3 μm and protein content of 1%. After 10 weeks, mice immunized by a single ip injection of encapsulated OVA showed significantly higher serum IgG levels than animals given an equivalent dose of OVA emulsified with FCA. However, after 12 weeks, the antibody levels were not significantly different. After sc booster doses, the secondary responses to OVA in microparticles remained higher than responses to unencapsulated OVA. Further experimentation yielded information on how the size of the microparticles effected immune response. Microspheres of 1.5 μm were significantly more immunogenic than 72.6-μm microspheres (54).

Positive results have also been obtained with model oral vaccines. Orally fed ovalbumin-loaded polyacrylamide microspheres of 2.55 μm in diameter were shown to induce a increase of IgA response when compared to a soluble control group (62). The rats were primed intraperitoneally 14 days before receiving oral doses of microspheres for 4 consecutive days. The primary and memory sIgA response in saliva were measured at 14 and 65 days postimmunization, respectively. Primary responses lower in encapsulated formulations, but memory responses were higher.

It is important to keep in mind, before discussing any specific formulations, that a major goal of controlled-release vaccines is to provide the initial immunization and booster doses in a single shot. Patients would no longer need to return for three or four doses to gain immunity, and medical personnel costs would be greatly reduced. Therefore, determinants of the release rates from various formulations are vital to the development of "single-shot" vaccines. Most of the examples in the literature address this issue and are careful to include good descriptions of the release characteristics of their specific formulation. These examples of microsphere-based vaccines are numerous, many more than can be fully presented here. A description of some, categorized by disease, follows.

Specific Vaccine Formulations

Again, most of the work on polymer-based vaccines, whether delivered parenterally to elicit systemic IgG immune responses or orally to elicit mucosal IgA responses, has been centered on PLGA microspheres. Table 5 summarizes some of the literature on polymer-based vaccines, including information about the specific antigen delivered, polymer used, route of delivery, and size of formulation. The section following Table 5 describes a few of these examples further.

Diphtheria. Diptheria is a localized infection of either mucous membranes (most often the oropharynx) or skin caused by *Corynebacterium diptheriae*. The infection causes pathology by means of DT produced by the bacteria. DT is currently included in the diphtheria–tetanus–pertussis (DTP) vaccine, commonly included in vaccination schedules worldwide, and is effective at preventing diph-

Table 4. Examples of Polymer-Based Vaccines Using Model Antigens

Model antigen	Comments
Bovine serum albumin	10- to 100-μm spheres made of PLGA showed greater adjuvanticity than both Alum and FCA when administered subcutaneously (57).
Bovine serum albumin	Poly(methyl methacrylate) and polystyrene particles between 62 and 306 nm possess adjuvant effect after intramuscular administration (58).
Bovine serum albumin, gamma globulin, and ribonuclease	First study to show that an antigen in a subcutaneously implanted polymer pellet (EVAc) elicited long-term antibody responses (49).
Human serum albumin	Intraperitoneal administration of polyacryl starch particles elicited both humoral and cellular response (59).
Ovalbumin	Antigen absorbed onto poly(butyl-2-cyanoacrylate) particles demonstrated increased oral immunogenicity in rats (53).
Ovalbumin	Intraperitoneal administration in poly(lactic acid) microspheres showed greater primary and secondary responses (60).
Ovalbumin	Oral administration in an acid-resistant acrylic polymer results in IgA and IgG responses (55).
Ovalbumin	Particle size study for subcutaneously administered PLGA microspheres showed better response with 3.5-μm spheres than 1.2-μm spheres (51).
Ovalbumin	Subcutaneously administered PLGA microspheres demonstrated antibody response. 1.5-μm spheres were more effective than 72.6-μm spheres (54).

Table 5. Examples of Polymer-Based Controlled Release Vaccines showing Antigen and Polymer Used, Microsphere Size and Route of Vaccine Delivery

Antigen	Polymer	Particle size	Route Delivery	Refs.
Bordatella pertussis fimbriae	PLGA	0.8–5.3 μm	ip	63
Bordatella pertussis hemagluttinin	PLGA	1 μm	in	64
Diphtheria toxoid	PLGA	30–100 μm	im	65
Escherichia coli, CFA/I	PLGA	10–200 μm	ig	66
Escherichia coli, CFA/II	PLGA	Not stated	po	67
Hepatitis B surface antigen	PGA	1–10 μm and 20–60 μm	ip	68
Human imunodeficiency virus, gp120	PLGA	Not stated	sc	69
Influenza virus, formalinized	PLGA	2.2–10.8 μm	sc and po	70
Malarial antigen	PLA and PLGA	1–10 μm and 10–100 μm	sc	71
Mycobacteria tuberculosis, 38-kDA antigen	PLGA	0.67 μm mean	ip	72
Simian immunodeficiency virus, formalinized	PLGA	Not stated	im, po, and it	73
Staphylococcal enterotoxin B	PLGA	1–10 μm	sc	74
Staphylococcal enterotoxin B	PLGA	1–10 μm	po	75
Staphylococcal enterotoxin B	PS, PMMA, PLA and PLGA	1–10 μm	po	76
Tetanus toxoid	PLA and PLGA	10–60 μm	sc	77
Tetanus toxoid	PLA and PLGA	1–10 μm and 10–100 μm	sc	71
Venezuelan equine encephalitis, formalinized	PLGA	<10 μm	sc	78
Vibrio cholerae cell-free lysate	PLGA	1–10 μm	po and ii	40

Note: PLA = polylactic acid, PLGA = poly(lactide-*co*-glycolide), PS = polystyrene, PMMA = poly(methyl methacrylate), ii = intraileal, im = intramuscular, in = intranasal, sc = subcutaneous, ip = intraperitoneal, it = intrathecal, po = oral.

theria. However, in an attempt to improve the delivery of this toxoid, it has been encapsulated in PLGA microspheres by the in-water encapsulation technique (65). In vitro drug release studies of this formulation show that 90% percent of the drug was released in 60 days. When mice were subcutaneously immunized once with these microspheres, antibody titers over 3 months were comparable to mice receiving the conventional three-injection schedule. It appears that the toxoid retained its antigenicity upon encapsulation, and its slow release from the microspheres allows for a boosting effect. This controlled release of the diphtheria toxoid certainly appears to show promise for the development of a single-dose vaccine, and further work needs to be conducted to determine the longevity of the immune response and whether the other vaccines traditionally given with diphtheria toxoid can also be incorporated.

Enterotoxigenic Escherichia coli. Vaccination of rabbits with entererotoxigenic *E. coli* colonization factor antigen (CFA/I), a surface fimbrial adhesion that is important for successful adhesion of the bacteria to the intestinal wall, induces intestinal mucosal responses and protects from colonization and disease (66). CFA/I fimbriae were purified and encapsulated into a 50:50 PLGA copolymer at 0.1% w/w. In vitro release of the encapsulated antigen began within 2 h and occurred for up to 72 h. Rabbits were intragastrically immunized with either encapsulated or soluble antigen, resulting in greater systemic immune responses in those fed encapsulated antigen. One of the animals also showed sIgA antibodies in its feces. In clinical trials, 10 human volunteers vaccinated with a prototype vaccine based on this work tolerated it well, and 5 developed IgA responses. When challenged by live enterotoxigenic bacteria, the vaccine showed a 30% efficacy, hardly overwhelmingly protective but still very promising. Work continues on variations of this vaccine, which is now in phase II clinical trials (67).

Hepatitis B. Recombinant Hepatitis B surface antigen (HBSA) has been shown to be effective as a hepatitis B vaccine. This vaccine has recently been added to the standard vaccinations administered to children and people at risk in the United States. However, to achieve a long-lasting immune response, one needs a minimum of three intramuscular injections. In order to improve this system, HBSA has also been encapsulated in polymer microspheres for sustained release. In one very interesting study, five different formulations of HBSA encapsulated in polyglycolic acid (PGA) microspheres were studied. Solvent evaporation and solvent extraction methods were used to produce microspheres of either 1–10 or 20–60 μm in size. In addition, formulations containing the known adjuvants MDP (*N*-acetyl-muramyl-L-alanyl-D-isoglutamin) and Alum were also fabricated and studied. The in vivo studies called for groups of guinea pigs to receive the equivalent of 20 μg of antigen or a negative control of blank microspheres intraperitoneally. Blood samples were obtained periodically, and a booster was given at 16 weeks. The smallest spheres, 1–10 μm, showed the best early response at 2 and 4 weeks; however, this decreased at 6 weeks when the 20- to 60-μm spheres showed the highest antibody response. A combination of these two formulations showed the longest immune response (16 weeks) and is possibly the more favorable formulation. Although the vaccine including Alum did not show any improved response, the greatest response by far was seen with the microspheres that were loaded with both MDP and HBSA. This demonstrates that known immunological adjuvants can indeed be coincorporated into microsphere formula-

tions with the antigen and still contribute to an increased immune response (68). With further work, such a system may be able to reduce the number of injections needed for immunity and therefore allow for a more effective vaccination program against hepatitis B.

Human and Simian Immunodeficiency Virus. A large number of possible vaccines for AIDS are currently under investigation. Many of them are focused at stopping the colonization of mucosal surfaces by the causative virus, HIV. PLGA microspheres loaded with formalin-treated simian immunodeficiency virus (SIV), the simian virus analogous to HIV, have been shown to induce effective protection from vaginal challenge of virus in female macaques (73). A number of immunization routes (oral, im, intrathecal) were used in a variety of schedules. Animals immunized orally showed IgM, IgG, and IgA responses after all doses, but none showed protection from intravaginal viral challenge. When intramuscular priming in the thighs was combined with oral boosting, systemic IgG levels were maintained, and transient increases in vaginal sIgA levels were seen. Five of six macaques immunized this way and vaginally challenged by SIV did not become infected. Although it is unclear whether the vaginal antibodies were the result of successful oral vaccination or intramuscular vaccination close to this site, these results have promise for the development of an HIV vaccine that protects at the vaginal mucosa level. This is incredibly important to help control the spread of HIV infection, as the male–female spread of the virus is currently its fastest-growing means of transmission.

Other PLGA-based vaccines for HIV are also under development. One is directed toward a peptide taken from the principal neutralizing determinant of HIV-1. The vaccine has been extremely well characterized, with good assessments of particle size and distribution, microsphere surface structure, antigen loading and efficiency, in vitro release rates, and measures of stability during storage. After oral administration and combined oral and subcutaneous administration to guinea pigs, the microspheres were shown to elicit high levels of serum IgG toward HIV. Future work will seek to combine this immunogen with approximately 15 other HIV peptides in an attempt to cover much of the worldwide variability of HIV and use the controlled-release vaccine in clinical trials (79).

Another single-shot HIV-1 vaccine based on PLGA microspheres is also in development (69). The HIV-1 subunit antigen, MN rgp120, is encapsulated by a double-emulsion technique. Release from the microspheres was studied to determine whether a release profile mimicking repeated administration could be engineered. An initial release of MN rpg120 occurred over a period of 2 days. This was followed by a lag phase; the microspheres began to release protein in a continuous manner over 4 weeks as part of the second burst. This second burst occurred due to the bulk erosion of the polymer matrix. The second burst has been successfully controlled by different formulations to occur at 1, 2, 3, or 4 months. Guinea pigs given a single injection of a microsphere formulation with a second burst that occurred at 6 weeks postinjection showed much greater immune responses than control animals immunized with MN rgp 120 and Alum. This work is promising in that it suggests that a common feature of controlled-release formulations, the burst effect, may actually be beneficial in the design of self-boosting, single-dose vaccines.

Influenza Virus. Biodegradable microspheres can also be used to encapsulate and orally deliver whole, inactivated pathogens. A good example of this exists with the influenza virus. Formalin-treated influenza virus was encapsulated in 2- to 10-μm PLGA microspheres. After systemic immunization, encapsulated vaccine induced antibody levels comparable to the virus in solution. When oral formulations were used as boosters for animals initially vaccinated systemically, mucosal antibodies were higher than and systemic antibodies were comparable with levels in animals vaccinated and boosted solely systemically. Again, this type of protection is important for pathogens such as influenza that generally infect through mucosal surfaces, specifically the nasal mucosa in this case. Animals challenged by active virus after this vaccination produced antibodies and were virtually completely protected (70).

Pertussis. Pertussis, or whooping cough, is a disease of the respiratory tract that, although under good control in the United States and other countries with widespread use of the combined DTP vaccine, is a major cause of worldwide morbidity and mortality. The existing vaccine has been based on a killed, whole-cell vaccine of the causative bacteria, *Bordatella pertussis*. However, because of some serious adverse effects to this killed vaccine, a new acellular pertussis vaccine has been developed and incorporated in the new combined vaccine, the DTaP (diphtheria–tetanus–acellular pertussis). One of the antigens included in this acellular vaccine, filamentous haemagglutinin (FHA), has been incorporated in biodegradable PLGA microspheres for delivery as a controlled-release vaccine. FHA, like CFA/I in *E. coli*, is important in the attachment of the bacteria to the mucosal surfaces of the host. Intranasal administration of FHA-loaded PLGA spheres showed both strong systemic IgG and pulmonary sIga, similar to that obtained with soluble FHA. Protection from intranasal challenge was very good, with improved clearance of bacteria from the respiratory tract in those animals vaccinated intranasally compared to those vaccinated intraperitoneally (64).

Staphylococcal Enterotoxin B. Staphylococcal enterotoxin B (SEB) is a toxin produced by *Staphylococcus aureus*, which causes food poisoning. SEB was encapsulated in 1- to 10-μm PLGA microspheres made from an emulsion-based solvent extraction technique and delivered both orally and subcutaneously. In the earlier oral study, the PLGA microspheres (<10 μm) were observed to be taken up by the Peyer's patch with "good" uptake and could therefore be useful in this application (76). Those that were >5 μm remained fixed in the lymphoid tissue for an extended period of time, but the smaller spheres were able to cross through, entering the mesenteric lymph nodes, systemic circulation, and eventually the spleen. The oral vaccination with these spheres resulted in disseminated sIgA immune responses at various sites including saliva,

gut, and bronchioles. Soluble enterotoxoid delivered orally showed no immune response (75). When injected subcutaneously, these microspheres induced an antibody response 500 times that of soluble SEB and approximately equal to that induced by the same amount of antigen administered with FCA. Another important finding included in this work was that vaccine-loaded microspheres $>10\,\mu m$ did not possess nearly as great a response as those 1- to 10-μm. This finding was explained by the fact that those spheres greater than $10\,\mu m$ could not enter draining lymph nodes and thus were less effective. Also, a mixture of blank microspheres and soluble toxin showed just the same response as the soluble antigen, thus indicating that the vaccine needs to be incorporated into a slow-release polymer device and not just presented together with it to obtain an adjuvant effect (74).

Tetanus. A different type of single-shot system has been studied to deliver tetanus toxoid. Instead of a single, extended release, pulsed-release formulations have been suggested based on different-sized PLGA microspheres (80). In such a system, the vaccine is a mixture of different-sized vaccine-loaded PLGA microspheres with various release times. Specifically, 2-μm spheres were engineered to release their contents over 1–14 days, followed by larger spheres that released at 1–2 months and 9–12 months for boosting purposes. This straightforward approach may prove to be more useful, as the pulsed formulation may be more effective in delivering a booster dose, which is necessary for a long-term humoral response. However, it is complicated by the fact that the vaccine is actually a combination of two (or more) different controlled-release formulations and would therefore involve more steps in manufacture.

