Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

About AACC

Dedicated to achieving better health through laboratory medicine, AACC brings together more than 50,000 clinical laboratory professionals, physicians, research scientists, and business leaders from around the world focused on clinical chemistry, molecular diagnostics, mass spectrometry, translational medicine, lab management, and other areas of progressing laboratory science. Since 1948, AACC has worked to advance the common interests of the field, providing programs that advance scientific collaboration, knowledge, expertise, and innovation. Preface

It has been 4 years since the publication of the previous edition of the "White Book." As the field of clinical laboratory medicine continues to evolve, so has this book. With the release of the fourth edition of the *Contemporary Practice in Clinical Chemistry*, we have made some important changes. Notably, the book has moved from being published by our professional organization (AACC Press) to a major international publishing house (Elsevier), and we have added a Co-Editor to the book in Mark Marzinke. Both of these changes have been beneficial to the publication of this edition, and we are confident that these new collaborations will facilitate continued growth in future iterations of the "White Book."

Often times, when a major professional (or personal) task is accomplished, one tends to be satisfied with the result; however, it is also natural to think about improvement strategies or what could have been done differently. Our approach to this book has been no different. Consequently, in the fourth edition, we have tried to address any shortcomings or omissions from previous iterations, and we have augmented our exemplary roster of existing contributor authors with some of the newest and brightest in our field. We sincerely hope these changes have enhanced the content and communication of the material. This edition also includes new sections on Testing in Alternative Matrices, Applications of Mass Spectrometry, Clinical Hematology, and Clinical Microbiology.

This book is intended to be a supplement for the many other excellent training resources available in Clinical Chemistry. Therefore, the "White Book" aims to provide a clear and concise summary of a wide variety of topics to serve as a starting point for study and discussion. It is both our hope and goal that this resource will continue to be used by a wide variety of people in our field, from students to postdoctoral trainees to more experienced professionals and clinical laboratory scientists and directors.

A project like this does not happen without many experts willing to donate their time and share their knowledge on the written page—we are very grateful for each author who was willing to participate in the fourth edition of the "White Book." Thanks to you all! We also express our gratitude to our AACC colleagues and external subject matter experts within the field of Clinical Laboratory Medicine for the helpful feedback and suggestions, and for targeted criticism when needed. Last, we must thank our colleagues at Elsevier for their help in compiling all the chapters, reviewing of all the material, and keeping us moving toward completion—a transition between publishers is a big undertaking, and we appreciate their patience and support during the process.

March 2020

Bill Clarke and Mark Marzinke

Chapter 1

Preanalytical variation

Zahra Shajani-Yi and James H. Nichols

Department of Pathology, Microbiology and Immunology, Vanderbilt University Medical Center, Nashville, TN, United States

Learning objectives

After reviewing this chapter, the reader will be able to:

- Understand why preanalytical variation is a significant contributor to laboratory errors.
- Identify the common sources of preanalytical variation.
- Discuss the potential effects of phlebotomy, tube additives, and order of draw.
- Discuss ways to detect and reduce preanalytical errors.

Laboratory testing comprises the majority of information in the electronic medical record [1,2]. Laboratory services accounted for 2.3% of health care expenditures in the United States with over 6.8 billion laboratory tests performed, with clinical pathology, anatomic pathology/cytology, and molecular/esoteric tests accounting for 66%, 23%, and 8% of performed tests respectively [3]. Hospital test volumes also grew by an average of 6% annually [3]. As the number of laboratory tests increases, the opportunity for errors that adversely affect patient care also increases. These errors can occur in any of the three phases of the total testing process: the preanalytic, analytic, or postanalytic phase (Fig. 1.1). An understanding of the sequence of events required for laboratory testing provides a foundation for assessing the likelihood of errors occurring at each step of the testing process.

This process begins as the clinician examines a patient and determines the need for a laboratory test. The correct test must be ordered, the patient must be prepared, and an appropriate sample must be collected. The sample is then transported to a laboratory, received, and processed for analysis. During analysis, the sample may be aliquoted, diluted, or subjected to subsequent testing before the final result can be verified for release. The clinician must then receive and interpret the result and decide on the appropriate treatment or follow-up and place the follow-up orders and instructions, and staff must schedule and carry out these orders for the patient.

Historically, quality initiatives have focused on the analytical phase of testing, and over the years, the number of errors attributed to this phase has decreased [4]. Interestingly, the majority of laboratory-related errors occur outside of the actual laboratory, either in the preanalytical or postanalytical phase. Recent studies report that approximately 46%–68% of all laboratory errors occur in the preanalytical phase [5,6].

Errors can occur during: (a) the ordering process, either through the clinician laboratory test order entry or when the order is manually transcribed; and (b) sample collection if a patient is not properly prepared or the sample is incorrectly labeled. Additional errors include: (c) specimen collection where specimens are either collected in the wrong type of tube with potentially interfering additives or if the tubes are collected in the wrong order; and (d) delays and/or inappropriate storage or handling during delivery of specimens to the laboratory. Finally, upon reaching the laboratory, testing accuracy is compromised if (e) samples are not adequately processed and stored for analysis.

Accurate laboratory test results demand high-quality specimens. Unfortunately, in most systems, the resources allocated for the pre- and postanalytical processes are not sufficient, as the importance of preanalytics is often overlooked. Many of the mistakes that are referred to as "laboratory errors" arise due to poor communication and action by others involved in the testing process or poorly designed processes that are outside of the laboratory's control. This chapter will focus on the most common sources of preanalytical variation and discuss some quality system processes for reducing the preanalytical errors. Understanding the causes of preanalytical errors coupled with proactive ongoing monitoring allows the laboratory to develop preventive measures to mitigate the risk of releasing inaccurate results.

Order entry

Errors in laboratory orders commonly occur due to the similarity of test names, improper use of synonyms,

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00001-6

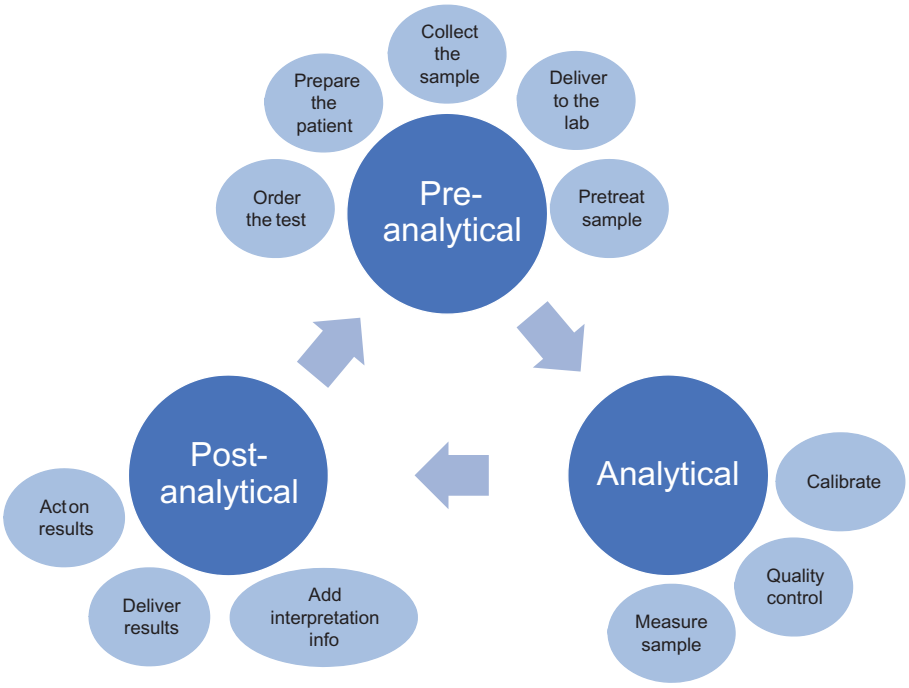

FIGURE 1.1 Steps in the testing process.

failure to enter orders correctly into the hospital electronic computer system, lack of knowledge about tests, and transcription errors (Table 1.1). Tests that are commonly misordered due to similar names are: (1) C-reactive protein for inflammation versus high-sensitivity C-reactive protein for cardiovascular risk assessment; (2) lipoprotein versus lipoprotein panel; (3) calculated versus direct low-density lipoprotein; and (4) 1,25-vitamin D (calcitriol) versus 25-vitamin D (calcidiol). Tests that also require supplementary clinical information often have high rates of errors. At our institution, in order to calculate a second trimester prenatal quad screen report, information such as the patient's date of birth, estimated due date, ethnicity, weight, diabetics, and smoking status must be provided by the clinician. Inaccurate reporting of such clinical data can lead to improper risk factors being calculated and subsequently reported.

Differences in methodology can also have implications for clinicians when they are trying to order a test. For example, testosterone can be measured accurately for most men by immunoassay, whereas women, children, and men with hypogonadism have lower testosterone concentrations and should therefore have testosterone measured by mass spectrometry. Ideally, a test name and description should be able to convey to the ordering provider if the test is appropriate for their patient. Further adding to these issues are the cases where orders are manually transcribed from written notes or requisitions, such as outpatient locations. These transcriptions are often performed in the specimen receiving section, where staff try to decode and/or determine what the clinician intended to order.

Redesigning the requisition and computer entry screens can greatly facilitate the order entry accuracy. In general, grouping common tests and liberal use of footnotes on written requisitions or pop-up screens for computer entry can enhance appropriate test selection by staff, but physicians begin to ignore these reminders due to information or alert fatigue. Expert systems and rules can check for duplicate orders and prevent common errors, like the addition of tests to an inappropriate tube type or collection of a specimen at an inappropriate time.

The key to improving the accuracy of test ordering is to implement a computer order entry system that requires physician ordering. This ensures that the correct physician and medical necessity are linked to each order for billing compliance. A physician order entry system also reduces the errors associated with verbal orders and manual transcription. Physicians often verbally dictate their test orders to residents and nursing staff who transcribe the tests onto written requisitions or computerized order entry systems. Staff may not be aware of the differences between specific tests or the effects of test methodology on results. Misunderstanding of a physician's request can also occur in the midst of a trauma or critical patient situation. A College of American Pathologists (CAP) Q-Probes study estimated that nearly 5% of physician requests were associated with one or more data entry errors [7]. At least 10% of the institutions surveyed had errors with one in five requisitions [7]. The study

TABLE 1.1 Sources of preanalytical variation.

Source of variation	Potential solution
Order entry	
Similar test names	Set up computer order entry screens with explanatory notes or pop-up screens
Duplicate orders	Construct expert systems and rules to detect duplicate orders
Transcription entry errors	Verify computer entry against written orders
Patient preparation	
Diet/supplements	Fast or restrict diet if necessary before testing Ask patients about supplements (e.g., biotin)
Time of collection	Proper collection for TDM and hormones Document drug administration accurately with respect to specimen collection
Specimen collection	
Patient identification	Verify the use of two identifiers
Needle size	Prevent hemolysis by routine smaller gauge needles
Tube selection/order of draw	Sign posted and smart laboratory labels
Prolonged use of tourniquet	Limit tourniquet use to 1 min
Fist clenching during phlebotomy	Encourage patients to rest arm during phlebotomy
Inadequate tube filling	Use vacuum collection tubes
Specimen clotting	Ensure tubes are more than 3/4 full during collection Mix tubes by gentle inversion immediately
Urine stability	Provide preservatives in collection container
Processing, transportation, and storage	
Outpatient clinic delayed processing	Provide equipment to process specimens on site
Exposure of tubes to environment	Protect and insulate specimens during transportation
Add-on testing	Validate and optimize storage stability for each analyte

concluded that verbal orders, high bed occupancy, and a failure to monitor the accuracy of order entry/having a policy to confirm correct order entry led to higher institutional error rates [7]. Accurate physician orders for laboratory testing are the first step in quality laboratory testing. Errors at the start of the laboratory test process can escalate to inappropriate specimen collection and the need to redraw a patient, leading to a delay in reporting test results and reaching a diagnosis, and subsequently delays implementing treatment.

Patient preparation

Once a correct order is placed, the patient must be prepared so that the results can be properly interpreted. Factors such as diet, exercise, medications, and time of collection (morning vs evening) can affect many laboratory tests. For some analytes, these effects are well-known—for example, ingestion of a meal will cause an increase in glucose and triglycerides, yielding values that are outside the fasting reference interval. For other analytes, the effects may not be recognized by physicians as significant contributors to result in variation, such as posture and exercise. A set of books by Donald Young is available that cites the basic scientific literature for general effects of drugs, disease, and preanalytical variables on clinical laboratory tests [8]. The manufacturer's package insert also describes the conditions and limitations for interpreting the result.

Catecholamines, epinephrine, and norepinephrine rise in response to smoking, exercise, stress, and ingestion of caffeine. In addition, cocoa is known to contain catechols that stimulate increases in catecholamines. Dietary restriction of chocolate- and caffeine-containing sodas, coffee, and tea is recommended for several days before the collection of 24-hour urine or plasma catecholamine specimens. Exercise can affect laboratory tests stimulating the release of catecholamines and other hormones, including β-endorphin, cortisol, glucagon, growth hormone (GH), and prolactin. Strenuous exercise works in muscles and can lead to increased levels of muscle enzymes, including creatinine kinase, creatinine, and aspartate aminotransferase (AST). Posture and moving from a recumbent to standing position cause shifts in fluid to the lower extremities and decrease plasma volume by ∼14% after 30 minutes. These fluid shifts concentrate on protein and lead to increases in serum osmolality, albumin, α_2-macroglobulin, transferrin, and total protein after 30 minutes of

standing. Protein-bound analytes, like calcium, also increase in proportion to the hemoconcentration produced by an upright position.

Timing of specimen collection is a further consideration and is particularly essential for therapeutic drug monitoring (TDM). Most therapeutic drug reference intervals or normal values are standardized to trough (predose) concentration for patients on an intermittent dosage regimen at steady state. The trough level is the lowest concentration of drug before the next dose. After consumption, drug levels will rise to a peak concentration and then slowly decrease as the drug is eliminated. The next dose repeats the rise and fall of drug concentration, as the drug is absorbed and eliminated. Collection of TDM specimens just before a dose will guarantee the trough concentration. Collection at other times will generate higher than expected levels that could be misinterpreted as too high or a possible overdose. Aminoglycoside antibiotics with concerns for both toxic side effects and minimal inhibitory concentrations to provide effective bacteriostatic and bactericidal activity may require both peak and trough levels for patient management. The peak concentration is generally considered to occur 30−60 minutes after completion of an intravenous (IV) dose of aminoglycoside antibiotics. Timing of peak specimens is therefore as critical as with trough specimens. Effective communication is required between the staff administering the medication and the phlebotomists collecting the specimen to ensure that an appropriate specimen is collected. Errors often occur when specimen collections are made with respect to when the drug is scheduled to be given rather than when the drug is actually administered. Good documentation, procedures, and communication can prevent such misunderstandings.

Most hormones have concentrations that vary throughout the day or month, and the reference ranges established for interpretation assume that the samples are collected at the proper time. Some hormones are released in a pulsatile manner and exhibit diurnal variation, with values that are higher in the morning and lower in the evening and overnight. In normal healthy patients, adrenocorticotropic hormone (ACTH) and cortisol concentrations are higher in the morning (between 04:00 and 12:00 hours) and have lower concentrations in the late evening and overnight. Iron also demonstrates diurnal variation with peaks between 08:00 and 16:00 hours and a nadir between 18:00 and 04:00 hours. Conversely, GH demonstrates a maximum peak 2 hours after the commencement of sleep. Follicle-stimulating hormone and luteinizing hormone have daytime peaks that are 15%−18% higher than nocturnal lows in women during the early follicular phase. These daily fluctuations are in addition to the wider variations seen during the follicular, midcycle, and luteal phases of the monthly menstrual cycle. Interpretation of the fertility hormone levels must be made with respect to the phase of the menstrual cycle and time of the day that the specimen is collected. Stress from illness and bed confinement can lead to increased cortisol, glucose, and insulin and decreased GH and thyroid-stimulating hormone. The collection of some laboratory tests, like glucose tolerance testing for the diagnosis of diabetes mellitus, should wait until the patient is discharged from the hospital. Patient preparation is an important consideration for guaranteeing a quality specimen and interpretable laboratory results.

Supplements can also affect laboratory results; in particular, biotin (also known as vitamin B7) supplement use has been increased, as biotin has recently been promoted for thickening hair, strengthening nails, and improving skin. Previously, high-dose biotin therapy was confined to patients with biotinidase deficiency, certain forms of alopecia, or multiple sclerosis. Many immunoassay manufacturers rely on biotin−streptavidin capture in their assays, and patients taking biotin may have a falsely increased result in competitive assays and a falsely low result in sandwich assays. The popularity of biotin supplementation has led to an increase in the reported cases of biotin interferences, increasing the potential for misdiagnoses [9]. Clinicians and patients should be aware that biotin can interfere with their test results and refrain from biotin supplements for approximately 1 week before obtaining laboratory testing on a platform that uses biotin−streptavidin capture. At the minimum, specimens should be collected at least 8 hours after the last dose of biotin, with the realization that residual biotin can affect some immunoassays.

Urine specimens can be affected by other factors. The concentration of analytes in urine is subject to renal function (ability of the body to eliminate the analyte) and the amount of water in the sample. Urine concentration is subject to hydration status, and urine is most concentrated in the morning and less concentrated as the subject is eating, drinking, and moving throughout the day. The concentration of an analyte like a drug may be less concentrated in the afternoon compared with the morning simply due to changes in urine water and the subject's hydration state. For this reason, many tests results are reported as ratios with respect to the concentration of creatinine that is eliminated relatively constantly based on the subject's renal function. Urine tests are also averaged over a 24-hour collection period to minimize further the effects of differences in a patient's hydration over the day. Collection of samples less than or greater than a 24-hour period of time can affect the daily average elimination estimates for urine tests.

Specimen collection

Once a physician order has been placed and the patient is appropriately prepared for the test, a proper specimen

must be collected at a suitable time. Patient identification is mandatory before any medical procedure including phlebotomy and laboratory testing. The Joint Commission has made patient identification one of its top patient safety goals, mandating the use of two unique identifiers to confirm positively the identity of a patient, such as the patient name in addition to the medical record number or another unique identifier [10]. Although it may appear to be easier to preprint labels before the time of collection, this practice is strongly discouraged. Preprinting labels will lead to samples with improper collection times and could lead to mislabeled samples, when one patient's label is applied to another patient's specimen. The former can lead to specimen rejection or result misinterpretation, whereas mislabeled samples can lead to a misdiagnosis. Given the severity of consequences from mixing up or mislabeling a laboratory specimen, the need to identify positively the patient cannot be overemphasized. Newer portable barcode systems are being deployed in hospitals, allowing the phlebotomist to scan a patient's wristband and print barcode labels at the bedside on demand. These systems are connected to the laboratory and hospital information systems and can stamp actual collection times and track specimens during transport and analysis in the laboratory.

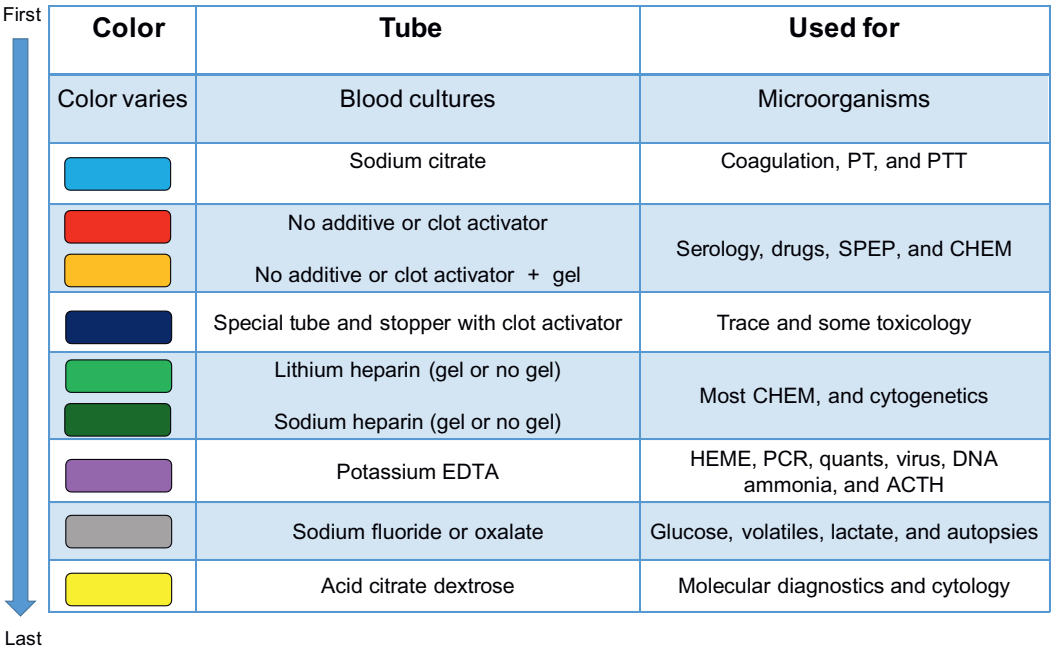
Tube type and order of draw

A number of tubes are available for specimen collection. Red-stopper tubes contain no additives or a clot activator, whereas other types of colored stoppers indicate the type of blood preservative or anticoagulant. Tubes are also available with a gel barrier that helps separate red blood cells from serum and plasma during centrifugation. Gel-barrier tubes provide the advantage of saving labor by allowing analysis directly from the collection tube. The primary tube can be centrifuged, analyzed, and stored without the need to aliquot the serum and plasma away from the cells. Chemistry analytes can be collected in red-top serum tubes, gold-top serum tubes (also known as serum-separator tubes), or green-top heparin preservative tubes for plasma analysis. Hematology specimens for cell counts require purple-top ethylenediaminetetraacetic acid (EDTA) preservative tubes, and coagulation specimens require blue-top citrate preservative tubes. Light-green, lithium heparin tubes are utilized for chemistry and electrolyte panels, while dark-green, sodium heparin tubes are utilized for drug analysis. The sodium content in the dark-green tubes will interfere with sodium analysis on chemistry and electrolyte panels of tests, while the lithium in the light-green tubes will interfere with lithium analysis. There are also special tubes for trace metals and toxicology (royal-blue top; manufactured to limit sample contamination with metals), blood culture (manufactured for sterility and microbiologic analysis), and glucose tolerance testing (gray top; manufactured with fluoride to inhibit glycolysis after sample collection). Drugs, proteins, lipids, and other analytes can bind to the gel barrier and may require red-top no-additive tubes without gel. Newer collection tubes contain plastic (ring-based) barriers and provide a physical separation of cells upon centrifugation, and use of plastic prevents drug and protein binding, unlike the gel-barrier tubes. A variety of different tube additives each pose specific test limitations, and this is one of the reasons why a universal anticoagulant tube has not been developed that is applicable to all tests. Whenever contemplating a change in the tube type or manufacturer, the laboratory should perform a thorough validation to determine the suitability of specimens received or stored in the laboratory before analysis.

The tube collection order used during phlebotomy can lead to further preanalytical errors. Phlebotomists are trained to collect blood culture and citrate tubes for coagulation measurements (light-blue top) first, followed by nonadditive serum (red-top) tubes. Heparin tubes (green), EDTA tubes (lavender), and other additive tubes are collected last (Fig. 1.2). Tubes should be collected in this order so that preservatives from the previous tube do not carry over to contaminate the next tube, as additive carryover can affect some laboratory tests [11]. For example, potassium EDTA binds divalent cations and alters coagulation results and analytes that require calcium and magnesium, such as potassium, calcium, and analytes such as AST, alanine aminotransferase, and alkaline phosphatase. Heparin can further carry over and impact coagulation testing if a heparin sample is collected prior to a sodium citrate tube. Correct order of draw can become a problem when blood draws are decentralized to nursing and clinical staff who may not be as familiar with the potential for laboratory interference from the tube-additive carryover.

Needle size, tourniquet use, and line collection

Appropriate selection of equipment is essential to the collection of a good specimen, specifically the size of the needle. Phlebotomy needles range from 18- to 23-gauge, with 25-gauge needles attached to butterfly-winged collection sets; smaller numbers indicate larger diameter needles. In general, the larger diameter 18-gauge needles are used for blood donor collection, and smaller 21- and 23-gauge needles are used for routine laboratory specimen collections. The smaller 25-gauge butterfly collection sets are reserved for difficult sticks from geriatric, cancer, and pediatric patients. Newer needles are manufactured with sheaths that cover or retract the needle after use to prevent accidental needlesticks. Needles also come in a variety of lengths depending on the depth of the vein to be punctured. Although smaller needles are less painful for the



Color	Tube	Used for
Color varies	Blood cultures	Microorganisms
	Sodium citrate	Coagulation, PT, and PTT
	No additive or clot activator No additive or clot activator + gel	Serology, drugs, SPEP, and CHEM
	Special tube and stopper with clot activator	Trace and some toxicology
	Lithium heparin (gel or no gel) Sodium heparin (gel or no gel)	Most CHEM, and cytogenetics
	Potassium EDTA	HEME, PCR, quants, virus, DNA ammonia, and ACTH
	Sodium fluoride or oxalate	Glucose, volatiles, lactate, and autopsies
	Acid citrate dextrose	Molecular diagnostics and cytology

FIGURE 1.2 Order of draw.

patient, they also increase the risk of sample hemolysis and the lysis of red blood cells in the sample, which could interfere with laboratory analysis. Smaller bore needles exert more shear stress on cells, leading to increased hemolysis. Phlebotomists must be alert during specimen collection, because small needles, difficult sticks, and a slow flow of blood can cause specimen hemolysis, which can lead to test interference depending on the analyte and may require recollection.

The prolonged use of a tourniquet can lead to hemoconcentration and pooling of blood. Use of a tourniquet for over 1–3 minutes can cause elevations in protein and albumin, calcium, potassium, and hemoglobin. It is recommended that phlebotomists should have everything in place prior to placing the tourniquet in order to minimize the time that the tourniquet is in place. Fist clenching during phlebotomy with a tourniquet in place can further lead to increases of 1.0–1.4 mmol/L in potassium levels.

Using collection tubes with a vacuum in the tube allows for the appropriate amount of blood to be collected, and manufacturers have designed collection systems to facilitate the collection of multiple tubes. Use of a syringe to collect blood that is then injected through the stoppers of multiple tubes can lead to specimen hemolysis, filling errors, cross-contamination, and loose stoppers that can leak during transportation to the laboratory. The use of a needle and a syringe to puncture the stopper should be strongly discouraged, as this practice is dangerous and poses a risk of needlestick injury. In addition, tubes containing additives must be thoroughly mixed after collection for the additive to be distributed; undermixing can lead to specimen clotting, whereas overmixing can induce hemolysis. Phlebotomists are encouraged to invert gently each tube 5–10 times after collection.

Additional problems can be encountered when collecting specimens through lines or catheters. The presence of an IV, arterial, or catheter line does offer staff easy access to the patient, but the practice of collecting specimens through lines and catheters should also be strongly discouraged due to the potential for contamination and dilution [12]. IV lines contain fluids that are being given to the patient and pose a risk of diluting a specimen that is being collected through a line or increasing the concentration if the analyte to be tested is contained in the IV fluid, such as sodium or glucose. Lines are meant to administer fluids to a patient and are not intended for specimen collection. Some newer catheters are made of a plastic material that is rigid for insertion but becomes pliable when the catheter reaches body temperature. This type of line is particularly problematic, because it is directional. Although fluids can be administered and the line stays open, drawing backward causes the line to collapse, making specimen collection difficult and increasing the risk of hemolysis. Heparin is used to flush and keep the access open on some catheters, particularly heparin locks with arterial access lines; however, heparin can interfere with other laboratory tests. It is understandable why clinical staff are hesitant to stick a patient with a line already inserted; however, discarding a small amount of blood as a line flush before collecting a specimen should be discouraged, as it does not guarantee that a proper sample

can be obtained. D25W (25 g of dextrose per 100 mL of solution), vancomycin, and several other large drugs and antibiotics tend to stick to lines and cannot be adequately flushed. Carryover of line fluid requires the laboratory to cancel the specimen and request for a recollection of the test, which both inconveniences the patient and delays the turnaround time for test results [13].

Staff training and periodic competency evaluation is suggested to ensure consistent specimen quality from all staff involved in specimen collection. Unfortunately, even with standardized training and periodic competency assessments, staff can continue to make errors during specimen collection. Our laboratory, for instance, has experienced several cases where staff collected one tube and, after phlebotomy, realized that they needed a different tube, resulting in one tube being poured into a tube with another additive. In another instance, a microtainer was inadvertently collected in a purple-top EDTA additive tube. When the staff realized they needed a gel-barrier tube, they opened the cap and inserted the purple-top EDTA microtainer into a gel-barrier serum tube and sent it to the laboratory. These staff did not realize that the tubes contained different additives that could affect the test results (Fig. 1.3). We even had two recent cases where a specimen was received and centrifuged, and the red blood cells were delivered to the technologist instead of plasma. Even with adequate training, staff should have regular retraining and constant reminders of the proper procedure to follow.

There are some technologies available to ensure staff collect the correct tube from the correct patient in the proper order and thus reduce phlebotomy-associated errors. Several companies now distribute portable personal data-assistant devices that can upload a list of patients requiring phlebotomy. The devices contain a barcode scanner, so staff can scan their identifications to access the software and access the lists of patients to collect. Each phlebotomist's identification is then linked to the specimen collection event and tubes collected at that time. This provides a tracking mechanism required for laboratory accreditation and troubleshooting phlebotomy errors. After staff positively identifies the patient with two unique identifiers, the device can scan a patient wristband, and the patient's name will appear (as additional verification of identification) with a list of laboratory tests pending, tubes to be collected, and proper order of draw. As each tube is collected, staff can scan the tube and a label is printed at the bedside, reducing the possibility of mislabeling and capturing the exact time of specimen collection. After the tubes for a patient have been collected, the device can be downloaded to a laboratory information system, which captures the collection information and acts as a tracking mechanism for the transportation of the specimens to the laboratory. Manufacturers even offer wireless versions of these collection devices. Implementation of these systems has reduced phlebotomy and labeling errors and has the potential to reduce specimen recollections and delays in result turnaround time.

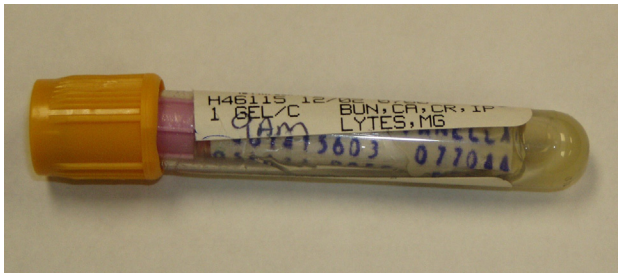


FIGURE 1.3 Inadvertent specimen collection: a purple-top EDTA microcontainer was collected from a patient. After phlebotomy, staff realized they needed to collect a gel-barrier tube instead; therefore they pushed the purple-top microcontainer into the large gel-barrier tube and sent it to the laboratory. The staff did not understand when they were called to cancel the specimen, claiming that the specimen was in a gel tube.

Processing and transportation

After collection, specimens should be transported to a laboratory, processed, and analyzed as soon as possible as delays can compromise the results. Glucose, for instance, decreases at a rate of 5%−7% per hour in whole blood at room temperature [14]. Glycolysis will continue until the specimen is processed by centrifugation, and serum and plasma are separated from the cellular components of blood. Patients with increased white blood cell counts have a higher number of cells and greater metabolic demand, so glycolysis in their whole blood will be faster than that in specimens from normal patients.

Other analytes are unstable in unprocessed blood or when stored at room temperature instead of refrigerator or freezer temperatures. Specimens need to be processed by centrifugation as soon as possible after collection (for plasma) or specimen clotting (for serum). For most chemistry analytes, laboratories should seek to process blood by centrifugation within 30−60 minutes of collection, with serum and plasma aliquoted (for tubes without gel barriers) and stored refrigerated until analysis. Ammonia, however, is an unstable analyte, and increases beyond the total allowable error limit can be seen after just 30 minutes at room temperature. Samples are recommended to be chilled, transported on ice, centrifuged within 15 minutes of collection, aliquoted off the cells, and plasma analyzed within 90 minutes to 2 hours when stored refrigerated. Care must be taken to centrifuge specimens only once, as recentrifugation can release cellular components like potassium and lactate dehydrogenase, and the plasma sample should remain undisturbed and vertical after centrifugation. Remixing plasma gel samples after

centrifugation has been recently shown to cause falsely increased values of 25-vitamin D on some assays due to resuspension of cells and platelets [15]. For this reason, a proper technique when processing plasma samples is essential; all samples should be aliquoted and not poured over so that cell debris and particulate matter do not enter the sample and compromise the results. This can be an issue with pediatric samples collected in microcontainers, where well-meaning staff members are so concerned that a sample will be canceled for insufficient volume that they will invert the tube and tap to ensure that every last drop is aliquoted, carrying debris and particulates that float above the separator after centrifugation. This cellular debris can interfere with chemistries as well as immunoassays on automated instrumentation.

Many hospitals rely on automated processes to transport samples to the laboratory, such as pneumatic tube systems that connect the laboratory processing areas directly to the inpatient medical units. For outpatient testing, clinics and phlebotomy stations should be provided with centrifuges and equipment to process the specimens on site before transportation to the core laboratory by courier in order to minimize sample instability. For example, if glucose is not appropriately processed at an outpatient collection facility, glucose values will continue to decrease and the result reported may be (falsely) critically low.

There are other laboratory tests that require special handling, processing, and storage. Hematology testing is performed on whole blood samples and thus these do not require centrifugation, but must be well mixed before analysis by automated cell counting systems. Hematology samples also must be protected from freezing that could result in hemolysis. Samples for metanephrines, on the other hand, require prompt centrifugation and freezing of serum and plasma to maintain stability. Additional attention may be needed to protect samples for bilirubin analysis from light during transportation, processing, and storage. Ammonia and hormones such as ACTH, gastrin, and calcitonin are unstable and must either be tested or frozen immediately. For urine specimens, there are a variety of preservatives available, depending on the stability of the analyte. Some urine preservatives are acceptable to add to the sample within 2 hours of the completion of a 24-hour or random urine collection, whereas other preservatives must be added before sample collection to prevent microorganism growth, prevent ion precipitation, or to preserve the sample for urine culture. The optimal preservative will depend on the laboratory's analytical methodology and recommendations for one laboratory may not be acceptable to another laboratory due to differences in analysis.

Special consideration and equipment may need to be made for collection, processing, and transportation of laboratory samples at outpatient locations. Clinics may need to have centrifuges, freezer capabilities, refrigerators, and storage space for preservatives, collection containers, and phlebotomy supplies. In the summer, samples may need to be transported in coolers with ice packs to maintain constant temperature and protect from overheating, whereas in the winter, samples may need to be transported in coolers (without ice or cold packs) to protect samples from freezing temperatures. Delays in processing or transportation can also further compromise the specimen and analyte stability [16].

Laboratories must also arrange for appropriate storage of specimens after analysis. Clinicians frequently add - on tests after the initial orders have been completed. Most chemistry samples can be stored for 7 days when refrigerated, allowing for specimen retrieval when additional testing is ordered; however, adequate storage space is necessary. Stored specimens are also useful to troubleshoot questionable results and for legal documentation, as the samples can be retrieved and analysis repeated when necessary.

Detecting preanalytical errors

Although phlebotomist training, prompt processing, and transportation to the laboratory are the first line of defense for preventing preanalytical errors, the laboratory must also create quality systems to inspect routinely specimens for common preanalytical errors. One obvious error is collecting a specimen in the wrong type of tube. If a potassium ethylenediaminetetraacetic acid (K_2EDTA) (purple-top) hematology specimen is sent to chemistry for an electrolyte or potassium order, the laboratory can recognize that the wrong type of tube was collected and can contact the ordering physician, cancel the specimen, and request a recollection in the correct tube type. An issue that cannot be detected prior to analysis is the scenario where a clinic mistakenly collects the K_2EDTA specimen, processes the specimen, and sends a plasma aliquot for electrolyte analysis but labels it as a serum specimen. This type of error will be detected only after analysis, and only if upon review of the results, a technologist realizes that the potassium level has increased into the critical and nonphysiologic range. Fortunately, laboratory information system rules can also be set up to flag erroneous results, such as test results that are nonphysiologic or unable to support life, results that are in a life-threatening critical range either high or low (critical error flags), or results that differ significantly from previous results (delta checks). Erroneous and critical result flags should call attention to potential preanalytical issues with sample contamination from inappropriate tube additives, dilution with IV fluid, and specimen clots or other sources of preanalytic error. The delta check flag calls attention to test

results that differ from a previous result by more than a predetermined limit. Delta checks help in the detection of preanalytical errors, such as mislabeled specimens, but are limited to patients who have a history of previous results for comparison.

The presence of specimen interference is another common source of error. Some interferences may be metabolic (increased urea) or disease-related (increased bilirubin), whereas other interferences may be the consequence of failing to prepare the patient (lipemia and nonfasting samples), a difficult phlebotomy (hemolyzed red blood cells), or administration of certain therapies (drugs or monoclonal antibodies) or supplements (vitamin B7 or biotin). Serum indices are a spectrophotometric estimate of specimen interference from icterus (presence of bilirubin), lipemia (lipids and chylomicrons), or hemolysis (hemoglobin in serum). The presence of significant interference used to be handled by the visual inspection of the sample, and technologists traditionally handled each specimen and appended a note to those results that might be affected by apparent interference, yet this method is highly subjective. Today, although fewer specimens are handled directly, a quantitative estimate of icterus, lipemia, and hemolysis can be measured with every patient specimen on high-volume automated chemistry analyzers. This measurement is based on the ratio of sample absorbance at various wavelengths multiplied by a correction factor (Fig. 1.4). Manufacturers publish acceptance thresholds for icterus, lipemia, and hemolysis that will cause clinically significant interference for tests in the method's package insert; however, it is strongly recommended that laboratories verify the manufacturer's recommendations by constructing their own interference curves or matrices.

Serum interference curves can be constructed by performing an experiment outlined in the Clinical Laboratory Standards Institute (CLSI) EP07 protocol for dose response testing [17]. A series of test samples, systematically varying only in the concentration of interferent, is prepared by making quantitative mixtures of two pools, one at the highest concentration of the interferent to be tested, and the other at the lowest [17]. Alternatively, varying amounts of interferent can be spiked into a sample pool to create a set of samples with the same analyte concentration but varying amounts of interferent. Creation of a sample set requires that each sample be spiked with the same volume of the interferent, so there is no dilutional difference between the individual samples, and the total volume added is only a small proportion (ideally $<10\%$) of the sample so that the sample matrix is not significantly altered. All samples are analyzed in one analytical run, and the results are graphed to determine the level of interferent required to cause significant bias or shifts in the true test results. If there is no interference, all samples will generate the same test result within assay precision. Interference is characterized by a difference in results from baseline (zero interferent sample) with samples containing increasingly higher concentrations of interferent. Interferences can be positively or negatively biased, generating higher or lower results in proportion to the amount of interferent (Fig. 1.5). Tables can then be constructed to summarize the interference cutoffs or limits

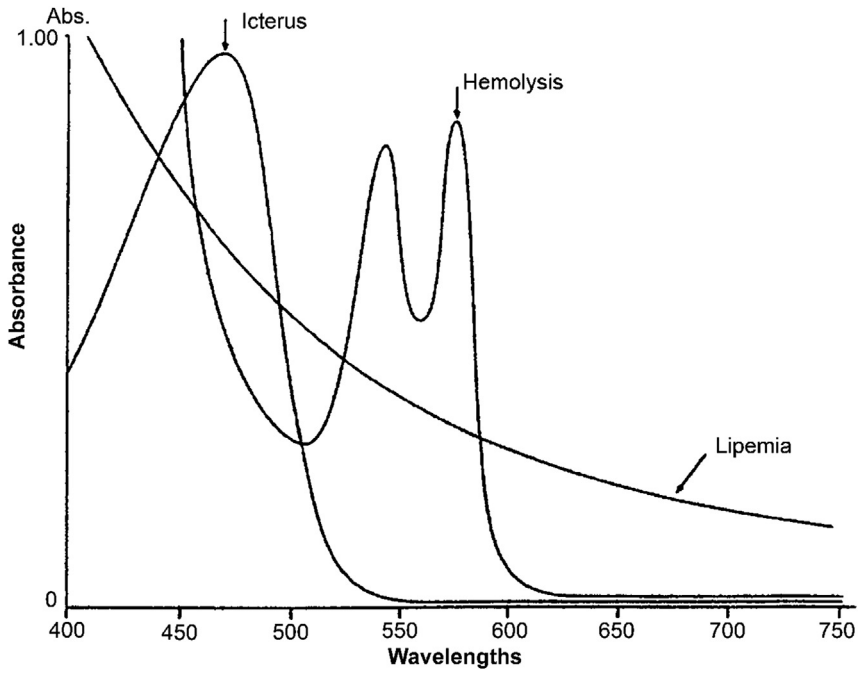

FIGURE 1.4 Serum indices. Interference in a serum or plasma specimen can be determined spectrophotometrically by a ratio of wavelengths and a correction factor that links absorbance to the intensity of interference. *Reproduced with permission from Clinical Chemistry Learning Guide Series, Abbott Diagnostics (2017).*

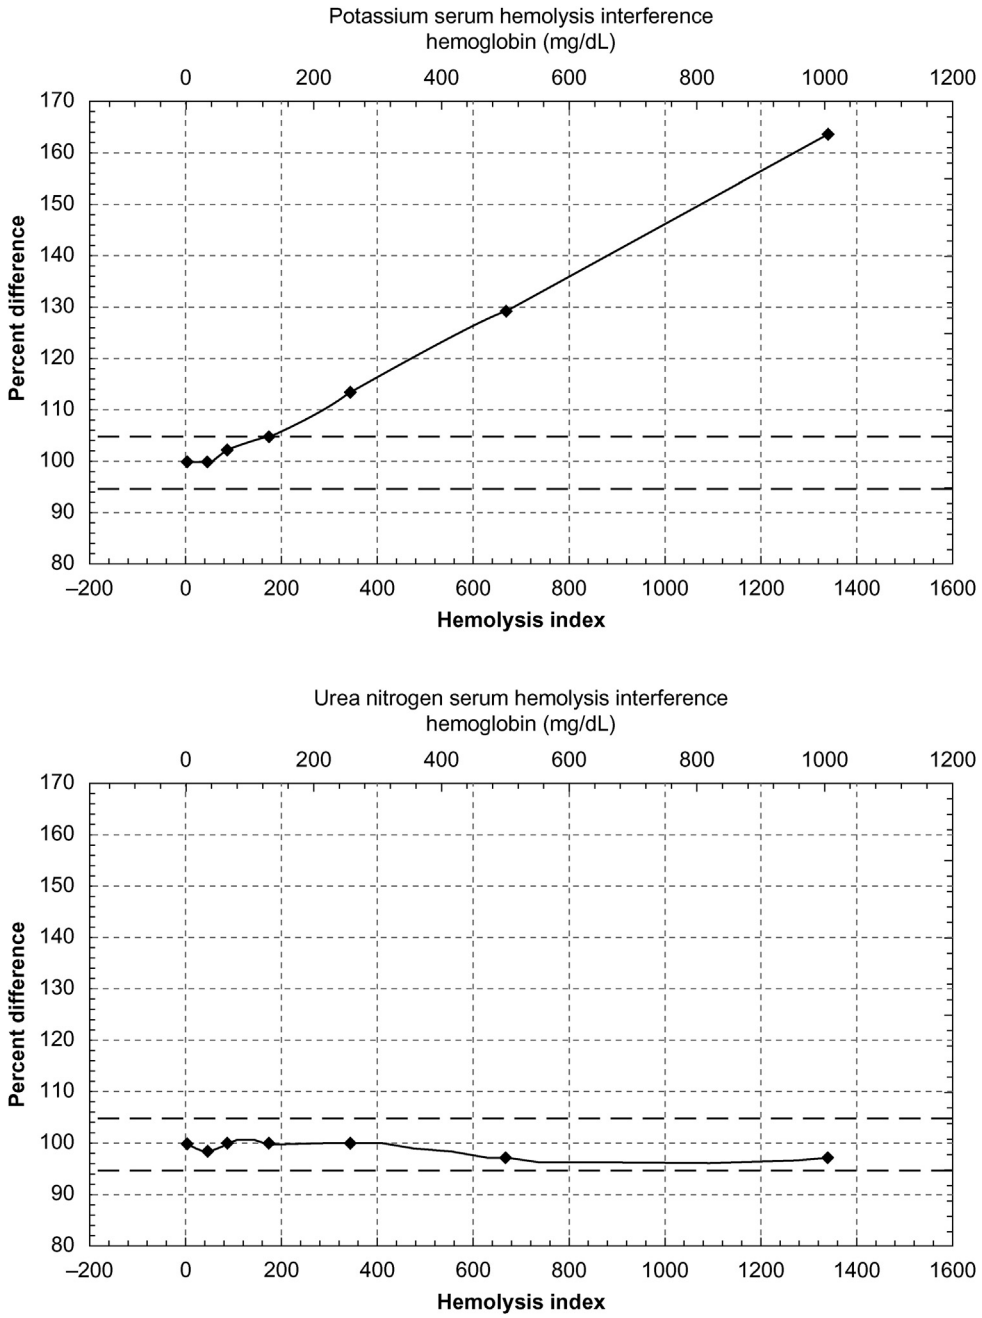

FIGURE 1.5 Serum interference curves. Hemolysis interference curves for potassium and urea nitrogen in serum. Hemoglobin (mg/dL) *(upper x-axis)* is the amount of hemoglobin spiked into a serum sample pool, whereas the hemolysis index *(lower x-axis)* is a spectrophotometric estimation of interference level (color intensity) from an automated chemistry analyzer. Dashed lines indicate our laboratory's tolerance limits for clinical significance as a percentage of difference from a sample with no interferent (e.g., 5% for potassium and urea nitrogen).

for each analyte (Table 1.2). For patient specimens, the serum indices can be compared with the predefined interference limits to determine whether the level of interference is clinically significant. The ability to conduct quantitative serum indices on every sample has removed the historical subjectivity from technologists visually estimating specimen quality. Serum indices add to critical values, delta checks, and other flags that can detect potential specimen issues.

Unfortunately, there are few ways to detect reliably the metabolic or drug interferences unless the interferent is colored or the interference generates an error during analysis. Sometimes, these errors can be detected by delta checks if the drug or the metabolite changed, since a recent test was conducted and the interference is significant. In other instances, a clinician may call the laboratory and indicate that the test result does not match the patient's clinical symptoms. Establishing and maintaining a good relationship with clinicians are important factors to establishing a quality laboratory service. The laboratory relies on clinicians to raise issues and provide feedback and is best served when clinicians question unusual

TABLE 1.2 Serum interference tables.

Icterus interference					
Test	**Limit I index**	**Laboratory tolerance (%)**	**Direction**	**Manufacturer index limit**	**CAP limit (%)**
Urea	29	<5	↓	60	± 9%
Potassium	53	<5	↔	Not significant	± 0.5
Cholesterol	15	<3	↓	25	± 10%
Glucose	15	<5	↓	60	± 10%
Lipemia interference					
Test	**Limit L index**	**Laboratory tolerance (%)**	**Direction**	**Manufacturer index limit**	**CAP limit (%)**
Urea	1119	<5	↔	1000	± 9%
Potassium	1119	<5	↔	Not significant	± 0.5
Cholesterol	1119	<3	↔	1250	± 10%
Glucose	1119	<5	↔	1000	± 10%
Hemolysis interference					
Test	**Limit H index**	**Laboratory tolerance (%)**	**Direction**	**Manufacturer index limit**	**CAP limit (%)**
Urea	1337	<5	↔	1000	± 9%
Potassium	175	< 5	↑	At all levels	± 0.5
Cholesterol	670	<3	↔	700	± 10%
Glucose	670	<5	↓	1000	± 10%

Index limits (icterus, lipemia, and hemolysis) for the selected analytes indicate our laboratory's tolerance for clinical significance (percentage of bias from a sample with no interferent). Manufacturer limits (from package insert) and CAP proficiency survey tolerance recommendations are shown for comparison. Interferences noted are only an example and not a representative of a specific manufacturer or instrument model. Direction of interference is included: ↔, no change; ↑, positive interference and high bias; ↓, negative interference and low bias. *CAP*, College of American Pathologist.

results, discuss them with the laboratory, and work together to resolve the source of the problem. Manufacturer's package inserts are vital sources of information when results are questioned, and most package inserts indicate the levels of drugs, metabolites, icterus, lipemia, or hemolysis that can cause significant interference. Stored specimens are an additional resource when investigating potential interferences, since stored specimens can be retested by the same methodology or sent to another laboratory for analysis by a different methodology if necessary.

Summary

Preanalytical variation is an important source of laboratory errors. The laboratory is responsible not only for the analysis of a specimen but also for ensuring control over preanalytical, analytical, and postanalytical processes to guarantee quality results for patient care. Understanding the sources of preanalytical variation and taking steps to minimize potential for errors before the specimen arrives in the laboratory are efforts that can reduce the need for specimen recollections, minimize delays in the turnaround time of test results, eliminate unnecessary medical follow-ups, and facilitate improved patient outcomes. Some preanalytical interferences such as icterus, lipemia, or hemolysis can be detected by the laboratory, preventing results from being released and warning clinicians of the potential for interference; unfortunately, other errors and interferences may not be easily detected. Too often, not enough attention is placed on minimizing the causes of preanalytical errors. Preanalytical errors can be decreased by having trained phlebotomists conduct blood draws, assuring that samples are transported to the laboratory in a timely fashion, having a well-trained specimen processing and receiving staff, and by maintaining a close working relationship between the laboratory and the information technology staff. The laboratory is an integral part of the health care team, and teamwork is required to ensure the integrity of specimen results from patient order through specimen collection, analysis, interpretation, and implementation of patient treatment. Preanalytical variation

is a significant component of the laboratory testing process and everyone, from clinicians to medical directors to nurses to laboratory staff, must be aware of the potential for error and work together to guarantee quality results. As the volume and complexity of testing increases, the laboratory and clinicians should foster a solid partnership to ensure appropriate test selection, interpretation, and use of the laboratory.

Self-assessment questions

1. Which of the following contribute to preanalytical variation?
   - **a.** biologic variation
   - **b.** sample collection errors
   - **c.** delays in processing
   - **d.** all of the above
2. When do most errors in laboratory testing occur?
   - **a.** while ordering the correct test
   - **b.** before the sample arrives in the lab
   - **c.** during specimen analysis
   - **d.** during physician interpretation
3. CAP estimates what percentage of physician requests are associated with errors in data entry?
   - **a.** 5%
   - **b.** 10%
   - **c.** 20%
   - **d.** 25%
4. What can be done to enhance staff efficiency and ensure specimens are collected at the right time?
   - **a.** Preprint sufficient labels to allow staff to collect multiple patients during a phlebotomy round.
   - **b.** Use coat pockets to store supplies and collected tubes between the patients.
   - **c.** Communicate with staff and check medical record documentation prior to collecting specimens.
   - **d.** Ensure specimens are collected only when it is convenient for the patient.
5. Which of the following are possible resources for information on laboratory interference?
   - **a.** *Physician's Desk Reference* with drug inserts on prescription medications
   - **b.** Dr. Young's books on laboratory test effects
   - **c.** manufacturers
   - **d.** all of the above
6. Which of the following are possible sources of preanalytical variation?
   - **a.** season of the year
   - **b.** working in the night shift
   - **c.** sunlight
   - **d.** all of the above
7. Prolonged use of the tourniquet can lead to increases in which analyte?
   - **a.** calcium
   - **b.** digoxin
   - **c.** phosphate
   - **d.** triglycerides
8. Which of the following is most a concern for preanalytical variation?
   - **a.** collecting a specimen through an IV line
   - **b.** inadequate filling of the collection tube
   - **c.** patient identification
   - **d.** all of the above
9. Why are newer PDA technologies for phlebotomy collection an advantage?
   - **a.** to save time
   - **b.** to provide positive patient identification
   - **c.** to track the phlebotomist and specimen
   - **d.** all of the above
10. Which of the following tubes will clot?
    - **a.** green-top heparin
    - **b.** lavender-top EDTA
    - **c.** red-top activator
    - **d.** gray-top fluoride/oxalate
    - **e.** light-blue top citrate
11. What is hemolysis?
    - **a.** breakdown of red blood cells
    - **b.** a yellow by-product of hemoglobin breakdown
    - **c.** high triglycerides that make the sample turbid
    - **d.** an assay interference from radiopaque dye
    - **e.** a and b

Chapter 2

Statistical methods in laboratory medicine

Daniel T. Holmes

Department of Pathology and Laboratory Medicine, University of British Columbia, Vancouver, BC, Canada

Learning objectives

After reviewing this chapter, the reader should be able to:

- Understand and apply descriptive statistical analyses and visualizations to a laboratory medicine data set.
- Describe how to determine if a data set is significantly different from the normal distribution.
- Understand the application of statistical tests of central tendency.
- Explain the differences between different linear regression methodologies.
- Discuss how to numerically evaluate diagnostic test performance.

Introduction

The purpose of this chapter is to introduce the major statistical concepts and tools required for clinical practice. This is not a resource as used in undergraduate statistics courses. There are no derivations or proofs and few explanations on how to perform statistical calculations by hand. There are many free resources and textbooks that do an excellent job of this. Rather, this chapter is intended to highlight important content and key conceptual notions. However, in the modern era, it is impossible to divorce statistical analysis from a software tool, and it is therefore necessary to pick a representative tool to accompany this chapter. Traditionally, this would have been the pervasively installed spreadsheet software. However, spreadsheet programs do not have the specialized statistical tools required for clinical practice. For this reason, I have elected to use the R statistical programming language to perform the calculations demonstrated. This does not mean that this chapter will introduce the R language, as there are many online texts [1,2] and open-learning resources [3] for this. Rather, by showing example R code, the student will be able to see that, in a few lines, a great deal can be accomplished and it is my hope to inspire readers to learn R for use in their clinical practice.

Basic descriptive statistical analysis

Consider a data set taken from the Intersalt study [4], where diastolic blood pressure (BP) and 24-hour urine sodium excretion were collected on individuals from several countries.

The data set happens to have 52 entries, but only the first 10 are displayed in Table 2.1.

Central tendency and dispersion

In lab medicine, we need to be able to calculate the mean, standard deviation (SD), median, interquartile range (IQR), and selected quantiles (usually expressed as percentiles).

TABLE 2.1 Representative data from the Intersalt study.

Diastolic pressure (mm Hg)	Sodium excretion (mmol/day)	Country
72.0	149.3	Argentina
78.2	133.0	Belgium
73.9	142.6	Belgium
61.7	5.8	Brazil
61.4	0.2	Brazil
73.4	148.9	Canada
79.2	184.3	Canada
66.6	194.1	Colombia
82.1	135.6	Denmark
75.0	138.7	East Germany

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00002-8

Mean

The mean of x, denoted $\bar{x}$, is calculated by:

$$\bar{x} = \frac{\sum_{i=1}^{n} x_i}{n} \tag{2.1}$$

that is, "add up all values of x and divide by the total number of values." The problem with expressing results as a mean is that the mean is strongly affected by outlier results. By way of example, turnaround times for lab tests should not be expressed by using the mean, because there are often problematic individual samples with very large turnaround times.

In R, the mean of the BP results can be calculated by reading the data, and by using the `mean()` function:

```
# Any text preceded by a "hastag" (#) is ignored by R and serves
# an informational comment.
library(DAAG) #load the package that contains the dataset
data(intersalt) #load the intersalt data
mean(intersalt$bp) #calculate the average blood pressure
```

```
## [1] 73.15192
```

The R output, shown here (and throughout this chapter) preceded by ## marks, shows us that the mean diastolic BP is 73.2 mmHg.

Median

The median is the middle value of the data set. That is, if we order the whole data set from lowest to highest values, the middle value, calculated as the $\left(\frac{n+1}{2}\right)^{\text{th}}$ entry, is the median. However, we encounter a problem when there are an even number of data points, because there is no middle value. In this circumstance, the median is given by the average of the two middlemost values. Our Intersalt data set has 52 values, so, if we sort the BP values and calculate $\left(\frac{n+1}{2}\right)$, we get the number 26.5, which is to say that the median lies halfway between the 26th and 27th values.

We can do this out the long way:

```
sort(intersalt$bp) #display the raw data sorted
```

```
##  [1] 61.4 61.7 62.9 66.1 66.6 67.2 67.4 67.9 68.0 68.4 69.9 70.0 70.2 70.7 71.2
## [16] 71.4 71.7 72.0 72.1 72.4 72.4 72.6 72.7 72.9 73.1 73.1 73.2 73.4 73.5 73.9
## [31] 73.9 74.7 75.0 75.2 75.5 75.6 75.7 76.0 76.2 77.2 77.4 77.5 77.9 78.2 78.2
## [46] 78.5 79.2 79.2 79.6 79.7 81.4 82.1
```

From the data, we can see that the 26th and 27th data points are 73.1 and 73.2, respectively. Therefore the median is 73.15. In the R language, this can be accomplished with the `median()` function:

```
median(intersalt$bp)
```

```
## [1] 73.15
```

Standard deviation, interquartile range, and quantiles

The SD is the square root of the mean square deviation of the results and is a measure of the dispersion of the data. Readers are no doubt aware that the SD has predictable meaning in normally distributed data sets (a concept to be discussed). The SD is defined as:

$$\sigma_x = \sqrt{\frac{\sum_{i=1}^{n} (x_i - \bar{x})^2}{n}} \tag{2.2}$$

where $\bar{x}$ is the mean value of x. Most textbooks quote the formula with $n-1$ in the denominator, which makes the result an unbiased estimate of the SD, accounting for limitations associated with finite data sets. It is therefore preferential to use the following:

$$\sigma_x = \sqrt{\frac{\sum_{i=1}^{n} (x_i - \bar{x})^2}{n-1}}. \tag{2.3}$$

In the R language, the SD function is `sd()`, and the calculation is achieved as follows:

```
sd(intersalt$bp)
```

```
## [1] 4.786562
```

Quantiles and the interquartile range

Quantiles are a way of expressing how the data are distributed. The quantiles of the variable x are any set of intervals of x that define bins with an equal number of counts. The reader is likely familiar with the concept of percentiles, bins that each contain 1% of the data. Another common approach is the quartile, where there are four intervals of x to define bins containing 25% of the data.

Because the SD does not provide predictably interpretable information for non-Gaussian distributions, when the distribution has skewness or excess kurtosis, the IQR is frequently provided as an alternative. The IQR is the difference between the 75th percentile and the 25th percentile, thereby defining a range of x encompassing the central 50% of the distribution, not necessarily centered about the mean and median of the distribution.

In the R language, the IQR is determined by using the `IQR()` function:

```
IQR(intersalt$bp)
```

```
## [1] 5.875
```

However, if there is a desire to calculate a specific quantile, this can be achieved with the `quantile()` function. There are a number of strategies for inferring the quantiles of a distribution, and R implements nine of them, any one of which can be specified if desired. The simple strategy of linear interpolation, recommended by the Clinical Laboratory Standards Institute (CLSI) Document EP28-A3C [5], is available, but not as default.

The following R code calculates estimates of the 10th, 25th, 50th, 75th, and 90th percentiles of the BPs of the Intersalt study.

```
quantile(intersalt$bp, probs = c(0.1, 0.25, 0.5, 0.75, 0.9))
```

```
##    10%    25%    50%    75%    90%
## 67.220 70.575 73.150 76.450 79.130
```

To specify the linear interpolation strategy recommended by the CLSI, the `type` parameter can be set to 6.

```
quantile(intersalt$bp, probs = c(0.1, 0.25, 0.5, 0.75, 0.9), type = 6)
```

```
##    10%    25%    50%    75%    90%
## 66.780 70.325 73.150 76.950 79.200
```

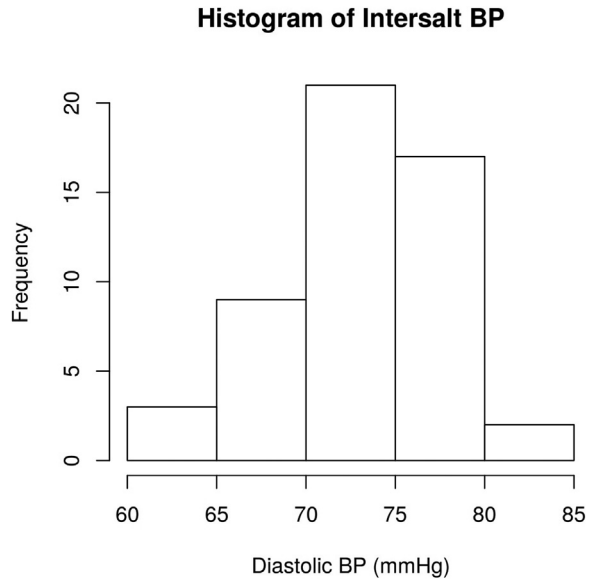

FIGURE 2.1 A histogram of the Intersalt diastolic blood pressure data.