Tuberculosis. An effective vaccine for tuberculosis still does not exist. The efficacy of the BCG vaccine used in Europe is questionable, considered somewhere between zero and total depending on which population study is considered. In addition to this, vaccination with the BCG vaccine causes people to that positive for purified protein derivative permanently, thus obscuring people who have been exposed to the mycobacteria. As a result, the vaccine has not gained worldwide acceptance, and the United States, in particular, has opted against its use in favor of being able to identify exposed individuals. PPD-positive individuals can then be entered into aggressive antibiotic therapy for 6 months. This option is obviously not ideal. And now, with the emergence of multidrug-resistant *M. tuberculosis* in various areas around the world and the strong association between HIV infection and tuberculosis, the need for an effective vaccine has never been greater.

A 38-kDa antigen from *M. tuberculosis* has been encapsulated in PLGA microspheres and tested for immunogenicity in vivo. When compared to antigen delivered subcutaneously and intraperitoneally with incomplete Freund's adjuvant (IFA) delivered similarly, the PLGA vaccine showed both increased systemic IgG and improved T cell responses (important for intracellular organisms such as *M. tuberculosis*). In another measure of improved cellular immune responses, in vitro antigen-induced gamma interferon (IFN-γ) levels in T cells from microsphere-administered animals were 10 times greater than those given the IFA vaccine. Unfortunately, challenge experiments comparing PLGA vaccine, IFA vaccine, the BCG vaccine, and a control of blank microspheres did not show any differences in the health of the animals (72). Still, these results, specifically the induction of cellular immune responses by microsphere formulations, is promising for the development of vaccines for intracellular organisms.

COMPARISON BETWEEN LIPOSOMES AND MICROSPHERES

This article has described quite a few examples of controlled-release vaccines based on either liposomes or thermoplastic microspheres; other systems are also being explored and may prove to be effective in the future. These include vaccines based on hydrogels (81,82) and starches (59,83), but they are not discussed further here. It is unclear which type of system is the most promising. Very few studies have been conducted comparing liposomes and microspheres with one another. One direct comparison between PLGA-encapsulated and liposome-encapsulated antigens from *Vibrio cholerae* has shown that a liposome-based vaccine induced the greater immune response (40). Antigenic proteins from lysed *V. cholerae* were collected and loaded into PLGA microspheres and liposomes. PLGA microspheres were made by a modified water-in-oil solvent extraction method. Multilamellar liposomes were made using the process known as dehydration–rehydration vesicles. Rabbits were immunized by multiple regimens, and systemic IgG and intestinal sIgA were measured. Immune protection was assessed by measuring the fluid volume in ileal loops. The greatest protection was offered by intraileally administered liposomes followed by intravenous boosters. Orally administered microspheres followed by oral boosters showed a 33% immunity to challenge. Although in this one case liposomes appeared to work better, it is unclear if any generalizations can be made. Of course, different investigators will have different opinions. Liposomes seem to be closer to widespread use (as stated earlier, there is already a liposome-based vaccine licensed in Europe), but this is probably just because liposome technology is a bit more established. As time passes, it is likely that a microsphere-based system will also be proven effective and used in humans. Both methods do have great promise and may have their own advantages and disadvantages depending on the specific antigen under consideration.

FUTURE DIRECTIONS

As mentioned, a large number of investigators are working on controlled-release vaccines, and only some of the current literature has been presented here. Many of the vaccines have made it to clinical trials and, as mentioned earlier, a liposome-based hepatitis vaccine is already licensed in Europe. Future work needs to concentrate on more fully understanding the interactions among polymer, antigen, and biological organism so that formulations best suited to

induce the type of immune response desired can be engineered. For example, the uptake of particulates by the GALT needs to be better understood, and materials other than PLGA, that may exhibit greater uptake by this tissue and greater potential to elicit immune responses need to be identified. Substantial advances in vaccine technology are likely to come using controlled-release technology, with the most exciting potentially being the development of oral vaccines that induce mucosal immunity.

As this article is being written, new directions and applications for controlled-release vaccines are being considered. With the development of better nonviral vectors for gene therapy, controlled-release DNA vaccines are likely sometime in the future. Very recent studies have shown that thermoplastics can indeed be used to deliver plasmid DNA both subcutaneously (84) and orally (18), resulting in transfection and protein production. Plasmid DNA encoding the insect protein luciferase has been successfully encapsulated in PLGA microspheres and delivered to mice orally successfully, eliciting both systemic and mucosal antibody responses to the luciferase (85). This is an extremely exciting development that opens up a new avenue of research toward the development of controlled-release vaccines.

INTRODUCTION

Veterinary medicine offers many challenges to the scientist developing controlled-release products (1). These challenges arise from the diverse nature of the field, which covers a multitude of animal species that differ in size, habits, social behavior, and so on; farm management practices in which farmers may not have any direct contact with their flock or herd for many weeks or even months; and anatomical and physiological constraints that are peculiar to an individual animal species. These factors present the formulation scientist with a unique opportunity to develop innovative solutions to challenging and demanding delivery problems (1).

The purpose of this article is to provide a comparison between human and veterinary controlled-release drug delivery, to highlight some of the factors that influence the development of controlled-release products for animals, to describe relevant issues pertaining to the design and development of controlled-release products for various routes/clinical conditions, and to describe the various conceptual and commercially available controlled-release drug delivery systems that are available for those routes or conditions.

Because the largest body of veterinary and controlled-release literature focuses on food-producing and companion animals, these two areas are also the focus of this article. However, it should be realized that there are other areas of minor market interest such as the fur industry, wildlife management, and zoological medicine that also present unique and interesting opportunities for controlled drug delivery. For example, consider the challenges within the area of wildlife management. Not only would it be desirable to have the formulation fulfill all the normal physical and chemical stability criteria associated with a controlled-release product, but there may also be the need for it to be designed to allow delivery through the barrel of a dart gun!

FACTORS INFLUENCING CONTROLLED DRUG DELIVERY IN ANIMALS

Controlled drug delivery to animals can be conveniently divided into two broad categories—those delivery systems developed for food-producing animals and those developed for companion animals. Food-producing animals consist primarily of cattle, sheep, swine, and poultry, together with fish and any other animal from which meat or other products such as eggs or milk are obtained. Companion animals are those that are considered pets, primarily dogs and cats, but animals such as horses, birds, lizards, rabbits, and so on can also be considered companion animals. Rabbits, birds, and lizards are sometimes classified as "exotic" animals. Because the latter species represent only a small proportion of the companion animal market, drug delivery systems that have been developed for the more mainstream species (e.g., dogs and cats) or indeed, for children, are often adapted for use in the exotic species because the markets are not usually large enough to warrant development of such specialized products.

In the food animal pharmaceutical business, many issues make the development of a controlled drug delivery system particularly challenging. For example, the profit margins associated with the raising and selling of farmed animals are rather slim. As a result, it is not atypical for only a few cents per dose to make a large difference to the farmer's overall profit. Therefore, the formulation scientist must produce a product under considerable cost constraints. In addition, the product manufacturers must also accept that their profit margins will be slim. However, this low profit margin can actually be used to the controlled release formulator's advantage because every visit of the veterinarian is associated with the cost of his or her time and expertise to the farmer as well as the cost of rounding up individual animals for treatment. Thus, the more frequently a product needs to be administered (e.g., once a day versus once a season), the more the cost of the treatment increases for the animal handler. Therefore, it behooves the formulation personnel to develop a controlled release product to reduce the number of times an administration procedure is required during the treatment period. Innovative adjustments in a once-a-day administration to make it a one-time-only administration can vastly improve the marketability of the product. Moreover, the development of a more complex controlled-release delivery system that delivers the active agent over an entire season has the potential to open huge areas of the market, allowing the handling of the animals only once, when they are turned to pasture.

In contrast, the companion animal market is somewhat different in that the potential cost and profit margins associated with a product developed for a companion animal can be much higher compared to one developed for the food animal market. First, the companion animal owner does not own, and therefore does not have to treat, several hundred animals in his or her herd or flock. Rather, the outlay is directed toward a single animal. Second, the price of the delivery system is not determined by the profitability of the animal but by the arbitrary value of the animal to the owner. Theoretically, therefore, the companion animal market will support the development of more complex and expensive dosage forms.

When one analyzes markets in the United States for both food and companion animals, one can divide the markets into three areas: pharmaceuticals, biologicals and feed additives. The breakdown of each of these U.S. markets is listed in Table 1, in which both the companion animal and food animal markets are combined. It is interesting to note that in contrast to human health, where one single drug formulation can accrue over $1 billion sales to a company, the entire animal health market in the United States has been estimated to be less than $3 billion total.

The highest yields (in market dollars) within the veterinary field are in the areas of antibiotics and endoparasiticides, each grossing over $500 million total in 1997. Biologicals offer the next largest portion, at nearly $500 million. This latter category includes items such as vaccine dosage forms of all kinds for all species. Insecticides and parasiticides account for the next largest category, while hormones and vitamin nutritionals account for

Table 1. Summary of Market Areas in the Animal Health Industry

Therapeutic area	1997 U.S. sales (millions of $)
Antibacterials	551.9
Biologicals	483.2
Hormones	266.6
Insecticides and parasiticides	414.1
Internal parasiticides	540.2
Vitamins and nutritionals	134.7
Other (analgesics, anesthetics, lab diagnostics, antiseptics, grooming aids)	415.3
Total	2,806

the remaining largest portions of the market. The remainder of the market still represents a large portion in total; however, these are the sum of several individual therapeutic areas, each of which represents only a fraction of total U.S. animal health sales.

In relation to the global economy, U.S. sales represent almost one-third of the entire world animal health industry. Table 2 shows that the next largest animal health products consumer is Russia, but it accounts for less than 10% of the entire world market. Japan follows closely behind Russia, with China and France each accounting for about 5–6% of the entire world market. The total contribution of all the other countries represents at most 5% of the global market. It should be noted, however, that with the establishment of the European Union, the numbers in Table 2 will inevitably change owing to the unification of the animal health market within this region. In addition, given the large Chinese population coupled with the small fraction of the world market, many have suggested that the most untapped potential for veterinary pharmaceuticals lies within China.

From Tables 1 and 2 it can be calculated that the total worldwide market is estimated to be approximately $9–10 billion. This offers many global opportunities worldwide, and therefore it is no wonder that several animal health companies have consolidated in the last several years to improve their efficiency in the light of the broad-reaching competitiveness of the industry.

Table 2. Market Share of Specific Countries in the World Animal Health Market

Country	Worldwide sales (%)
U.S.A.	28.7
Russia	8.8
Japan	7.6
China	5.4
France	5.4
Brazil	4.6
Germany	4.6
U.K.	2.9
Spain	2.8
Italy	2.5
Central Europe	2.2
South Korea	2.0
Others	22.5

COMPARISON OF HUMAN AND ANIMAL CONTROLLED DRUG DELIVERY

Reasons for Producing Controlled Drug Delivery Systems

In humans one reason for developing a drug into a controlled-release drug delivery system is to reduce the dose frequency to improve patient compliance (2–4). An additional reason is to improve the efficiency of therapy and thereby improve the health of the patient (2,3). In the veterinary field, the reason for developing a drug into a long-acting controlled-release drug delivery system is to minimize animal handling to reduce the stress to animals from repeated administration and to reduce the cost in terms of money and time spent by the end-user on drug administration.

Dosing Interval

The dosing interval of human and veterinary products differs widely. In humans it is common that an improvement in compliance and efficacy is obtained if the number of required doses is reduced twofold, resulting in (approximately) an 8- to 12-h duration of action of the drug (5). In a few cases the aim to decrease the number of required doses multifold to provide a very extended duration of drug action in the order of months also exists, as in Norplant (6). This contrasts markedly to the animal case, where an increase in drug action by only several hours would rarely be useful. In animals, in most cases, the duration of drug action though the development of a controlled-release product must be extended by at least several days, and in the vast majority of cases, in the order of months to cover an entire season (e.g., a flea or tick season for companion animals or a growing season for food-producing animals).

Drug Candidates

In humans, typical drug types that are incorporated into controlled-release products have short biological half-lives (2,7,8), which is the reason why a twofold increase in drug delivery can result in improvements over single-dose therapy. In contrast, drugs used in the veterinary field may possess half-lives that may be very short or very long. It is the need to deliver that drug over an entire season (for weeks or months) and not the short duration of biological activity of the drug, that dictates the need to incorporate it into a controlled-release formulation.

Pharmacokinetics

The pharmacokinetics of a given drug in humans differs between infants, children, and adults and may change as a function of disease status. The same applies to animals. In addition, in the veterinary field, the pharmacokinetics of a given drug differs markedly between different species. The pharmacokinetics of a given drug in a given animal is an important consideration when developing an animal health product and presents challenges when developing

the same drug product for different animal species. Commonly, more than one formulation of delivery device must be prepared based on species as well as the age of the animal.

Physiology and Anatomy

The physiological and anatomical characteristics of the human species differ only slightly between the young and adult of the species. However, the physiological characteristics of the different routes for drug delivery differ substantially between various animal species. The differences that exist in skin between animal species (e.g., thickness, composition, number of hair follicles, etc.) can influence the design of transdermal preparations where, for example, different mechanisms for absorption can be exploited. For instance, follicular penetration routes may be exploited in sheep but not in pigs. The differences in anatomy between species can also influence the design of a delivery system as is observed in ruminant versus monogastric animals. Because of the peculiarities of the ruminant gastrointestinal tract, delivery systems can be designed to be retained for months in a manner impossible to mimic in monogastrics.

Delivery System Design

There are vast differences between human and animal controlled drug delivery with respect to the scope and latitude associated with the geometry of the delivery system. For example, with human controlled-release drug delivery systems, dose size can be product limiting (8). For example, the physical size of a solid oral dosage form can limit its development because its size influences the ease of swallowing (8). A similar scenario applies to the development of implants for human use. The pain associated with too large a volume of an injection or too large an implant can prohibit the development of a controlled-release injection or implant in humans. In contrast, although there are constraints on the physical size of a delivery system, whether oral, implant or injection, in general in animals (particularly farmed animals), the overall size of a delivery system can be much larger such that dose size is not the limiting factor in the design of the delivery system. It should be noted, however, that because the animal is generally much larger than its human counterpart, it will require larger doses to be administered to produce the desired therapeutic effect. It should also be realized that this is not the case for all animals because the size of different species varies—for example, compare cattle with cats. The geometry of the delivery system for humans is in general defined by history and revolves around product shapes that humans are used to seeing, such as round flat tablets. In contrast, in animals the geometry of the delivery system is generally dictated by the administration devices that are available for that route for drug delivery, such as balling guns, intravaginal applicators, implanters, and so on.

Site of Absorption

In humans oral products would be expected to traverse the length of the gastrointestinal tract and release drug along its entire length. Subcutaneous or intramuscular injections or implants would be expected to release from the injection site. With veterinary products orally administered products to ruminant animals are often retained at a specific site within the gastrointestinal tract (the rumer) (9) for several months, as opposed to continuing along the length of the gastrointestinal tract. Injections are more preferably placed subcutaneously in animals. Intramuscular administration is less favored because it can decrease meat quality in food-producing animals.

Means of Administration

Administration is an interesting aspect in the development of a controlled-release product for animals. In the case of humans, self-administration is feasible, and orally administered products usually are easily swallowed with a glassful of water. Topical products are specifically designed to be easily placed on the skin. Factors such as size, shape, ease of administration, and safety to the person administering the product over a series of time intervals are built into the product. Injections or implants are often administered by a second person; however, a patient can be trained to self-administer an injection, or products may be designed to facilitate this process (e.g., insulin pens). In contrast, with a veterinary product, the means of administration must be carefully considered and be part of the product development process. The issues of safety, ease of use, and so on just outlined must still be thought through for animal products but in addition, so should a series of other additional considerations. These include

- How will the delivery system be administered?
- What will the handler safety be for one person administering to several hundred animals over several time intervals (e.g., feedlot cattle for every shipment that comes in)?
- Is the administration device easy to use, or has it the potential to cause repeated stress syndromes?
- Will it be easy to train nontechnical people in its use?
- Can standard equipment be used to administer the product?
- How does the required administration method of the product fit into to current animal-handling practices?
- Can the device withstand "downstream" operations (such as rendering) without harming the equipment used in those operations?
- Can the package it is presented in withstand the various field conditions it will be subjected to (e.g., plastic versus glass)?
- Can the administration device withstand several hundred administrations, severe weather conditions, rough handling, and large animals (i.e., what is the administration device's life expectancy?).