The CLSI strategy can also be accomplished by hand by: (1) sorting the results; (2) calculating the rank of the desired quantile estimate by multiplying it by $(n + 1)$, where n is the number of observations; and (3) interpolating the desired quantile estimate from the value found from step (2).

For example, if the 95th percentile is desired and there are 52 observations, then the rank of the 95th percentile is $0.95 \times 53 = 50.35$. This means that the sample with the 50.35th rank represents the 95th percentile estimate. That is, we must interpolate a value that is 0.35 (i.e., 35%) of the way between the 50th and 51st results (taken from the list shown above) as follows:

$$79.7 + 0.35 \times (81.4 - 79.7) = 80.295.$$

If one wants to find the reference interval of a population of putatively normal values, this can be accomplished with the `quantile()` function. There is no reason (beyond compliance) to believe that the CLSI-recommended method (type = 6) is the best in all circumstances, but, in most cases, all the R methods will perform similarly.

Is my data normally distributed?

Many of the decisions we make in clinical laboratory medicine are predicated on whether the data are significantly different from the normal distribution. Most students assume that, if a histogram looks like a "bell curve," this is sufficient evidence of normality. It is not. However, if the distribution is highly skewed, then it is certainly evidence that the data are *not* normally distributed.

There are a number of simple tests to answer the question, "Is my data's distribution significantly different from the normal distribution?"

Make a histogram

The first approach is to prepare a histogram. In the R language, this is achieved with the `hist()` command (see Fig. 2.1):

```
hist(intersalt$bp,
     xlab = "Diastolic BP (mmHg)", # provide x-axis label
     main = "Histogram of Intersalt BP") # provide y-axis label
```

Prepare a normal QQ plot

The normal quantile−quantile (QQ) plot is a rapid and effective manner of gauging the normality of a distribution. The plot compares the empirical quantiles of a sampled distribution with the corresponding theoretical quantiles of the normal distribution. The closer the normal QQ plot is to the line of identity, the better the assumption of normality becomes. It is very easy to prepare in the R language, as there is function `qqnorm()` dedicated to generating it (see Fig. 2.2)

```
qqnorm(intersalt$bp)
qqline(intersalt$bp) # adds the line of identity
```

In this case, the left tail shows larger deviation from normality than the right, but the relative straightness of the normal QQ plot gives confidence that a normal assumption is reasonable.

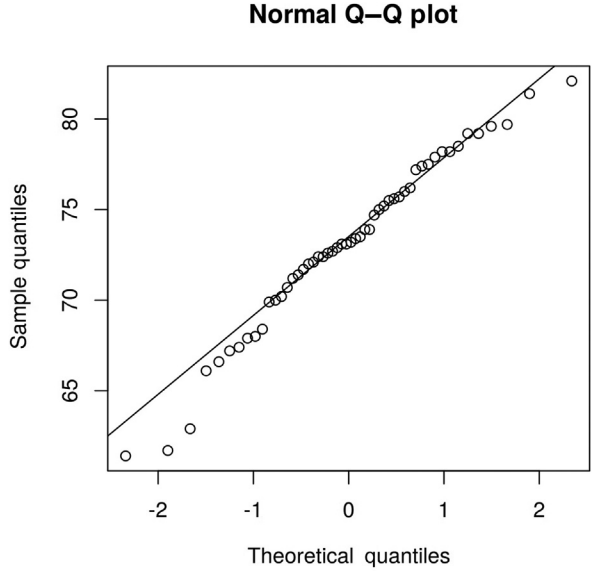

FIGURE 2.2 A normal quantile−quantile plot.

Calculate the skewness and kurtosis

The skewness is a numerical measure of a distribution's asymmetry, either leftward or rightward. A distribution is said to have a negative skew when the left tail is longer and a positive skew when the right tail is longer.

Skewness is calculated from the ratio of the "third moment" of the distribution, denoted m_3, to the cube of the SD, s, as follows: (Fig. 2.3)

$$\text{Skewness} = \frac{m_3}{s^3} = \frac{\frac{1}{n}\sum_{i=1}^{n}(x_i-\bar{x})^3}{\left[\sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(x_i-\bar{x})^2}\right]^3} = \frac{\frac{1}{n}\sum_{i=1}^{n}(x_i-\bar{x})^3}{\left[\frac{1}{n-1}\sum_{i=1}^{n}(x_i-\bar{x})^2\right]^{3/2}}. \quad (2.4)$$

The skewness of a normal distribution is 0. Interpretation of skewness is somewhat arbitrary, but rules of thumb are applied as follows:

- If the absolute value of the skewness is <0.5, it is considered mildly skewed.
- If the absolute value of the skewness is ≥ 0.5 and is <1, it is considered moderately skewed.
- If the absolute value of the skewness is ≥ 1, it is considered highly skewed.

We do not need to go to the trouble of using Eq. (2.4) to calculate the skewness unless we feel so determined. The calculation (including confidence intervals) is built into the R language's DescTools package and can be called as follows:

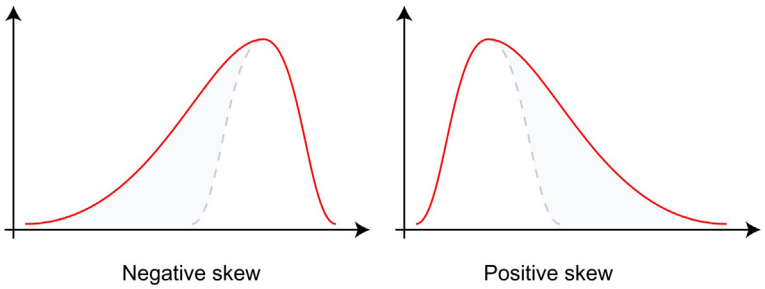

FIGURE 2.3 Negative (*left*) skew and positive (*right*) skew.

```
library(DescTools)
Skew(intersalt$bp, conf.level = 0.95)
```

```
##         skew       lwr.ci       upr.ci
## -0.46010230 -0.92059805 -0.01591163
```

Our result of −0.46 indicates only mild negative (leftward) skewing.

Kurtosis is a numerical measure of the tailedness of a distribution. It is calculated in an analogous fashion to that of Eq. (2.4) but using the ratio of the distribution's *fourth* moment to the *fourth* power of the SD. Strictly speaking, the normal distribution has a kurtosis of 3, but, for simplicity, the kurtosis is often reported as the "excess kurtosis," which is the raw value minus 3. This causes the excess kurtosis of the normal distribution to be 0, the excess kurtosis of "leptokurtic" (tall, slender, and pointy) distributions to be greater than 0, and the excess kurtosis of "platykurtic" (short, flat, and broad) distributions to be less than 0. We can calculate the excess kurtosis in R using the following:

```
Kurt(intersalt$bp, conf.level = 0.95)
```

```
##       kurt     lwr.ci     upr.ci
## -0.1618429 -0.8408011  1.1293546
```

Similar to the skewness, the excess kurtosis of −0.16 has a 95% confidence interval that includes 0, suggesting that it is not significantly different from that of a normal distribution.

Statistical tests for normality

A number of statistical tests for normality are implemented in R. Examples include the Shapiro–Wilk Test [6], its simplified variant, the Shapiro–Franci test [7], the Lilliefors (Kolmogorov–Smirnov) test [8], and the Anderson–Darling test [9]. These are presented here with references to the procedures but without the underlying calculations.

The Shapiro–Wilk test

This is implemented in R with the `shapiro.test()` function:

```
shapiro.test(intersalt$bp)
```

```
##
##  Shapiro-Wilk normality test
##
## data:  intersalt$bp
## W = 0.97341, p-value = 0.2932
```

The *P*-value indicates that the distribution is not significantly different from the normal distribution.

The Shapiro–Francia test

This function is implemented in the DescTools [10] package and is invoked as follows:

```
ShapiroFranciaTest(intersalt$bp)
```

```
##
##  Shapiro-Francia normality test
##
## data:  intersalt$bp
## W = 0.97639, p-value = 0.326
```

The *P*-value indicates that the distribution is not significantly different from the normal distribution.

The Lilliefors test

This function is implemented in the DescTools [10] package and is invoked as follows:

```
LillieTest(intersalt$bp)
```

```
##
##  Lilliefors (Kolmogorov-Smirnov) normality test
##
## data:  intersalt$bp
## D = 0.077987, p-value = 0.598
```

The *P*-value indicates that the distribution is not significantly different from the normal distribution.

The Anderson–Darling test

This function is implemented in the DescTools [10] package and is invoked slightly differently, as the distribution (in this case, the normal distribution) to which your data are to be compared and the associated defining parameters (in this case, the mean and the SD) need to be specified.

```
m <- mean(intersalt$bp)
s <- sd(intersalt$bp)
AndersonDarlingTest(intersalt$bp, "pnorm", mean = m, sd = s)
```

```
##
##  Anderson-Darling test of goodness-of-fit
##  Null hypothesis: Normal distribution
##  with parameters mean = 7.315e+01, sd = 4.787e+00
##
## data:  intersalt$bp
## An = 0.35745, p-value = 0.8891
```

The *P*-value indicates that the distribution is not significantly different from the normal distribution.

Detecting outliers

An outlier is a data point that differs significantly from other observations and should be considered for remeasurement or removal from the data set, since it may reflect an experimental error or contamination of the cohort with subjects who do not conform to the a priori assumptions. For example, suppose that you are performing a reference interval study for fasting serum insulin on a healthy adult population and you find one insulin result that is disproportionately high. After investigating, you find that this subject is obese and was not excluded as per study protocol. You conclude this subject's data should be removed, because they are likely insulin-insensitive. Alternatively, you might hypothesize that this subject's specimen had a heterophile interference and their sample requires remeasurement. However, unless you discover a valid reason to exclude a result based on analytical error or clinical grounds, it is *not good scientific practice* to remove outliers. Rather, readers are encouraged to use statistical tests resistant to the effects of outliers.

While a thorough discussion of identification and management of outliers is beyond the scope of this chapter, it is useful to present some of the traditionally employed strategies for finding them.

The Grubbs test

The Grubbs test [11] is based on the assumption that the data are normally distributed. The test is used to identify a single outlier, and the test statistic, G, is defined as:

$$G = \frac{\max|x_i - \bar{x}|}{s}$$

where $\bar{x}$ is the sample mean, s is the SD, and max refers to the largest value. So, for example, if we take a small data set of 10 values: $\mathbf{x} = \{-1.3, 0.7, -0.8, -0.7, 0.1, -0.3, -0.7, 0.0, 0.6, 4.2\}$, we can see that the mean is $\bar{x} = 0.18$ and $s = 1.55$, so that $G = 2.60$, which is the value associated with $x_{10} = 4.2$.

The critical value for the test statistic, G, can be found in a table for different values of α and N or calculated by using the following formula (for the two-sided hypothesis):

$$G > \frac{N-1}{\sqrt{N}} \sqrt{\frac{t^2_{\alpha/(2N),N-2}}{N-2+t^2_{\alpha/(2N),N-2}}}$$

where $t_{\alpha/(2N),N-2}$ denotes the upper critical value of the student's t-distribution for $N-2$ degrees of freedom and a significance level of $\alpha/2N$. In this case, the critical G is 2.29, and the calculated value of G of 2.60 means that $x = 4.2$ is an outlier, because its value of G exceeds the critical value. A one-sided formulation of the formula above is obtained by simply replacing $\alpha/2N$ by α/N.

Grubbs' test is implemented in the R outliers' package, and the same analysis can be invoked as follows:

```
library(outliers)
x <- c(-1.3, 0.7, -0.8, -0.7, 0.1, -0.3, -0.7, 0.0, 0.6, 4.2)
grubbs.test(x)
```

```
##
##  Grubbs test for one outlier
##
## data:  x
```

```
## G = 2.59630, U = 0.16778, p-value = 0.001165
## alternative hypothesis: highest value 4.2 is an outlier
```

This gives us the same results but with some additional statistical information.

Dixon test

Dixon's Q-test [12] is another test used for the identification of outliers, which again assumes that the data are normally distributed. Suppose that we have a data set that we have *sorted* (i.e., $x_1 < x_2 < x_3 \ldots < x_N$) and the potential outlier is x_N. First, we calculate the "gap" value, Q, which is the difference between x_N and its nearest neighbor x_{N-1}:

$$Q = \frac{|x_N - x_{N-1}|}{w}$$

where w is the range of the data, that is, $w = x_N - x_1$. If w exceeds a critical value (which can only be obtained from tabulated values, not a formula), then the data point is considered an outlier. Critical values Q for $\alpha = 0.1$, 0.05, and 0.01 are provided in Table 2.2.

Considering the small data set we used above, first, we sort it to obtain this data set: −1.3, −0.8, −0.7, −0.7, −0.3, 0.0, 0.1, 0.6, 0.7, 4.2. The value in question is 4.2. Its nearest neighbor is 0.7. The calculated value of Q is:

$$Q = \frac{|4.2 - 0.7|}{4.2 - (-1.3)} = 0.64.$$

This value $Q = 0.64$ exceeds the critical value of 0.466 for 10 observations and $\alpha = 0.05$, as shown in Table 2.2.

A slightly more sophisticated variant Dixon's Q-test taking into account the sample size [13] is implemented in the R outliers' package, and the same analysis can be invoked as follows:

```
library(outliers)
x <- c(-1.3, 0.7, -0.8, -0.7, 0.1, -0.3, -0.7, 0.0, 0.6, 4.2)
dixon.test(x)
```

```
##  Dixon test for outliers
##
## data:  x
## Q = 0.7, p-value < 2.2e-16
## alternative hypothesis: highest value 4.2 is an outlier
```

The reader will notice that the calculated value of Q is different than the above, which is attributable to the slightly more sophisticated approach used.

Tukey's fences

Another way to flag a potential outlier was suggested by Tukey [14]. If a result is more than 1.5 IQRs below the first quartile, Q_1, or more than 1.5 IQRs about the third quartile, Q_3, then the result can be considered an outlier. For the data set we have been considering in this section, the first quartile can be calculated to be $Q_1 = -0.700$, the third quartile to be $Q_3 = 0.475$, and the IQR to be IQR = 1.175. The Tukey fences are therefore [−2.4625, 2.2375]. Because 4.2 lies outside this interval, it is considered an outlier.

Chauvenet's criterion

Chauvenet's criterion [15] is another means of identifying an outlier in a normally distributed data set. The principle behind the test is that, if a value falls outside a probability band centered at the mean of the data, then it can be considered an outlier. Despite its frequent application in the field of clinical chemistry, its use is not recommended because of errors in its derivation; it was considered antiquated some 60 years ago [16]. The reader determined to use Chauvenet's criterion may do so as follows.

A measurement can be rejected if its probability of occurrence is less than $1/2N$ [15]. For the data we have been considering in this section, $N = 10$, the mean is 0.180, the SD is 1.548, and the z-score of the prospective outlier, $x = 4.2$, is 2.596. The minimum acceptable probability is $1/2N = 1/20 = 0.05$. Any observation having a probability of occurrence less than this is considered an outlier.

From the perspective of how z-tables for the standard normal distribution are tabulated (i.e., presenting the area under the distribution function from $-\infty$ to z), this corresponds to a z-score for a probability of $1/4N$. In this case, for the data set we have been evaluating, the critical $z = 1.960$. Because our calculated value for $z = 2.596$ exceeds 1.960, we can say $x = 4.2$ is an outlier.

In the R language, the Chauvenet's criterion can be calculated with the `qnorm()` function for any value of N

TABLE 2.2 Critical values for Dixon's Q statistic.

Number of values	3	4	5	6	7	8	9	10
Q90%:	0.941	0.765	0.642	0.560	0.507	0.468	0.437	0.412
Q95%:	0.970	0.829	0.710	0.625	0.568	0.526	0.493	0.466
Q99%:	0.994	0.926	0.821	0.740	0.680	0.634	0.598	0.568

by calculating `qnorm(1 - 1/(4*N))`. For example, if $N = 30$, the critical z is calculated as follows:

```
N <- 30
qnorm(1-1/(4*N))

## [1] 2.39398
```

Those invoking Chauvenet's method will often apply it serially, removing outliers until no samples fail the criterion. This is not sound practice.

Common inferential statistics

This section will not cover the theoretical basis for these tests. This is covered in all introductory statistical textbooks, some of which are available online [17,18]. Rather, this section will inform the reader when each type of test is appropriate, how to perform the test, how to interpret the results, and how to perform the test in the R language.

The two-sample *t*-test

The two-sample *t*-test is a way of assessing whether the means of two populations are different. In statistical terms, it is more correct to say, "the test allows us to accept or reject the null hypothesis," where the null hypothesis is the hypothesis that the means are equal.

The *t*-test, in its simplest form, compares the means of two unrelated populations. For example, if you were comparing the mean mid-winter plasma vitamin D concentration in a cohort of Icelanders to Floridians (who are in no way matched), you would use a two-sample *t*-test.

The assumption of the *t*-test is that the quantity being compared in the two populations is normally distributed. One may wish to assume that the variances of the two populations are equal or not, but the ensuing calculations will be different accordingly. If the reader wishes to assess the normality of the distributions, strategies in the section "Is my data normally distributed?" can be applied. If the data are found not to conform to a normal distribution, normalizing transformations such as the logarithm, Box−Cox [19], or one of many others available in R [20] can be employed first. Finally, the data should be sampled independently from the two populations.

Examples

Suppose that we have a small sampling of mid-winter plasma vitamin D levels from Icelandic and Floridian adult males (see Table 2.3) that we wish to compare with a *t*-test.

In the R language, a *t*-test is accomplished as follows:

```
t.test(VitD$Iceland, VitD$Florida)

##
##  Welch Two Sample t-test
##
## data:  VitD$Iceland and VitD$Florida
## t = -12.432, df = 21.113, p-value = 3.516e-11
## alternative hypothesis: true difference in means is not equal to 0
## 95 percent confidence interval:
##  -40.00254 -28.54069
## sample estimates:
## mean of x mean of y
##  51.77245  86.04407
```

The output indicates that the difference between the two means, 51.8 and 86.0, is statistically significant based on the *P*-value since $P \ll .05$.

If a one-sided *t*-test is preferred because there is an a priori assumption that the Icelandic vitamin D levels should be lower, then the code is modified as follows:

```
t.test(VitD$Iceland, VitD$Florida, alternative = "less")
```

TABLE 2.3 Independently sampled plasma vitamin D levels from Icelandic and Floridian adult males.

Iceland VitD (nmol/L)	Florida VitD (nmol/L)
52.6	85.0
68.3	84.9
46.6	85.2
59.0	76.8
54.9	81.4
37.4	94.6
50.2	94.9
60.9	82.2
48.7	81.9
39.2	92.1
58.6	88.0
46.4	90.1
51.7	80.2
37.6	87.3
64.6	91.3
–	81.8
–	85.0

The paired *t*-test

The results are similarly significant to the *t*-test.

Wilcoxon signed-rank test

This is the nonparametric equivalent of the paired *t*-test. It makes no assumption about the distributions of the original population themselves, but it does assume that the distributions of the *differences* are at least symmetrical (though there is no need for the differences to be normally distributed). In the R language, the syntax to obtain the Wilcoxon signed-rank test on paired data sets, x_1 and x_2, is:

If the data are paired, that is, one is comparing populations before and after some intervention or the populations respectively comprise cases and matched controls, then the appropriate test is a paired two-sample *t*-test. The test assumes that the distributions of the *differences* between the paired values of the two populations are normally distributed rather than the two distributions themselves. So, if we were comparing the vitamin D levels of a single group of Icelanders in the summer versus winter, we would use a paired *t*-test. The syntax for calling a paired *t*-test on two populations, x_1 and x_2, in R is similarly straightforward:

```
t.test(x1, x2, paired = TRUE)
```

Wilcoxon rank-sum test (Mann–Whitney *U*-test)

This is the nonparametric equivalent of the *t*-test and as such does not require that the populations compared be normally distributed. Applying this test to the vitamin D data, as shown in Table 2.3, and using the R language implementation of this test, we have:

```
wilcox.test(VitD$Iceland, VitD$Florida)
```

```
##
##  Wilcoxon rank sum test
##
## data:  VitD$Iceland and VitD$Florida
## W = 0, p-value = 3.535e-09
## alternative hypothesis: true location shift is not equal to 0
```

```
wilcox.test(x1, x2, paired = TRUE)
```

The chi-square test

The chi-square test is used to test for statistically significant differences in frequencies observed in different categories.

Application to proportions

For example, if we had four clinical chemistry training programs and we knew how many students had passed and failed over the course of the last 20 years, we could look for

TABLE 2.4 Relationship between smoking frequency (heavy, regular, occasional, and never) and exercise frequency (frequent, some, and none) in survey data from the MASS package in R.

	Heavy	Never	Occas	Regul
Freq	7	87	12	9
None	1	18	3	1
Some	3	84	4	7

significant differences in the pass/fail frequencies to make evidence-based recommendations to our younger colleagues.

	School A	School B	School C	School D
Pass	35	33	34	25
Fail	4	3	5	11

In the R language we can construct a data frame or matrix to house the data and apply the chi-square test as follows:

```
chisq.test(cbind(pass,fail))
```

```
##
##  Pearson's Chi-squared test
##
## data:  cbind(pass, fail)
## X-squared = 8.7483, df = 3, p-value = 0.03283
```

The resulting *P*-value of 0.03 indicates that school D, aptly named, should not be on the recommendation list.

Another R function, `prop.test()`, is specifically tailored for testing proportions. Not surprisingly, it gives the same result:

```
prop.test(cbind(pass,fail))

General application to contingency tables

If you have a more general contingency table, you can apply the chi-square test similarly. For example, the MASS package in the R language [21] has a data set containing survey responses from 237 statistics students from the University of Adelaide. A contingency table for smoking and exercise can be prepared from this data set: (Table 2.4)

Applying the `chisq.test()` function directly to this contingency table gives:

```
library(MASS) #load the package with the data
data(survey) #load the data
cont.table <- table(survey$Exer, survey$Smoke) #prepare table
chisq.test(cont.table)
```

```
##
##  Pearson's Chi-squared test
##
## data:  cont.table
## X-squared = 5.4885, df = 6, p-value = 0.4828
```

These results indicate that there is no significant relationship between exercise frequency and heaviness of smoking.

Methods of regression

Ordinary least squares

In laboratory medicine, regression is used to prepare calibration curves, assess linearity, and compare methods. Usually, we are discussing linear regression with a single explanatory (independent) variable, but regression can be mulitvariate and it can be nonlinear. For the moment, we will confine ourselves to discussing the simplest regression method, ordinary least squares (OLS) linear regression. The method, usually attributed to Carl Friedrich Gauss, works by finding the line that minimizes the sum of squared residuals of a sequence of points (see Fig. 2.4).

The residuals, in this case, are the vertical distances between the points and the line. The minimization of these squared distances leads to a regression line whose slope and intercept can easily be calculated.

OLS regression assumes that there is *no error* in the independent (i.e., *x*-axis) variable. This is never true in bioanalytical chemistry, of course. However, there are settings where the error in the *x*-axis variable is low relative to that of the *y*-axis variable. For example, if you are doing a method comparison against an absolute reference method, it might be reasonable to assume no error in the *x*-axis. Another example is a calibration curve, where the assigned concentrations of the calibrators are considered correct but the instrument responses on the *y*-axis are subject to error. OLS regression also assumes that the scatter about the regression line is constant and not a function of *x*. This property of constant error is called "homoscedasticity," and it is likewise almost never true (see Fig. 2.5). If the data exhibit obvious heteroscedasticity, weighting is often applied to the regression (to be discussed).

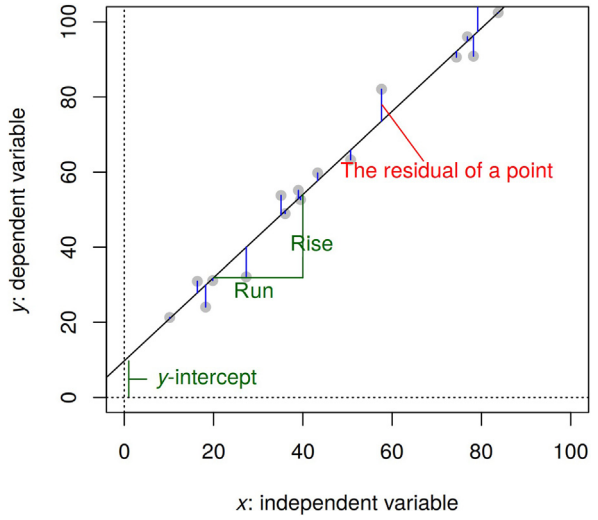

FIGURE 2.4 Typical scatterplot with the residuals of the points shown as vertical blue line segments. The ordinary least squares regression line is shown in solid black.

Computational methods for OLS regression report back a number of useful parameters and diagnostics for us to examine. These are usually the slope, the *y*-intercept, the residual standard error (RSE), and the coefficient of determination, R^2.

The slope is a measure of the regression line's steepness and is calculated from the ratio of the rise to the run (see Fig. 2.4). The *y*-intercept is the *y* value of the intersection of the regression line and the *y*-axis (i.e., the line $x = 0$). If the values on the *x*- and *y*-axes are measurements of the same quantity using two different analytical methodologies, the nonzero *y*-intercept indicates that the *y*-axis method has a constant bias compared with the *x*-axis method, and the fact that the slope is not equal to 1 indicates that the *y*-axis method has a proportional (i.e., *x*-dependent) bias compared with the *x*-axis method.

The RSE is given by:

$$\mathrm{RSE} = \sqrt{\frac{\sum_{i=1}^{n} \mathrm{resid}_i^2}{n-2}} \tag{2.5}$$

where resid_i is the residual of the *i*th value of *x*. The RSE therefore gives a measure of the spread of the residuals and is a goodness of fit measure of the linear regression line to the data.

The coefficient of determination is the square of the Pearson correlation coefficient, *r*, where *r* is defined as:

$$\begin{aligned} r &= \frac{\sum_{i=1}^{n}(x_i-\bar{x})(y_i-\bar{y})}{\sqrt{\sum_{i=1}^{n}(x_i-\bar{x})^2}\sqrt{\sum_{i=1}^{n}(y_i-\bar{y})^2}} \\ &= \frac{\sigma_{xy}}{\sqrt{\sigma_x^2\sigma_y^2}} \\ &= \frac{\sigma_{xy}}{\sigma_x\sigma_y} \end{aligned} \tag{2.6}$$

The numerator of *r*, denoted σ_{xy}, is referred to as the *covariance* of *x* and *y*. The correlation coefficient is a

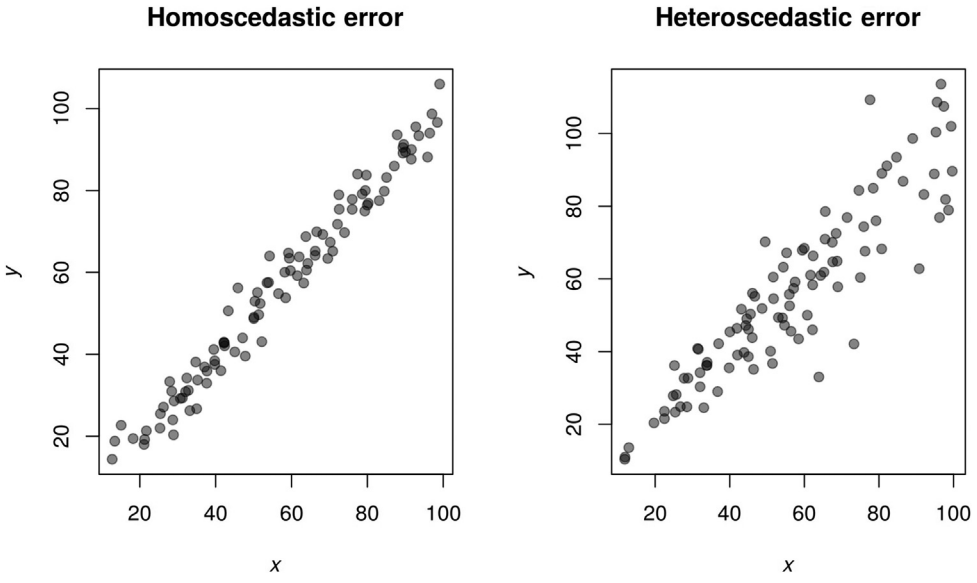

FIGURE 2.5 Examples of data showing homoscedastic error (*left*) and heteroscedastic error (*right*).

measure of how close two variables are to having a linear relationship with one another. It can take on values between -1 and $+1$. If the value is positive, the OLS regression line will have a positive slope, and, if the value is negative, the regression line will have a negative slope. This is because the OLS slope can be expressed as $\beta = r \times \sigma_y/\sigma_x$, meaning that r and β have the same sign since both σ_x and σ_y are positive. A value of $r = 0$ implies that the data are uncorrelated.

The correlation coefficient is an oft-abused quantity in methodological comparisons, because it can be inflated by the inclusion of an outlier that lies close the regression line, thus imparting the illusion of "good correlation." The author has even seen manuscripts where said outlier is excluded from the scatterplot and the inflated value of r is ascribed to the remaining visible data. Fig. 2.6 shows an extreme example of this phenomenon.

In the R language, the OLS regression is built in as the `lm()` function. Using the data shown in Fig. 2.4 and Table 2.5, the summary of the results of the linear model is obtained as follows:

```
x <- c(89.0,79.2,35.1,57.6,96.7,98.2,18.2,16.4,39.5,43.3,

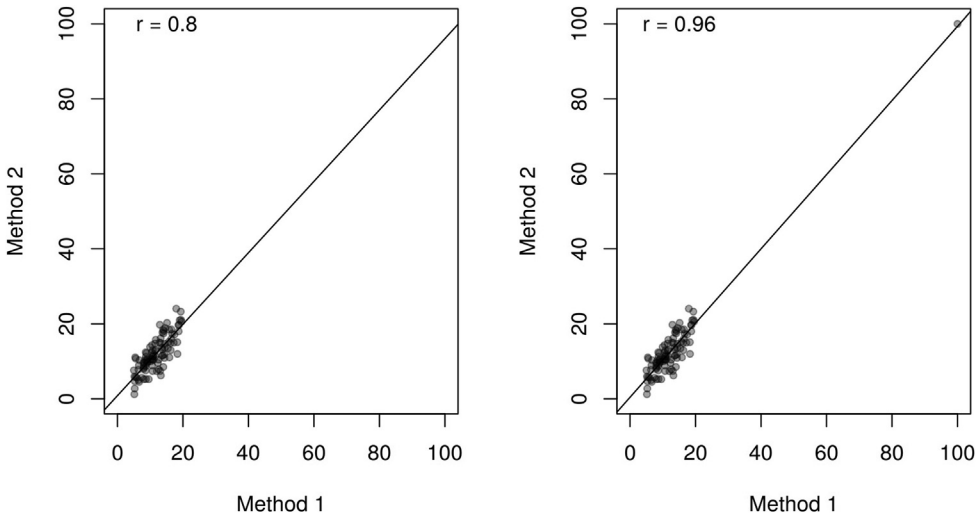

FIGURE 2.6 The spuriously positive effect of an outlier on the correlation coefficient.

Among a number of other results, we can see that the intercept of the regression line is 9.71, and the slope of the regression line is 1.11. The RSE is 4.81, and $R^2 = 0.979$.

Weighted ordinary least squares

As mentioned, the assumption of OLS regression is that the data show a homoscedastic error. When this is not the case, there is often a desire to limit the effect of the "spread" of x results. This can be accomplished by applying weights to the residuals in the calculation process, which can be chosen to make the regression line to be more affected by the lower values of x and less affected by the higher values of x. This is also common practice in calibration curve preparation, where accuracy of results in the concentration domain of the low calibrators is more important than that of higher calibrators.

Typically, one can weight with $1/x$ or $1/x^2$ weights. This is accomplished in the R language very easily. A small set of mock data is created:

```
xh <- c(1,3,4,6,7,8,10)
yh <- c(1.2,2.9,5.5,7.2,6.2,10,8.1)
summary(lm(yh ~ xh, weights = 1/xh))
```

```
##
## Call:
## lm(formula = yh ~ xh, weights = 1/xh)
##
## Weighted Residuals:
##       1       2       3       4       5       6       7
## -0.1496 -0.2470  0.5915  0.3693 -0.4099  0.6103 -0.6805
##
## Coefficients:
##             Estimate Std. Error t value Pr(>|t|)
## (Intercept)   0.3604     0.6044   0.596 0.576941
## xh            0.9892     0.1408   7.023 0.000903 ***
## ---

##
## Residual standard error: 0.5609 on 5 degrees of freedom
## Multiple R-squared:  0.908,  Adjusted R-squared:  0.8896
## F-statistic: 49.33 on 1 and 5 DF,  p-value: 0.0009028
```

The effect of the weighting is best appreciated graphically (see Fig. 2.7).

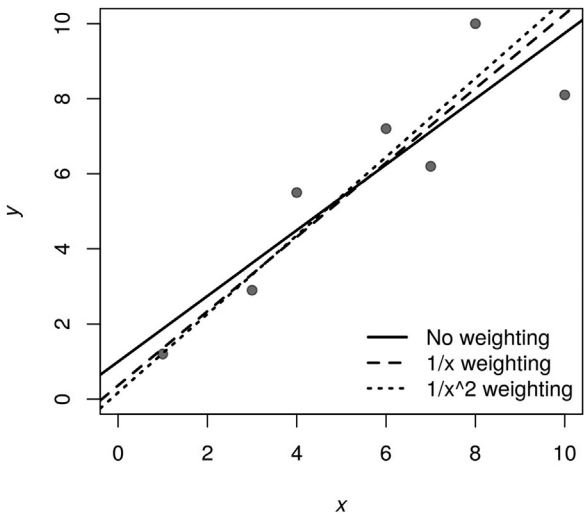

FIGURE 2.7 The effect of weighting an ordinary least squares regression of heteroscedastic data.

Deming regression

Some of the deficiencies of OLS regression are addressed by the method of Deming [22,23]. Specifically, Deming regression does not make the assumption that the x-axis variable has no error. Rather, the data of both the x- and y-axes are considered to have error associated with them. Accordingly, Deming regression calculates its residuals as the *perpendicular* distance to the regression line rather

than the vertical distance, as shown in Fig. 2.8. The Deming approach assumes that the error (i.e., scatter) is independent between the variables (which should be method comparison studies) and that it is normally distributed. However, Deming regression requires prior knowledge of the ratio of the variances of the error. That is, it does not assume that the variables x and y have the same analytical coefficient of variation. Unless specified, the ratio of the variance is assumed to be 1, and this may not be a correct assumption.

A number of packages that can perform Deming regression are available for the R language. These include the mcr [24] package from Roche Diagnostics and the deming package from Mayo Clinic [25]. Using the mcr package, the `mcreg()` function generates the Deming regression results as follows, assuming a value of 1 for the ratio of variances, as expressed in the parameter setting `error.ratio = 1`:

```
library(mcr)
x <- c(89.0,79.2,35.1,57.6,96.7,98.2,18.2,16.4,39.5,43.3,
       74.4,78.2,10.2,76.8,27.3,50.7,39,19.8,36,83.8)
y <- c(110.7,107.7,53.8,82.1,112.8,112.8,24,30.9,52.7,59.8,
       90.6,90.9,21.3,96,32.1,63.3,55.1,31.1,48.9,102.5)
deming <- mcreg(x,y,method.reg = "Deming", error.ratio = 1)
printSummary(deming)
```

```

## Bootstrap results generated with environment RNG
```

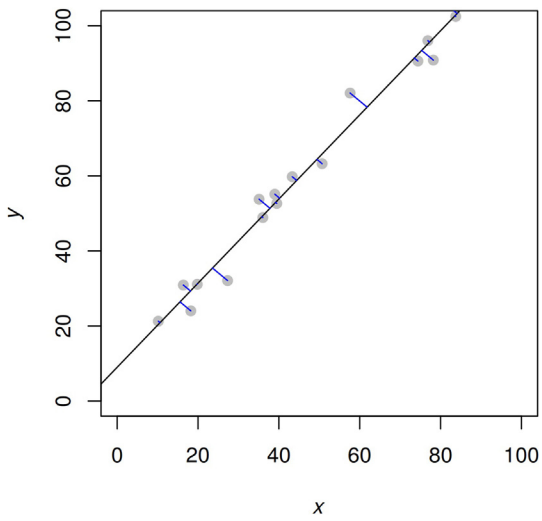

FIGURE 2.8 Perpendicular residuals of Deming regression.

```
wdeming <- mcreg(x,y,method.reg = "WDeming", error.ratio = 1)
```

Deming regression can also be weighted for the same motivations that weighting is performed in OLS regression. Weighting is specified by choosing the regression setting the parameter `method.reg = "WDeming"`:

```
x <- c(1,3,4,6,7,8,10,8)
y <- c(1.2,2.9,5.5,7.2,6.2,10,8.1,1)
pb <-  mcreg(x, y, method.reg = "PaBa")
printSummary(pb)
```

In this case, a slightly different intercept and slope of 8.01 and 1.14 are produced.

Passing–Bablok regression

The reader is undoubtedly aware that both OLS and Deming regression are unduly affected by outlier points. There exists a class of regression methods resistant to the effect of a small number of outliers. These are called "robust" regression methods, and Passing–Bablok (PB) regression is among them [26–28]. The general approach of PB regression is to identify all possible pairs of points in the data set, calculate a slope for each pair, and use the median as the slope of the regression line. The intercept is then calculated in a mathematically consistent manner. No assumptions are made about errors in the x or y variables, and there are no assumptions about the distribution of the error (i.e., scatter) about the regression line. The problem with PB regression is that it is

computationally intensive in that when there are N data points, there are $\binom{N}{2} = \frac{N(N-1)}{2!}$ possible pairs of slopes, making the calculation quite slow for large data sets. While there are many strategies for robust regression, it is a peculiarity of Clinical Chemistry as a field that it is culturally devoted to this particular method. Like Deming regression, PB regression is available in the R language in both the mcr and deming packages. To illustrate its resistance to the effect of an outlier, we can introduce the outlier point $(x, y) = (8, 1)$ into the data set used in Fig. 2.7 and compare the effect on PB regression, OLS regression, and Deming regression. These are calculated in R in a manner analogous to Deming regression:

```
library(pROC)
data(aSAH)
ndka.roc <- roc(outcome ~ ndka, data = aSAH)
plot(ndka.roc)
```

```
ndka.roc
```

```
##
## Call:
## roc.formula(formula = outcome ~ ndka, data = aSAH)
```

The regression coefficients of the three approaches are shown in Table 2.6 and illustrated in Fig. 2.9.

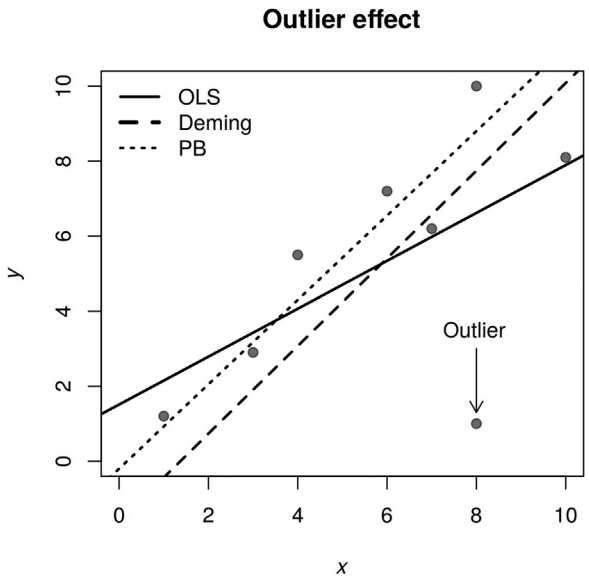

FIGURE 2.9 Illustration of the effect of an outlier on ordinary least squares, Deming, and PB regression.

Evaluation of diagnostic test performance

It is common to discuss sensitivity of an assay from an analytical perspective. That is, "How low can the assay measure?" Likewise, we talk about assays from the perspective of their analytical specificity. That is, "What are the known cross-reacting substances and how much do they interfere (%) on a molar basis?"

We can also discuss the sensitivity and specificity of tests from an epidemiological perspective, which addresses assay performance from a *diagnostic* perspective rather than an *analytical* perspective. The calculation of sensitivity and specificity requires knowledge of the true disease state of the individual by some other means (gold-standard testing or clinical criteria).

Sensitivity

The sensitivity of a test can be remembered by the brief phrase "positivity in disease." More accurately, *the sensitivity of a diagnostic test is the probability of obtaining a positive result in a diseased individual.*

- The sensitivity of a diagnostic test is an intrinsic property of the diagnostic test and the diagnostic threshold defined by the user.
- A test that has perfect (100%) sensitivity catches *all* diseased individuals but does not necessarily catch *only* diseased individuals.

Mathematically, the sensitivity is defined as:

$$\text{Sensitivity} = \frac{\text{TP}}{\text{TP} + \text{FN}} \tag{2.7}$$

where TP is the number of true positives and FN is the number of false negatives. The reader may convince themselves that this is indeed the probability of a positive result when a test is applied to a diseased individual.

Graphically, if we imagine that healthy individuals have a different distribution of possible results and diseased individuals have a distribution of possible results, we may visualize Eq. (2.7) as shown in Fig. 2.10.

Specificity

The specificity of a test can be remembered by the brief phrase "negativity in health." More accurately, *the specificity of a diagnostic test is the probability of obtaining a negative result in a healthy individual.*

- The specificity of a diagnostic test is an intrinsic property of that test and the diagnostic threshold that is defined by the user.
- A test that has perfect (100%) specificity catches *only* diseased individuals but does not necessarily catch *all* diseased individuals.

Mathematically, the specificity is defined as:

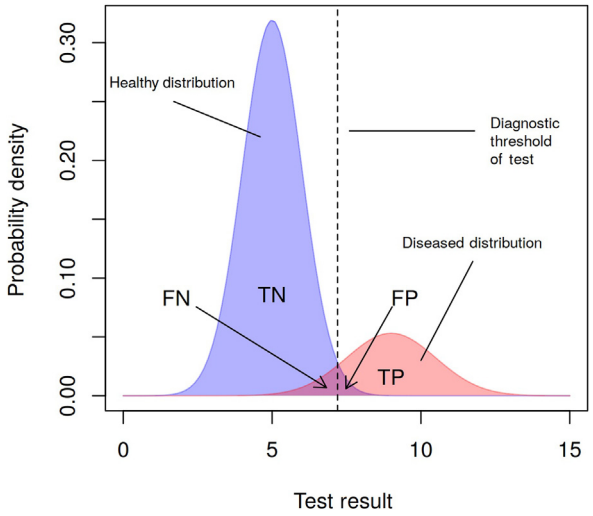

FIGURE 2.10 True/false positives and true/false negatives visualized as areas of overlapping normal distributions of test results in the diseased and healthy populations. The diagram assumes that test results higher than the diagnostic threshold are positive and that test results lower than the diagnostic threshold are negative. The true negatives are represented by the area of the healthy distribution (*blue*) that lies to the *left* of the diagnostic threshold level. The true positives are represented by the area (*pink*) to the *right* of the diagnostic threshold level. The false negatives are represented by the small portion of the diseased distribution to the left of the diagnostic threshold, and the false positives are represented by the small portion of the healthy distribution that lies to the right of the diagnostic threshold.

$$\text{Specificity} = \frac{\text{TN}}{\text{TN} + \text{FP}}. \tag{2.8}$$

Positive predictive value

The positive predictive value (PPV) of a diagnostic test is *the probability that a subject who tests positive is diseased*. This is represented mathematically as:

$$\text{PPV} = \frac{\text{TP}}{\text{TP} + \text{FP}}. \tag{2.9}$$

The PPV is *not* an intrinsic feature of the diagnostic test. Rather, it is dependent on the population to which the test is applied. When the prevalence of the disease in question is low, the PPV will be correspondingly low. As the prevalence approaches 0, the PPV will also approach 0. Using the fact that $\text{Prevelance} = \frac{\text{TP}}{\text{TP} + \text{FP} + \text{TN} + \text{FN}}$, Eq. (2.9) can be reexpressed as follows:

$$\text{PPV} = \frac{\text{sensitivity} \times \text{prevalence}}{\text{sensitivity} \times \text{prevalence} + (1 - \text{specificity}) \times (1 - \text{prevalence})} \tag{2.10}$$

which demonstrates that, as the prevalence goes to 0, the PPV also goes to 0. The consequence of Eq. (2.10) is that screening tests provide little value when applied to populations of low disease prevalence, because most positives will be false positives.

Negative predictive value

The negative predictive value (NPV) of a diagnostic test is *the probability that a subject who tests negative is healthy*. This is represented mathematically as:

$$\text{PPV} = \frac{\text{TN}}{\text{TN} + \text{FN}}. \tag{2.11}$$

The NPV is gauge of the reassurance that can be provided to a patient who tests negative.

Likelihood ratios

There is an alternative manner of expressing the concepts from the section "Evaluation of diagnostic test performance," which is that of likelihood ratios. The first required concept is one of *odds*. Most readers will have a sense from colloquial usage that probability is expressed as a number between 0 and 1, while odds are expressed by numbers that may be greater than 1. The relationship between odds and probability is as follows. If the probability of an event's occurrence is p_e, then the odds for that event's occurrence, o_e, is:

$$o_e = \frac{p_e}{1 - p_e}. \tag{2.12}$$

It can be shown that, if one defines the positive likelihood ratio for a diagnostic test, denoted LR^+, as follows:

$$\text{LR}^+ = \frac{\text{sensitivity}}{1 - \text{specificity}} \tag{2.13}$$

then there is a relationship between the pretest odds of disease and the posttest odds of disease given by:

$$o_{\text{post}} = \text{LR}^+ \times o_{\text{pre}}. \tag{2.14}$$

Eq. (2.14) is a simplified formulation of *Bayes' theorem* and has very important implications for the use of diagnostic tests. The pretest odds, o_{pre}, is directly calculated by using Eq. (2.12) using the pretest probability of disease (i.e., the prevalence) *in the population to be tested*. The posttest odds of having disease is then simply a multiple of the pretest odds, which underscores the notion that if the pretest odds (and therefore the pretest probability) are low, then the odds (and probability) of finding a diseased individual using the test are likewise low.

TABLE 2.6 Comparison of outlier effects on commonly employed regression methods.

Method	Slope	Intercept
Least squares	0.6	1.5
Deming	1.2	1.6
Passing–Bablok	1.1	0.2

As a rule of thumb, if $LR^+ > 10$, the test has a large effect on increasing the probability identifying a diseased individual, if $5 \leq LR^+ \leq 10$, the test has moderate effect on increasing this probability, and if $LR^+ < 5$, the test is weak effect on increasing this probability.

Similarly, we can formulate an analogous version of Eq. (2.14) for negative tests:

$$LR^- = \frac{1 - \text{sensitivity}}{\text{specificity}} \tag{2.15}$$

and

$$o_{\text{post}} = LR^- \times o_{\text{pre}} \tag{2.16}$$

where Eq. (2.16) determines the posttest odds of being *healthy* based on the pretest odds of health.

Example calculation

Let us suppose that we have developed a diagnostic test, which we can call *my patented biomarker* (MPB), to determine whether a patient has irritable bowel syndrome (IBS) versus inflammatory bowel disease (IBD). A positive test indicates the presence of IBD. Suppose that MPB testing is performed on a cohort of patients who have had colonoscopies and long-term clinical evaluation, so that they are correctly clinically classified as either IBS or IBD. Suppose that the MPB results on a cohort of 117 people with chronic diarrhea were as follows:

From Table 2.7, we can infer that TP = 17, FN = 5, FP = 3, and TN = 92. This means that the prevalence of the disease in the testing population is Prev = (TP + FN)/(TP + TN + FP + FN) = 0.188. Therefore, using Eq. (2.12), we can calculate the positive pretest odds of IBD as $o^+_{\text{pre}} = \frac{\text{prev}}{1 - \text{prev}} = 0.232$. From Eq. (2.7), the sensitivity is found to be Sens = TP/(TP + FN) = 0.773, and from Eq. (2.8), the specificity is found to be Spec = TN/(TN + FP) = 0.968. This means that the positive likelihood ratio can be calculated:

$$LR^+ = \frac{\text{sens}}{1 - \text{spec}} \simeq \frac{0.773}{1 - 0.968} = 24.2$$

TABLE 2.7 A table of test performance of a blood biomarker my patented biomarker for inflammatory bowel disease in a mixed cohort of inflammatory bowel disease and irritable bowel syndrome.

	IBD+	IBD
MPB+	17	3
MPB	5	92

and from this, we can determine the positive posttest odds:

$$o^+_{\text{post}} = LR^+ \times o^+_{\text{pre}} = 24.2 \times 0.232 = 5.61.$$

Because the PPV corresponds to the disease prevalence in the population of patients who test positive, by substituting $o^+_{post} = 5.61$ into Eq. (2.12) and solving for the corresponding probability, the reader should be able to convince themselves that the PPV = 5.61/6.61 = 0.849, which matches the value calculated directly by using Eq. (2.9).

Receiver operating characteristic curves

The tacit assumption of the section "Likelihood ratios" was that the appropriate cutoff of a diagnostic test is already established. However, when we are evaluating a new diagnostic test which generates a numerical (and not dichotomous) result, we do not know the cutoff that will produce the best diagnostic accuracy. This is where receiver operating characteristic (ROC) curves can be used. These serve to both determine the appropriate concentration above which (or below which) to declare tests as "positive" and also give objective measure as to the test's diagnostic utility via the area under the ROC curve.

The ROC curve is a plot of sensitivity (y-axis) versus 1 − specificity (x-axis) for all possible diagnostic cutoffs. Considering Fig. 2.10, if the vertical dashed line representing the diagnostic threshold of the test was moved to a value of 5, the TN rate would decrease by about 50%, while the FN result would go to nearly 0. The FP rate would go up sharply, and the TP rate would be nearly 1. Naturally then, the sensitivity and the specificity would change. If we slide the vertical dashed line through all possible values of the test result and plot sensitivity versus 1 − specificity for all of these values, the ROC curve is obtained.

Interpreting a receiver operating characteristic curve

When we apply a diagnostic test to a population of healthy and diseased individuals, the more separated the

two distributions are, the better the diagnostic test will perform. In a situation where the healthy and diseased are well-separated, the ROC curve will look rectangular and will have an area under the curve (AUC) approaching 1. In contrast, if the test has no discriminating power between the healthy and diseased populations, the ROC curve will approach the line $y = x$ and will define an area close to $\frac{1}{2}$. Examples of the effect of population overlap on the corresponding ROC are shown in Fig. 2.11.

For this reason, ROC curves that have larger area indicate better discriminating power of the test, and better clinical test utility is expected. Obviously with any real experimental data, there will be a margin of error in the AUC, and this should be considered when comparing the AUCs of different tests.

The optimal diagnostic threshold of the test is generally defined as the value that will optimize the sum of specificity and sensitivity. Geometrically, this will be the point on the ROC curve that is furthest from the light gray line of identity shown in the ROC curves of Fig. 2.11.

There are no rules about what AUC is "good enough" but as a rule of thumb:

- $AUC > 0.9$ is excellent.
- $0.8 \leq AUC < 0.9$ is good.
- $0.7 \leq AUC < 0.8$ is fair.
- $AUC < 0.7$ is poor.
- $AUC = 0.5$ has no discriminating power.

Preparing a receiver operating characteristic curve

ROC curves are tedious to generate in spreadsheet programs but have been implemented in a number of packages for the R language.

By way of example, the R package pROC [29] provides a mock data set for 113 patients with an aneurysmal subarachnoid hemorrhage using s100 calcium-binding

TABLE 2.8 Representative data from the aSAH data set from the pROC package showing the relationship bteween s100b, ndka, and clinical outcome after aneurysmal subarachnoid hemorrhage.

Subject	Outcome	s100b	ndka

2	Good	0.14	8.54
3	Good	0.10	8.09
4	Good	0.04	10.42
5	Poor	0.13	17.40
6	Poor	0.10	12.75
7	Good	0.47	6.00
8	Poor	0.16	13.20
9	Good	0.18	15.54
10	Good	0.10	6.01

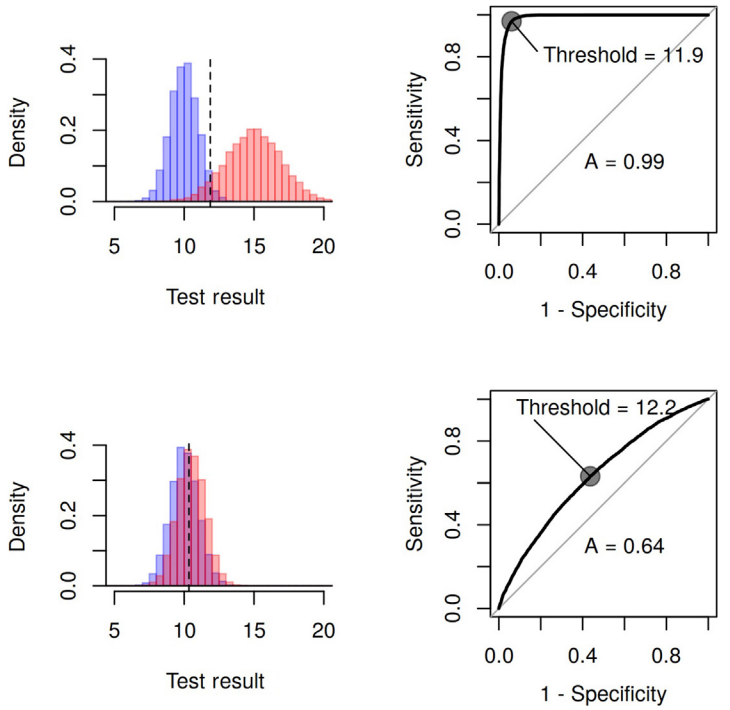

FIGURE 2.11 A comparison of receiver operating characteristic curves generated from a test with good discriminating power (*top*) between healthy (*blue*) and diseased (*red*) populations and poor discriminating power (*bottom*). The optimal test threshold that maximizes the sum of sensitivity and specificity is identified on each ROC curve and by vertical dashed lines on histograms.

protein B (s100b) and nucleoside diphosphate kinase A (ndka) as biomarkers of good or poor outcome. Relevant columns of the first 10 rows of the data set (Table 2.8) give the reader an understanding of how it must be structured to prepare an ROC curve.

The package makes preparing an ROC curve a trivial matter. Here is the code to create a curve based on ndka:

```
##
## Data: ndka in 72 controls (outcome Good) < 41 cases (outcome Poor).
## Area under the curve: 0.612
```

Fig. 2.12 shows the resulting ROC curve. The AUC, in this case 0.61, is calculated in the output among many other statistics discussed in the package documentation [29]. More elaborate ROC representations can be prepared with ease. For example, Fig. 2.13 shows the s100b threshold providing optimal diagnostic accuracy, the optimized sensitivities, and specificities with their confidence intervals, and a confidence band on the ROC.

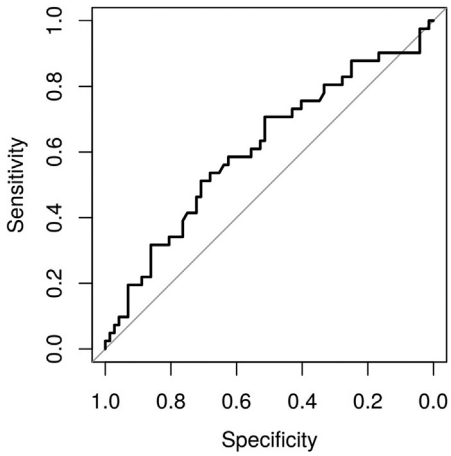

FIGURE 2.12 A basic receiver operating characteristic curve prepared by the roc( ) function and in the pROC package.

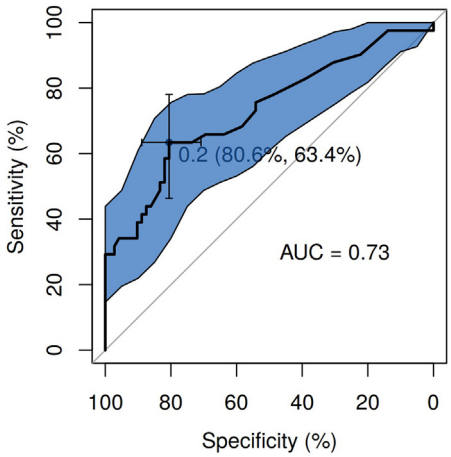

FIGURE 2.13 Receiver operating characteristic curve for biomarker S100b to predict poor or good outcome after subarachnoid hemorrhage.

Suggested additional topics for study

- Method validation statistics
- Quality control statistics
- Dealing with missing values
- Traceability and commutability
- Biological variation and reference change values
- Total allowable error and uncertainty in the measurement
- Multivariate regression
- Nonlinear regression
- The propagation of error
- Analysis of variance and Kruskal–Wallis
- Resampling techniques
- Statistical analysis and data visualization in R or Python

Self-assessment questions

1. The SD is:
   a. the average difference between any value and the mean
   b. the variance divided by 2
   c. the square root of the variance
   d. the mean squared difference between individual values and the mean
   e. the mean difference between any value and the mean
2. If the probability of an event occurring is 90%, what is the corresponding odds?
   a. 9
   b. 10%
   c. 90
   d. 10:1
3. Regarding Passing–Bablok regression, which of the following is false?
   a. It is computationally expensive.
   b. It is a form of so-called robust regression.
   c. It has unique popularity in the field of clinical chemistry.
   d. It relies on the principle of minimization of squared residuals.
   e. It may give different slope and intercept if the units of reporting are changed.
4. If a linear regression line has a slope of 1.07 and *y*-intercept of 12:
   a. There is a proportional bias of 12.
   b. There is a constant bias of 12.
   c. There is a constant bias of 0.07.
   d. The correlation coefficient will be negative.
   e. *y* values will typically be less than the corresponding *x* values.
5. In a population of 190 subjects with a disease prevalence of 10%, a diagnostic test is performed. It is found that there are 15 true positives, 4 false negatives, 160 true negatives, and 11 false positives. The posttest odds of a positive test is:
   a. 57%
   b. 1.36
   c. 0.11
   d. 78%
6. The normal QQ plot is:
   a. useful to determine if the data follow a χ^2 distribution
   b. a plot of the quantiles of the sample distribution against the theoretical quantiles of the normal distribution
   c. sigmoidal when the sample distribution is Gaussian
   d. a way of comparing the mean of two distributions
7. Which of the following is true of OLS regression:
   a. It assumes that there is no error in the *x*-axis data.
   b. It assumes that the error in the *y*-axis data is homoscedastic.
   c. Its residuals are vertical.
   d. The procedure minimizes the sum of the squared residuals.
   e. All of the above.
8. In a distribution that has positive skewness:
   a. The mean and the median are likely equal.
   b. The mean and the mode are likely equal.
   c. The median is likely lower than the mean.
   d. The median is likely higher than the mean.
   e. The distribution is platykurtic.
9. $1/x$ weighting is useful in linear regression when:
   a. There is homoscedastic error.
   b. The error is constant.
   c. The scatter in the data shows no spreading as *x* increases.
   d. There is a need to make the small values of *x* affect the regression line more than the large values of *x*.
   e. Deming regression is not available in your spreadsheet program.
10. Which of the following cannot be used to assess the normality of a distribution?
    a. a histogram
    b. a QQ plot
    c. a Shapiro–Wilk test
    d. a Kaplan–Meier curve
    e. calculation of the skewness and kurtosis

Chapter 3

Reference intervals: theory and practice

Victoria Higgins, Michelle Nieuwesteeg, and Khosrow Adeli
Clinical Biochemistry, The Hospital for Sick Children, University of Toronto, Toronto, ON, Canada

Learning objectives

After completing this chapter, the reader should be able to:

- Discuss the value of reference intervals to laboratory medicine.
- Describe the processes of establishing reference intervals, including selection of a reference population, consideration of analytical and preanalytical variables, and statistical methods for calculating reference intervals.
- Identify the challenges associated with establishing reference intervals for subgroups of the population (i.e., pediatrics and geriatrics).
- Explain the process, value, and limitations of transferring and verifying reference intervals.
- Understand the concept, challenges, and limitations of harmonization in laboratory medicine, especially reference intervals.

Introduction

Concept of reference intervals and importance to laboratory medicine

Reference intervals are fundamental tools used by medical practitioners to interpret patient laboratory test results and help differentiate between healthy and unhealthy individuals [1]. Sometimes referred to as "normal" or "expected" values, reference intervals provide the range of laboratory test results that would be expected in a healthy population. Therefore reference intervals serve as "health-associated benchmarks," where results that fall outside of the reference interval may be interpreted as abnormal, indicating the need for additional medical follow-up and/or treatment [2].