Storage Conditions

The required storage conditions for the product can also be contrasted between human and veterinary medicine. Human products can be refrigerated relatively easily if nec-

Next Page

essary and indeed some human products, for example, insulin and other biologicals, carry this provision on the label. However, this is not the case for veterinary pharmaceuticals. A veterinarian or other end-user would not typically have access to a refrigerator. Indeed, once the product has left the ideal storage conditions of the supply warehouse or surgery, most veterinary products are stored in the back of a car or in a non-temperature-controlled environment on the farm. Veterinary products are therefore required to be developed to withstand higher temperatures. This impacts heavily on the product's stability requirements, which must be addressed and overcome by the formulator during the development stages of the controlled-release product.

Regulatory Considerations

For human products, regulatory requirements include toxicity, safety, dosing intervals, therapeutic effect, stability, approved excipients, and the like. Veterinary products not only include all of the above but also require tissue residue and handler safety issues to be addressed, particularly for food-producing animals. This typically involves a full tissue-residue analysis to be performed, first with radiolabeled drug to determine the sites of deposition and then with nonradiolabled drug to prove it in the final formulation. From these data, a "tissue withdrawal" time is determined to inform the farmer of when the animal is fit for slaughter. Obviously, the shorter the withdrawal time is for the product, the more desirable the overall product profile.

In Vivo/In Vitro Correlations

In vivo/in vitro correlations for the purpose of product development, quality control, and so on are much more challenging for a product required to release over several months versus a few hours or a day. In animals, therefore, proof of control of the release to prevent dose dumping can be more challenging when the dose is for several months as opposed to a single day. Rarely do in vitro correlations exist to predict exact performance. The final determination is in the actual use.

VETERINARY CONTROLLED-RELEASE DRUG DELIVERY AND DELIVERY SYSTEMS

Intraruminal Drug Delivery

Intraruminal drug delivery systems are designed to be administered to, and retained in, the rumen of ruminant animals (e.g., cattle, sheep) and to deliver drugs over extended periods (months).

The anatomical and physiological characteristics of the stomach of ruminant animals are relatively complex. The stomach is large and composed of four compartments: the rumen, reticulum, omasum, and abomasum. The rumen is the largest compartment and may contain 80–200 L of ruminal fluid of pH 5–7 (9). The temperature of the rumen is in the range of 38–42°C and has a total internal gas pressure in the range of 1–1.1 atm arising from the conversion of foodstuffs into absorbable nutrients through microbial fermentation (9). This process is accompanied by the evolution of up to 600 L/day of gas. The composition and density of ruminal materials varies with the location (9). At the bottom of the rumen, the material is relatively well digested and mixed with copious amounts of fluid and is, therefore, of relatively high density. The upper layers of the rumen contain the newly ingested materials, which are much drier and of relatively low density (9).

A characteristic of the ruminant animal is that it spends much of its life grazing open pasture and is not extensively handled by the farmer. Consequently, the administration of pharmaceuticals is challenging, time-consuming, and costly because of the need to initially herd the animals into a convenient location to permit drug administration. The need to reduce handling of such animals on a regular basis for drug administration provides one of the biggest opportunities for the application of controlled-release technology to animal health and production.

Cardinal has recently outlined several key design features that are required of a controlled-release intraruminal drug delivery system (9). These include the inherent needs to (*1*) design the delivery system around a balling gun to allow for oral administration, (*2*) design the delivery system with a shape compatible with passage down the esophagus, (*3*) design the device with some mechanism that allows for long-term retention in the rumen of the animal (i.e., prevents regurgitation), and (*4*) incorporate some form of controlled-release technology that allows for the long-term delivery of the drug (up to 180 days) (8).

Several balling guns are commercially available (10). Regurgitation of the delivery system by the animal is prevented by either geometric design or density of the product. The literature suggests that a density of 1.8 or greater is required to prevent regurgitation of delivery systems from the rumen of cattle (11). When the density is less than 1.6, a significant number are not retained in cattle. The concept behind retention of the device in the rumen through geometry relies on creating a device that can be administered in a small enough size to allow for administration but will change its size or shape following administration to a form that is much greater in size than the esophagus.

Many controlled-release drug delivery systems have been developed for intraruminal administration over the last few decades (Table 3). For extensive reviews on intraruminal drug delivery, the reader is referred to Refs. 9, 36, 59, and 60.

Postruminal drug delivery

The process that allows the ruminant to utilize cellulose and nonprotein nitrogen is called rumen fermentation (61). Although this biological process is beneficial to the animal, it presents challenges to the drug delivery formulator because it also destroys or modifies bioactive materials (nutrients and drugs) that have been administered orally to prevent or treat disease (61). Thus, although ruminants could potentially benefit from the administration of bioactive materials (such as supplemental amino acids or saturated fatty acids), the administration of such materials orally through simple addition to feed is not practical. If the formulator wishes to persist with the administration

VETERINARY CONTROLLED-RELEASE DRUG DELIVERY AND DELIVERY SYSTEMS

Intraruminal Drug Delivery

Intraruminal drug delivery systems are designed to be administered to, and retained in, the rumen of ruminant animals (e.g., cattle, sheep) and to deliver drugs over extended periods (months).

The anatomical and physiological characteristics of the stomach of ruminant animals are relatively complex. The stomach is large and composed of four compartments: the rumen, reticulum, omasum, and abomasum. The rumen is the largest compartment and may contain 80–200 L of ruminal fluid of pH 5–7 (9). The temperature of the rumen is in the range of 38–42°C and has a total internal gas pressure in the range of 1–1.1 atm arising from the conversion of foodstuffs into absorbable nutrients through microbial fermentation (9). This process is accompanied by the evolution of up to 600 L/day of gas. The composition and density of ruminal materials varies with the location (9). At the bottom of the rumen, the material is relatively well digested and mixed with copious amounts of fluid and is, therefore, of relatively high density. The upper layers of the rumen contain the newly ingested materials, which are much drier and of relatively low density (9).

A characteristic of the ruminant animal is that it spends much of its life grazing open pasture and is not extensively handled by the farmer. Consequently, the administration of pharmaceuticals is challenging, time-consuming, and costly because of the need to initially herd the animals into a convenient location to permit drug administration. The need to reduce handling of such animals on a regular basis for drug administration provides one of the biggest opportunities for the application of controlled-release technology to animal health and production.

Cardinal has recently outlined several key design features that are required of a controlled-release intraruminal drug delivery system (9). These include the inherent needs to (*1*) design the delivery system around a balling gun to allow for oral administration, (*2*) design the delivery system with a shape compatible with passage down the esophagus, (*3*) design the device with some mechanism that allows for long-term retention in the rumen of the animal (i.e., prevents regurgitation), and (*4*) incorporate some form of controlled-release technology that allows for the long-term delivery of the drug (up to 180 days) (8).

Several balling guns are commercially available (10). Regurgitation of the delivery system by the animal is prevented by either geometric design or density of the product. The literature suggests that a density of 1.8 or greater is required to prevent regurgitation of delivery systems from the rumen of cattle (11). When the density is less than 1.6, a significant number are not retained in cattle. The concept behind retention of the device in the rumen through geometry relies on creating a device that can be administered in a small enough size to allow for administration but will change its size or shape following administration to a form that is much greater in size than the esophagus.

Many controlled-release drug delivery systems have been developed for intraruminal administration over the last few decades (Table 3). For extensive reviews on intraruminal drug delivery, the reader is referred to Refs. 9, 36, 59, and 60.

Postruminal drug delivery

The process that allows the ruminant to utilize cellulose and nonprotein nitrogen is called rumen fermentation (61). Although this biological process is beneficial to the animal, it presents challenges to the drug delivery formulator because it also destroys or modifies bioactive materials (nutrients and drugs) that have been administered orally to prevent or treat disease (61). Thus, although ruminants could potentially benefit from the administration of bioactive materials (such as supplemental amino acids or saturated fatty acids), the administration of such materials orally through simple addition to feed is not practical. If the formulator wishes to persist with the administration

of such bioactive materials orally, they must develop delivery systems that are stable in the rumen (i.e., that protect the drug from the harmful environment of the rumen) and that release their contents postruminally. Ideally, nutrients, drugs, and other active compounds incorporated into postruminal delivery systems should be fully protected from fermentation in the rumen and then be completely released and available for absorption or for performing their intended postruminal function (61). Many factors need to be considered when developing and designing a postruminal drug delivery system, including the typical retention times of particles and solids in the rumen and abomasum, pH of the rumen and abomasal fluid, the ruminant digestive process, the dynamics of ruminal motility, and the effects of rumination on particle degradation.

Several methods have been developed for protecting nutrients, drugs, and other active compounds from the environment of the rumen and are shown in Table 4 (61).

Intramammary Drug Delivery

The intramammary route for drug delivery is primarily used for the treatment of mastitis in cows and can be classified according to two main areas: lactating and dry (nonlactating). A once-only administration is beneficial to both these areas because it reduces handling of the animal. Each of these areas offers specific challenges to the delivery of an active agent. For example, the requirements for drug delivery to lactating cattle requires that the active ingredient be removed from the mammary gland or milk as soon as possible after the treatment period has elapsed so that there is no issue with regard to the presence of drug in the milk. In contrast, intramammary delivery in dry cows would allow for the formulation to be developed such that the drug persisted for a longer period of time after the treatment period had elapsed. Dry cow applications, therefore, lend themselves more readily to controlled drug delivery applications because the prolonged exposure of the infected site to drug improves the efficacy of treatment, and the concerns for drug residues in milk are not an issue.

A list of the various formulation types which have been explored for the intramammary route is shown in Table 5. Early developed formulations for intramammary drug delivery were aqueous based. Such formulations suffered from the disadvantage that they were short acting; however, they did distribute well over the infected areas (66). To overcome the problem of the short action, aqueous-based formulations have been developed that are coformulated with a water-soluble polymer such as poly(ethylene glycol). Oil-based formulations have also been investigated that allow for prolonged release of the active ingredient in the udder (66–71); however, they suffer from the disadvantage that they often irritate the udder mucosa (67) and distribute less homogeneously throughout the udder than aqueous preparations (66). Ointment-based products have also been studied and appear to offer an improvement over oil-based products. A further formulation type that has been investigated is the encapsulated drug product (68,69,72). Such formulations appear less irritating and more uniformly distributed around the udder. In addition, in some cases they also release drug over a prolonged period of time.

In recent years, with the rise of biotechnology, researchers have been investigating the use of vaccines and recombinant therapies to treat mastitis (73–78). These vaccines should offer the longest-term protection because they allow the animal to develop an immunity to the organisms that are causing the mastitis in the first place. However, because several types of organisms have been implicated in the cause of mastitis, the best vaccine would have to offer protection against a large spectrum of organisms and to date, no such vaccine exists.

Steroid Hormone-Containing Growth Promotants

Steroid hormone-containing implants improve the average growth of the animal. They contain either singularly or in combination estrogenic, androgenic, or progestegenic drugs (Table 6) (79). Growth response depends on the level and type of hormone incorporated into the delivery system, and commercially available controlled-release products differ in their hormone content, delivery matrix, and release pattern. Implants contain drugs incorporated into either lactose, cholesterol, polyethylene, or silicone rubber delivery matrix. Lactose-based implants are shorter acting (approximately 40 days) compared to cholesterol-based implants (approximately 80 days). Silicone rubber matrices provide the longest duration of release for estrogens (approximately 200–400 days). The amount of drug released from these delivery systems is greatest initially and slowly decreases with time, and release kinetics are typically described by either a first-order kinetics or a square-root-of-time mechanism (80). The most comprehensively described steroid hormone-containing implant is the Compudose delivery system (36,81,82). Compudose is a silastic implant composed of a drug-free silastic cylinder coated with a layer of silastic containing 20% dispersion estradiol. It has a surface area of 4.84 cm^2 and has been shown to release drug by a square-root-of-time mechanism.

Development of a steroid hormone-containing controlled-release implant requires that the implantation procedure is given consideration. Implants should not cause tissue irritation, and the administration site must be chosen such that it does not allow the delivery system to enter the food chain. Historically, the ear has been chosen as the site for administration because it represents an inedible portion of the carcass and is discarded on slaughter, accessible to the administrator, and well perfused with blood; as well, administration is relatively pain free and, therefore, provides minimal distress to the animal. The disadvantage of using this site is the need for restraint of the animal. Steroid hormone-containing controlled-release implants are not manufactured sterile, and therefore there is the need for an aseptic administration procedure. Implantation of commercially available implants into the subcutaneous tissue of the ear requires the use of a specially designed implanter.

The route of administration dictates the maximum size of the implant, which is an important consideration because modifying the surface area of the implant is an effective way of modifying release rate. The literature suggests that the optimum release profile for a steroid

Table 3. Intraruminal Drug Delivery Systems

Product name/ inventor	Description of delivery system	Drug	Retention mechanism	Animal and approximate release time	Mechanism of release
Paratect bolus	Hollow stainless steel cylinder about 4 in. in length and 1 in. in diameter that is filled with a drug reservoir comprising a paste of the drug/poly(ethylene glycol) 400. Each end of the cylinder is capped with rate-controlling membranes prepared from a microporous sintered polyethylene disk whose pores are filled with cellulose triacetate (12–15).	Morantel tartrate	Density	Cattle (90 days)	Diffusion through the water-filled channels of the two porous membranes at each end of the cylinder
Paratect Flex (16,17)	A central sheet of drug loaded a 50:50 mixture of ethyl vinyl-acetate coated on both sides with a layer of ethyl-vinyl acetate that renders each surface of the drug reservoir impermeable to drug to form a trilaminate structure. A series of holes is then punched in the device that transverse the complete trilaminate. The trilaminate sheet is then rolled into a cylinder and maintained as a roll with a water-soluble tape.	Morantel tartrate	Geometry trilaminate sheet that unrolls following administration to increase its dimensions	Cattle (90 days)	Moratal tartrate is a water-soluble salt and cannot permeate EVA. Drug is released from both the outer edges of the trilaminate and from the inner surface of each hole that was punched through the matrix. The kinetics of drug release from the outer edges follows the typical $t^{1/2}$ kinetics. The release from each hole is a function of increasing surface area at the receding drug boundary and increase in the diffusional pathlength over time within the depleted zone, which results in a net overall decrease in the release rate with time and thus a release rate that is relatively constant with time. The release rate is a function of the number and the diameter of the perforations and the usual parameters that control the rate of release from dispersed matrix devices.
Spanbolet II	Rectangular-shaped delivery systems approximately 3.5 in. by 0.5 in. by 0.5 in. in size. Manufactured by compressing drug, carnauba wax, barium sulphate, poly(ethylene glycol) and iron powder (18)	Oxytetracyclines	Density	Cattle (50 days)	Slow erosion of device within rumen

Laby	The device is composed of a hollow cylinder capped at both ends. One end is closed and serves to help constrain a spring that acts against a piston that in turn acts against an erodible composition containing drug or nutrient. The erodible composition comes in contact with the exterior environment via a portal in the second endcap. Attached to the cylinder are polymeric wings that are constrained to the side of the cylinder during administration by a water-soluble tape. This basic design has been subject of extensive work that has appeared in the patent literature, which describes improvements in device-retention mechanisms, core composition, piston/spring design, and delivery of multiple drugs with a single device (19–27).	This device design has been commercialized for the delivery of various compounds (e.g., albendazole and monensin) for sheep and cattle.	Geometry (expanding polyethylene wings that fold against the device on insertion but open within the rumen)	Sheep and cattle (100 or 135 days)	The drug/nutrient-release rate is controlled via erosion of the tablet formulations incorporated into the device via the portal in the second endcap.
Beecham I	A matrix device in the form of a large sheet that can be rolled up to form a cylinder and constrained by a water-soluble tape; the size of the sheet is such that its unrolled dimensions are greater than that of the diameter of the esophagus. The device utilized a trilaminate sheet in which the inner lamina was composed of a core matrix of drug dispersed in an ethylene-vinyl acetate copolymer. This inner lamina was coated with a layer that was either imprevious to fluid (and drug) or prepared with a filler such as starch or lactose to control the overall drug permeability properties in the coating (28).		Geometry; water-soluble tape dissolves and trilaminate unrolls.	Cattle (90 days)	Controlled release is achieved via two rate-limiting barriers containing a highly water-soluble compound that rapidly dissolves, leaving water-filled pores through which the drug leaches out.
Beecham II	A similar device configuration to the one above was also described by Griffin and Brewer but was composed of two lamina: One lamina was impermeable to drug, whereas the second lamina was an erodible dispersed matrix of drug plus ethylene-vinyl acetate (29).		Geometry; water soluble-tape dissolves and the laminate unrolls.	Cattle (90 days)	The drug-release rate was controlled via erosion of the erodible lamina.
Time capsule	A core containing zinc oxide and binding and releasing agents covered over all but one open end by a waxy coat (30)	Zinc oxide (± selenium and cobalt)	Density	Cattle (4 weeks) and sheep (6 weeks)	

Table 3. Intraruminal Drug Delivery Systems *(continued)*

Product name/ inventor	Description of delivery system	Drug	Retention mechanism	Animal and approximate release time	Mechanism of release
Pulsatile bolus (Hollaway device)	Cylindrical device loaded with a steel ball in its rounded base for retention; the inside of the cylinder is filled with a series of drug-containing compartments, each separated by layers of degradable cellulosic partitions (31).	Monensin	Density	Cattle	A dose of drug is delivered (pulsed) from each drug-loaded compartment following exposure after dissolution/ erosion of each of the cellulosic partitions. The dosage regimen can be controlled via the composition of each drug compartment and by the thickness and composition of the dividing layers.
IVOMEC SR Bolus	The device has recently been described by cardinal (9): The product is composed of a membrane cup that is extruded from cellulose acetate and various plasticizers. This cup is filled with an osmotic tablet that swells following the imbibement of water through the membrane cup. Placed above the tablet are a partition layer, a drug-containing layer, and a densifier. Both the partition layer and the drug layer are prepared from paraffin waxes and Cab-O-Sil. Drug is suspended at a concentration of 22% in the drug layer. The softening point of the partition layer is somewhat higher than the drug layer so that the partition layer will basically serve as a piston to help direct the flow of the drug-containing layer through the exit port channel located centrally in the densifier. The drug layer begins to soften in the range of 31–35°C. Under these conditions the drug is maintained as a suspension during storage and delivery without settling. At temperatures greater than about 35°C, the material has the requisite fluidity to flow through the exit channel and exit port screen. The densifier is made of sintered iron fillings designed such that it has a crush strength similar to that of bone (32,33). This is to ensure that the densifier will not harm the equipment utilized in rendering plants following slaughter of the animal. The central port in the densifier is covered with a capscreen made from plastic and designed such that the drug suspension is forced through a series of small openings in the capscreen (34).	Ivermectin	Density	Cattle (110 days)	Imbibement of water through the semipermeable membrane followed by expansion of the hydrogel that constantly forces a drug-containg vehicle through an exit port

Osmotic pressure–based ruminal bolus	Thombre et al. (35) describe a delivery device similar in overall design to that of the Paratect bolus but utilizing a novel osmotic technology suitable for the long-term delivery of drugs in which the drug is delivered as a solution in oil. This system utilized both the cylinder and membranes of the Paratect bolus as described above; however, the membranes and core formulations were suitably modified to convert the overall mechanism of drug delivery from diffusion control to an osmotic-based mechanism. In this system the core formulation was composed of an oil such as octanol, isopropyl myristate, or soybean oil and a swellable polymer such as PEG 600 or poly-vinyl alcohols dispersed as pellets within the oil. The drug was dissolved within the oil phase. One microporous polyethylene membrane was impregnated with cellulose triacetate and wetted with PEG 400. The other microporous membrane was either unimpregnated or treated with various other options to permit the membrane to be permeable to oil.	An ionophore with potential as a growth promotant	Density	Cattle	Osmotic-based release mechanism
Rumensin ABC	Consists of a plastic capsule about 16 cm long (utilizes Laby device technology) (36,37)	Monensin sodium	Geometry; following administration, two plastic wings unfold.	Cattle (100 days)	
Autoworm/Multidose 130	The delivery system is made up of a steel endweight connected to a magnesium alloy spindle. Around the spindle are placed five drug-loaded lifesaver-shaped tablets that are encased in PVC caps and separated by scaling washers (36,37).	Oxfendazole	Density	Multidose 130 delivers five doses of oxfendazole to grazing cattle over approximately 130 days. The first dose is delivered at about 21 days following administration.	Pulsed delivery at 23 days intervals as the drug-loaded lifesavers become exposed, following corrosion of the metal at a relatively constant rate
Marston erodible system	Erodible bolus containing cobalt oxide and other diluents (38)	Cobalt	Density		Erosion due to dissolution or abrasion due to the solution or mechanical action of the rumen

Table 3. Intraruminal Drug Delivery Systems *(continued)*

Product name/ inventor	Description of delivery system	Drug	Retention mechanism	Animal and approximate release time	Mechanism of release
Pierce et al. erodible bolus	An erodible bolus comprising 2% active in combination with 5% monostearin, 10% carnauba wax, and 83% barium sulfate (39)	*S*-methoprene		Cattle	Erosion
Wood et al.	A combination of glycerol monostearate, carnauba wax, and barium sulfate (40)	Potent antiparasitacides		Cattle (120–180 days)	The devices can be configured to deliver drug at rates that range from about 0.001 to about 0.075 mg/kg/day.
Hemingway et al.	An erodible device composed of a core matrix of compressed particles containing the drug or nutrient, which is then coated with a rigid polymeric coat (41)	Minerals and vitamins	Density		The coating is insoluble in rumen fluids and is brittle and progressively fractures off following erosion of the core matrix. The duration of activity of this device is a function of the composition of the core matrix.
Baker	The delivery system is a relatively rapidly acting bolus composed of a core layer and an outer layer. Each layer is composed of the therapeutic agent, a water-swellable polymer, and inert materials so blended as to create a rapidly acting outer layer and a slower-dissolving core matrix (42).	Antibacterials			Dissolution
Soluble glass bolus	Glass-based delivery systems formed by melting the glass and nutrient components at high temperatures (up to 700°C) and drawing the melt into the desired shape (43–49)	Trace nutrients, copper, cobalt, and selenium	Density	Sheep (365 days)	Drug is released by diffusion of drug and/ or dissolution of the glass.
Lilly	Comprises a stainless steel cylinder that is coated with a mixture of drug dispersed in a copolymer of lactic acid and glycolic acid (50–52)	Density	Monensin	Cattle (90 days)	Erosion of the drug-loaded polymer

Monensin RDD	The core matrix is a mixture of 40% drug and a biodegradable copolymer prepared from lactic and glycolic acids (80:20 w/w). The core matrix is adhered to the inner surface of a metal cylinder by hot-melt adhesives and then placed inside a plastic case that has openings in the end large enough to allow drug release but of sufficient dimensions to prevent solid foreign material from the rumen contents from entering the device and physically abrading the core (53–55).	Monensin	Density	Cattle (150 days)	Controlled hydrolysis and degradation of the low-molecular-weight copolymer
Bagnall and Gyuril device	The device is composed of a series of cylindrical drug reservoirs. The drug formulation is maintained within the cylindrical reservoir by a plug (56).	Oxfendazole	Density	Cattle (three pulses at 30-day intervals)	Expulsion of the plug through the generation of a gaseous internal pressure within the cylindrical reservoir; the timing of release is regulated by an electrical circuit and a chemical squib that generates the necessary pressure. The squib is activated via a current that is controlled by an electrical circuit that regulates the timing for the application of current. The whole system is activated by placement within the rumen fluids that acts to close the circuit.
Kwan and Steber	A system that is composed of several doses of drug held together using an adhesive; each dose is composed of a bilaminated core that contains a layer containing drug and a layer that is comprised of sufficient weight to retain the delivery system in the rumen. Each dose is coated with a hydrophobic polymer that controls the time that the drug is exposed to ruminal fluid. A delivery system is described that contains three doses, each coated with a different biodegradable polymer (57,58)		Density	Multiple pulses	Degradation of polymer matrix; the polymer coatings surrounding each dose degrade at different rates and control the time of release of drug.

Table 4. Methods for Protecting Nutrients, Drugs, and Other Active Compounds from the Environment of the Rumen

Approach	Method	Advantages	Disadvantages
Heat treatment	Heat treatment of proteins reduces their solubility and degradation in the rumen (62).	Low cost	Heat treatment promotes reaction of amino acids with carbohydrates and reduces their bioavailability. Predictability and control of rumen protection is poor. Postruminal release of the active material is generally inversely related to the degree of rumen protection.
Chemical treatment	Chemical treatment reduces protein solubility and increases the amount of protein escaping rumen fermentation. A variety of chemical agents have been evaluated including formaldehyde, other aldehydes, acetic acid, and tannins among others (63,64).	Generally low cost	Use of formaldehyde raised significant safety concerns and has been abandoned in some countries. Chemical treatment is unsuitable for amino acids and other nutrients or drugs. Rumen protection and postruminal availability are quite variable.
Low-solubility peptides, amino acid derivatives or analogs, and calcium salts; for example, peptides of lysine and/or lysine with other amino acids have been investigated.	Analogs tested include *N*-stearyl-methionine, *N*-hydroxymethyl-methionine (HMM-Ca), α-hydroxy-γ-methyl-mercapto butyrate calcium, and methionine hydroxy calcium (HMB-Ca) (65).		Poor bioavailability postruminally (e.g., lysine peptides); Limited protection from rumen degradation for methionine analogs (65)
Lipid-based formulations (embedding in a fatty matrix) (61)	To formulate a lipid-based product, active compounds are either embedded in a lipid matrix or are formulated in small spheres and coated with lipid. The low solubility of the formulation in the rumen allows a large part of these materials administered orally to reach the small intestine and be absorbed. For this reason, they are formulated as calcium salts or in lipids that have poor solubility in the rumen. Lipid-protected products rely on their inherent resistance to enzymes in the rumen to maintain the integrity of the protective coating and their digestion by enzymes postpostruminally to release the active component.	Embedding in a lipid matrix or the process of applying a lipid coating has the advantage of using low-cost food-grade materials compared with formulated polymeric coatings.	Lipid matrix systems exhibit low payloads. Postruminal release of the active material for absorption is usually low and generally inversely related to the degree of rumen protection. Amino acids and small peptides are readily water soluble and do not remain inside the lipid matrix and become released into the rumen.
Ruminally inert, pH-sensitive polymers (reverse-enteric coating system) (61)	The bioactive material is coated with a coating system composed of a basic polymer such as poly(2-vinylpyridine-*co*-styrene, 8020), a pigment material such as talc or aluminum, and a hydrophobic substance such as stearic acid at a typical ratio of 31.563.55.0 by weight.	Process can be applied to a variety of nutrients, drug, or other active compounds	The coating efficiency was shown to be highly dependent on the solubility of active ingredients, pellet size, and smoothness of pellet surfaces Because the polymeric coating is soluble in acid, the coating should not be in direct contact with acidic feed components such as silage. The coated particles should not be added along with other feed ingredients into a feed-pelleting machine because the coating cannot survive in a high-shear and abrasive pelleting process. Only a few polymers are suitable as the coating material.

Table 5. Delivery Systems for Intramammary Applications

Types of delivery formulations	Reference

Vaccines and recombinant therapies	73–78

hormone-containing controlled-release implant is unknown (80). The literature is unclear as to whether an initial burst followed by a declining release rate, a constant release rate, or an increasing release rate is desirable (80).

The need to remove the implant is not a consideration because the delivery system will remain in the animal for its life span and be discarded at slaughter with the inedible portion of the carcass.

Vaginal Drug Delivery

The use of controlled-release drug delivery systems in estrous control has a history dating back to the early 1960s when polyurethane sponges were first investigated as a means to deliver synthetic progestagens to sheep (83). Both the intravaginal and subcutaneous route for drug delivery are used to administer controlled-release drug delivery systems for estrous control (Table 7). Compounds used to control the estrous cycle include progesterone, methyl acetoxy progesterone, fluorogestone acetate, and estradiol. Other drugs for example, melatonin, antibiotics, oxytocin, prostaglandins, GnRH, and a variety of other synthetic progestagens, have been shown to be systemically absorbed from the vagina of farmed animals. To date, polymers utilized for systemically delivering drugs via the vaginal cavity of animals in commercially available products have been limited to polyurethane and silicone (85).

Several factors that affect the design and development of an intravaginal veterinary drug delivery system have recently been identified and discussed by Rathbone et al. (87). These include applicator design, end-user acceptance, dimensions and geometry of delivery system, retention rate, retention mechanism, dimensions of the device, release rate, ease of use, animal comfort, irritation (mucopurrelant discharge production), polymer used to manufacture delivery system, drug properties, presence or absence of additives, ease of removal, damage to vaginal mucosa and cervix, applicator design, removal mechanism, and manufacturing process (87). A further valuable overview of this area has been published by Chien (88).

Long-Acting Injectable Products Used in Food-Producing Animals

Many of the various long-acting injectable drug delivery systems discussed elsewhere in this encyclopedia have also been explored in veterinary medicine. For example, biodegradable polymers, liposomes, and other microencapsulated materials have been investigated for use in animals; however, to date none have been commercialized (89–92). Carter et al. (93) provide an excellent overview of long-acting injectables in veterinary medicine. Implants containing steroids for growth promotion and those formulated for estrous control have already been presented, and injectables used in companion animals are discussed in a following section. Therefore, the focus of this section are the other applications for long-acting injectables for food-producing animals, such as antibiotics and antiparasiticides.