Clinical laboratories provide valuable information to physicians and health care providers to aid in clinical decision-making, including diagnosis and management of disease [3,4]. Over the past several decades, there have been significant technological advancements in laboratory medicine, leading to increased accuracy and precision of biochemical assays, improved analytical quality of laboratory procedures, and a growing number of novel biomarkers that are assessed to aid in disease diagnosis, prognosis, and monitoring [5]. However, the tools used to interpret laboratory test results and their impact on patient care and safety have received less attention from laboratorians and clinicians. Arguably, the quality of the reference intervals used to interpret test results may be equally important as the quality of the result itself [6]. In modern medicine, it is essential that reference intervals are updated frequently to keep pace with changing methodologies and that well-defined reference intervals are established for novel tests. It is clear that the lack or inappropriate use of reference intervals can result in misdiagnosis, unnecessary medical follow-up, increased patient risk, and higher health care costs. Although the concept and use of reference intervals are generally straightforward, establishment of accurate reference intervals can be complex, requiring recruitment of healthy subjects, awareness of analytical and preanalytical factors that can affect testing, careful statistical analysis, and consideration of important covariates (e.g., age, sex, and ethnicity). Establishing a new reference interval requires a minimum of 120 healthy reference subjects per partition, as recommended by the Clinical and Laboratory Standards Institute (CLSI) [7]. Given the complexity of establishing a new reference interval, most laboratories adopt reference intervals provided by the instrument manufacturer or attempt to transfer and validate an existing reference interval. Verification of a reference interval requires a much smaller sample size of healthy subjects (i.e., minimum $n = 20$ per partition [7]), and is thus much more feasible for individual laboratories to perform. This chapter will review procedures for establishing reference intervals, factors that affect reference interval determination, implementation and transference of reference intervals, global reference interval initiatives, and approaches for reference interval harmonization (hRI).

Reference intervals versus clinical decision limits

Statistically, reference intervals are defined as limiting values within which a specified percentage (usually the central 95%) of values from an apparently healthy reference

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00003-X

population would fall. According to this definition, typically, the 2.5th and 97.5th centiles of the test result distribution are used to define the upper and lower reference limits, as depicted in Fig. 3.1. This means that 2.5% of individuals with the highest test results and 2.5% of individuals with the lowest test results are excluded (reviewed in Ref. [8]). In some cases, this definition may be modified. For example, only the upper or lower limit may be considered for analytes, where only one side of the distribution is clinically significant. In addition, for some analytes, a different centile may be used to provide greater specificity. For instance, the 99th centile of a healthy population is used to establish the upper reference limit for cardiac troponin [9].

The International Organization for Standardization (ISO) directive for medical laboratories (ISO 15189) requires biological reference intervals or clinical decision limits to be available and appropriately reviewed and updated [10]. Clinical laboratories use reference intervals to interpret most laboratory test results; however, decision limits are used for a limited number of biomarkers. Reference intervals describe the distribution of values from an apparently healthy population. Individual test results can be compared to the reference interval to determine if the test value fits within the defined reference range, established from the distribution of values based on an apparently healthy reference population. In contrast, clinical decision limits, as the name suggests, distinguish between particular clinical states. Decision limits provide threshold values; values exceeding or falling below the threshold indicate a significantly higher risk of a clinical outcome or may satisfy criteria for diagnosis of a specific disease [10]. Furthermore, multiple thresholds may be used to indicate levels of increasing risk for a disease (e.g., borderline high and high). In contrast to reference intervals, decision limits are often established from clinical outcome studies, including prospective cohort studies and meta-analyses, but can also be based on consensus of expert panels. The CLSI EP28-A3c guidelines state that "when decision limits determined by national or worldwide consensus exist, these limits, rather than reference intervals, should be reported" [7].

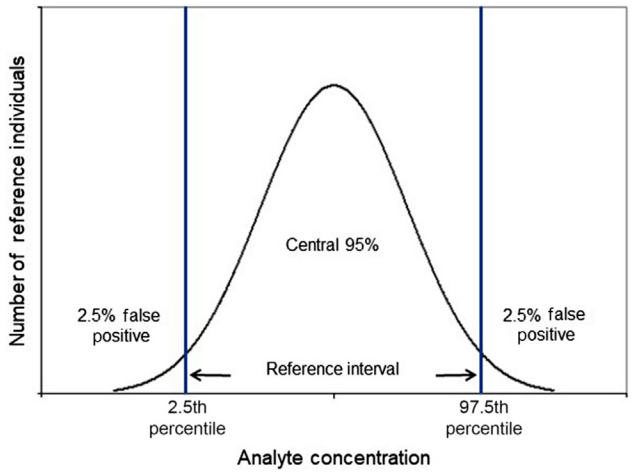

FIGURE 3.1 Graphical representation of a reference interval. A reference interval is defined as the central 95% of laboratory test results from a healthy, reference population. An example of a normal distribution for analyte concentration is shown.

Current gaps and recent initiatives in reference interval establishment

Patients and their health care workers assume that reference intervals are readily available to medical laboratories and health care institutions performing clinical tests and interpreting test results. Unfortunately, this is not always the case and many laboratories depend on outdated and incomplete information when reporting test results. In many cases, the same reference intervals are used to interpret test results for children and adults, which can lead to erroneous and inaccurate interpretation. Available reference intervals also suffer from several limitations including small sample sizes, and the use of outpatient or hospitalized patient samples. There has thus been an urgent need for the development of new up-to-date laboratory reference interval databases based on healthy children, adult, and geriatric populations. It is often difficult to obtain sufficient numbers of healthy reference samples to stratify reference intervals according to multiple covariates [11]. This can pose a major challenge when establishing accurate reference intervals, particularly for pediatric or geriatric populations where it is more difficult to collect large numbers of blood samples from healthy individuals. As a result, many existing reference intervals were determined decades ago using methods and/or instruments that are no longer relevant given the technological advances in laboratory testing. Further, reference intervals are lacking for many novel/emerging biomarkers. Thus current and future initiatives should consider these gaps in the design of their reference interval studies.

A number of international initiatives are recognizing the current gaps in reference intervals and the need to establish values that are up-to-date and appropriate for the local population. In Canada, Canadian Laboratory Initiative on Pediatric Reference Intervals (CALIPER) has partnered with the Canadian Health Measures Survey (CHMS) to evaluate data collected from over 12,000 Canadians, ranging in age from 3–79 years, in order to establish reference intervals for over 50 common biochemical, endocrine, and hematology biomarkers for pediatric, adult, and geriatric populations [12–14]. CALIPER also has established a comprehensive pediatric reference interval database of age- and sex-stratified reference intervals for over 170 pediatric biomarkers currently available (described further below) [15–31]. In Australia, a direct reference interval study, called Aussie Normals, has surveyed 1876 healthy male and female participants aged 18–65 years.

All individuals were from the Australian Capital Territory, which has a multicultural population, representative of other regions in Australia. The study established reference intervals for 91 analytes, with individuals excluded on the basis of pregnancy, diabetes, renal disease, and cardiovascular disease [32]. In Europe, several reference interval initiatives have been established. Nordic Reference Interval Project (NORIP) is a collaborative initiative among five Nordic countries to measure 25 of the most common chemistry analytes [33]. Laboratory Reference Ranges for Turkey, conducted by the Association of Clinical Biochemists in Turkey, is a reference interval initiative aimed at updating all outdated reference intervals for the Turkish population [11]. REALAB, an Italian reference interval initiative, has developed reference intervals for 23 chemistry analytes plus 13 additional markers, based on 61,246 samples collected from hospital patients [34]. Although this is not the preferred method recommended by the CLSI, many reference studies use this approach to estimate reference intervals due to the challenges of collecting large numbers of blood samples from healthy individuals.

Methodological approaches to establishment of reference intervals

The CLSI and the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) provide detailed guidelines for the clinical laboratory community on defining, establishing, and verifying reference intervals [7,35–41]. The recommendations for the selection of reference individuals, preanalytical and analytical considerations, outlier exclusion, and statistical methods for reference interval determination and partitioning are described below and are summarized in Fig. 3.2.

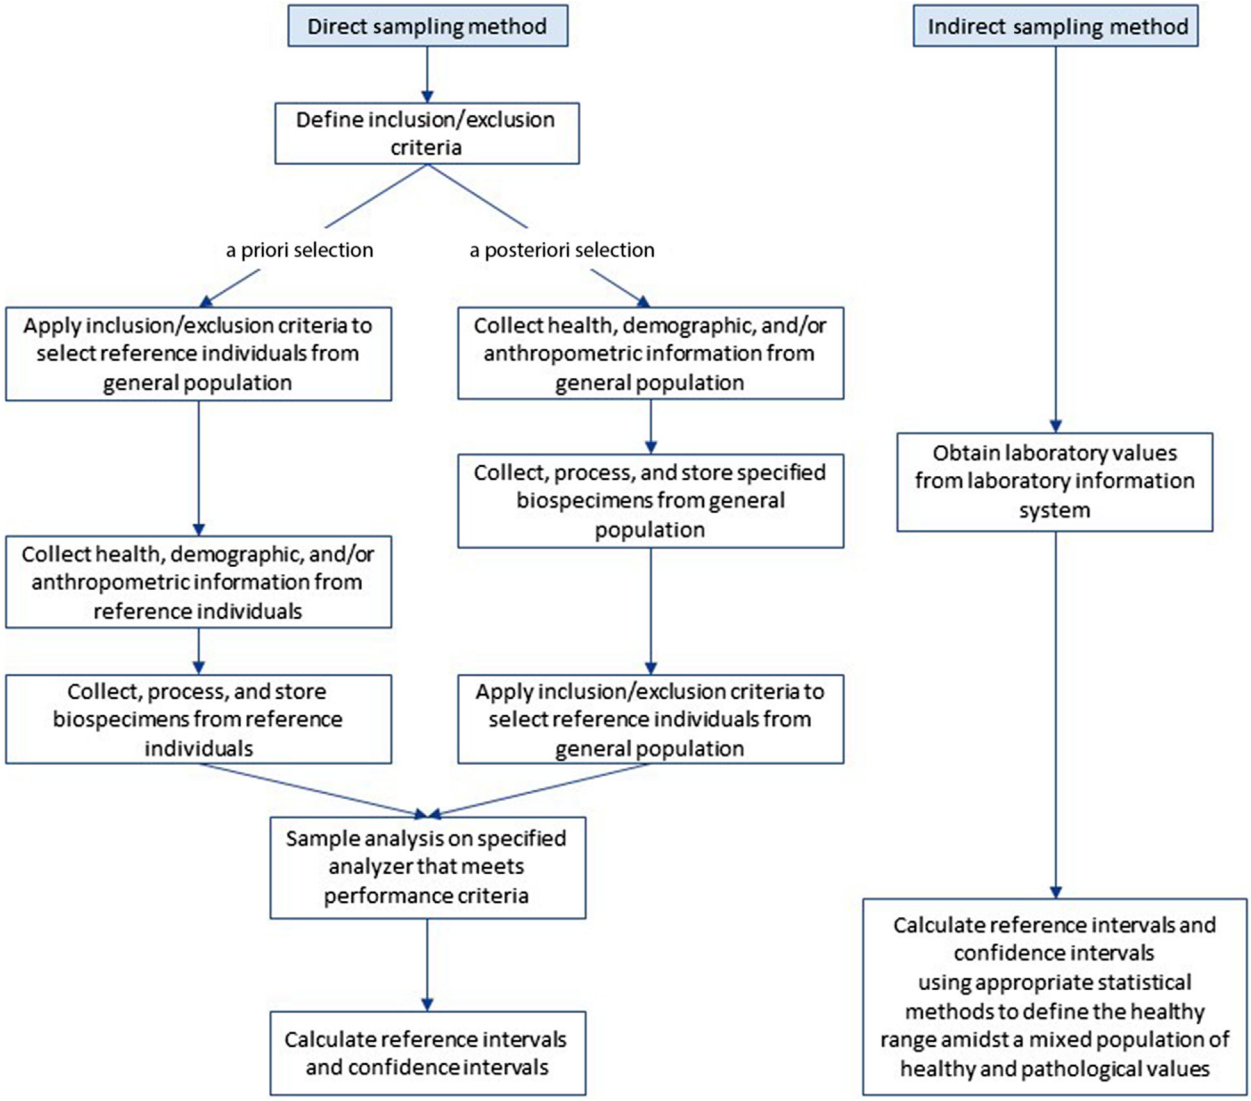

FIGURE 3.2 Flowchart of direct and indirect reference interval establishment processes.

Population-based reference intervals

Population-based reference intervals are derived from a group of well-defined reference individuals that, ideally, are similar to the target patient in all respects other than the disease condition under investigation. Population-based reference intervals are widely used in contrast to individual reference intervals, based on values obtained from the same individual, as they are more impractical to establish and implement. Thus this chapter will refer only to the establishment of population-based reference intervals.

Selection of reference individuals

The quality of a reference interval can depend heavily on the selection and recruitment of appropriate reference individuals [8,11,42]. According to the CLSI EP28-A3c guidelines, reference intervals should be based on direct sampling of healthy individuals from the age group(s) of interest, using well-defined inclusion/exclusion criteria. Important factors to consider when selecting reference individuals include *direct* versus *indirect sampling* and application of a priori versus a posteriori selection criteria.

Direct versus indirect sampling

Direct sampling is the preferred method recommended by the CLSI [7] and involves the selection of healthy individuals using defined inclusion/exclusion criteria. Using this method, "unhealthy" individuals are not included, and thus do not jeopardize the validity of the reference interval. The challenges associated with the direct sampling method, however, include the difficulty and cost associated with collecting a sufficient number of blood samples from healthy individuals to calculate accurately reference intervals [39]. Statistical methods used to establish reference intervals using data obtained by direct sampling are discussed in the section "Statistical determination of reference intervals."

In contrast, *indirect sampling* uses laboratory values obtained from a patient population, which includes both healthy and pathological subjects, to estimate reference intervals. This approach is easier and less costly than the direct sampling technique. However, the use of indirect sampling is not recommended by the CLSI due to the risk of including values from diseased individuals, which may result in skewed, broader, or less sensitive reference intervals [7]. However, the CLSI does acknowledge that, in some cases, the use of indirect sampling may be necessary when it is too difficult to recruit sufficient numbers of healthy individuals [7]. This is often the case in pediatrics, where issues such as small sample volume and parental consent can pose significant challenges to recruitment of a healthy reference population. Statistical methods that have been proposed to calculate reference intervals based on the indirect sampling method include the Hoffmann [43], Bhattacharya [44], modified Bhattacharya to accommodate Gamma distributions [45], and methods proposed by Arzideh et al. [46,47] for data that typically require a Box−Cox transformation and Gaussian distributed data. All proposed methods attempt to define the range of data explained by healthy subjects amidst a mixed population of both healthy and pathological samples. Furthermore, all methods assume the majority of observations in the data set are from healthy individuals, an assumption difficult to ascertain depending on the patient population employed.

A priori versus a posteriori sampling

Both a priori and a posteriori sampling approaches can be used to establish reliable reference values. The determination of which method to use often depends on the nature of the study. In a priori sampling, well-defined inclusion/exclusion and partitioning criteria must be established before reference individuals are selected. In addition, an appropriate questionnaire designed to reveal these criteria is necessary. Exclusion criteria should exclude individuals from the reference sample group based on assessments indicating lack of good health (e.g., recent or chronic illness, use of prescription or nonprescription medication, use of tobacco or alcohol, and diet) [7]. Reference intervals can be partitioned by several covariates that are known to affect the level of the specific analyte (i.e., sex, age, Tanner stage, and ethnicity), and therefore the questionnaire should include these factors as well. This procedure is typically applied for analytes with well-established methods and laboratory procedures, and known sources of biological variation. Information from the literature is used to develop exclusion and partitioning criteria, which are included in the questionnaire to exclude individuals from the sampling process [7]. In contrast, in the a posteriori approach, exclusion and partitioning occur after sample collection and analysis. This approach is recommended for analytes that are new or for which well-documented information does not exist in the literature regarding laboratory procedures and biological variation. However, this approach may require a more detailed questionnaire to capture information on all potential covariates that may be used as exclusion or partitioning criteria [7].

Preanalytical and analytical variables

A number of preanalytical and analytical variables can influence test results and reference intervals. Therefore these variables must be carefully considered and controlled in both the patient population and in reference individuals. The CLSI EP28-A3c guideline lists a variety of preanalytical and analytical variables that should be considered when developing reference intervals [7].

Preanalytical variables include subject preparation, specimen collection, and specimen handling considerations. Depending on the analyte, subjects may need to be

in a fasted or a nonfasted state, may require a rest period from physical activity prior to sample collection, or may need to abstain from substances that could affect analyte levels, such as pharmacological agents, caffeine, alcohol, tobacco, or vitamin C. In addition, some analytes vary with circadian rhythm or stage of the menstrual cycle (in the case of females) and, thus, these factors should also be considered. Other subject-related variables may include prior diet and stress level. Specimen collection considerations include time of day, environmental conditions during collection, body posture, specimen type, blood flow, equipment, tourniquet time, collection technique, sample volume, and anticoagulants. Regarding specimen handling, it is important to consider variables such as transport, storage, clotting, separation of serum/plasma, and sample preparation for analysis.

Analytic variability of the method used for measurement can also impact reference intervals, and thus it is important that the measurement of reference samples and patient samples are performed in an identical manner [2,7]. The methods used should be clearly described, and between-run analytical imprecision, limit of detection, linearity, recovery, reportable range, interference characteristics (i.e., hemolysis, icterus, and lipemia), and traceability should be reported. Instrument and equipment maintenance and normal operation must also be equivalent, as should quality control procedures for reagents, calibration, controls, and calculation methods. Additional consideration should include reagent lot-to-lot variability, instrument-to-instrument variability (if multiple analyzers are used), and technologist variability [7].

Outlier exclusion

Before reference intervals are calculated, the data should first be examined for the presence of observations with extreme values that have the potential to influence the estimation of reference values. Although reference populations are usually selected to minimize the number of outliers in the distribution, in actuality, this is often impossible to achieve. Thus the frequency distribution of the data should first be inspected for the presence of outliers. Frequency histograms or box plots can be used to inspect visually the data for the presence of outliers. However, statistical methods should be applied to remove outliers prior to reference interval determination. According the CLSI EP28-A3c guidelines, two methods are recommended for outlier removal: Dixon's test or Tukey's method [7].

Dixon's test calculates the absolute difference (D) between the suspected outlier (which can be an extreme large or extreme small value) compared with the next largest/smallest observation and compares this with the range of all observations (R), including extremes. In Dixon's test, a ratio of 1/3 is used as a cutoff, where, if D/R exceeds the 1/3 ratio (meaning that D is greater than or equal to 1/3 of the range R), then the outlier should be removed. If two or more outliers are suspected on the same side of the distribution, the 1/3 rule can be applied to the least extreme outlier and removed collectively with more extreme values [48,49]. Dixon's test requires the data be normally distributed, and data that do not follow a Gaussian distribution should be transformed before applying Dixon's test. In addition, it should be noted that Dixon's test should only be applied once to remove outliers, which may not always be practical depending on the nature of the distribution. Furthermore, Dixon's tests preferentially identify and remove outliers with high values compared with those at the lower end of the normal distribution, which should be considered before choosing to use Dixon's test or Tukey's method for outlier removal [48].

Tukey's method involves calculating the 25th and 75th percentiles of the data set ($Q1$ and $Q3$, respectively), and subsequently using these values to determine the interquartile range (IQR; $Q3-Q1$). The IQR is used to determine the boundaries for outlier exclusion, where the lower boundary is calculated by $Q1-1.5\times\text{IQR}$ and the upper boundary is calculated by $Q3+1.5\times\text{IQR}$. Any value below the lower boundary or above the upper boundary should be removed as outliers [50]. Similar to Dixon's test, Tukey's method requires a normally distributed data set. The data may be transformed to achieve normality using a method such as Box–Cox transformation, or an adjusted Tukey test may be used on a skewed data set [51]. Unlike Dixon's test, however, the Tukey method may be applied to a data set more than once to remove outliers and does not preferentially favor removal of outliers from one side of the distribution over the other. Thus Tukey's method may be better suited for outlier removal when both the upper and lower limits of the reference interval must be determined [2].

Partitioning and minimum sample size

Partitioning is used when significant differences exist in analyte levels between subgroups, such as between sexes or different age groups. Partitioning or establishment of separate reference intervals for different subgroups of a reference population may be necessary for certain analytes. For established analytes, the clinical or physiological significance of partitioning may already be known. For new markers, however, this information may not be available. The CLSI recommends that for each partition, or subgroup, a minimum number of 120 reference individuals should be included in the calculation of the reference interval [7].

The decision to partition reference intervals into distinct subgroups is often based first on visual inspection of the reference distribution. For instance, bimodal or polymodal

distributions contain more than one peak and may be an indication that the data contain two or more distributions, which should be partitioned according to age, sex, and/or other factors. The final decision to partition, however, should be based on a statistical test to determine whether the difference in the means between two subgroups is statistically significant. There are several tests that can be used for the purpose of partitioning. Sinton et al. [52] recommend that partitioning is only required if the difference in means is greater than 25% of the 95% reference interval. In contrast, Harris and Boyd [53] suggest partitioning if the ratio of the subgroup standard deviations is ≥ 1.5. It should be noted, however, that the Harris and Boyd method requires Gaussian distribution of the data. The CLSI EP28-A3c guidelines also list an alternate method proposed by Lahti et al. that can be used on data of any distribution and focuses on distances between the reference limits instead of the distances between the means [7,54]. While partitioning of categorical variables, such as sex, is relatively straightforward using the methods described above, partitioning based on continuous variables, such as age, can be more complex. In these cases, continuous reference intervals may better reflect the relationship between the age and the analyte concentration [55–57].

Statistical determination of reference intervals

The CLSI EP28-A3c guideline primarily focuses on two statistical methods to calculate reference intervals: the traditional nonparametric method, which requires no assumption about the distribution of the data, and the robust method, which requires fewer observations to calculate the reference interval and is not sensitive to outliers [7]. Parametric methods may also be used to calculate 95% reference intervals, although this method assumes the data follow a Gaussian distribution. Various statistical approaches for calculating reference intervals based on the direct sampling method will be discussed in this section.

Nonparametric analysis

The traditional nonparametric rank order analysis is recommended by the CLSI to calculate reference intervals due to the simplicity of this statistical method and the fact that this method makes no assumptions regarding data distribution given the common non-Gaussian distribution of analyte measurement. In this approach, the reference values are sorted from the lowest to highest and rank-ordered, with the smallest value receiving a rank of 1 and the largest value receiving a rank of n [7]. The lower reference limit is then determined by calculating the observation that corresponds to the 2.5th percentile $[r_1 = 0.025(n + 1)]$ and the 97.5th percentile $[r_2 = 0.975(n + 1)]$. If the values of r_1 and r_2 are not integers, then one should interpolate between the two limiting values. It should be noted that the nonparametric rank method is not recommended for data with less than 120 reference values. The CLSI also recommends that 90% confidence intervals are calculated for each end point of the reference interval [7]. An alternative nonparametric method is the Harrell–Davis nonparametric bootstrap method [58], which provides a more accurate estimation of the reference interval by continuous resampling, but requires more complex computation and demands more statistical expertise.

Robust analysis

The CLSI recognizes that, in some cases, it is not possible to obtain a minimum number of 120 reference samples. In this case, the robust method developed by Horn and Pesce [1,59] is recommended as an alternative approach, although the method is more complicated. The robust method assigns each reference value a statistically calculated "weight." The weights are proportional to each value's distance from the mean, with greater weights assigned to central values than the more distant values. The weighted values represent a new data set with a distribution that closely approximates the underlying distribution of the data. Bootstrapping is used to repeat the algorithm multiple times, generating successive distributions, which each time resemble the underlying distribution more closely. After sufficient bootstrapping, an estimate of the 95% reference interval can be computed. As few as 20 reference samples may be used to estimate reference intervals using the robust method, however, in order to achieve 90% confidence level, the minimum recommended number of observations is 80 [7].

Parametric analysis

For data with a Gaussian distribution, reference intervals can be calculated using parametric analysis, which uses the mean and 1.96 standard deviations of the data set to calculate the 2.5th and 97.5th percentiles. Prior to parametric analysis, it is important that the data are checked using statistical tests (such as the Anderson–Darling test recommended by the IFCC) to ensure that the data fit a Gaussian distribution. If the data are skewed, transformation can be used to approximate a Gaussian distribution. However, the IFCC recommends a two-step approach for data transformation to correct for skewness and kurtosis, respectively, such as the method outlined by Harris and DeMets [60]. When the data are Gaussian or can be transformed to be Gaussian, the parametric method produces reference intervals with the least biased estimates (i.e., most accurate) and the lowest mean squared error (i.e., most precise) across a wide range of sample sizes (i.e., $n = 40–480$), according to a systematic comparison of the performance of traditional

nonparametric, parametric, and robust methods [61]. As the distribution of reference values for most analytes is often not Gaussian, parametric analysis often requires complex statistical theory and computer programs to test whether transformed data conform to a Gaussian distribution. Due to the complexities of parametric analysis and the common non-Gaussian distribution of analyte concentration, the nonparametric approach is recommended by the CLSI [7].

Covariates that affect reference interval determination

The specificity and sensitivity of reference intervals may be improved by partitioning the reference population where appropriate. A number of physiological factors may contribute to clinical variation in analyte levels within a population, which should be considered when establishing reference intervals [62]. Reference intervals are frequently partitioned by age and sex. However, other important covariates may also influence analyte concentration including pregnancy, organ maturity, growth, hormonal changes, and sexual development. These covariates are not relevant to all age groups or analytes, but may result in important differences in some cases. For instance, levels of fertility hormones may be different in pregnant versus nonpregnant women, requiring separate reference interval partitions. In addition, during development, levels of fertility hormones, important for indicating pediatric endocrinopathies, may vary with age, sex, and sexual development (Tanner stage), and should be partitioned accordingly.

Ethnicity is also emerging as a recognized factor that contributes to the differences in the concentration of some analytes, as a result of genetic and/or environmental factors [1,63,64]. Currently, the majority of reference intervals are based on a predominant Caucasian population, which could be inappropriate for the ethnically diverse patients served by many laboratories. Ethnic differences in analyte measurements (e.g., routine chemistry, fertility, endocrine, cancer, and hematologic markers) between several ethnic groups (e.g., Black, Caucasian, East Asian, Hispanic, South Asian, South East Asian, and West Asian) were recently reviewed, highlighting potential differences between the ethnicities for a subset of analytes [65]. Thus establishment of ethnic-specific reference intervals for a subset of biomarkers may lead to more accurate diagnosis/treatment and improved patient care. However, prior to implementing ethnic-specific reference intervals in clinical practice, it is important to consider concurrently reported significant ethnic differences, population demographics, environmental factors, and disease risks to ensure these reference intervals will improve clinical assessment.

Partitioning by genetic differences provides another potential means of reducing interindividual variation within a reference interval, improving their clinical utility. Including this additional covariate may reduce misidentification of unusual test results that are caused by genetic variation [66]. A statistical framework to estimate the utility of partitioning reference intervals based on genetic variation has been proposed [66]. This exercise uncovered important considerations when deciding whether to partition based on genetic variation, including the size of the genetic effect and the prevalence of the polymorphism in the population [66]. Furthermore, the complexity of genetic variation effect on reference values would have to be simplified inherently to permit reference interval partitioning, as multiple genes and environmental factors contribute to the total variance in analyte concentration [66]. Genetic information has been considered during the establishment of reference intervals for apolipoprotein E [67] and haptoglobin [68]. Incorporating genetic variation information into reference interval establishment may become common with clinically available whole-genome data and a better understanding of the effect of genetic polymorphisms on laboratory data [69].

Age-dependent reference curves

The statistical methods most commonly employed for reference interval calculation provide discrete upper and lower reference limits for a particular age and sex subgroup. However, biomarker concentrations do not abruptly change with age, as discrete reference intervals suggest. Rather, biomarker concentration changes continuously with age, particularly throughout the pediatric age range due to rapid periods of growth and development. Therefore rather than treating age as a categorical variable, it can be treated as a continuous variable in the development of age-dependent reference curves. Reference curves have been widely used to provide accurate reference data for body measures in the pediatric population, including growth reference charts by the World Health Organization [70] and the Centers for Disease Control and Prevention [71]. Continuous reference intervals are now emerging for laboratory biomarkers, using both direct [72,73] and indirect sampling methods [74–78]. Although indirect sampling methods are more feasible, direct sampling methods are still preferred to establish reference intervals due to reduced preanalytical and analytical variations and minimization of errors [79]. Several statistical methods for direct reference interval establishment have been proposed including parametric (e.g., fractional polynomials [80]), semiparametric (e.g., lambda-mu-sigma method [81]), and nonparametric methods (e.g., nonparametric quantile regression [82,83]). Statistical methods for developing continuous reference intervals using the indirect sampling method have also been proposed, including a method developed by Zierk et al. [75,78]. Although continuous reference intervals better reflect the dynamic trend in biomarker concentration with age, their implementation in clinical practice

remains an obstacle, as laboratory information systems are currently unable to accommodate a mathematical function for laboratory test interpretation. Therefore while continuous percentile curves provide a more accurate representation of normative biomarker concentration, age and/or sex partitions are still required for practical use, which inherently reduces the complexity of true age-related trends.

Pediatric and geriatric reference intervals: challenges and recent advances

While a number of ongoing national initiatives have begun to close the gaps in establishing up-to-date reference intervals, many of these studies have focused on the adult population, generally analyzing samples collected from reference individuals between 18 and 65 years of age. Unfortunately, reference intervals for older and younger individuals pose unique challenges to sample collection and reference interval calculation, often requiring stratification by multiple covariates and an increased number of reference individuals. Thus large knowledge gaps remain in reference intervals for pediatric and geriatric populations. The following sections will describe the challenges and procedures for establishing reference intervals in these age groups, and will review recent initiatives aimed at addressing these gaps.

Pediatric reference intervals

Establishing reference intervals specific for the pediatric population is a task of utmost importance but also of great complexity, requiring both time and resources. Traditionally, pediatric laboratory tests have been interpreted based on adult normative values. However, children cannot be viewed as simply "small adults" in medical practice. Children and adolescents differ from adults in many aspects, including physical size, organ maturity, rates of growth, developmental stages, and immune and hormone responsiveness [2]. In addition, newborns respond to infections differently from adults, as they have little to no history of infectious disease exposure and often require special laboratory testing [5]. Furthermore, puberty is a unique developmental stage that occurs in adolescence, which can profoundly affect various analyte levels. For example, levels of sex and growth hormones are low in infants, but increase during and after puberty, while markers of bone growth (e.g., alkaline phosphatase) are elevated in children and then decrease in adulthood with the cessation of bone growth [12]. These notable trends highlight the importance of developing pediatric-specific reference intervals. A major challenge faced during reference interval determination in the pediatric population is recruiting a sufficiently large and healthy reference population. There is a need for large-scale public relation campaigns to recruit a sufficient number of participants, which can be costly and time-consuming. Parental consent is needed prior to collecting blood from young subjects and thus poses an additional barrier. Also a sufficient sample volume can be difficult to be obtained from children and certified phlebotomists with special training are required to perform pediatric blood collection.

Pediatric reference intervals should reflect the dramatic physiological and hormonal changes that take place over the course of development. Body weight and length increase at a considerable rate during the first year of life. During puberty, important hormonal changes take place in addition to accelerated growth and sexual maturation. These events are all unique to the pediatric age range and can dramatically affect the levels of many analytes. It is, therefore, incredibly important that pediatric reference intervals reflect the differences in development and physiological function at different ages. Extensive partitioning is required to ensure reference intervals are specific for these different physiological stages. Additional complexity arises from subjectivity in differentiating between statistically relevant and clinically relevant partitions. Sometimes partitions will be deemed statistically relevant (e.g., according to the Harris and Boyd method), but clinically, it may not be necessary to have separate partitions for specific age and/or sex categories. Alternatively, partitions may not be statistically relevant, but clinically, a known physiological change may justify separating specific age and/or sex partitions as appropriate.

Regional initiatives to address the gaps in pediatric reference intervals have been performed with an extensive number of healthy children across the pediatric age range and for both sexes. These include the KiGGS (German Health Interview and Examination Survey for Children and Adolescents) study in Germany, the CALIPER initiative in Canada, the Children's Health Improvement through Laboratory Diagnostics (CHILDx) Study in the United States, and initiatives of the Scandinavian Societies of Clinical Chemistry. The KiGGS study, part of the health monitoring system of the Robert Koch Institute, aimed to collect, for the first time, comprehensive and nationwide data on the health status of children and adolescents aged 0–17 years. From 2003–06, information was collected by means of surveys, medical examinations, tests, and laboratory analyses from 17,641 children at 167 locations in Germany. The KiGGS study successfully addressed their aim of collecting comprehensive, nationwide data on the health status of German children and adolescents, evident through several publications [84,85]. These include studies on general health (i.e., mental health issues, subjective health, and accidental injuries), chronic diseases (i.e., bronchial asthma, hay fever, and neurodermatitis), and health factors (i.e., alcohol consumption, physical activity, sports, and tobacco consumption). More recently, this research group from Germany developed percentile charts from laboratory data collected from 10 German centers, including

laboratory results from over 350,000 pediatric patients. They also created a website application (www.pedref.org/hematology) that allows visualization of hematology test results using percentile charts and z-scores, providing precise test result interpretation. CALIPER is a Canadian initiative that began in 2009 to address the critical gaps in pediatric reference intervals. Since its inception, CALIPER has recruited over 10,000 children and adolescents aged 0− < 19 years and has established age- and sex-specific reference intervals for over 170 biomarkers, including routine chemistry analytes, proteins, enzymes, fertility hormones, and tumor markers [15−20,23−25,28,29,31]. In 2002 the CHILDx was initiated at ARUP Laboratories to determine pediatric reference intervals for a number of clinical laboratory assays using samples collected at ARUP and Primary Children's Medical Center in Salt Lake City, Utah. Reference intervals have been established for 35 assays (goal of 66 assays) for children aged 6 months to 6 years and 58 assays (goal of 144 assays) for children aged 7−17 years [86−93]. The Nordic countries have also been successful in establishing pediatric reference intervals for 21 biochemical properties. These reference intervals were established using pediatric samples (aged 5−19 years) collected from schools in the Copenhagen area in Denmark as part of THE COPENHAGEN Puberty Study (ClinicalTrials.gov ID: NCT01411527) conducted in 2006−08 [94].

Geriatric reference intervals

Another subpopulation that poses unique challenges to establishing reliable reference intervals is the geriatric population. The geriatric population seeks health care more often than individuals representing the age group 20−50 years [95]. However, there are relatively few published reference interval studies specific for the geriatric population and statistical approaches for their calculation vary widely [96]. Defining and obtaining a healthy reference population is essential for calculating representative reference intervals, and this is one of the most challenging tasks when studying the geriatric population. As individuals age, there is a large increase in the proportion of individuals who are not healthy. In 2013 Horn and Pesce reported that to obtain healthy reference samples from individuals aged 70−80 years old, 9 out of every 10 people would have to be excluded, on average [1]. The guidelines most commonly followed to develop adult reference intervals, CLSI EP28-A3c, are essentially silent on how to address concerns specific to elderly populations. Analogous to the developmental processes that occur in the pediatric population, the geriatric population undergoes the physiological process of aging, which has a large impact on circulating biochemical markers in the elderly [96]. Geriatric patients often have one or more morbidities, are prescribed more than one medication, and vary widely in their physical ability, which all affect their biological state [97]. These factors require extensive partitioning to account for the differences in analyte levels, necessitating an even larger minimum sample size.

In an elderly population, it is difficult to decipher the extent of the apparent increase in biological variation that is part of the "normal" aging process [98]. For example, creatinine concentrations increase with age [12,99], but limits have not been established for what would be considered a normal increase rather than an increase that is indicative of disease. This represents a challenge in the process of outlier removal, since these outliers may represent natural variability within a specific group of individuals. This variability could be assessed with a statistical method, such as a sensitivity analysis to determine how influential outlying observations are on reference interval estimates [100]. As previously mentioned, geriatric subjects commonly have one or more comorbidities or are taking multiple medications, and therefore data may represent a patient population, rather than a healthy community representative sample. Although it is not recommended by CLSI to use patient data, it may be a useful estimate for this complex population. If hospital data sets are used, an indirect method (e.g., Hoffmann, Bhattacharyya, or Arzideh method) should be used to select apparently "healthy" individuals from the data set to ensure reference intervals are reliable and valid.

Typically, adult reference intervals are partitioned according to age groups, which show homogeneity in the analyte of interest. However, chronological age partitioning may not be suitable for elderly populations as one's chronological age is often not indicative of their biological state. Therefore using the characteristic approach to age partitioning could lead to grouping heterogeneous health states together. A more useful method would be to group individuals that have similar biological states through visually assessing the data to identify groups with similar analyte levels. This could be done by creating scatter or box plots against age, sex, number of morbidity, and/or type of morbidity [96]. The same statistical methods mentioned above in "Partitioning and minimum sample size" can be used here to test significant differences between the partitions. An additional challenge faced when partitioning geriatric reference intervals is due to difficulties in obtaining large enough sample sizes for these age groups. Partitions can be appropriately set based on a statistical test, but the sample sizes in the partitions may be inadequate. On the other hand, two very different groups may be inappropriately combined with the single purpose of attaining the recommended sample sizes. In both of these cases, the differences in the partitioning factor (i.e., age, biological state, and so on) are not adequately portrayed.

One ongoing initiative for geriatric reference intervals is the Swiss Senior Labor study (www.seniorlabor.ch),

which involves nearly 1500 elderly participants (60 years or older) to develop geriatric-specific reference intervals for various analytes including vitamin D [25(OH)], vitamin B12, homocysteine, and folate [101,102]. This group used CLSI EP28-A3c guidelines to establish reference intervals, specifically the nonparametric method as the sample size was large and the data were skewed. Exclusion criteria used, specific for classifying elderly patients as "healthy," excluded patients with clinical history suggestive of cognitive impairment as well as survival of less than 1 year following the study [101]. A study in 2012 reported reference values for 31 routine laboratory tests in a population of subjects aged 75 years [103]. Recognizing the challenges of using very strict criteria for defining a "healthy" population and the tradeoff with sufficient sample size, this study excluded all individuals with diabetes mellitus and then calculated reference values for the whole group and also for subgroups without cardiovascular disease [103].

Another study was conducted in 2013 to establish reference intervals for serum creatinine in the healthy geriatric population, using 3640 healthy Chinese individuals aged 60−89 years [104]. This study excluded participants on the basis of several factors including a diagnosed acute or chronic disease, undergone surgery in past 6 months, use of prescription medication within the previous 2 weeks, high blood pressure for over 3 years, and structural abnormalities of heart, liver, lungs, or kidney tested by ultrasonic wave, electrocardiogram, or chest X-ray film [104]. A recent Canadian initiative used data from the CHMS (a survey of Statistics Canada) to establish reference intervals for Canadians aged 3−80 years for common biochemical assays, immunoassays, and hematology assays [12−14]. The same exclusion criteria (including use of prescription medication or diagnosed serious medical or chronic illness) was used for all subjects, regardless of age, which resulted in approximately 70% of subjects aged 40−79 years excluded. A meta-analysis of 64 studies on geriatric reference intervals [96] showed extensive gaps in the reporting of statistical methods used for reference interval calculation. This observation highlights the need to apply rigorously current guidelines to reference interval determination for geriatric populations. Another promising new initiative is the Canadian Longitudinal Study on Aging (CLSA), which is a large, national, long-term study that will follow approximately 50,000 men and women between the ages of 45 and 85 for at least 20 years (www.clsa-elcv.ca/about-study). CLSA plans to establish a comprehensive geriatric reference interval database.

Reference interval transference and verification

When reference intervals are established, they are specific for the instrument, method, and population from which they were determined. To ensure all laboratories have access to reference intervals that are reliable for their specific procedures and populations without performing a full reference interval study, transference methods may be used to adapt previously established reference intervals.

Methodological approach to transference

For individual laboratories, determining reliable reference intervals for every new analytical test and method is often beyond their capabilities, making it very convenient and cost-effective if reference intervals established in another laboratory could be used. For reference intervals established in one laboratory (donor) to be used in another laboratory (receiver), the fulfillment of certain conditions is required. These include (1) the reference interval to be transferred must have been obtained properly and its generation must be fully documented; (2) the analytical systems must be comparable; and (3) the test subject populations must be comparable [7,105]. Transferring reference intervals, as opposed to performing an entirely new study, poses a major advantage of obviating the need for the laboratory to obtain samples from a large number of reference individuals.

The method of reference interval transference is the calculation of a new reference interval for a different laboratory based on an existing reference interval using the regression equation from a method comparison. First, fresh samples from a patient population are used to investigate the relationship between the analytical methods. The correlation between the analytical systems needs to be sufficiently high ($r^2 > 0.70$) in order to use regression statistics to calculate a new reference interval from the existing one [105]. Even if the analytical systems correlate extremely well ($r^2 > 0.9$), there may still be a significant difference between the laboratory results measured on the two systems due to bias [105]. For regression methods to be used sufficiently, laboratory test values must have a large enough range ratio and the intercept should be small in relation to the reference interval [105]. If the methods correlate sufficiently, linear regression is used to calculate the best fit regression line. Finally, the best fit regression line is used to calculate the transferred reference interval based on the existing reference interval. An example of an acceptable method comparison to allow reference interval transference is shown in Fig. 3.3. In this example, the analytical systems correlate extremely well ($r = 0.988$), the slope (1.02) is close to 1, and the y-intercept (−0.15) is close to 0. Furthermore, the reference interval to be transferred was 4.2−10.2, and the y-intercept (−0.15) would be sufficiently small. The final recommendation for a laboratory to adopt potentially transferred reference intervals is for the populations of both laboratories to be homogenous, meaning there are no major ethnic, social, or environmental differences among them [7]. Complete demographic information on the

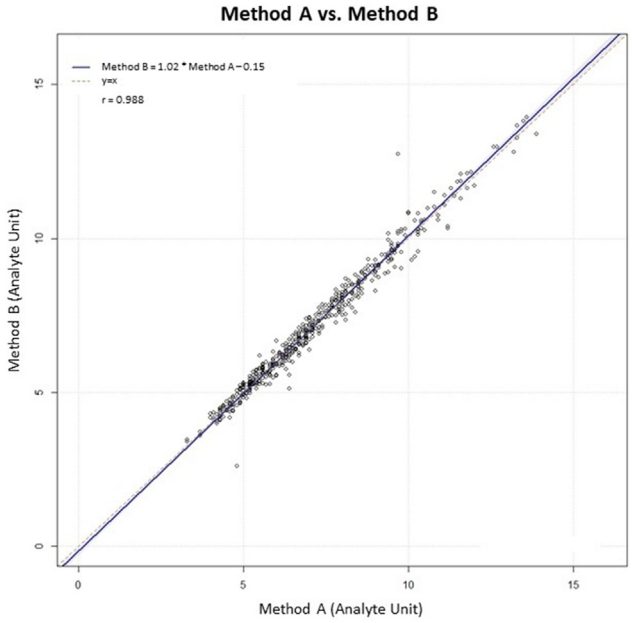

FIGURE 3.3 Graphical representation of an acceptable method comparison for transferring reference intervals. Values for a given analyte obtained by Method A (used to derive reference interval) strongly correlates ($r = 0.988$) with those obtained by Method B. A linear regression line acceptable for transferring the reference interval is obtained, demonstrated by minimal scatter around the regression line, a slope close to 1.0, and y-intercept close to 0.

original reference sample groups must be available and must correspond to the demographics of the new population [105]. However, it is not always practical for populations of both laboratories to be homogenous. The next step in adopting reference intervals from another laboratory is to verify the transferred reference intervals. If the transferred reference intervals are successfully verified using the receiving laboratories' local population, the populations from both laboratories can be assumed to be homogenous.

Limitations of the transference method

There are some caveats of using the transference method to establish reference intervals for a laboratory, rather than performing a new reference interval study. First, it is critically important to use an appropriate distribution of values. If a sufficient range is not represented, the correlation may appear worse than it is. Alternatively, if the range of samples is too large, the quality of the correlation can be overestimated. Second, the magnitude of the intercept calculated through linear regression must be interpreted based on how it compares to the range of data and the reference interval. If the intercept is large compared to the reference interval, the method bias may negate the appropriateness of transferring. Particularly, for immunoassays that are not traceable, if the confidence interval for the y-intercept does not encompass zero, it can be difficult to remove bias across the entire measuring range by simply using a slope correction. Finally, for particular analytes, linear regression may not be the most appropriate method to compare the two sets of data. Correction of the mean bias between the methods may be a better approach for analytes with a narrow range of values or discrete integers [7].

Transference initiatives

In 2013 a group from Yamaguchi University Graduate School of Medicine in Japan published results of a transference study for nonstandardized analytes in an Asian population [106]. First, common reference intervals for nonstandardized analytes in an Asian population were determined using centralized measurements [106], meaning that all specimens were transported to central laboratories, and therefore a single reagent and platform were used to eliminate assay-related variations. To transfer these reference intervals to other laboratories, specimens were measured on the central laboratory system as well as each of 37 local laboratory systems. Reference intervals were transferred using a calculated regression line from method comparison analysis. The coefficient of variation of slope b [CV(b)] was used to express the error in converting reference intervals using the regression line. A CV(b) of 10% was set as the cutoff value to allow the reference interval to be transferred. A limitation to this study, however, was that <40 samples were used for comparison in most cases, which is less than recommended in the CLSI guideline [7].

The CALIPER initiative has also performed a series of transference studies to broaden the applicability of their pediatric reference interval database [21,22,26,27,30]. CALIPER reference intervals were initially established on a single analytical system, the Abbott ARCHITECT assay platform. Transference studies were completed to address this limitation and allow these reference intervals to be applicable to four other major analytical systems, Beckman Coulter [22,26,27], Ortho [22,30], Roche [21,22], and Siemens [22]. Briefly, to perform transference, a method comparison was performed by analyzing patient samples on the original assay platform used to establish reference intervals and the platform for which transferred reference intervals were being calculated. If the methods correlated strongly ($r^2 > 0.70$), regression was used to determine the line of best fit. However, if methods were poorly correlated ($r^2 < 0.70$), the reference intervals could not be reliably transferred. The appropriateness of the linear model was assessed using quantile−quantile (Q−Q), studentized residual, and Bland−Altman plots. If the criteria of these three graphs were met, the line of best fit was used to calculate the transferred reference interval. The calculated 95% confidence intervals around each limit were used as limits with

which to verify the transferred reference intervals. Verification was then performed by analyzing 100 local reference samples that adequately encompassed as many age and sex partitions as possible. Reference intervals were considered verified when >90% of the reference samples fell within the transferred reference intervals, inclusive of the 95% confidence intervals. Although these studies provide reference intervals transferred to additional analytical platforms, these transference data are for specific assays, and the data do not validate reference intervals for individual analyzers, specific populations, or geographic locations.

Transference studies are invaluable to laboratory medicine to ensure robustly established reference intervals can be used by laboratories nationally and internationally, regardless of the analytical instrument they use. However, before implementing a reference interval into clinical practice, the newly transferred reference interval or a preexisting reference interval must be validated to ensure the donor and receiver laboratory populations are the same and there are no instrument biases.

Verification of transferred reference intervals

Three approaches can be used to assess if a preexisting or transferred reference interval can be accepted for use in a receiving laboratory: (1) a subjective assessment; (2) a statistical test on a relatively small number of reference individuals; and (3) an evaluation of a larger number of reference individuals.

A subjective assessment of the acceptability of the transferred reference intervals can be performed by ensuring all pertinent factors of the original reference interval study are consistent with the receiving laboratory's practice and test subject population [7]. This acceptability is based on an expert opinion following a careful examination of the conditions by which the reference interval was initially determined [105]. The pertinent factors must include the demographic variables and geographic location of the reference population, the preanalytical and analytical procedures, analytical performance, and the method of estimating reference intervals [7]. All factors must correspond to those in the receiving laboratory. This is an extremely subjective procedure, which poses many risks, and thus the second and third approaches are more commonly used.

The second approach is to assess a small number of reference individuals ($n = 20$) from the receiving laboratory's local healthy population. When using this approach, however, the analytical and preanalytical factors of the original reference value study still need to be consistent with the receiving laboratory's procedures. First, outliers need to be eliminated using either the Reed/Dixon [49,107] or Tukey [50] methods and new local reference samples must be obtained to replace them. If no more than two of the 20 reference subjects' values (or 10% of the test results) lie outside the preexisting or transferred 95% reference limits, this reference interval is considered valid for application in the receiving laboratory. If three or four test results exceed these limits, an additional 20 local reference samples must be obtained, with outliers once again removed. If no more than two of these new test results lie outside the reference limits, this reference interval is acceptable for use in the receiving laboratory. On the other hand, if three or more exceed the limits again (or if five or more in the original sample of 20 fall outside the limits), the analytical procedures used and biological characteristics of the populations must be reexamined and/or the receiving laboratory should establish its own reference intervals through a full-scale study [7]. This is a robust validation procedure, with the probability of false rejection of a reference interval <1% when one or more sets of 20 local reference samples are used [7]. However, if the preexisting or transferred reference interval is too wide for the receiving laboratory's local population, a false-negative result may occur. This highlights the criticality of ensuring the methods and populations are comparable between the laboratories prior to performing validation.

The third approach that can be used is similar to the second approach, but more extensive. This approach is most often used for analytes with reference intervals that are critically important for local clinical interpretation of the assay. In this approach, a larger population of reference individuals (e.g., $n = 60$) from the receiving laboratory's local population is assessed. Once again, the analytical and preanalytical factors of the original reference interval study need to be consistent with the receiving laboratory's procedures. Performing this larger study will have more statistical power for discovering differences between the original donor laboratory and the receiving laboratory's subject population.

The methods of transference and verification greatly improve the applicability of reference intervals to medical laboratories using different analytical instruments. A new focus is now harmonization in laboratory medicine, including harmonization of reference intervals, to standardize test result interpretation and increase transferability of results between the laboratories.

Toward reference interval harmonization

Harmonization in laboratory medicine is achieved through addressing all aspects of the total testing process (TTP) to ensure comparability and concordance of data obtained by different medical laboratories. The scope of harmonization in laboratory medicine is widespread to include aspects of the preanalytical, analytical, as well as the postanalytical phases, including test requests, sample collection, sample handling and transportation, tests and test profiles, terminology and units, reporting formats,

reference intervals and decision limits, and criteria for interpretation. Harmonization is fundamental to the quality of laboratory medicine with the ultimate goal of improving the accuracy and consistency of laboratory medicine and benefit patient health care and outcomes [108]. Many patients and physicians assume that they will receive the same, or at least comparable, result from a laboratory test measured by different laboratories at different times on the same sample and that results are interpreted accurately and consistently [109]. However, this is unfortunately not often the case, as many laboratory test results remain highly variable and poorly harmonized. Those requesting laboratory tests, receiving laboratory reports, developing information systems, and even laboratorians and physicians may be unaware of these critical differences, especially when results are transferred between the laboratories and differences in reporting units or methodology are not clarified. If clinicians assume these results can be directly compared, there is great potential for misinterpretation of laboratory test results and, consequently, erroneous diagnosis and/or treatment. The main drivers for laboratory medicine harmonization are first and foremost patient safety and the need for requesting physicians to be able to compare directly results from different clinical laboratories. As we are moving toward full electronic reporting of laboratory results to enable them to be viewed by a range of users, there is a greater need for harmonizing test names, units, and reference intervals associated with results.

Numerous studies have shown that the reference intervals for clinical analytes have larger variation than the analytical inaccuracy of their measurement [110,111]. Most recently, a national survey created and disseminated by the Canadian Society of Clinical Chemists (CSCC) hRI Working Group reported that reference interval variation was greater than test result variation for the majority of analytes assessed [112]. Furthermore, reference interval variation was particularly prominent in the pediatric population and varied substantially even between laboratories using the same analytical instrumentation. Therefore if the same patient sample is measured in two different laboratories using the same assay but different reference intervals, the patient's laboratory test result will be interpreted differently and may result in inappropriate diagnosis and/or treatment. In some cases, there are sound scientific reasons for differences in reference intervals, such as ethnicity and analytical methodology; however, both the UK Pathology Harmony study and CSCC hRI Working Group state that laboratories using the same instrument and reagents were often using different reference intervals without a sound explanation [112,113]. One way to mitigate this problem is to use the same reference interval or common reference interval. hRI is the use of a common reference interval across different analytical platforms and/or assays for a specified analyte. The ideal conditions to use a harmonized reference interval are where sound calibration and traceability are in place and where bias would not prevent the use of a common reference interval as evidenced from a between-method comparison. Assays that are traceable to reference measurement systems will be most capable of achieving harmonization, as it is the analytical quality of the assays that determine which analytes have the ability to share harmonized reference intervals (RIs). Several countries and regions have developed common RIs through either direct studies or using a consensus process. An organized plan and structured procedure are important to derive and validate common reference intervals, which will eventually be used to achieve a major national change in pathology reference intervals. Procedures developed and used by a few national initiatives are described in the next section.

One of the earliest hRI initiatives is the NORIP, which has established common reference intervals for 25 clinical chemistry analytes using a reference population of apparently healthy adults from five Nordic countries [33]. In this study, 102 participating laboratories collected blood samples from at least 25 healthy reference individuals and analyzed 25 commonly requested serum/plasma components from each reference individual. A reference material (control; consisting of fresh frozen liquid serum with values traceable to reference methods) was analyzed together with other serum pool controls in the same series as the project samples. Analytical data, method data, and data describing the reference individuals were submitted to a central database for evaluation and calculation of common reference intervals for the Nordic countries. The Pathology Harmony approach in England had an initial focus on clinical biochemistry reference intervals with a subsequent expansion to hematology and immunology [113]. Their harmonization technique used a three-phase process. First, they identified the variation and looked for scientific reasons supporting these differences. If a valid scientific basis was found for variation, the analyte was not harmonized. If there was no underlying evidence to explain identified variation, the second step was to review all reference interval data for the specific analyte and reach a consensus through expert group discussions. Finally, a harmonized reference interval was established and implemented into laboratories.

There have also been efforts by the Australasian Association of Clinical Biochemists (AACB) to encourage and assist laboratories to achieve hRI for common chemistry analytes where sound calibration and traceability are in place. The AACB and the Royal College of Pathologists of Australasia have recommended the implementation of a first panel of common reference intervals for use in Australia (Australasian Harmonised Reference Intervals for Adults and Australasian Harmonised Reference Intervals for Paediatrics)

[32]. The Australasian approach consisted of a checklist assessment process to assess the evidence for the use of common reference intervals, based on the following criteria: (1) define the analyte; (2) define the assays used, accuracy base, analytical specificity, and method-based bias; (3) consider important preanalytical differences and actions in response to interference; (4) define the principle behind the reference interval (e.g., central 95%); (5) describe the evidence for selection of common reference intervals [data sources (literature, lab surveys, and manufacturers), data mining, and allowable bias goal as the quality criterion for acceptance]; (6) consider partitioning based on age, sex, etc.; (7) define degree of rounding; (8) assess clinical considerations of the reference interval and flagging rates; (9) consider use of common reference interval; and (10) document and implement [32]. The Japanese Association of Medical Technologists (JAMT) has also established common reference intervals for 27 serum analytes for which certified reference materials are available and nine analytes frequently measured in routine tests. A hundred laboratories collaborated to recruit, sample, and measure the analytes of 3371 subjects aged 18−65 years. Allowable limits of trueness and intermediate precision based on JAMT criteria were applied to all reference values measured in these laboratories, and those within the allowable limits were used to establish common reference intervals. A characteristic feature of this study is the establishment of reference intervals by the collaboration of many core laboratories certified for metrological traceability nationwide [114].

The extensive effort to derive harmonized reference values for consistent and reliable interpretation of laboratory test results is wasted without effective communication of the information to end users. Laboratory acceptance should be sought at a national level prior to introducing common reference intervals. To assess the likely adoption rates for common reference intervals, a survey can be used to determine whether the laboratory is using a common reference interval already, would accept the common reference interval, or collect information as to their reason why they would not accept the common reference interval. National acceptance of new pathology reference intervals requires ongoing discussions by all involved stakeholders. In addition, criteria must be in place for each laboratory planning to adopt common reference intervals and use them in their clinical practice. Clinical laboratories can implement common reference intervals given there is verification of similar preanalytical conditions, traceability of the analytical method used, and similar characteristics of the tested population [115]. Although establishing and implementing harmonized reference intervals are critically important and will be of extreme value, continuing work is required. Consultation with clinical societies and education of local clinicians is critical if the new common reference intervals are to be used. Maximum benefit from harmonized reference limits will only be realized when all aspects of the TTP are harmonized.

Limitations of population-based reference intervals

Although population-based reference intervals are widely accepted and have numerous advantages for routine clinical application, there are some limitations that should be noted. First, it is important to consider the population from which the reference interval was derived. Differences between the reference population and the individual being tested (e.g., in terms of ethnicity) have the potential to cause misleading clinical interpretation of the test results. As 95% reference limits are normally calculated, laboratories should also be aware that 5% of healthy subjects will remain outside the reference interval and may subsequently be classified as "abnormal." Similarly, it is possible for individuals with subclinical or undetectable disease to be included in the calculation of reference intervals; therefore reference intervals may not necessarily be representative of a truly healthy population. Finally, the usefulness of a population-based reference interval may be evaluated by assessing the index of individuality (II), determined by the ratio of within-subject (CV_I) to between-subject (CV_G) biological variation ($II = CV_I/CV_G$). Analytes with a low II (≤ 1) have significant variation in analyte concentrations between individuals, and thus population-based reference intervals for these analytes may be less sensitive. For analytes with a high II (≥ 1), there is more variation within subjects than between subjects, and population-based reference intervals are more sensitive and, thus, more appropriate for these analytes.

Concluding remarks

In conclusion, reference intervals are central to laboratory medicine, serving as "health-associated benchmarks" by which clinical laboratory test results are compared and interpreted as either normal or abnormal. Reliable and accurate reference intervals have been severely lacking, especially in the pediatric and geriatric populations, due to the complexity of their establishment and the need to continuously update databases, as new assays and technologies are developed. Several aspects need to be considered when establishing reference intervals including selecting appropriate reference individuals and using the appropriate method and questionnaire to do so, preanalytical and analytical factors when handling and analyzing samples, exclusion criteria and outlier removal, partitioning of reference intervals based on key covariates, and selection of the appropriate statistical method to compute reference intervals.

As this process is time-consuming, costly, and often beyond the capabilities of individual laboratories, reference

intervals can be transferred from one laboratory (from which the reference interval was established) to another laboratory. Transferring reference intervals involves the calculation of a new reference interval for a different laboratory or analytical instrument by using the regression equation from a method comparison. Following transference, verification is used to assess if the transferred reference interval or a preexisting reference interval can be accepted for use in a receiving laboratory. Ensuring comparability and concordance of data obtained by different medical laboratories has been a recent central focus in laboratory medicine and can be achieved through harmonization. Harmonization of the TTP, including harmonization of reference intervals, will standardize test result interpretation, increase transferability of results between laboratories, and ultimately lead to successful implementation of harmonized reference intervals into clinical practice.