The use of the more technologically advanced systems, such as polylactide–glycolide polymers, has not been widely applied in the markets of veterinary injectables be-

Table 6. Controlled-Release Steroid Hormone-Containing Implants

Product	Estrogen	Androgen	Progesterone	Time to hormone concentration at which production is no longer enhanced (days)
Ralgro®	36 mg resorcyclic acid lactone (zeranol)			70
Ralgro Magnum	72 mg zeranol			Unpublished
Calfoid	10 mg estradiol 17β		100 mg	Unpublished

Table 7. Controlled-Release Intravaginal Inserts and Subcutaneous Drug Delivery Systems Used for the Control of the Estrous Cycle in Cattle

Delivery system	Description of delivery system	Principle animal for which delivery system designed	Drug	Route
PRID	Comprises micronized progesterone (1.55 g) uniformly suspended throughout silicone rubber that is cured onto a stainless steel spiral coiled to produce a spiral-shaped cylinder approximately 4 cm in diameter and with a length of 12 cm; the delivery system has a hard gelatin capsule attached to its inner surface and a string to aid removal.	Cattle	Progesterone	Intravaginal
CIDR-B	Consists of a preformed T-shaped nylon spine over which is molded a silicone rubber skin containing 1.9 g of micronised progesterone; one end of the device has two flattened wings that are hinged to the body of the device. The wings retain the device in the vagina by gently exerting pressure against the walls of the anterior vagina. At the bottom end of the device is attached a plastic tail to aid removal.	Cattle	Progesterone	Intravaginal
Sponge	Cylindrical-shaped polyurethane sponges impregnated with varying amounts of synthetic progestagens	Sheep and goats	Fluorogestone acetate; methyl acetoxy progesterone	Intravaginal
Rajamehendran rubber tubing	The device contained progesterone and estradiol 17β and was manufactured by cutting silicone rubber tubing into 20-cm lengths, sealing one end with silicone medical adhesive, and then pouring in diethyl ether containing 1 g of progesterone. After the diethyl ether had evaporated, the open end of the tubing was sealed with more adhesive. Approximately 1 mL of adhesive containing 10 mg estradiol 17β was then coated around the end of each tube. Two of these tubes were then centrally tied together, and lengths of string were secured to each of the free ends to be pulled together and knotted to form the umbrella-shaped intravaginal device. Following insertion, the string was allowed to protrude from the vulva to enable removal of the device at the end of treatment.	Cattle	Progesterone/estradiol	Intravaginal
IBD	The Intelligent Breeding Device is a technologically advanced, controlled-release drug delivery system in which estradiol, prostaglandin, and progesterone are released at different rates and at specific times (estradiol, 1 h after insertion; prostaglandin, 6 days later; and progesterone, continuously for 10 days).	Cattle	Progesterone/estradiol/ prostaglandin	Intravaginal

SYNCRO-MATE-B	A small ear implant containing 6 mg norgestomet (= 5% load) in the polymer Hydron, which measures approximately 3 mm × 18 mm and weighs approximately 0.125 g. The implants come encased within a protective plastic sheath and are supplied in individually sealed foil packaging.	Cattle	Norgestomet	Subcutaneous (ear)
SYNCRO-MATE-C	An ear implant that utilized the Microsealed Drug Delivery® (MDD) technology. The ear implant was formed by dispersing crystalline norgestomet in microreservoirs of aqueous PEG 400 throughout a matrix of polymerized silicone. The resulting solid composition was then cut into tiny cylindrical forms for implantation in the ear of cattle.	Cattle	Norgestomet	Subcutaneous (ear)
Ear implant (Crestar)	An ear implant containing 3 mg norgestomet homogeneously dispersed throughout a silicone matrix	Cattle	Norgestomet	Subcutaneous (ear)
CIDR-S	CIDR-S was rabbit eared in shape, containing 9% w/w micronized progesterone homogeneously distributed throughout silicone cured over a nylon spine. The device had a string attached to its lower end to aid removal.	Sheep	Progesterone	Intravaginal
CIDR-G	The CIDR-G is a T-shaped intravaginal device comprising of a preformed nylon spine than has a filament of flexible nylon preformed onto it to aid its removal. The device is coated with silicone impregnated with 9% w/w USP-grade micronized progesterone	Sheep	Progesterone	Intravaginal
Sil-Estrus	Comprised a solid silicone rod containing 375 mg of progesterone (10% w/w initial load), which measured 0.9 cm in diameter and 5.0 cm in length	Sheep	Progesterone	Subcutaneous (in the wool-free area under the foreleg along the brisket)
C-shaped plasthyd device	Comprised of a C-shaped delivery system manufactured from the polymer Plasthyd	Sheep	Progesterone	Intravaginal
Lutamate Plus	Poly(D,L-lactide) microspheres	Horse	Progesterone/estradiol	Intramuscular
Ovuplant	A cylindrical implant 2.3 mm in diameter and 3.6 mm in length containing 2.1 mg of Deslorelin (as Deslorelin acetate) in an inert matrix	Horse	Deslorelin	Subcutaneous

Source: Refs. 84–86.

cause the development of such products for a veterinary market is not economically favorable. As a result, the development of a controlled-release injectable in veterinary medicine has been based on three approaches: reliance on the pharmacokinetics of the particular drug compound, the use of a nonaqueous vehicle, or the manipulation of drug and/or vehicle composition to create a suspension.

For example, Ivomec® injection (Merial) is a solution of 1% w/w ivermectin in propylene glycol and glycerol formal that is given subcutaneously at ~200 μg/kg in cattle and 300 μg/kg in pigs. This injection is given once a month for the treatment of endoparasites. The main reason the injection is so long lasting is that the half-life of ivermectin in cattle is long and the potency of the compound is high, allowing even trace levels of the drug in the blood to be effective (94). The half-life of the drug, combined with its formulation into a nonaqueous vehicle (which allows for the creation of a depot at the site of injection), prolongs the action of the drug for over a month. Similar results are also seen with the doramectin and moxidectin products because they are of the same drug classification and exhibit similar half-life profiles.

In the area of antibiotics, florfenicol and oxytetracycline have been developed as long-acting injectables, Nulfor® injection (florfenicol) was developed by Schering-Plough to replace a chloramphenicol product needed to be administered at frequent intervals to combat bovine respiratory disease, or shipping fever. The dose of florfenicol is approximately 20 mg/kg; however, its solubility is low in most solvents. Therefore, to improve the drug's solubility, the formulators devised a complex nonaqueous cosolvent system that allowed for sufficient drug to be administered to allow administration once every two days. The solvents added to the formulation included propylene glycol, poly(ethylene glycol) and *n*-methyl pyrrolidone (95). This system allows for dosing at 48-h intervals.

Similarly, oxytetracycline was also developed to combat shipping fever. The development of the Liquamycin® LA by Pfizer has been well documented in the literature (96). In this case, tetracyclines were well known to also be insoluble as well as irritating, upon injection. To alleviate this problem, the formulators identified 2-pyrrolidone as a solubilizer and developed methods of chelating the oxytetracycline with magnesium ion to reduce the irritation upon injection. The theory was to prepare a solution of drug that was close to saturation so that upon injection, the drug would slowly deposit a fine precipitate, creating in effect a drug suspension depot at the injection site. This depot formulation would reduce the irritation and necrosis that had been previously observed. The resulting formulation succeeded in reducing the irritation and provided release of drug over 2 to 3 days.

Topical Dosage Forms for Food-Producing Animals

Various classes of long-acting topical formulations have been used in food-producing animals (Table 8). Historically, the application of topicals for food-producing animals has been primarily for ectoparasite control. The short-term formulations were applied by hand as dusts, ointments, sprays, and/or liquids. Dips have also been used in which a vat is prepared containing the active ingredient, and the cattle is trotted down into the vat and run up a ramp on the other side. Each of these formulation types, however, would only provide treatment for a few days at the most, because they would inevitably be rubbed off by the animals or washed off by the rain. Therefore, it became necessary to develop methods for prolonging the delivery of active agents over longer periods of time so that the animals would not have to be handled frequently (97).

Table 8. Classes of Long-Acting Topical Formulations for Food Animals

Class of formulation	References
Oil-based liquids; spot-ons	97
Wax bars/cables/dust bags	97
Ear tags, e.g., PVC matrices	98
Ear tags, reservoir type	99,100
Microencapsulation formulations	101

The earliest controlled-release dosage forms for topical delivery were oil-based, which promoted the adhesion of the drug to the skin. Another early approach was to create a system in which the animals repeatedly dosed themselves. This was the principle behind the oil cables, wax bars, and dust bags that were impregnated with the active agents and left hanging near the locations in which the animals resided (97). The cattle would rub against the cable, bar, or bag and then rub itself or others, administering the active agent. The disadvantage of these systems was that the level of dosing could not be controlled and relied heavily on the behavior of the animal.

Eventually, people recognized the utility of placing the active ingredients into polymer matrices such as poly(vinyl chloride) (98). In these cases, the drug substances were blended into a monolithic structure and molded into a tag that was, for example, fixed on the ear. The tag then released the active agent over a prolonged period of time, such as several months. The active ingredient was transferred over the body of the animal by the natural rubbing motion of the animal on itself, as well as onto other animals. This dosage form is the most common in use today for the controlled release of topical ectoparasiticides.

In spite of its broad use, the monolithic tag concept does have disadvantages. For example, the tag delivers the largest portion of the active agent in the first part of the efficacious life span of the product. This is because the high concentrations of active agent provides a large driving force for delivery. In the latter half of the product life, the amount of drug substance delivered is greatly reduced because of the lower amount of active agent remaining in the matrix. Moreover, drug utilization is poor, and only a fraction of the active agent that is loaded into the matrix is actually released. Because of these limitations of the monolithic tag, a second generation of tag devices was developed in which the release profile was more zero-order, or more uniform, over the life of the product. This resulted in products that utilized a greater percentage of the total active agent loading (99–101). Such devices are based on reservoir technology rather than matrix technology. The tag is comprised of a depot of the active agent imbedded into

a drug reservoir within the tag, which is covered by a membrane whose properties control the release of the active ingredient. Because the active agent exists as a solid in the depot, the rate of release is governed by the vapor pressure of the active, its solubility in the membrane, and its diffusivity through the membrane. These types of tags can also release drug substance to the animal for several months (99).

Microencapsulation has also been explored for the prolonged delivery of topical ectoparsiticides. For example, Despins et al. (101) developed a microencapsulated formulation containing permethrin and compared it with an emulsifiable product. The authors found that the microencapsulation product prolonged its efficacy but only by a short period of time. The release of the active ingredient to the skin appeared to be limited by the residence time of the formulation on the skin.

In addition to those formulations just described, there exist pour-on or spot-on applications, such as IVOMEC pour-on. These dosage forms are low-volume products that are applied (poured) directly over the back of the animal. In the case of IVOMEC pour-on, the prolonged pharmacokinetics of the active ingredient, ivermectin, is the main reason for the long-acting efficacy. Ivermectin is efficacious in very low quantities, and at a dose of 5 mg/10 kg body weight, enough of the active agent is absorbed to be efficacious for up to 28 days (102). A similar duration length is observed for other avermectin-type pour-on products containing ingredients such as duramectin and moxidectin.

Controlled-Release Technologies in Companion Animals

The therapeutic applications for companion animal health are as diverse as those already discussed for the food animal species. Those areas that will be discussed in this section include parasite control technologies; chemotherapeutic parenteral systems such as antibiotics, insulin, and estrous control; and finally ophthalmics. Products available for dogs and cats will be primarily reviewed, with the understanding that similar technologies could be employed for the other species, and in fact the exact same products are typically used and adapted for use in more exotic species.

Parasite Control. One of the largest markets in companion animal drug delivery is in endo- and ectoparasite control and elimination. In ectoparasite control, the most popular compounds are included in the Interceptor (Norvartis) and Heartgard (Merial) products. These are milbemycin based and ivermectin based, respectively. The main reason for the long-acting nature of these orally administered dosage forms is the high potency of the compounds combined with their long biological half-lives. This allows for small dosages to be formulated into tablets that are easily given to companion animals, in particular dogs, at monthly intervals.

The most traditional mode of ectoparasite control is the ubiquitous flea collar. First developed in the late 1960s from vinyl resins containing dichlorvos, these collars have progressed to a variety of polymers containing an equally broad spectrum of active agents. The main basis of the technology of these collars is the incorporation of an active ingredient blended into the plastic matrix. The basic incompatibility between the plastic and the liquid and/or solid active agent forces the active to migrate to the surface of the collar, allowing it to be available to the fur of the animal, thereby eliminating the parasites.

Other technologies have also been explored for the release of ectoparasiticides. Reservoir systems in which the active agent is incorporated into a depot that is surrounded by a rate-controlling membrane have been explored, as have mechanical approaches (such as pumps) that release the active agent slowly over a long period of time. A history of ectoparasiticide collars has recently been published that discusses the development of the technologies used in this area from the vinyl collars to the recent technologies of today (L.C. Witchey-Lakshmanan, unpublished data).

The two most dramatic improvements in ectoparasite control have been in the development of spot-on products and orally active compounds, which provide protection for as long as 1 month per administration. Spot-on products can be applied with only a few milliliters of liquid along the back of the animal or at the base of the neck, and the duration of action of the active ingredient is sufficient to allow for control over approximately 30 days. Examples of these products include Frontline® TopSpot by Merial, Advantage® by Bayer, and Ex-Spot® by Schering-Plough (103). The staying power of these medications depends on the unique properties of the active agents and excipients with which they are compounded. For example, the active ingredient in Frontline is purported to remain unaffected by rain or washing because it sequesters into the sebaceous oils of the animal and releases slowly from there.

Program® and Sentinal® from Novartis also provide month-long protection; however, the initial presentations were in oral tablet form and are not effective against adult fleas. In this case, the long half-life of the drug substance allows for the long-acting control of the ectoparasites, similar to the mode discussed for the endoparasite products. More recently, Novartis has released an injection suspension in a prefilled syringe for which they claim 6-month efficacy against fleas. This is currently available for cats but is contraindicated for dogs due to injection site irritation.

Parenteral Chemotherapeutic Systems ***Antibiotics and Cancer Therapies.*** In companion animal medicine, it can be advantageous to formulate the therapeutic ingredient into a sustained-release injectable dosage form that would allow administration of the active ingredient by the veterinarian at the clinic and would obviate the need for the pet owner to have to administer tablets. The administration of tablets can be quite challenging for the owner of a companion animal, especially for those who own cats, because the animal will often spit the tablet or liquid out of its mouth if the flavor is not to its liking. Indeed, once an adverse taste or feel of an oral preparation has been established to the feline patient, the owner will most likely find the animal under the furniture or behind a cabinet at the next dosing time. Therefore, a long-acting injection can

improve the convenience to the owner, improve "patient compliance," and reduce the stress of the administrator.

As with long-acting injectable products used in food-producing animals, most of the long-acting injectable formulations discussed in other parts of this encyclopedia, such as implants, PLGA microspheres, liposomes, and so on, have also been investigated in companion animals. In contrast to human medicine, the use of advanced drug delivery approaches in animals is still primarily used only experimentally. For example, antimicrobial-laden poly(methyl methacrylate) beads have been used in human medicine since the 1970s for the treatment of internal infection. These beads are typically on a wire "string" and surgically implanted into the location of interest. Once the infection is eliminated, these beads are then surgically removed. A similar application can be found in experimental companion animal medicine for the treatment of osteomyelitis and other internal infections (104). Naturally, one would wish to avoid the second surgery for the removal of the polymer beads once they are spent. This would lead one to the development of a biodegradable system that would deliver the active agent and then be absorbed by the body. Examples of such work can be seen by Garvin et al. (105) and Gupta et al. (106). Here, polylactide–glycolide-type polymers were prepared as microspheres or compressed rods and administered to dogs. Although these studies were developed for eventual use in humans, these still demonstrate the feasibility of such drug delivery approaches in the canine itself.

Liposomes have also been used for a variety of infections and cancers in animals (107–110). Gentamicin can be encapsulated for injectable delivery (107), as can other chemotherapeutic agents (108). Kruth (109) has presented an interesting article on the delivery of various biologically active agents for treatment of infections and cancers in companion animals. Included in this review is the use of liposomes in small-animal practice. Collagen implants loaded with chemotherapeutic products have also been used in companion animals for intratumoral treatment of skin cancers in veterinary patients (110).

Insulin. The types of insulin used for the treatment of diabetes in dogs and cats are often those also used in humans. For example, diabetes can be treated in humans by using porcine or beef insulin. This is acceptable because human insulin is similar to bovine and nearly identical to porcine insulin, differing only by one amino acid. Similarly, dog insulin is identical to porcine insulin and cat insulin is nearly identical to bovine insulin, which also only differs by one amino acid group (111). Now that recombinate human insulin is available, companion animals can be treated with that as well.