Self-assessment questions

1. Which of the following statements are true regarding selection of reference individuals?
   a. According to CLSI, reference intervals should be based on indirect sampling of healthy individuals from the age group(s) of interest.
   b. Use of a posteriori selection criteria is not recommended by the CLSI.
   c. The quality of the reference interval is not affected by the reference population.
   d. Lack of appropriate inclusion/exclusion criteria can jeopardize the validity of the reference interval.
   e. In indirect sampling, partitioning takes place after sample collection and analyte testing.
2. Which of the following statement(s) are true regarding calculation of reference intervals?
   a. According to CLSI, a minimum of 120 reference individuals are needed per partition/subgroup.
   b. According to CLSI, only nonparametric rank order analysis should be used to calculate reference intervals.
   c. Reference intervals usually represent the central 98% of values from an apparently healthy reference population.
   d. Outliers should be excluded before reference intervals are calculated using either the Harris and Boyd or the Tukey method, as recommended by CLSI.
   e. The robust method by Horn and Pesce is recommended by the CLSI as the preferred method for calculating reference intervals by parametric analysis.
3. Which of the following is NOT an example of preanalytical variation?
   a. fasted versus nonfasted state of subjects
   b. tourniquet time
   c. separation of serum/plasma
   d. prior diet and stress level
   e. reagent lot-to-lot variability
4. Which of the following statements are NOT true regarding reference intervals and clinical decision limits?
   a. In some cases, only one side of the reference distribution is clinically significant.
   b. Reference limits represent cut points associated with disease.
   c. HbA1c is an example of an analyte for which clinical decision limits are used.
   d. For some analytes, the 99th percentile may be used to calculate reference intervals when greater specificity is required.
   e. For the majority of biochemical markers, reference intervals are used to interpret laboratory test results.
5. Which of the following is NOT true regarding partitioning of reference intervals?
   a. The Harris and Boyd method is one of the methods recommended by the CLSI.
   b. Partitions may be statistically valid but not clinically relevant.
   c. Age, sex, and ethnicity are examples of covariates that may necessitate reference interval partitioning.
   d. Construction of continuous reference intervals is never recommended by the CLSI.
   e. Partitions may be clinically relevant but not statistically valid.
6. Which of the following is NOT true regarding establishing reference intervals using the indirect method?
   a. The indirect method is applied to a population containing both healthy and pathological subjects.
   b. The majority of observations in the data set are assumed to be from healthy individuals.
   c. The traditional nonparametric method is most commonly used to establish indirect reference intervals.
   d. Indirect sampling may be necessary when recruitment of a large sample population is difficult.
   e. Indirect methods are used to define the data distribution from healthy subjects among pathological subjects.
7. Age-dependent reference curves:
   a. can be established using direct or indirect methods
   b. can more easily be implemented into laboratory information systems
   c. can be established using several statistical methods, including fractional polynomials and nonparametric quantile regression
   d. A and C
   e. all of the above
8. Which of the following is NOT true regarding pediatric reference intervals?
   a. The pediatric population differs from adults in regards to organ maturity, developmental stages, and immune responsiveness.
   b. The pediatric population always requires their own reference interval.
   c. Recruiting a sufficiently large and healthy pediatric reference population can be a challenge.
   d. Growth and sexual maturation during puberty can affect the levels of many analytes.

e. KiGGS, CALIPER, and CHILDx are regional initiatives developed to address gaps in pediatric reference intervals.

9. Which of the following is true regarding geriatric reference intervals?
- **a.** Geriatric reference values should be partitioned by chronological age, as this is indicative of their biological state.
- **b.** Unlike the pediatric population, it is not a challenge to recruit a sufficiently large and healthy geriatric reference population.
- **c.** There are specific CLSI guidelines with detailed recommendations to establish geriatric reference intervals.
- **d.** There are few studies on geriatric reference intervals and the statistical approaches used vary widely.
- **e.** Reference interval partitions are rarely needed in the geriatric population, as it is very homogenous.

10. Reference intervals are specific for the _____ from which they were determined:
- **a.** instrument
- **b.** analytical method
- **c.** population
- **d.** instrument and analytical method
- **e.** instrument, analytical method, and population

11. Which of the following is a condition that must be fulfilled for reference intervals established in one laboratory to be used in another laboratory?
- **a.** The reference interval to be transferred must have been obtained properly.
- **b.** The analytical systems must be comparable between laboratories.
- **c.** The test subject populations must be comparable.
- **d.** Full documents must be available on the generation of the reference interval to be transferred.
- **e.** All of the above conditions must be fulfilled.

12. If the r^2 value for the correlation between methods is less than _____, the reference intervals cannot be reliably transferred.
- **a.** 0.50
- **b.** 0.60
- **c.** 0.70
- **d.** 0.80
- **e.** 0.90

Chapter 4

Method validation

Athena K. Petrides[1,2], Jayme L. Dahlin[1,2], and Stacy E.F. Melanson[1,2]
[1]Department of Pathology, Brigham and Women's Hospital, Boston, MA, United States, [2]Harvard Medical School, Boston, MA, United States

Learning objectives

After reviewing this chapter, the reader will be able to:

- Discuss the regulatory requirements associated with clinical method validation studies and the different organizations involved in generating these requirements.
- List the critical components of clinical method validation studies.
- Describe acceptance and rejection criteria for clinical method validation studies.
- Define a laboratory developed test and outline relevant validation parameters and processes.

Introduction

The evaluation of method performance characteristics is an essential responsibility of any clinical laboratory. Although now considered a rather heavily regulated routine function, it is one of the most important services laboratory medicine can offer to optimize patient care. This became widely evident and publicized in 1987 when the *New York Times* revealed that several undiagnosed cervical cancer deaths were linked to false-negative Pap smear results. In response to this report, the United States Congress voted for further oversight of any hospital, independent, or physician-owned clinical laboratory, which led to the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88) being signed into US public law. Along with defining which analytical characteristics require assessment, this landmark federal law also states that laboratories must enroll in proficiency testing (see Chapter 15: Laboratory regulations and compliance), lists qualifications and functions for testing personnel, and enforces a quality control (QC) program.

Most assays performed in the clinical laboratory have already been approved by the US Food and Drug Administration (FDA), a process which requires the manufacturer to present data on their method validation. According to CLIA '88, clinical laboratories are only required to verify the manufacturer's claims by evaluating a limited set of criteria (Table 4.1). However, if the method is to be used differently than intended by the manufacturer, or if it has not been FDA-approved, it is then considered a modified test, and is held to the same regulatory standards as a laboratory developed test (LDT). In such cases, the clinical laboratory is responsible for evaluating the full set of performance criteria described in subsequent sections of this chapter. Even though federal law outlines the minimum requirements for method evaluation, state departments of public health may enforce stricter criteria.

Regulations

Even though law defines which performance characteristics should be evaluated, it neither includes acceptability criteria nor a standard procedure for assessing the listed characteristics. The National Committee on Clinical Laboratory Standards (NCCLS) was the first committee assembled to create standards in laboratory testing. Their first publication in 1969 on how to create manuals for laboratory instruments was endorsed by many agencies, including the FDA, the College of American Pathologists (CAP), and the Centers for Disease Control and Prevention. Another voluntary agency, the Clinical and Laboratory Standards Institute (CLSI), emerged in 1977 and focused primarily on standardizing reference materials and methods across laboratories. The two committees, NCCLS and CLSI, partnered in 2005 and are now known as CLSI. This agency has published over 300 standards that are solicited within the United States and internationally.

Accrediting agencies are now also issuing guidelines based on CLSI standards around key parameters for assessment as well as appropriate acceptability criteria. The Joint Commission, a nonprofit agency, offers an accreditation to both the laboratory and the hospital that is accepted nationwide as an indicator of quality. The CAP Laboratory Accreditation Program also accredits

laboratories, often using a more rigorous and customized checklist than other agencies for FDA-approved tests. Both agencies refer to CLSI standards as evidence of compliance with respect to method evaluation. A comparison of requirements for method verification between the various agencies and committees issuing guidance documents is summarized in Table 4.1.

According to CLIA '88, testing falls into the following FDA-defined categories based on assay complexity: waived, moderately complex, and highly complex. Waived testing can be performed under a CLIA certificate of waiver, thus negating the need for a rigorous method verification process. However, each of the testing categories, including waived testing, has a different set of criteria for method verification, which can differ depending on the ruling committee or agency (Table 4.1).

Analytical goals and method selection

The need for method selection arises frequently in the clinical laboratory. A laboratory may be insourcing a send-out test or implementing a new assay to the market to enhance patient care. The laboratory may also be upgrading or switching instrumentation and selecting an analytical platform with multiple methodologies. Furthermore, troubleshooting may prompt the review of other available methods. For example, the clinical and/or analytical performance of an assay may no longer be adequate, requiring the laboratory to investigate alternatives. Importantly, the manufacturer may issue a notification stating that the laboratory must transition to a new assay formulation. In this scenario, the laboratory can choose to adopt the new formulation if the validation is acceptable, or switch assays. The manufacturer may also discontinue an assay, thus prompting the laboratory to determine whether the clinical utility warrants selecting a different method. Regardless of the scenario, the laboratory must research available assays and their performance as well as available instrumentation prior to performing method validation. In clinical practice, this process is often more time-consuming than the validation itself. An overview of definitions used in method evaluation and verification is provided in Table 4.2.

Utilizing established analytical goals for method selection is the critical first step in this process. It is recommended that laboratories define acceptability criteria, including analytical goals for all tests in the laboratory that can be used to guide method selection. In addition, parameters such as sensitivity and specificity (see Chapter 2: Statistical methods in laboratory medicine) are important to define, as testing with acceptable analytical performance may not necessarily meet the standards for clinical care. Instrumentation, cost, turnaround time, manufacturer reliability and service, informatics requirements, and other parameters should also be considered [1,2]. This chapter focuses on analytical acceptability and method validation. In addition, laboratories should not assume that the new method will be superior to the predicate method.

Multiple resources are available to help laboratories define analytical goals. For regulated analytes, many laboratories will use CLIA guidelines [3]. For nonregulated analytes, such as lactate and B-type natriuretic peptides, guidelines published by CAP or other proficiency testing programs are helpful in defining analytical benchmarks. Laboratories may also choose to discuss analytical goals with their clinician colleagues. Clinical goals ensure that the testing can accurately diagnose, monitor, and/or prevent disease, and can shape acceptable analytical performance criteria. However, this approach may be more

TABLE 4.2 Definition of common terms.

Term	Definition
Accuracy	The ability to recover the correct amount of analyte present in a specimen
AMR	The range of numeric results a method can produce without pretreatment not otherwise part of the usual analytic process (e.g., dilution); also referred to as "range" (CLIA)
Between-run precision	Assesses the imprecision of the assay over the long term (e.g., 10–20 days); also referred to as "day-to-day precision"
Calibration	Known standards are used to create a working curve to ensure the method produces accurate results
Carryover	The unintended transfer of substances (e.g., analyte, reagent, and diluent) between samples or assay compartments
CRR	The range of values an assay can quantitatively report with sample pretreatment such as dilution or concentration
CV	Measure of reproducibility of an assay either within a single run or between runs; CV = (SD/mean × 100)
Confidence interval	An interval that will contain the true value a certain percentage of the time
Constant bias	Results are always greater (or lesser) by the same amount; represented by b in the straight line equation ($y = mx + b$)
Correlation coefficient (R)	Specifies the degree of correlation not the degree to which the methods match. Ranges from −1 to +1 with result of 0 = no correlation and results of −1 or +1 as a perfect correlation
Intercept	Value of the y-variable when the x-variable has a value of zero
Interference	The modulation of the assay readout by nonanalyte substances in a sample (exogenous and/or endogenous); artifactual increase or decrease in apparent concentration or intensity of an analyte due to the presence of a substance that reacts nonspecifically with either the detecting reagent or the signal itself (CLIA)
Least-squares regression	The method of statistically placing the location of the estimated line or curve among the data, so that the sum of the squares of the distances of each data point from the line in the perpendicular direction from the x-axis is minimized
LOB	The highest apparent analyte concentration expected in blank sample replicates containing no analyte
LOD	The lowest analyte concentration likely to be reliably distinguished from the LOB and at which detection is feasible
LOQ	The lowest concentration at which the analyte cannot only be reliably detected but at which some predefined goals for bias and imprecision are met; may meet or exceed the LOD
Linearity	The ability of an assay to provide results that are directly proportional to analyte quantity in a test sample
Matrix effect	The direct or indirect alteration or interference in response due to the presence of unintended analytes or other interfering substances in a sample
Medical decision point	Value(s) that are clinically important for patient management
Method comparison	The testing of the same sample by two independent laboratory assays for the same analyte for the purpose of characterizing test inaccuracy and systemic errors
Outlier	A result that exceeds 10 times the standard error of estimate
Parallelism	Relative accuracy from recovery tests for endogenous analytes in a biological matrix compared with calibrators
Precision	Ability to obtain the same result upon repeated measurement of a specimen
Proportional bias	Results are always higher or lower by the same proportion; represented by m in the equation of a straight line ($y = mx + b$)
Random error	An error caused by factors that vary from one measurement to the next measurement
Recovery	Hundred times measured mean/assigned value; utilized in reportable range experiments
Reportable range	The span of test result values over which the laboratory can establish or verify the accuracy of the instrument or test system measurement response

(*Continued*)

TABLE 4.2 (Continued)

Term	Definition
Selectivity	The ability of the bioanalytical method to measure and differentiate analytes in the presence of components that may be expected to be present (includes metabolites, impurities, degradants, or matrix components)
Slope	A number that describes both the direction and steepness of a line
Specificity	Ability of the method to assess, unequivocally, the analyte in the presence of other components that are expected to be present (e.g., impurities, degradation products, matrix components, etc.).
SD	The amount of variation or diversion of a set of values
Systematic error	A consistent and repeatable error typically indicating an issue with the assay or instrument
TAE	The amount of error that is allowed without invalidating the results. It includes both imprecision and inaccuracy in the method and accounts for both systematic and random errors. It is also referred to as total error, total analytical error, or allowable total error.
Within-run precision	Assesses the repeatability of the assay in the short term
Validation	A more comprehensive evaluation that establishes method performance by examining many characteristics of the assay. It allows the laboratory to evaluate the assay's performance in their patient population
Verification	A less comprehensive evaluation that confirms claims in manufacturers' package insert but does not confirm that the assay is suitable for the laboratories patient population

AMR, Analytical measurement range; *CLIA*, Clinical Laboratory Improvement Amendment; *CRR*, clinically reportable range; *CV*, coefficient of variation; *LOB*, limit of blank; *LOD*, limit of detection; *LOQ*, limit of quantification; *R*, correlation coefficient; *SD*, standard deviation; *TAE*, total allowable error.

challenging due to a potential lack of consensus among different clinicians and/or subspecialties. Importantly, analytical goals should be matrix-specific, particularly for testing available in multiple matrices. Once these goals are defined, only methods that meet these goals should be selected for evaluation and implementation.

Analytical goals provide the laboratory a benchmark to objectively evaluate data in order to help make a decision regarding method acceptability. If method selection is not goal-based, the laboratory runs the risk of relying on subjective data and/or assuming manufacturer claims are consistent with the needs of a target patient population. While important, other factors such as cost should not outweigh analytical performance. If laboratories have goals at the onset, in practice, it is less likely they will lose a fiscal argument typically posed by administration.

It is routine to define analytical goals as total allowable error (TAE). TAE is a simple and convenient parameter. It incorporates both imprecision and inaccuracy, or stated in other terms, random and systematic bias. The sum of these two sources of error should not exceed the analytical goal for TAE. Once the laboratory has defined analytical goals and other relevant testing parameters (e.g., cost and other logistics), they can initiate the method (or analytical platform) selection process. Prior to selecting an assay, homework should be done to narrow down options to a list of candidate assays and vendors that will likely meet the analytical goals. Published studies can help. In addition, laboratories may learn valuable information from attending pertinent academic conferences and vendor exhibitions, although they should be cognizant of relying on manufacturer claims without verification. Social media, or for those that remember rotary phones, a phone call to a colleague, can also assist with method selection.

The next decision after selecting a testing method is whether method verification or validation is warranted, as the two processes are different (Table 4.2). Method verification is a less comprehensive evaluation that confirms claims in manufacturers' package inserts, but verification does not confirm that the assay is suitable for a specific patient population. On the other hand, method validation is a more comprehensive assessment that establishes method performance by examining many characteristics of the assay. Method validation enables the laboratory to evaluate assay performance with respect to their laboratory infrastructure (i.e., instrumentation, workflow, and personnel) and their specific patient population. Laboratories should perform method verification prior to implementation. The remainder of this chapter will focus on method validation.

Helpful tips and tools prior to performing validation

Other preparatory steps may be helpful to complete prior to performing the validation. Purchasing a specialized

software program for evaluating and analyzing data for laboratory tests is highly recommended. Several options are available including EP Evaluator (Data Innovations, Burlington, VT, USA), Analyze-It (Analyze-it, Leeds, UK), or a homegrown template using R-programming packages [4]. Statistical evaluation of analytical parameters, such as precision, accuracy, reportable range, method comparison, sensitivity, and reference interval modules, is usually available in these programs. The laboratory should try to standardize and use one program throughout the laboratory, but ensure enough licenses for multiple users. Standardization will make it easier to train staff and review results.

Laboratory directors should review data from proficiency testing programs, such as CAP, as some proficiency tests are subdivided into specific techniques/instrumentation. This may inform the laboratory about possible bias between new and predicate methods, and thereby guide the selection of method validation experiments. For example, if the coefficient of variation (CV) is high at the low end of the analytical range, or if there is a bias at the high end of the analytical measuring range (AMR), the laboratory may want to include additional precision studies or additional correlations at the low and high ends of an assay, respectively.

Method vendors are frequently willing to assist with method validation, and we recommend requesting their input early in the process. Manufacturers may provide QC materials, calibrators, and reagents free of charge—it never hurts to ask. Some will even perform the experiments and enter the data into your software program of choice. Manufacturers should also be engaged in any troubleshooting during the method verification and/or validation to confirm the instrument and/or assay is configured properly. Note that if one is validating a third party product, manufacturer support may be challenging as manufacturers will typically only support vendor-specific reagents or products.

Laboratories should develop a validation plan. Table 4.3 summarizes the key validation components of unmodified nonwaived assays, as well as LDTs. Of note, it will often benefit the laboratory to save specimens with unusual or infrequently encountered results (e.g., positive hepatitis B IgM and high acetaminophen concentrations) for correlation studies (assuming the analyte is relatively stable at $-20^{\circ}C$ or $-80^{\circ}C$). It is also wise to begin with precision and reportable range (described in detail below) studies, which do not require patient samples. If the method does not meet the predefined precision and/or reportable specifications, one does not need to progress to finding patient specimens for method comparisons. The considerations for validation of a nonwaived FDA-approved assay and LDT differ (Table 4.1). In this chapter, we will first discuss method validation basics for FDA-approved assays, followed by the crucial components of LDT validation studies.

Method validation basics

Precision and accuracy

There are two popular ways to assess the imprecision of an assay: (1) within-run or repeatability; and (2) between-run or within-laboratory (Table 4.2) [5]. If multiple sites or instrumentation are involved, additional experiments, as outlined in the CLSI approved EP05-A3 (Evaluation of Precision of Quantitative Measurement Procedures) document, will be required [5]. In general, quantitative assays may include precision at the lower limit of quantification (LOQ), low, medium, and high ranges of the assay to characterize imprecision across the AMR. This is because, in many cases, imprecision is greater in magnitude as the analyte concentration approaches the LOQ. Limit of blank (LOB) and limit of detection (LOD) will be discussed later in this chapter.

Within-run precision ("repeatability") assesses assay precision over the short term, where variables such as reagent lot and operator are consistent. It typically represents the lowest imprecision the assay is able to achieve. Although matrix-specific patient samples are ideal, typically a laboratory will repeat QC samples at multiple analyte concentrations with 10−20 samples in one run in 1 day and calculate the mean, standard deviation (SD), and CV to determine assay imprecision. Practically speaking, if the repeatability of the assay is unacceptable, it is not worth further studies as it is unrealistic to achieve a better CV than that within-run, and an alternative assay or approach should be pursued by the laboratory.

Between-run or within-laboratory precision assesses the total imprecision of the assay. Most laboratories will repeat aliquoted QC at various levels two times for 10 consecutive days or one time for 20 consecutive days. Similar to within-run precision, the mean, SD, and CV are calculated. The recommended number of repeats and levels of QC varies. According to CLSI EP05-A3, a "20 × 2 × 2" design is ideal, where the laboratory runs two runs per day with two samples each run for 20 days (not necessarily consecutively) [5]. The levels should be spread evenly throughout the reportable range and include levels at or near the medical decision point(s). Patient pools can also be utilized instead of, or in addition, to QC material. A key benefit of using patient pools is that such samples will more realistically assess potential matrix effects. It is the responsibility of the medical director to decide whether or not to follow specific guidelines and which ones will be followed (e.g., CLSI and FDA).

Acceptable between-run imprecision is usually less than 25% of the TAE (Table 4.2). The level of imprecision

TABLE 4.3 Components of nonwaived method validation.

	Example studies	Important considerations
Unmodified nonwaived[a]		
Precision and accuracy	Within-run precision (repeatability):10–20 repeats at multiple levels in 1 day	If repeatability is not acceptable, troubleshooting should occur before any other studies as repeatability represents the best possible performance
	Between-run precision (total precision): multiple levels run once or twice per day for 20 days	Acceptability will vary by analyte
	Accuracy: compare results to reference materials or other materials with known concentrations	QC or proficiency samples can be utilized or comparison to a definitive or reference method can be performed
Reportable range	Three to seven specimens run multiple times with concentrations throughout the desired range. Assigned values are compared with measured values	Should span the medical decision point(s) and challenge the limits of the assay
Method comparison	Run a minimum of 40 specimens using the comparative and new method that span the medical decision point(s)	Unless the new method is compared with a reference or gold standard method, accuracy cannot be determined
Laboratory developed test (includes additional studies below)[a]		
Carryover	Run specific sequence of high and low QC samples in one continuous experiment	Acceptability will depend on clinical context
Matrix effects	Run at least three QC specimens from at least two analyte concentrations each; compare specimens prepared in independent sources (preferred) or pooled assay matrix with those prepared in solvent	Acceptability will depend on clinical context; can also perform postcolumn infusion for chromatographic techniques
Stability	Run at least three QC specimens from at least two concentrations each for short-term, long-term, and postprocessing stability	Acceptability will depend on clinical context; stability conditions (temperature, duration, freeze–thaw, etc.) are determined by assay workflow and expected handling/storage conditions
Selectivity/ specificity	Assess at least six independent blank biological matrices for otherwise false-positive results. Spike analyte-free matrix with known analyte analogs in at least two QC levels	Run each analyte separately for multiplex assays
Interferences	Spike known interferants (exogenous and endogenous) in at least two QC levels	Acceptability will depend on clinical context
Recovery	Run at least three QC specimens from at least two analyte concentrations each; compare spiked specimens extracted from pooled matrix with blanks extracted then spiked with identical levels of analytes	Recovery of less than 100% indicates incomplete extraction
Sensitivity	Run at least three calibration experiments along with blank specimens; determine SD of calibration slope and blank response	Multiple methodologies to estimate sensitivity
Dilution	Within-range: for each dilution factor, dilute a high QC range specimen with five technical replicates. Above-range: for each dilution scheme, dilute an above-ULOQ specimen with five technical replicates	For above-range dilutions, calculate theoretical recovery
Specimen requirements	Determine acceptable matrices, containers, handling, and storage conditions	Base handling and storage conditions on stability validation

LOQ, Upper limit of quantitation; *QC*, quality control; *SD*, standard deviation.

varies by test and methodology, with the majority of routine automated chemistry analytes, such as sodium and potassium, exhibiting imprecision far less than 10% and LDTs having imprecision between 10% and 25%. Unacceptable precision can be due to a variety of factors. Poor repeatability (within-run) may be due to variation in pipetted volumes, whereas poor between-run precision may be due to reagent lot changes, calibration cycles, and/or operator rotation. Before rejecting the studies, the laboratory should seek to determine the cause of any high imprecision.

Precision data cannot only determine assay imprecision, but it may also provide information on QC or instrument performance. Trends in QC or patient pool results (whichever are used for precision studies) over time should be reviewed. If QC results continue to drift over time, it is concerning and may indicate a degradation in QC materials or an instrumentation failure (Fig. 4.1). If there is an issue with analyte stability, results of patient pools may decrease over time. Moreover, if results continue to rise over time, it may indicate loss of calibration. Concerning results should be reviewed with the manufacturer.

Samples with known concentrations, such as QC materials, can be utilized to establish accuracy; "the ability to recover the correct amount of analyte present in a specimen" (Table 4.2). Laboratories can also include measurement of remnant or previously evaluated proficiency testing samples in their method validation studies to verify accuracy. Although it can be more challenging, comparison of the method or a subset of samples with a definitive or reference method is ideal to ensure that results are accurate.

Reportable range

According to CLIA, reportable range is defined as "the span of test result values over which the laboratory can establish or verify the accuracy of the instrument or test system measurement response" [3,6]. The terms linearity, assay range, analytical range, AMR, and clinically reportable range (CRR) may also be used, and are defined in Table 4.2. While AMR is defined as the range of values an assay can quantitatively report without additional sample dilution or concentration, CRR refers to the range of values an assay can quantitatively report with sample pretreatment such as dilution or concentration.

Linearity assesses the relationship between observed values and a known concentration. It is important for clinicians to know that the relationship between the known concentration and the reported result is linear as they use results to make medical decisions. CLSI guideline EP06-A provides recommendations on how to assess linearity [5]. Laboratories can purchase linearity material or dilute high-concentration patient pools. If it is challenging to find high concentrations of some analytes, such as therapeutic drugs, the laboratory may need to spike samples using high-concentration reference materials. Importantly, matrix-appropriate specimens should be diluted according to the manufacturers' instructions (e.g., with manufacture diluent). The number of samples utilized to determine the reportable range for a nonwaived FDA-approved assay varies from three to five; five to seven independent concentrations are recommended according to CLSI EP-06A [6]. Regardless of the guidance followed, the laboratory should ensure that the samples span the medically relevant range as well as challenge the limits of the assay (i.e., choose concentrations expected to fail). The number of repeats of the material also varies from three to four and provides additional assessment of imprecision in the method.

Software programs are frequently utilized to display the reportable range with assigned values on the *x*-axis and reported values on the *y*-axis. Recovery is defined as 100 times (×) the measured mean of the replicates divided by the assigned value (Table 4.2). Visual inspection of the recovery and comparison of assigned and reported values are important. Outliers or concerning trends can usually be detected after visual inspection alone. However, recent CLSI guidelines (EP06-A) suggest that the polynomial method should be utilized to analyze the data [6]. This method estimates the magnitude of nonlinearity at every level and controls for unacceptable repeatability. Many programs will perform the polynomial analysis, but acceptability criteria are user-defined and based on medical significance.

Individual points should be plotted as opposed to average concentrations, which can conceal imprecision. Troubleshooting is required if the plot reveals deviations from linearity or evidence of instrument failure. The laboratory may need to involve the manufacturer to assist with troubleshooting. Common reasons for nonlinearity include improper sample preparation, an interference, or lack of calibration. Ultimately, if the reported value deviates significantly from the assigned value and cannot be corrected, the level should not pass and the preceding level should be used to define the upper limit of the reportable range. If results above the upper limit are medically required, laboratories may dilute samples into range and report results if dilutional challenges meet acceptance criteria.

Method comparison

Method comparison is the testing of the same sample by at least two independent laboratory assays for the same analyte for the purpose of characterizing test agreement including systemic and random errors. Laboratories should ideally compare their new method to a reference or gold standard method. However, this can be impractical, and consequently, many laboratories often compare

FIGURE 4.1 Precision experiment. Quality control with a target mean of 75 mg/dL of IgM was run over 20 days. The coefficient of variation, standard deviation, and 2 SD range were 10%, 7.5, and 60.0–90.0, respectively. The experiment passes; however, there is a concerning downward trend in results over time that should be investigated.

the new method with their existing method. A major limitation to this approach is that the laboratory cannot determine if the results are accurate; only if a clinically significant bias exists, that will affect patient care.

There are two important factors to consider when comparing methods: (1) the number of specimens in the comparison evaluation; and (2) the range of analyte concentrations or measurements in the comparison specimens. Both CLIA and CLSI have recommended a minimum of 40 specimens to be included in the comparative analysis [3,7–10]. Just as important as the quantity of samples, the specimens should span the medical

decision points and allow for an accurate assessment of bias across the AMR, and possibly even the CRR. A comparison of 40 specimens clustered around the AMR median may falsely reassure the laboratory and hide a bias at the low or high end of the AMR. The method comparison study should preferably occur over several days to reveal drift or change in results, though care should be taken to ensure specimen stability during the entire comparison.

Least squares linear regression ($y = mx + b$; also referred to as $Y = a + bX$ in other texts), either Deming or Passing–Bablok, can be utilized to compare results and detect any bias (Table 4.2). Most software programs allow the laboratory to choose their preferred analysis. X is the comparative method (plotted on the x-axis), y is the new method (plotted on the y-axis), m is the slope, and b is the y-intercept. Both Deming and Passing–Bablok regression models reasonably assume that each method is subject to error. Deming regression is usually the preferred analysis if results are well distributed and outliers are not present. Deming regression is also used if medical decision points are being compared. On the other hand, Passing–Bablok regression is preferred if outliers are present, as the Passing–Bablok regression model employs a nonparametric regression, which means the analysis is constructed by using the data as opposed to predetermined parameters. Outliers should not be removed from the analysis unless the cause is known (e.g., pipetting error). The cause of outliers should be determined, and only if appropriate may be removed from data analysis. Of note, Passing–Bablok regression analysis should not be used if the comparison has a very low or high number of specimens, or if a comparison of medical decision points is the primary goal.

Results can be presented in different formats to assist with interpretation. Analysis of the regression line is usually the first step. The correlation coefficient (R) indicates the degree of correlation and adequate range of data, but does not indicate how the methods compare. If R is less than 0.95 (some laboratories may set a looser limit of 0.90 or a stricter limit of 0.975), the laboratory needs to assess the range of data. The slope, y-intercept, and confidence intervals are also important. Identical methods have a slope equal to 1.0 and an intercept of zero at the 95% confidence interval; a feat rarely achieved.