The insulins currently available on the market for use in animals include short-, intermediate-, and long-acting insulins. Short-acting insulin is designed to be released for the immediate treatment of high glucose levels in the animal. Intermediate, or lente, insulin is typically given to the animal twice per day, with feedings scheduled according to the injection times. Long-acting, or ultralente, insulin can be used for once-a-day delivery. In addition, there are several combinations of insulin that have been specifically formulated to provide certain release profiles and are available on the market. Greco et al. (111) present an excellent table of the types of insulin that are available commercially for companion animal use.

For the most part, the pharmacokinetics of these three types of insulin is determined by the crystal size of the insulin itself. For example, lente insulin is composed of 30% prompt zinc–insulin crystals and 70% extended insulin zinc. The small zinc–insulin crystals allow for a slower release than what would be observed over a regular insulin preparation but still allows for fairly complete dissolution into the bloodstream. In contrast, ultralente insulin is compose of large zinc crystals that dissolve more slowly.

As in humans, research continues in the exploration of implanting islet cells into animals to produce insulin under more naturally modulated circumstances. In brief, the islets are generally encapsulated into a hydrophilic polymer that allows the glucose to migrate into the cells and allows the insulin to migrate out. In addition, implantable reservoirs containing insulin have been formulated in hydrogel-type materials to provide a similar effect. Various types of glucose-sensitive moieties are placed onto the polymer, which will cause the polymeric material to expand in the presence of glucose. The expansion in the polymer network allows for the unhindered diffusion of the insulin out of the reservoir. Once the glucose level decreases, the moieties respond by causing the contraction of the polymeric material, thereby trapping the remaining insulin within the reservoir and impeding its diffusion out of the hydrogel. Both of these approaches are in the experimental stage. Further reading on this topic can be found in Refs. 112–115.

Estrous Control. Estrous control in companion animals is important for many reasons, from controlling the numbers of the canine and feline population to synchronizing the estrous in a manner predictable for breeders. To this end, several products are available, but most of them are not long acting. Some research has explored the use of a medroxyprogesterone acetate product for canine population control. This product, known as Perlutex Leo® in Norway, has become popular in replacing surgery and has reduced the number of dogs in various locations (116). However, the use of the product has also been associated with the formation of uterine lesions and canine mammary tumors (116,117).

The potential use of testosterone implants has been examined in a few studies for the purpose of inhibition of estrous in dogs (118,119). For example, Vincent et al. (119) have examined the plasma concentrations of testosterone in castrated dogs following the administration of implants composed of poly(dimethylsiloxane) capsules that were filled with various amounts of testosterone.

Bone Growth Therapies. In the last 10 years the presence and activity of bone morphogenic proteins (BMP) have become known. These are biological factors whose function is to differentiate mesenchymal cells into chondroblasts and osteoblasts, inducing the formation of bone. Interestingly, these factors can be included into implants that can be placed into fractures to promote healing in instances that would not normally heal properly on their own.

A review of the development of delivery devices containing BMPr has been published (120). This review primarily discusses the patents issued that discover the BMPs as well as those regarding the delivery devices and methods. A review of BMP technology as it relates to veterinary medicine has also been published (121). Kirker-Head discusses the function of BMPs, the delivery devices, and other potential applications from bone graft replacement to soft tissue joining with bone.

Ophthalmic Drug Delivery

Historically, ophthalmic dosage forms have been ointments or drops that are cleared from the eye quite quickly, requiring that the medicine be delivered several times in a day. When the challenges of dosing ophthalmic drops to a 50- to 500-kg animal by holding it still enough to apply the medication and repeating this activity several times a day are considered, one can easily see the need for a long-acting ophthalmic dosage form.

A thorough review of ocular delivery in veterinary medicine has been presented recently by Baeyens et al. (122). They include a discussion of ocular diseases and the agents used to treat them, an excellent list of the available products currently on the market, and a disclosure of the technologies being explored to prolong the release of the active agents.

The typical excipient added to prolong the release of an ophthalmic product is a hydrophilic polymer, such as a cellulosic, which increases the viscosity of the ophthalmic solution and increases the duration of the solution in the conjunctival sac. Another method that has been used is to add gums such as gellan or carrageenan that cross-link in the presence of the calcium ions in the tear fluid. This cross-linking also increases the viscosity and thereby the residence time of the product in the eye. A final mechanism found in aqueous gels is to use poloxamers, which can be formulated as liquids at room temperature but will gel at body temperature.

Inserts and implants have also been developed for ophthalmic drug delivery. Soluble inserts are most desirable because they do not have to be removed. However, some of these inserts have been shown to be irritating to the eye (122). Gurtler et al. (123) discuss the development of a veterinary insert that releases gentamicin for the treatment of ocular infections. This device is prepared with a combination of ethylcellulose and carbomer (poly[acrylic acid]) and can provide efficacious drug levels for as long as 72 h. A silicone implant has also been used experimentally for the treatment of glaucoma in dogs (124). However, these implants required surgical removal once the therapy was complete.

Protein and Peptide Delivery

Somatotropins. Somatotropins (growth hormones) are protein hormones produced by the anterior pituitary that stimulate growth in virtually all vertebrate species (125) as a result of direct receptor stimulation and stimulation of insulinlike growth factor I (IGF-I), a related anabolic protein hormone (126).

The gastrointestinal tract is a hostile environment for somatotropins. Administration by this route results in extensive degradation. In addition, because of the size and physicochemical properties of somatotropins, they are poorly absorbed via this route. The administration route of choice is parenterally. However, somatotropins are relatively large water-soluble molecules with a molecular weight of approximately 21,000 comprising 191 amino acid residues and contain two disulphide linkages. In addition, these molecules have a tendency to form aggregates within both the delivery system and in the biological environment that are biologically inactive or poorly absorbed. As a result of these features, somatotropins present challenges to the formulation scientists developing controlled-release parenteral drug delivery systems. Several important factors must be considered when formulating somatotropins into controlled-release parenteral drug delivery systems. Such factors include the following (125,127–130):

Properties of the Somatotropin.

- Stability of the protein drug during drying, formulation, manufacturing, and postadministration must be ensured. Somatotropin degradation can occur through aggregation, deamination or oxidation.
- The inherent bioactivity of the somatotropin will dictate, amongst other things, its selection and dose size.
- Physiochemical properties of the protein such as isoelectric point, molecular weight, amino acid composition, aqueous solubility at different pHs, and salt concentrations and organic solubilities are also important.

Properties of the Formulation

- Shelf-life stability should be as long as possible. One method to prolong the chemical shelf-life of a somatotropin product is to manufacture and store the formulation in the dry state, for example, as a pellet or implant. Alternatively, oily preparations can be formulated. To increase the physical stability of liquid preparations, viscosity-inducing agents can be added to the formulation.
- Commercially feasible delivery systems must be small to be easily administered. Given the high level of active-agent loads in the delivery system required to achieve therapeutic levels over extended periods of time, the size of the delivery systems may becoming the rate-limiting factor in their success.
- A zero-order release profile seems preferable, but most drug delivery systems currently available release somatotropins through a pseudo-first-order process. Pulsed delivery offers an alternative and mimics the natural method by which somatotropins appear in the blood.
- The duration of delivery of somatotropins to farmed animals is at least 1–2 weeks and up to 6 weeks. Such extended times offer stability and efficacy challenges, given the other factors discussed in this section.
- Administration must be able to be integrated into different management practices. The administration

Next Page

procedure must also be relatively free from discomfort for the animal, and the delivery systems must not cause local irritation or a reaction while in the animal. For parenteral applications, solutions are easier to administer compared with implants, which may require specially designed implanters with large-bore needles.

- The bioactivity of the somatotropin needs to be considered and maintained throughout the shelf-life of the delivery system.
- The formulation needs to be such that aggregation of the somatotropin is avoided or minimized throughout the shelf-life of the sustained-release system.
- Interaction between the somatotropin and formulation should be considered and avoided to maximize shelf-life stability.
- The price of the controlled-release delivery system must be cost effective to realize commercial potential.
- The delivery system must be designed to efficiently utilize the incorporated dose.
- The delivery system must be reasonably aesthetic to appeal to the end-user. It must also be easily administered, offer improvements in control of therapy, adapt to farm management practices, be safe to the end-user and to the environment, and offer increased return on investment.

Considerations during Manufacture

- The bioactivity of the somatotropin needs to be considered and maintained during manufacture.
- Interaction between the somatotropin and formulation ingredients during the manufacture process should be identified and avoided.
- Issues such as method of drying the protein, storage conditions before and during processing, formulation processing conditions (e.g., light, time, heat, shear, etc.) and sterilization must be taken into consideration.

Considerations after Administration

- After administration, the formulation will absorb water from the surrounding environment and hydrate. This will result in the somatotropin existing at high concentrations in an aqueous environment and being exposed to elevated temperatures (37–39°C) for the duration of release. Thus, the aqueous stability of the somatotropin must be considered and known in the development of a controlled-release delivery system. Indeed, the in vivo stability of the somatotropins is the primary limitation for extending the duration of release, and formulators must investigate a variety of methods to improve to aqueous stability of somatotropins when their delivery system is exposed to condition typical of the in vivo environment.
- Because the animal enters the food chain, the level of somatotropin in the tissues must be evaluated so that none is left at the time of slaughter.
- The bioactivity of the somatotropin needs to be considered and maintained after implantation in the animal.
- The formulation needs to be designed such that aggregation of the somatotropin is avoided or minimized within the biological milieu.
- Interaction between the protein drug and formulation in the in vivo environment should be considered and investigated.

Table 9 documents various somatotropin drug delivery systems.

Other Peptides and Proteins. Many of the same controlled-release delivery systems that have been developed for somatotropins have been evaluated for the delivery of other proteins and peptides to animals. A prerequisite to the transfer of technologies between proteins is an inherent knowledge of the physicochemical properties of each individual protein or peptide prior to successful transposition of the technology. A delivery system and manufacturing process appropriate for the formulation of one protein or peptide may not be appropriate for a second. Table 10 documents delivery systems investigated for various protein and peptide compounds.

RECENT INITIATIVES

Vaccine Delivery

The market share for veterinary vaccines represents approximately 1% of the total world pharmaceutical market. With the increasing cost of research and development, production, licensing, and marketing of all medicinal products—including immunological veterinary products, their development, and clinical application—must be carefully considered. This section summarizes recent developments in the area of immunological veterinary products and discusses their potential applications. In addition, the specific application of molecular biology for the diagnosis, therapy, and basic investigation of diseases in animals is discussed.

The purpose of a vaccine is to protect a human or an animal against future exposure to an organism or pathogen that could potentially cause disease. Immunological veterinary products such as veterinary vaccines contribute greatly to the health of animals and reduced economic losses resulting from diseases, increase productivity, and ensure high-quality food for the customer.

There are two important issues that must be considered when formulating a veterinary vaccine: (*1*) the ability of the vaccine to protect against disease, that is, the need to identify what kind of immune response best controls the exposure to a particular pathogen and (*2*) the potential tissue damage that the vaccine may cause at the injection site. It is important to select the best vaccine for a particular pathogen or disease; the failure of the vaccine to protect against the particular disease for which it is administered results in animals that become ill later and therefore require additional treatment and costs. The dosage form, dose, route, and frequency of administration of a vaccine all play important roles in ensuring that an effective immune response is stimulated (186,187). The traditional means of evoking an immune response to an an-

Previous Page

procedure must also be relatively free from discomfort for the animal, and the delivery systems must not cause local irritation or a reaction while in the animal. For parenteral applications, solutions are easier to administer compared with implants, which may require specially designed implanters with large-bore needles.

RECENT INITIATIVES

Vaccine Delivery

The market share for veterinary vaccines represents approximately 1% of the total world pharmaceutical market. With the increasing cost of research and development, production, licensing, and marketing of all medicinal products—including immunological veterinary products, their development, and clinical application—must be carefully considered. This section summarizes recent developments in the area of immunological veterinary products and discusses their potential applications. In addition, the specific application of molecular biology for the diagnosis, therapy, and basic investigation of diseases in animals is discussed.

The purpose of a vaccine is to protect a human or an animal against future exposure to an organism or pathogen that could potentially cause disease. Immunological veterinary products such as veterinary vaccines contribute greatly to the health of animals and reduced economic losses resulting from diseases, increase productivity, and ensure high-quality food for the customer.

There are two important issues that must be considered when formulating a veterinary vaccine: (*1*) the ability of the vaccine to protect against disease, that is, the need to identify what kind of immune response best controls the exposure to a particular pathogen and (*2*) the potential tissue damage that the vaccine may cause at the injection site. It is important to select the best vaccine for a particular pathogen or disease; the failure of the vaccine to protect against the particular disease for which it is administered results in animals that become ill later and therefore require additional treatment and costs. The dosage form, dose, route, and frequency of administration of a vaccine all play important roles in ensuring that an effective immune response is stimulated (186,187). The traditional means of evoking an immune response to an an-

tigens to achieve adequate and lasting immunity is to administer it at timed intervals (initial and booster shot[s]) (Table 11).

Conventional vaccine formulations possess inherent disadvantages, and as a result, researchers have recently been focusing on the development of more suitable vaccine formulations. One approach has been the delivery of an antigen from an oil-based vehicle such as Freund's adjuvant (188). Such an approach has resulted in the reduction of the number of doses needed; however, because of the toxicity of the oil-based adjuvants, the search for a safer and more potent adjuvant continues. This search has resulted in the formulation of antigens into delivery systems that administer the antigen in particulate form rather than as soluble molecules. This approach facilitates recognition by the phagocytic systems and results in presentation of the antigen to the lymphocyte (189). Several particulate systems have been studied as vaccine delivery systems. These include emulsions, liposomes, nanoparticles, and microparticles. Each of these approaches are discussed in more detail in the following sections. The advantages of such vaccine delivery systems is that they can provide the ability to deliver antigens in a continuous manner or result in more control over the production of antibodies (190).

Emulsions. The manufacturing procedure of vaccine emulsions is relatively simple: The antigens are dissolved in a water phase and then emulsified in the oil in the presence of an appropriate emulsifier. The physicochemical characteristics of the final emulsion play an important determinant in the efficacy and handling of the vaccine. The controlled-release characteristics of an emulsion and dependent on certain properties of the emulsion, such as the viscosity of the oil phase, the oil–water phase ratio, and the emulsion droplet size. For example, a high oil content can cause unnecessary injection site irritation, and too large a droplet size can result in a physically unstable product, thereby reducing its shelf-life. Some problems may be observed with the oil/water emulsion type, but these can be overcome with multiple emulsion formulations (water/oil/water).

Foot and mouth disease (FMD) is as a highly contagious disease of domesticated and wild animals. FMD outbreaks can have devastating effects on the agricultural economies of developed, particularly FMD-free, countries, owing to the direct cost of control and indirect cost of trade embargoes. Oil-based FMD vaccines have been used in the field for many years, particularly in cattle in South America (191). Two novel oil-based FMD vaccines (FMDVs) were investigated by Salt et al., who examined their protective ability in pigs (191). In this study, the FMDV was formulated with new-generation, ready-to-formulate, mineral oil–based adjuvants. Basically, type C1 Oberbayyern FMDV antigen concentrate was emulsified using ISA 206 (Seppic, Paris) or ISA 25 as a water/oil/water or oil/water emulsion. Both formulations were shown to protect pigs against FMD virus within 4 days of vaccination. However, reimmunization was shown to be necessary after 21–28 days because of the continued risk of challenge.

Similar emulsion formulations were developed to protect a wild population of elephants against a natural outbreak of diseases caused by encephalomyocarditis virus (EMC) (192). The economic concerns associated with a wild population of elephants contracting EMC is that if the EMC virus spreads to swine, it may result in high piglet mortality due to myocarditis and respiratory failure (192). The experimental vaccine developed by Hunter et al. was tested in elephants, mice, and pigs. Their results showed that elephants vaccinated with the EMC vaccine formulation developed high antibody titers, whereas controls developed fatal or subclinical myocarditis. Similar results were also observed in mice and pigs. The vaccinated animals showed persistent antibody responses after a single vaccination and a lack of reaction to the adjuvant used (192). Their results suggested that the vaccine may be useful in wildlife species in zoos.

Perhaps nowhere in veterinary medicine has the practical application of vaccinations been more visible and rewarding than in the development of vaccines and diagnostics to assist in the control and eradication of pseudorabies (PR). Pensaert et al. (193) developed an emulsion vaccine formulation for PR in pigs (Aujeszky's disease). In this study, Aujeszky's disease vaccines and their ability to induce an immune response, which suppresses virus excretion optimally upon infection, were compared. All the pigs were vaccinated with glycoprotein deletion vaccines suspended in phosphate-buffered saline (PBS). Two additional groups were vaccinated with a gI-deleted vaccine virus suspended in an oil/water emulsion–excreted vaccine 2–6 days after injection. A 100- to 1,000-fold reduction in excreted virus titers was observed in vaccinated pigs compared with unvaccinated ones. Some vaccines suppressed virus excretion better than others, but no correlation could be made between the type of deletion and the degree of reduction in virus excretion. Similar results were obtained with two applications of inactivated vaccines. The lowest number of excreting pigs, the lowest duration of excretion, and the lowest titers were obtained in groups vaccinated with the attenuated vaccine suspended in emulsion (194).

Gliding bacterial adjuvant (GBA) has been characterized as a potent immune modulator, stimulating the growth of murine B lymphocytes in mice, inducing murine natural killer-cell activity, and promoting the release of several murine cytokines. Zeidner et al. tested gliding GBA emulsion formulations for their ability to activate feline peripheral T cells to secrete cytokines and to potentiate specific antibody responses in cats against a well-characterized T cell–dependent antigen and a recombinant immunogen derived from *Dirofilaria immitis* (194). The results of the trial showed that GBA also appeared to be a potent stimulator of feline T cell proliferation and induced both IFN and IL-2 production in cats. GBA has relatively low local and systemic toxicity and exhibits potent activity, both in PBS or within an oil vehicle. These characteristics make GBA an attractive new adjuvant for use in feline vaccines (194).

Liposomes. A variety of lipids have been used to create bilayer liposomal structures. Phospholipids were among the first chemicals used to form bilayer structures to mimic

Table 9. Parenterally Administered Somatotropin Controlled-Release Drug Delivery Systems

Delivery system type	Formulation of delivery system	Drug	Factors affecting release and stability	Disadvantages
Nonaqueous gels	Biocompatible vegetable oil (e.g., sesame oil, peanut oil) containing a dispersion of the somatotropin and incorporating thickening agents (e.g., aluminium monostearate, white beeswax, yellow beeswax). Appropriate amounts of thickening agent need to be added to achieve a compromise between physical stability and ease of injectability (126). Examples of nonaqueous gels for the delivery of somatotropins can be found in references (131–134)	N-terminated bovine somatotropin zinc salt (135) Bovine somatotropin (136)	Absence of water within the formulation results in a relatively long-term shelf-life. Viscosity of formulation can be modified to increase duration of release; can be achieved by selecting an oil from the range of hydrophobicity of oils or addition of excipients (e.g., esters of glycerol) or thickening agents. Improvement of the shelf stability, drug loading, injectability, and injection site; chemical and physical stability of the somatotropins, once injected into the animals, can also be achieved by alteration of the viscosity of the formulation.	Injectable nonaqueous gels form variable-shaped depots, which may affect the release profile from animal to animal (125) Release profiles are not zero order.
Microparticles (microspheres or microcapsules)	Microsphere matrix prepared from lactide/glycolide copolymers (D,L-lactide 50:50) using an anatomization process in liquid nitrogen containing about 10% drug load (137) Microsphere matrix prepared from glyceryl tristearate or glyceryl distearate using a spray prilling technique; microspheres containing 24.5% were suspended in soybean oil/ Miglyol®812 and administered subcutaneously (138). Microspheres of polyglycholic acid (139).	Human growth hormone Bovine somatotropin Porcine somatotropin	Fat-based formulations provided better physical stability and shelf-life for glyceryl tristearate or glyceryl distearate microspheres when reconstituted in an oil vehicle (140). Aggregation of somatotropin reported to occur within the polymer	Animal growth-rate studies suggest that the release profiles from such formulations are not zero order.
Liposome	Egg phosphatidylcholine, ethanolomine, and α-tocopheryl hemisuccinate and Tris salt vescicles (141) Hydrogenated soy phosphatidylcholine–cholesterol hemisuccinate liposomes (142)	Bovine somatotropin Bovine somatotropin	Coformulation of liposomes with other delivery systems may provide opportunities to exploit liposomes as delivery systems for somatotropins, e.g., Refs. 143–145.	Low product loadings, difficulty and cost of manufacture, and stability issues are associated with the use of liposomes as delivery systems for somatotropins.
Emulsion (multiple water-in-oil-in-water type)	Appropriately buffered aqueous phases (e.g., carbonate-buffer) and oil phases (e.g., mineral oil) and stabilizing agents (e.g., sorbitan surfactants) (146,147)	Bovine somatotropin	Somatotropin was incorporated into the primary aqueous phase. Multiple emulsion was achieved using polyoxyethylene sorbitan surfactants.	
Aqueous solutions gelled with polymers	Aqueous injections using carbohydrate polymers such as dextrins, heteropolysaccharides, and various gums (148)	Bovine somatotropin		Injectable nonaqueous gels form, variable-shaped depots that may affect the release profile from animal to animal.

Aqueous conjugates (suspended complex)	HGH- and BST-prepared conjugates with bovine serum albumin using glutaraldehyde or with immunoglobulin using carboimide (149)	Bovine somatotropin	The conjugated molecule exhibited increased solubility over BST alone in solutions of pH less than 5 (149)	
Hydrogels	Somatotropins suspended in silicone oil and placed into hydroxyethyl methacrylate–methyl methacrylate copolymer and hydroxyethyl methacrylate homopolymer cross-linked with ethyene glycol dimethacrylate cylindrical reservoirs that acted as a rate-limiting membrane have been described (150) Small spheres of somatotropin–chitosin (60:40) coated with a hydrogel comprising poly(vinyl alcohol) have also been described (151) In a matrix system, biodegradable thermoplastic hydrogels consisting of ABA or AB block polymers, where the block A is a glycolide and block B is polyethylene oxide or in the case of an ABA block polymer, a glycolide and trimethylene carbonate (152) Delivery systems comprising polymers of D,L-lactide–glycolide containing poly(ethylene glycol) (153)	Ovine, equine, and bovine somatotropins Porcine somatotropin Bovine somatotropin Bovine somatotropin		
Implants	A variety of methods are described in the patent literature, which describe the formulation and manufacture of both uncoated (154–158) and coated implants (by either a spray technique (e.g., ethyl cellulose/poly(ethylene glycol), poly(vinyl alcohol), poly(ethylacrylate methylmethacrylates) (159–162) or dip coating (e.g., molten blend of beeswax, carnauba wax, and Mazol®) (163). Controlled release from implants have also been achieved by placing the implant inside silicone tubes which had their ends covered by microporous polyethylene disks each having a 70-μm pore. The release of somatotropin from silicone tube-covered implants was designed to occur from the ends of the tubes (164).	Porcine somatotropin Bovine somatotropin Silicone tube-covered implants were prepared containing 40 mg of porcine somatotropin alone or 40 mg porcine somatotropin with sucrose.	Factors affecting release from coated implants include thickness of coating, ratio of drug to excipients, type of excipients, degree of polymer cross-linking, surface area of the rate-limiting membrane, coating material, presence/absence of coating, and solubility of the somatotropin.	Implants contain somatotropins at much higher concentrations than injection formulations. This may impact on the stability of the somatotropin following administration. Implant administration requires a relatively large bore needle. Implantation requires the design of a more complex administration system than a hypodermic syringe. Implants generally require a more complex manufacturing process, particularly if an aseptic implant is required.
Osmotic devices	Several osmotic devices have been described in the patent literature. The constant delivery of drug from the devices relies on the incorporation of expandable excipients surrounded by a semipermeable wall into specially designed dispensers (165–169).	Porcine somatotropin		Cost of final product, final product size, administration difficulties, and delivery system recovery issues after slaughter limit the application of this technology to the administration of somatotropins.

Table 10. Delivery Systems for Various Protein and Peptide Compounds

Peptide or protein	Use	Formulation of delivery systems
Somatotropins	Increased milk yield Accelerated growth Increased feed conversion efficiencies Increase in lean-to-fat ratio Reduced fat deposition Increased ovulation	See Table 9.
Somatotropin releasing hormone (growth hormone–releasing hormone)	Increased milk production Accelerated growth Increased feed conversion efficiencies Increase in lean-to-fat ratio Reduced fat deposition Increased ovulation	Silicone rubber matrix (170) Collagen implant (171,172) Cholesterol acetate implants (173) 50:50 poly(D,L-lactide-*co*-glycolide pellets (174)
Luteinizing hormone–releasing hormone	Control of fertility Stimulation of spermatogenesis and ovulation	Compressed implants containing lactose and calcium phosphate and coated with Eudragit NE30 D (175–177); compressed core excipient ratios, percentage active present, and coating thickness affected rlease rate.
Luteinizing hormone–releasing hormone agonists (e.g., nafarelin acetate, leuprolide acetate)	Estrus suppression	Microspheres of various ratios of poly(D,L-lactide-*co*-glycolide (178–182) Silicone rubber implant (183) Crosslinked poly(orthoester) (184,185)

Table 11. Examples of Conventional Veterinary Vaccines on the Market

Vaccine	Animal	Disease
PHF-VAX-3	Horse	Tetanus, fever,
EWTF	Horse	Influenza, tetanus
MHB[a]	Pigs	Pneumonia
Prime Pac_R PRRS	Pigs	Respiratory viruses
Scourmune[R] CRT	Pigs	*Escherichia coli*
AR-Pac[R]	Pigs	Atropic rhinitis
Pliguard[R] *E. coli*-1	Calves	*E. coli*
Eclipse[R]3	Feline	Panleukopenia
Fevaxyn FeLV	Cats	Leukemia
Galaxy[R]D	Dogs	Distemper vaccine

cell membranes (195). Liposomes can induce both a humoral and cell-induced immunity, which is clearly an advantage when formulating a vaccine (196). In addition, liposomes can serve as carriers of antigens and adjuvants, as depots for the controlled release of antigens, and as targeting agents for the delivery of novel antigens and adjuvants to antigen-presenting cells (APCs). Although, liposomes have limited applications in veterinary medicine, the literature contains several encouraging experimental results that demonstrate their potential application in this field.

Nakanishi et al. showed that the pulsed administration of APCs with various antigens to mice resulted in the introduction of potent antigen-specific immune responses (197). These authors investigated the relationship between the liposome surface charge and the adjuvant action of liposomes in inducing immune responses to soluble antigen. Results revealed that the positive charge on the surface of the liposomes was important for enhancing their immunoadjuvancy in the induction of antigen-specific immune responses (197).

Enteric diseases remain one of the great causes of motility and morbidity in both human and veterinary species. However, mucosal surfaces are also the target of significant diseases. Although immunization strategies have been available for many years and have achieved significant success in the reduction of disease incidence and mortality when applied to diseases affecting organs, there has been a remarkable lack of success in vaccination to control mucosal disease (198). It has therefore become apparent that novel strategies are required to achieve effective defenses at such sites.

All mucosal surfaces, but particularly the intestine, represent a physiological dilemma whereby selective absorption of essential nutrients must occur with concomitant exclusion of pathogen (198). The oral route of immunization is a trustworthy way to induce mucosal IgA antibody responses. However, this immunization route has the problem of antigen degradation by gastric acidity and proteolytic enzymes in the intestinal lumen. The poor immunogenicity of ganglioside antigen such as ganglioside-GM1 is well documented (199). Therefore, the stability of ganglioside liposomes to acidic solution, bile, and pancreatic solution has been examined in the literature (200). Liposomes that contained the antigen ganglioside-GM1 demonstrated that their stability to acidic solution, bile, and pancreatin solution would permit them to effectively serve as an oral vaccine delivery vehicle for inducing mucosal immune response (200).

Saponin (201) and muramyldipeptide (MDP) (202) was used as an adjuvant to deliver ovalbumin (OVA) intraperitoneally (ip) in rats based on their availability, ease of preparation and previously demonstrated adjuvanticity in systemic immunization applications. The subsequent anti-OVA–containing cell response in the intestine was assessed in the study. The adjuvants were formulated in either vegetable oil emulsion or liposome vehicles, these formulations being biodegradable alternatives to the min-

eral oil component used in Freund's adjuvants. Results showed that both saponin and MDP exhibited adjuvant activity for IgA responses to OVA when administered ip. Although data showed that both MDP and saponin given in an emulsion provided an alternative to Freund's adjuvant for ip stimulation of IgA responses, the success of liposomes as a systemic antigen delivery system suggested their potential as an alternative vehicle for ip use. Although these alternatives have been developed for veterinary applications in which they have proved to be both effective and practical, they also show promise for the development of improved delivery systems for human mucosal vaccines (203).

Nanoparticles and Microspheres. Microspheres are defined as small particles typically no greater in size than 1 μm. Nanospheres are defined as colloidal particles with a diameter less than 1 μm. In contrast to liposomes, microspheres or nanospheres are prepared from polymers that can be manipulated according to the release requirements of the formulation. Preparation of these particles is discussed elsewhere in this encyclopedia.

The advantages of delivering vaccines in microparticles is that they may reduce the number of vaccinations required to give a prolonged protective response and/or that release of the vaccine can be controlled by a number of different mechanisms. Antigen is released from microparticles either by diffusion through pores or by erosion of the matrix. Among the acceptable polymers available to prepare microparticles, poly(lactic acid) and poly(lactide-*co*-glycolide) (PLGA) have been chosen the most often. These polymers are biodegradable, biocompatible, and FDA approved for use in therapeutic products (204). Veterinary applications of microparticulate vaccines are limited, but investigations in this area are increasing rapidly. For example, a two-bait delivery systems for oral immunization of dogs against rabies was tested in small-scale field trials in Tunisia (205). The bait consisted of a freeze-dried core unit containing a biomarker covered with a paraffin matrix. The baits were placed on transect lines, which offered the possibility to vaccinate certain categories of dogs that were not accessible via a dog owner–mediated approach. Unfortunately, the method offered less safety than other systems, was less specific, was not readily accepted by the human population, and was costly.

Immunization against luteinizing hormone–releasing hormone (LH-RH) may offer an interesting experimental tool and also a veterinary vaccine capable of increasing meat production by immunological castration. Production of antibodies against LH-RH has been reported in sheep, cattle, rats, rabbits, and primates (206). However, because this decapeptide is only a weak antigen, immunization has traditionally required repeated injections of the synthetic hormone conjugated to a carrier and emulsified in Freund's complete adjuvant. However, Carelli et al. investigated a more superior method of immunization by using the synthetic adjuvant MDP conjugated with polylysine (207). Results revealed that those synthetic haptens and the synthetic adjuvant MDP could be usefully coupled to the polymeric carrier. Moreover, LH-RH mixed with MDP or conjugated with MDP–lysine and injected in an aqueous medium produced a greater binding activity than that observed with Freund's adjuvant alone (207).

Yersinia pestis is the causative agent of pneumonic and bubonic plague. *Y. pestis* vaccine offers protection against bubonic plague; however, vaccinated animals acquired pneumonic plague (207). Therefore, the ability of the vaccine to confer protection against pneumonic plague is questionable. In addition, undesirable side effects are common immunity induced by the vaccine is short lived, and further doses (one given every 6 months) are required to maintain the same level of protection (208). Subunit vaccines using protective components from *Y. pertis* may avoid adverse effects but require adjuvants or appropriately formulated delivery systems to boost immunity (209). To achieve this, one approach is to encapsulate antigenic material within polymeric carriers such as PLGA. For example, F1 antigen from *Y. pestis* was encapsulated in PLGA microparticles, which induced high serum titers when injected ip in mice (209). In addition, mucosal IgA was also detected. The 1-μm-diameter PLGA microparticles gave effective protection against challenge with *Y. pestis* after only one dose, which may be due to the microspheres having depot-release properties; therefore, less antigen and fewer doses were necessary for protection (209).

It is known that small particles are able to cross the mucosal barrier and penetrate into the blood circulation when administered nasally. Animal experiments using microspheres induced significantly higher levels of serum antibodies to the antigen than when the free antigen was administered to the nasal mucosa. In a similar study, F1 and V subunits of *Y. pestis* were encapsulated in PLGA and administered intranasally to mice. Results revealed that encapsulated subunits induced significantly elevated serum antibody titers to F1 and V relative to free antigen, and served to protect 66% of the vaccinated animals from inhalation challenge (210).

Nonparenteral immunization, such as simple mucosal application of antigenic proteins (for example, in the gastrointestinal or respiratory tracts), is usually ineffective in terms of vaccination (211). This is a result of enzymatic or chemical destruction combined with poor absorption into subepithelial compartments. To overcome these problems, some form of an antigen delivery system needs to be formulated, for example, biodegradable microspheres that protect the antigen from enzyme degradation in the lumen. Several investigations suggest the applicability of such an approach. Atarki et al. (212) investigated the possibility of using an inert oral delivery system to stimulate mucosal antiphosphorylcholine immunity. Phosphorylcholine was noted to be a hapten present on different pathogenic bacteria such as *Streptococcus pnemoniae, Salmonella typhimurium, Proteus morganii*, and *Neisseria menengiditis* and on parasites such as *Ascaris suum* and *Trichinella spiralis*, which invade or colonize via the mucosa at different anatomical sites. Oral administration of biodegradable microspheres loaded with phosphorylcholine induced a specific IgA response in intestinal, pulmonary, and vaginal secretions as well as a strong specific immune response in female Balb/c mice (211).

Genetically Engineered Vaccines. Modern vaccine technology has now provided us, through genetic engineering,

the ability to use genetic material as a vector to protect animals and human against a variety of diseases (213). These vaccines, especially those constructed of genetically engineered proteins, are expensive. However, currently available (nongenetically engineered) vaccines are not cheap. In addition, many of them provide only temporary immunity, and the weaker the vaccine, the greater the dose necessary to stimulate an immune response and the greater the risk of overactivating the immune response, resulting in shock and death. Genetically engineered vaccines have the potential to overcome these latter problems; however, when the first genetically engineered hepatitis-B vaccine was developed, it cost $150 for three injections. The vaccine was safe and effective. Nevertheless, few farmers or pet owners would be willing to pay so costly a price for a vaccine. The issue surrounding the cost of genetically engineered vaccines is the current stumbling block in their acceptance and use in veterinary medicine.

The new generation of vaccines include subunit, synthetic peptide, and live recombinant vaccines, which contain only the most critical proteins involved in inducing protection, or live attenuated vaccines, in which specific genes involved in virulence have been deleted, with a low probability of back mutation and reservation to virulence. However, genetically engineered vectors offer the advantage of being able to carry multiple antigens from a variety of pathogens and therefore provide the opportunity for immunizing animals with delivery systems that would be adaptable to various species. Hence, the induction of various types of immune responses, depending on the agent and the animal being immunized, might be possible.

The first recombinant DNA-derived modified live vaccine was licensed for manufacture and sale in 1986. Gene-deleted PR vaccines (PRV) OMNIVAC-PRV and OMNIMARK-PRV were a major breakthrough for PR control and eradication (214). PR is caused by a herpes virus that induces acute or fetal infections of baby pigs and a variety of clinical symptoms in older animals. Cattle, sheep, dogs, cats, rodents, and raccoons are also susceptible to fetal PRV infections. The annual cost to the U.S. producer of a PR outbreak has been estimated at $30–72 million. Unfortunately, vaccination does not prevent latent infection by field strains. Neither modified live virus (MLV) or inactivated conventional PRV vaccines have prevented infection. To maximize safety, a purified clone of a Bucharest (BUK) vaccine strain of PRV was chosen as the starting material for the genetic engineering of OMNIVAC-PRV and OMNIMARK-PRV. Although total eradication of PRV may be unrealistic, previous studies have shown that a saturation vaccination program using OMNIVAC-PRV with culling is effective without having to resort to depopulation.

The forms of antigen and its formulation have a significant influence on vaccine efficacy and on the duration of immunity. This is particularly important if the immunity is cell mediated or mucosal. With viral infections, the major targets for immunity are often surface glycoproteins that are found in mucosa. Hence, the surface glycoproteins are important for the attachment and entry of the virus to host cells; consequently, a virus vaccine in one species might be used in another. Babik et al. tested this hypothesis using purified glycoprotein B and C of the herpes virus to use as an experimental vaccine in cattle (215). In all cases, the purified protein induced neutralizing antibodies, and more importantly, calves were protected from infection.

The other type of live recombinant vaccine uses the most studied poxvirus, vaccinia virus (VV), as a vector, by incorporating immunogenic genes of disease agents into the VV genome (216). Vaccinia was used for almost 200 years as a vaccine for smallpox. A large variety of genes have been expressed in vaccinia virus recombinants, including enzymes, clotting factors, hormones, and importantly, genes that encode for protective immunogens. These latter genes have been derived from other viruses, bacteria, and parasitic organisms. This can be exploited to produce a recombinant vaccine directed toward multiple pathogens pertinent to a specific population. One of the potential advantages of the poxvirus vector is its large volume, which has a large capacity available for the insertion of multiple foreign genes. In addition, unlike many live vaccines, the lyophilized form of VV is heat stable. This is a major advantage in carrying out successful vaccination programs in developing tropical countries. When the VV vector is introduced into an animal, the virus replicates in the host cell, and the foreign genes are expressed together with those of VV. For example, rinderpest is an acute, febrile, and highly contagious viral disease of ruminants with a rapid course and a mortality rate exceeding 90% (216). It is characterized by inflammation, hemorrhaging, necrosis, and erosion of the gastrointestinal tract, accompanied by bloody diarrhea, wasting, and death. Cattle vaccinated with a VV vaccine were shown to be completely protected from rinderpest and exhibited no detectable illness or clinical disease (216,217).

Panicali et al. constructed recombinant VVs containing the cloned hemagglutinin gene from the influenza virus (217). Immunization of rabbits with recombinant poxviruses resulted in the production of antibodies reactive with authentic influenza HA. The production of antibodies directed against influenza HA suggested that the HA gene expressed in vaccinia is immunogenic. These data indicate the potential of genetically engineered poxvirus for use in generic live vaccine vehicles that have veterinary or human application (217).

Marek's disease (MD) is a malignant T-lymphomatosis of chickens and is caused by Marek's disease virus type 1 (MDV1) (218). MD is the first cancer that was made preventable by vaccination and has been largely controlled by use of live attenuated or naturally avirulent vaccines since the early 1970s. To examine the protective efficacy of the recombinant MD vaccine, specific pathogen-free chickens were vaccinated with rMDV1. Almost all birds were protected from MDV challenge via intramuscular, ocular, intranasal, and intratracheal routes at 4 weeks after vaccination. In addition, the rMDV1 provided 100% protection against virulent MDV1 challenge in chickens. Antibody responses against MDV1 antigen were observed up to as long as 11 weeks after immunization (218).

In the case of bovine respiratory disease, management systems vary around the world, with economic losses often occurring following weaning, movement, and confinement of animals. Respiratory pathogens in cattle such as bovine

respiratory syncytial virus (BRSV) and bovine herpes virus are challenging targets for DNA vaccine development (219). These viruses are important pathogens in cattle for which various live and inactivated vaccines are currently used in the field (220). Schrijver et al. compared the protection afforded by three different DNA application methods against BRSV infection in cattle (220). Intradermal (id) administration with a needleless injector reduced BRSV excretion significantly better after BRSV challenge than when administered iv or id with a needle. Serum antibody levels against G protein were high and showed less variation in calves vaccinated with needleless injectors compared with those in id- and im-vaccinated calves. Parenteral DNA application was shown to be capable of inducing the priming of the immune response at the respiratory mucosa (220).

DNA plasmid vaccines can stimulate very specific and powerful long-term immune responses against virtually any pathogen. These vaccines can be delivered by either direct injection or by gene gun. Delivery of genes via a gene gun involves coating gold particles with the plasmid of interest (221). Direct injection of DNA into all species requires larger quantities of plasmid to induce an immune response than if administered by a gene gun. The reason for this may be degradation of the plasmids before they are taken up by the cells in vivo and transported to the nucleus. Lodmell et al. demonstrated that direct intracellular epidermal delivery of plasmid DNA–coated gold particles via a handheld helium-powered gene gun would elicit protective immune responses against a rabies virus (222). The gun system permitted a more simple and rapid delivery of DNA compared with the more typical needle injection, and more importantly, the force of the particle bombardment propulsion was thought to propel the DNA-coated beads through the plasma membrane of the cells. In another study using an AccellR gene gun, particle-mediated immunization with DNA encoding the glycoprotein gene of the standard strain of rabies virus was shown to elicit highly protective levels of rabies virus–neutralizing antibody in mice. At 315 days postprimary immunization, 100% of the mice survived intraplantar rabies virus challenge (223).

It has also been shown that plasmid DNA-encoding canine parvovirus (CPV) induced immunity may protect dogs against challenge with virulent virus (224). Nucleic acid (NA)–vaccinated dogs showed an increase of serum IgG titer starting 1 week postinjection, which peaked at 2 weeks and remained detectable for at least 14 weeks. All NA-accinated dogs were protected against infection after virulent CPV challenge regardless of dose, whereas the control dog was fully susceptible. This study demonstrated for the first time that NA can protect dogs against an infectious disease (224).

In addition to inducing immune responses to infectious diseases, DNA immunization has also the potential for the control of ectoparasites (225,226). Recently, investigators have used concealed antigens as vaccines. Concealed antigens are antigens that do not normally induce immune responses during ectoparasite infestations because they are rarely exposed to the immune system (225). However, if the host contains antibodies to these antigens in the blood, these antibodies interact with the concealed antigen in the gastrointestinal tract and in combination with complement may result in lysis or disruption of gastrointestinal tract cell function and death of the ectoparasite. These concealed antigens are glycoproteins; therefore, administration of genes encoding these glycoproteins in plasmid should induce very high levels of immune responses to the appropriate epitope (226). Although there is limited literature indicating that DNA immunization works with concealed ectoparasite antigens, some reported studies have been promising (226). For example, immunization of rabbits against the midgastrointestinal tract antigen of mosquitoes demonstrated a lower survival rate of mosquitoes in those fed on immunized rabbit versus those fed on normal (nonimmunized) rabbits (225).

Gene Therapy

The identification of underlying genetic disorders has recently made gene therapy an attractive treatment option for a wide variety of disorders in both humans and animals. Gene therapy offers new opportunities to treat these disorders both by restoring gene functions that have been lost through mutation and/or by introducing genes that can inhibit the replication of infectious agents. Genes used in such therapies are viewed as medicines, and their development as a therapeutic agent faces similar issues to those encountered during the development of other drugs and proteins such as bioavailability, toxicity, activity, and cost/risk/benefit (227). The ideal gene therapy vector should be easy to formulate, nonimmunogenic, and nontoxic and should have a low cost/risk ratio; it has to reach to target cells and then should be transported to the nucleus where gene expression takes place, and it must be expressed in predictable controlled fashion.

The development of gene delivery systems has included both nonviral and viral vector systems. Viral vectors can arise from viruses that are extensively modified to provide immune responses with increased cloning capacity to permit the incorporation of genes and complex regulatory elements. Other viral vectors emerge through the modification of existing, relatively inefficient, nonviral delivery systems. Therapeutic applications of gene therapy in animals are currently limited, except for the genetically engineered vaccines that have been previously discussed in this section. However, the number of applications of nucleic acid probes or recombinant DNA products for clinical or diagnostic use in veterinary medicine is increasing rapidly (228,229).

Hormones, growth-stimulating factors, enzymes, cytokines, and immunomodulating proteins have all been cloned from the human genome for use in veterinary medicine.

Only a small number of genes from species of veterinary importance have been cloned so far. Two immunomodulating cytokines have been cloned for the cat α-interferon and tumor necrosis factor. Human interferon can also be administered either orally or subcutaneously to cats for the treatment of feline leukemia virus infection. Recombinant interferon acts as immunomodulator and antiviral agent (230).

Hemaropeietic growth factor is a regulatory molecule essential for controlling blood cell differentiation and in vitro proliferation and survival. Potentially, this agent may be useful in prevention and treatment of chemotherapy- or radiation-induced cytopenia and treatment of suppression of bacterial infections associated with clinical feline panleukopenia virus infection of kittens (231).

Hemophilia is a bleeding disorder caused by a deficiency in the clotting factor VIII. A canine model was used to determine if an adenoviral vector expressing a human factor VIII cDNA could be used to correct the hemophilia A phenotype. Results showed that the disease in dogs could be treated effectively using the human factor VIII. However, further advances in vector design are needed to enable sustained expression. Correction of the coagulation defect in a large-animal model is a crucial step to verifying the feasibility of gene therapy for this disease (232).

The polymerase chain reaction (PCR) is particularly important for identification and diagnosis of parasites as well as for many other applications in veterinary medicine. The key to the development of a nucleic acid probe is to identify nucleotide sequences that are unique to the particular organism of interest. The application of molecular biology in veterinary parasitology requires the classification of parasites, the diagnosis of infection, the development of the antiparasitic vaccine, the development of antiparasitic drugs, and the selection of a host with genetic resistance (233). This reaction can be used to screen a cDNA or genomic DNA library for classification and diagnosis and many other purposes. PCR primers and a probe derived from a gene encoding an intraerythrocytic piroplasm surface protein of *Theileria sergenti* has used. *Babesia bovis* has been diagnosed in chronically infected cattle by using PCR for a merozoite surface protein. High sensitivity was achieved with a limit of detection of parasitemia (233,234).

Molecular biology is also being applied to the improvement of chemotherapy against veterinary parasites. The use of antisense nucleotides for therapy generally relies on the synthesis of an antisense oligonucleotide and the delivery to the target, which is the parasite's nucleic acid. Therefore, an antisense oligonucleotide has to be synthesized and delivered into the parasite's cells, where it must not be degraded too rapidly and must hybridize with the parasite's nucleic acid to prevent the protein expression, which is essential for the survival of the parasite. Adequate delivery systems remain a problem in the practical application of antisense therapeutics to parasites.

Trends and Future Directions of Vaccines and Gene Therapy

This section has considered some of the recent progress in the development of new vaccines and genetically engineered products for improving animal health and their veterinary application using by molecular biology and biotechnology techniques. Vaccines have played, and will continue to play, a critical role in presenting, controlling, and eliminating diseases in animals and humans. Although applications of genetically engineered products are presently limited, the use of recombinant products is increasing. We are confident that in the future we will have unlimited potential for the production of safer and more effective vaccines, therapeutic proteins, and recombinant products and more sensitive diagnostic reagents.

CONCLUDING REMARKS

The veterinary area offers unique opportunities to the formulation scientist that arise from the diverse nature of the field, the desire of the end-user to fit drug therapy around farm management practices, and the anatomical and physiological peculiarities of an individual animal species. Many technologies have been developed to overcome the challenges associated with the delivery of drugs to animals, and numerous examples of innovative controlled-release drug delivery systems exist in the literature.