Laboratories must also review method comparison data for bias. If the results of the new method are consistently higher or lower than the current method, a constant bias is present. The intercept represented by b in the straight line equation $y = mx + b$ represents the constant bias (Fig. 4.2). Bias or Bland–Altman plots are most commonly employed to investigate proportional bias, where results are always higher or lower by the same proportion. Proportional bias is represented by slope or the m in the equation of a straight line ($y = m\,x + b$) (Fig. 4.3). In some cases, the laboratory will anticipate a bias such as when switching to a different immunoassay (e.g., parathyroid hormone and thyroid stimulating hormone) or

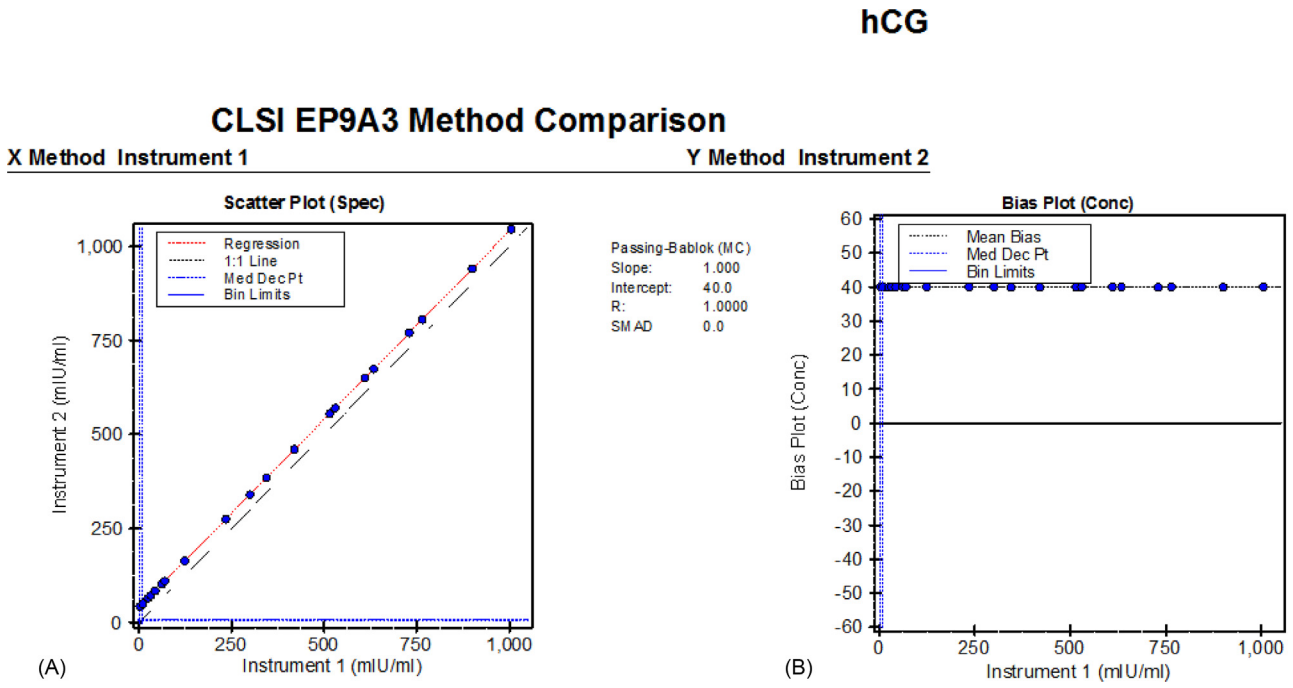

FIGURE 4.2 Constant bias. A method comparison experiment for human chorionic gonadotropin was performed. The Passing–Bablok regression analysis shows a constant bias of 40 mIU/mL (i.e., intercept of 40.0) between the two methods with a slope and R of 1.00. (A) Scatter plot. (B) Bias plot.

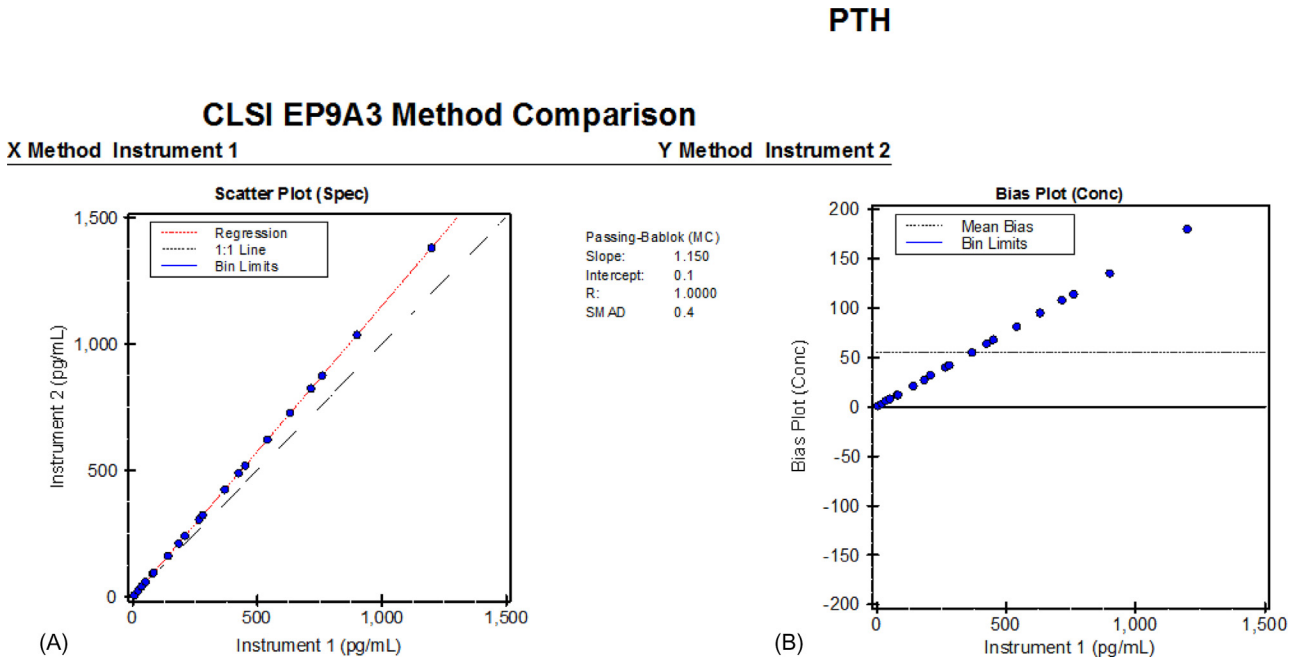

FIGURE 4.3 Proportional bias. A method comparison experiment for PTH was performed. The Passing−Bablok regression analysis shows a proportional bias of 15% (i.e., slope of 1.15) with an intercept of 0.1 and an *R* of 1.00. (A) Scatter plot. (B) Bias plot. *PTH*, parathyroid hormone.

changing methodologies (e.g., calcium and lipids). Proficiency testing results can be helpful to anticipate or confirm the type of bias. A clinical review of the data is critical to determine whether the bias is acceptable and if the reference range should be adjusted.

Medical decision point analysis is frequently employed for assays that have standard cutoffs or reference ranges such as therapeutic drugs, fasting glucose concentrations, and lipid profile measurements. The laboratory should calculate the percentage of cases for which the medical decision (e.g., both results higher than the reference range or cutoff) would be the same for both methods. Special consideration to unique populations should be given during method comparison studies. In addition, laboratories may need to verify how a method performs in pediatric patients, pregnant patients, or the critically ill; the latter of which may be difficult to define. If possible, the laboratory should gather specimens from these specialized populations and perform a focused method comparison.

A detailed discussion on reference intervals can be found in Chapter 3: Reference intervals: theory and practice. At a minimum, laboratories should perform a reference range verification study in order to verify the range provided by the manufacturer is acceptable in their patient population. To accomplish this, a laboratory can perform testing on 20 healthy individuals. If 18 out of 20 (90%) fall within the reference range, the reference range is considered verified. For some tests, a therapeutic interval is more appropriate than a reference interval (e.g., therapeutic drugs); therefore the laboratory may utilize published ranges believed to represent their patient population.

Validation of laboratory developed tests

As defined by the FDA, an LDT is "a type of in vitro diagnostic test that is designed, manufactured, and used within a single laboratory." These LDTs can be used to measure a variety of analytes, including ions, small molecules (xenobiotics and metabolites), and biological macromolecules (peptides, proteins, and nucleic acids), in a variety of matrices (blood, tissue, urine, saliva, and miscellaneous body fluids). LDTs enable laboratories to create customized assays to meet specific patient and system needs, such as for a specific patient population or if a given test is not commercially available. For example, a tertiary cancer center with a high volume of lymphoplasmacytic lymphoma ("Waldenstrom's macroglobulinemia") may choose to develop and validate an *MYD88* variant assay [11], whereas such a test may not be suitable for a local clinic or a rural hospital laboratory.

As they are not approved by the FDA, the performance of an LDT should be characterized for multiple variables by the performing laboratory. Assay parameters include the aforementioned precision, accuracy, reportable range, and method comparison experiments, as well as matrix effects, carryover, analyte stability, selectivity, interferences, dilution, sample preparation, and reagent stability. In addition to clinical context, the LDT validation must also take into account the specific assay

technology. For example, chromatography-based assays should rigorously characterize carryover, while ligand-binding assays should evaluate dilution scheme for possible prozone effects ("Hook effects"). Acceptability guidelines may also differ slightly depending on the assay technology, as current FDA bioanalytical guidelines do so for chromatography- and ligand-binding assays [12].

Carryover validation

Carryover is the unintended transfer of substances (analyte, reagent, and diluent) between samples or assay compartments (Table 4.2). This transfer can then perturb the readout of results for subsequent samples(s) [13]. While carryover usually reflects an immediately preceding or neighboring sample, it can appear to occur randomly and may reflect a delayed elution from a nonconsecutive sample. Carryover can occur anywhere along the assay procedure, including instrumentation, liquid handlers, and consumables.

Carryover is pertinent to a variety of assay methodologies, from automated chemistry analyzers to chromatographic methods to molecular diagnostics. Carryover is rather intuitive for chromatography-based methods such as ultra/high-performance liquid chromatography–mass spectrometry (U/HPLC-MS) [14]. For example, a sample may be retained on an autosampler or chromatographic column with suboptimal washing and reequilibration, only to be eluted and detected in the next sample. In automated chemistry analyzers and autosamplers, carryover can occur when cuvettes, sampling probes, or liquid handling components are contaminated or incompletely washed between samples [15,16]. For molecular assays, carryover usually refers to sample contamination from nucleic acids from environmental sources, previous samples, or concurrent samples [17]. For polymerase chain reaction (PCR)-based assays, even minor carryover or contamination can be significant because of analyte amplification.

Carryover can often be mitigated, though specific approaches will vary depending on the analytical methodology and source of carryover. For chromatography-based systems, this can be accomplished with alternative chromatography conditions, such as different columns or mobile phase conditions, longer system washes, multiple wash cycles, or longer equilibration times, even though such modifications may be at the expense of throughput [14,18]. When carryover is unavoidable, standard operating procedures (SOPs) can dictate running blank samples immediately after extraordinarily high analyte concentrations before running a subsequent sample. For molecular assays, carryover/contamination can be mitigated by careful laboratory design (separate pre- and postamplification areas), sterilization, automation, and certain reagents such as dUTP with uracil DNA glycosylase [19].

Carryover is formally evaluated by repeated testing of a high and low QC in a specific order [20]. One usually defines an acceptable level of carryover prospectively, based on factors such as clinical context and analytical performance. FDA bioanalytical guidelines recommend characterizing carryover, and using an acceptability cutoff of less than 20% lower limit of quantitation (LLOQ) [12]. Alternatively, some laboratories opt to use LLOQ and (upper limit of quantitation) ULOQ calibrators for carryover analyses as well. One suggested experiment is to run consecutive low (L) and high (H) QC samples in the following order: L1, L2, L3, H1, H2, L4, H3, H4, L5, L6, L7, L8, H5, H6, L9, H7, H8, L10, H9, H10, and L11. Carryover is assessed by looking for changes in the low QC samples, where multiple low QC samples are initially performed to define assay imprecision. Carryover would be expected in low QC samples immediately following high QC samples. Analysis can be aided by specialized software. For more extensive discussions of carryover, we refer the reader to CLSI protocol EP10-A3 [8].

Stability validation

The stability of an analyte during testing is a prerequisite for accurate and precise measurement. Certain analytes are susceptible to various forms of instability, which can be caused by chemical instability (e.g., nonenzymatic hydrolysis, oxidation, proteolysis, and photosensitive reactions), insolubility (e.g., precipitation or aggregation), protein denaturation (i.e., for enzymes), and contamination (i.e., live-cell samples). Characterization of analyte stability enables laboratory directors to select optimal handling and storage conditions to minimize the chance that a particular result is inaccurate.

Stability is relatively straightforward to assess (Table 4.4). Percent recovery in stored samples are calculated relative to control samples that are either unperturbed (e.g., not freeze–thawed or processed) or prepared fresh at the time of experiment (i.e., for short- and long-term storage assessments). Stability sample results should generally be within 15% of nominal concentrations (may vary, and FDA bioanalytical guidelines allow for up to 20% difference from nominal for ligand-binding assays). For quantitative assays, experiments should evaluate stability at two analyte concentrations (L and H) with at least three technical replicates to assess precision. Ideally, stability studies should utilize storage containers to be used in clinical operations. Alternatively, the percent difference (%DIF) between the stored or treated sample and the control sample can be calculated to evaluate acceptable stability. Even though the FDA recommends a comparison to the

TABLE 4.4 Components of stability validation.

Ambient conditions	Room temperature stability, usually a minimum of 6 h but often 12–24 h to model bench-top handling
Postprocessing	(i.e., after all reagents and sample preparation have been performed) should be characterized to determine the length of time a processed sample is expected to perform within acceptable performance specifications; in many cases, this involves testing a sample stored in an instrument autosampler to mimic a prolonged sample queue
Short-term storage	Refrigeration (4°C), often up to several weeks, to model typical laboratory workflows
Longer-term storage	Freezing (−20°C and/or −80°C), often up to several months depending on anticipated storage duration
Freeze–thaw	Samples should be tested for stability after a minimum of three complete freeze–thaw cycles, as certain analytes irreversibly precipitate or denature; in most scenarios, freezing should be done overnight and thawing should be performed at ambient temperatures

nominal concentration, calculating the %DIF excludes any bias introduced during the analyte spiking process.

Stability can be calculated as percent deviation from a theoretical (nominal) concentration (%NOM), or alternatively, it is calculated as a %DIF between stability-challenged and fresh (nonchallenged) QC samples. Both FDA and its European counterpart, the European Medicines Agency, discuss stability in terms of nominal concentrations [12]. In practice, percent nominal concentrations are determined by measuring samples immediately after their applied stability challenge, and by calculating the percent deviation from the nominal concentration determined by a freshly prepared calibration curve. By contrast, %DIF measures concentrations of the unperturbed and the stability-challenged samples in the same analytical run. The advantage of the latter approach is that each sample type is subjected to the same analytical run conditions.

Analyte stability should be characterized across the expected clinical sample handling and storage conditions, from sample collection to specimen shipment, storage, processing, and testing [21,22]. This typically includes ambient conditions, short- and long-term storage, freeze-thaw, and postprocessing stability.

In addition, the stability of analyte and internal standard stock solutions should be characterized, especially when the stock solutions are stored in different physical states or buffers from the source solution. Notably, in clinical operations, samples and reagents should not be utilized, which have been stored outside of the validated stability conditions. For more extensive discussions of reagent stability testing, we refer the reader to CLSI protocol EP25-A [23].

Selectivity/specificity and interference validation

Selectivity (often incorrectly used interchangeably with *specificity*) is defined by the FDA as "the ability of the bioanalytical method to measure and differentiate the analytes in the presence of components that may be expected to be present (Table 4.2). These could include metabolites, impurities, degradants, or matrix components." A similar concept is specificity, defined by the FDA as "the ability of the method to assess, unequivocally, the analyte in the presence of other components that are expected to be present (e.g., impurities, degradation products, matrix components, etc.)" [12]. In practice, it can be extraordinarily difficult to ascertain *unequivocal* specificity; therefore the former term selectivity is often preferred.

Each LDT should therefore assess the assay readout for analyte selectivity. In other words, this means providing evidence that the readout is *actually* quantifying the intended analyte. In principle, biological samples may contain nonanalyte substances that result in appreciable readouts. For example, analyte isoforms, isozymes, or posttranslationally modified analytes may contain epitopes recognized by a reagent antibody in an immunoassay. The FDA therefore recommends evaluating six independent sources of the relevant blank biological matrix to determine if endogenous substances result in significant signal in the analyte readout LLOQ (n.b., 10 sources for ligand-binding assays).

Interference is the modulation of the assay readout by nonanalyte substances in a sample, often referred to as "artifacts." There are two main types of interferences: endogenous and exogenous [24–26]. Exogenous interferences originate from outside the body and are therefore not normally found in clinical specimens. Each type of interferent can cause positive or negative bias in analytical results, depending on the assay methodology and other factors such as interferent concentration. In this way, sources of interference work to effectively reduce the selectivity and specificity of an LDT.

Examples of common potential endogenous interfering substances include bilirubin (i.e., icteric samples) and lipids (e.g., hypertriglyceridemia), which can interfere with light-based readouts; hemolysis, via release of red blood cell intracellular contents such as potassium, abundant enzymes like LDH and AST, and hemoglobin; paraproteins; immunoglobulins; and endogenous substances

chemically similar to target analytes of interest. For endogenous biomarkers, endogenous interfering substances may also include macromolecules with homology to the analyte of interest (proproteins/enzymes and isoforms). For some biological matrices, such as urine, normal biological variation can effectively create interferences in the form of protons (pH) and salts. Endogenous interfering substances can manifest as matrix effects.

For ligand-binding assays measuring endogenous analytes, an important related concept is parallelism (Table 4.2). The FDA notes, "Parallelism demonstrates that the serially diluted incurred sample response curve is parallel to the calibration curve." Why perform this experiment? The rationale is to verify if the binding characteristic of the endogenous ligand to the binding agent (e.g., antigen−antibody) is the same as for the calibrator [27]. While similar, this is not to be confused with dilutional studies. Parallelism validation utilizes samples containing high levels (near but less than the ULOQ) of an endogenous analyte, which are diluted to assess whether the dilution−response curve is parallel to a standard concentration−response curve [28]. Parallelism can flag potential matrix effects and interactions between critical assay reagents. There are no established criteria for what constitutes acceptable parallelism, but in general, test samples should be within 20%−30% of the corresponding calibrators [29−31].

Examples of potential exogenous interfering substances include heavy metals, where conventional urinalysis containers may leach trace amounts of heavy metals into otherwise analyte-free sample [32]; xenobiotics (e.g., other medications) and metabolites, where certain related and unrelated drugs may cross-react with immunoassay-based therapeutic drug monitoring assays or therapeutic monoclonal antibodies may produce positive readouts on protein electrophoresis [33]; adulterants, where oxidants, acids, or bases may be added to samples in illicit urine drug testing to chemically modify the tested analyte; and postcollection analyte addition, where urine samples spiked with drug after voiding to simulate compliance [34].

In mass spectrometry (MS), isobaric but chemically distinct substances may coelute with the assay analyte. As an example, consider a U/HPLC-MS/MS assay to quantify morphine-3β-glucuronide (M3βG). Since normal human metabolism also creates morphine-6β-glucuronide (M6βG), a selective method must distinguish between these two isobaric analytes so as not to inaccurately quantify M6βG as M3βG. In multiplexed methods, selectivity validation includes testing each analyte individually and measuring the readout of each multiplexed analyte (Fig. 4.4).

An LDT should characterize the effects of expected sample interferences, which is often done by determining the percent recovery of a spiked sample containing a potential interferent with a control sample. Interference can be tested in two manners: (1) in blank matrix to evaluate for signal creation; and (2) in QC or analyte-spiked samples to evaluate signal attenuation. In most clinical assay formats, the former would lead to false-positive readouts, while the latter would produce false-negative readouts.

Endogenous interfering substances can be assessed by several approaches [35,36]. First, a laboratory can utilize clinical samples of suboptimal specimen integrity, such as grossly icteric, lipemic, or hemolyzed samples. These samples can be tested as is, and also mixed with a known amount of analyte to compare percent recovery with a noncompromised sample containing the same amount of the analyte of interest. The advantages of this approach are the relative ease of acquiring samples and straightforward procedure, though the main disadvantage is the lack of standardization with respect to interferants from sample to sample. Therefore when using this approach, attempts should be made to quantify the interferant, such as

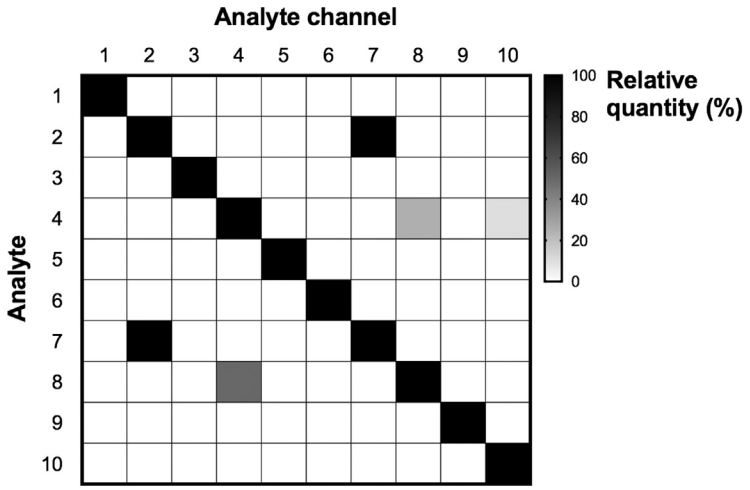

FIGURE 4.4 Selectivity testing in a multiplex laboratory developed test validation. In this hypothetical assay, 100 units of each analyte (1−10) are analyzed by each analyte channel (1−10). Analytes 2 and 7 are quantified at the same concentration, suggesting the method cannot differentiate between the two analytes. Analytes 4 and 8 cannot be differentiated, though the method does not measure the same quantities unlike analytes 2 and 7. Analyte 4 is identified in analyte channel 10, which could be due a sample impurity.

measuring hemolysis or icteric indices. Note that these indices are semiquantitative measurements based on light absorbances, and not known interfering substance concentrations.

Another approach to evaluate endogenous interfering substances is to spike blank matrix and/or QC samples with pure interferents, and compare percent recovery to noncompromised controls. This approach is more rigorous, though certain purified analytes are relatively expensive or unavailable, and such prepared samples may not fully create the biological milieu needed for interference. Whenever practical, the interference substance to be spiked should be in concentrated form (e.g., 20X). The purpose of using concentrates is to prevent significant dilution of the sample matrix and analytes upon spiking. This better enables the assessment of the actual interfering substances on assay results by not significantly diluting the sample matrix (especially in cases where the diluent may not fully approximate the sample matrix) and by allowing higher analyte concentrations (by not significantly diluting the QC samples).

Exogenous interferent testing is relatively straightforward, and usually involves spiking blank matrix and/or QC samples with known amounts of the exogenous interferent. Exogenous interferents could include concomitant medications in the patient population [37]. As there are no strict guidelines, specific interfering substance tolerabilities will depend on the discretion of the medical director, which involves evaluating results within the appropriate clinical context. For more extensive discussions of interferences, we refer the reader to CLSI protocol EP07-A3 [38].

Matrix effects validation

Matrix effects are the direct or indirect alteration in response due to the presence of unintended analytes or other interfering substances in a sample; in many ways, matrix effects studies may be viewed as a subset of interference validation. Endogenous matrix components include salts, carbohydrates, amines, lipids, peptides, nucleic acids, and related metabolites. Exogenous matrix components include additives from sample collection (e.g., heparin and calcium) or reagent components. The nature of matrix effects depends on the assay analyte, testing methodology, and matrix itself, and is often unpredictable a priori. For MS-based systems, matrix effects are typically manifested as ion suppression, though ion enhancement can occur as well [39].

There is actually no mandated threshold for matrix effects, meaning the degree of acceptable matrix effects are decisions by the medical director to be based on a variety of factors (e.g., clinical context and expended incidence). At a minimum, matrix effects must be characterized as part of an LDT validation [40]. This should include evaluation of at least two analyte concentrations, as the magnitude of matrix effects may be analyte concentration-dependent. There are several experimental approaches to characterize matrix effects, depending on the LDT methodology. For MS-based assays, this may include (1) constant postcolumn infusion of an analyte with a matrix injected into the chromatographic system; or (2) spiking different matrices in pre- and postextracted samples and comparing percent recovery [41,42]. Both can be relatively time-consuming, and the former is qualitative in nature, whereas the latter is quantitative. Postcolumn infusion examines matrix effects across the entire chromatographic run, whereas pre- and postextraction addition examines matrix effects at the retention time of the analyte of interest. Furthermore, postextraction addition is most appropriate when using stable-isotope internal standards. A more general method for assessing potential matrix effects is to spike at least 10 independent biological samples and assess variability (SD and CV). An important caveat to this general approach is that it reflects the mean matrix effects, and may not reflect matrix effects from individual samples [43].

There are several strategies to mitigate the effects of matrix effects in LDTs. A general strategy to mitigate matrix effects is sample dilution, which can potentially decrease the effective concentration of the interfering substance(s) in the sample and presumably its effect on the assay readout [44]. The amount of sample dilution must balance analytical sensitivity requirements and potential imprecision and bias introduced from dilution. If performed clinically, sample dilution constitutes a necessary validation parameter. Another strategy to mitigate matrix effects includes sample purification such as solid-phase extraction, liquid−liquid extraction, protein precipitation, or immunoenrichment, which can reduce the relative concentration of interfering matrix components. In assays involving chromatography, various parameters such as solvent composition and gradient can also be optimized. When measuring small molecules by MS, matrix effects are often mitigated through the use of deuterated internal standards [44]. In practice, such compounds may be unavailable or prohibitively expensive, forcing laboratorians to utilize internal standards with similar chemical properties and assay behaviors confirmed through experimental validation.

Recovery validation

The FDA defines recovery of an analyte as “the detector response obtained from an amount of the analyte added to and extracted from the biological matrix, compared with the detector response obtained for the true concentration of the analyte in solvent.” Recovery is especially important for analytes requiring preanalytical extraction,

purification, and/or enrichment. For evaluating recovery in the context of extraction, matrices are spiked with analyte, and then extracted. This value is then compared with blank matrices spiked with the same amount of analyte after undergoing an otherwise identical extraction. Recovery is then calculated by the relationship:

$$\%\text{Recovery} = [\text{Analyte}]_{\text{spiked}\rightarrow\text{extracted}} - [\text{Analyte}]_{\text{blank extracted}\rightarrow\text{spiked}} / [\text{Analyte}]_{\text{blank extracted}\rightarrow\text{spiked}} * 100$$

Notably, analyte recovery does not have to be 100%. However, analyte and corresponding internal standard recovery should be characterized for precision and reproducibility at multiple analyte concentrations (e.g., low, medium, and high QC values) by comparing measurements with control samples not subjected to extraction.

Sensitivity validation

The analytical sensitivity of an LDT should be characterized to determine the lowest concentration of analyte that can be reliably detected above the expected sample background. Some key parameters related to sensitivity are LOB, LOD, and limit of quantification (LOQ) (Fig. 4.5 and Table 4.2) [45]. The LOB is the highest apparent analyte concentration expected in blank sample replicates containing no analyte [$\text{LOB} = \text{mean}_{\text{blank}} + 1.645\ (\text{SD}_{\text{blank}})$], while the LOD is the lowest analyte concentration likely to be reliably distinguished from the LOB and at which detection is feasible.

There are a variety of methods that can estimate the LOD that incorporate various statistical assumptions. Ultimately, the best choice of estimating LOD depends on the LDT clinical context [46–48]. Often, the LOD can be determined by utilizing both the measured LOB and test replicates of a sample known to contain a low concentration of analyte [e.g., $\text{LOD} = \text{LOB} + 1.645\ (\text{SD}_{\text{low concentration sample}})$]. Other protocols can define LOD in terms of signal:noise ratios (e.g., greater than 3:1 or 10:1 signal:noise) and various multipliers based on imprecision. Another approach involves empirically testing serial dilutions of analytes until the analyte cannot be reliably detected. One practical approach to estimating LOD involves measuring repeated blank samples for imprecision, and calculating LOD based on the calibration curve using the relationship: $\text{LOD} = 3.3\ \text{SD}_{\text{Blank}}$/calibration curve slope [49].

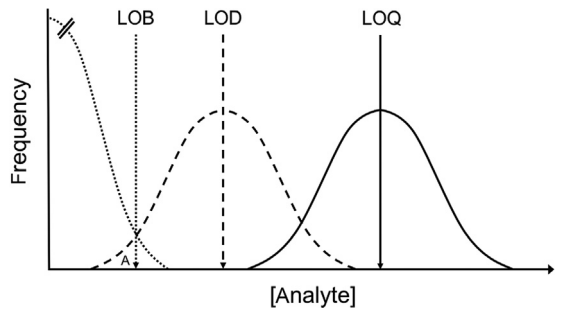

FIGURE 4.5 Key parameters related to assay sensitivity. The LOQ (solid line) and LOD (*dashed line*) are chosen, such that they meet the performance specifications for imprecision and bias. The LOD is chosen, such that a small proportion of samples with analytes at the LOD samples falls below the LOB (*dotted line*; "A"), and similarly, only a small/essentially nonzero proportion of blank samples exceeds the LOD. *LOB*, limit of blank; *LOD*, limit of detection; *LOQ*, lower limit of quantification.

The LOQ is the lowest concentration at which the analyte cannot only be reliably detected but at which some predefined goals for bias and imprecision are met. Note that the LOQ may be equivalent to LOD or it could be at a much higher concentration. Laboratories may also set the LOQ higher than the true LOQ depending on the clinical context (e.g., to avoid reporting analytically positive yet clinically insignificant findings).

Dilution validation

Dilution is the addition of a diluent (e.g., water, pooled serum, and buffer) to a sample. Sample dilution is often used when the analyte concentration is above the ULOQ or if there is a suspected interferent. An LDT should characterize the effects of sample dilution, specifically for percent recovery. In a well-behaved (linear) system, the amount of analyte detected in a diluted sample should be inversely proportional to the dilution factor. In certain cases, an analyte may be protein-bound and will not achieve equilibrium under the diluted conditions. For ligand-binding assays, dilution studies are also performed to rule out prozone ("Hook") effects, whereby exceedingly high analyte:ligand ratios disrupt expected binding behaviors [50].

The main considerations for dilution validation are the choice of diluent, the magnitude of dilutions, and testing within- and outside-range dilutions [51]. One should also consider the choice of diluent to be compatible with the testing methodology, and in general, "like" matrices should be utilized. For example, assays normally run in serum may dilute with pooled negative human serum. If not feasible (e.g., cases of rare matrices), a buffered solution or water may suffice. The magnitude of dilution should be based on the expected analyte concentrations. For example, if samples are occasionally encountered up to fivefold the ULOQ, a proposed dilution validation could examine the effect of 5- and 10-fold dilutions. Each dilution, whether it is within range or outside range, should be evaluated as a series of multiple technical replicates (e.g., five per dilution level), with acceptable precision between 15% and 20% CV and acceptable accuracy between 15% and 20% nominal

concentrations. Additional suggestions for dilution validation schemes can be found in CLSI documentation (e.g., EP34 and C62-A).

Reference standards

Assay performance is routinely compared with calibrators and QC samples derived from reference standards, which also include internal standards. Impure reference standards can adversely affect assay performance, most notably accuracy. Therefore it is critical to utilize reference standards with rigorously characterized identity and purity, and traceable lines of production and storage. For example, in therapeutic drug monitoring, a reference drug should have its chemical identity verified by multiple techniques such as ^{1}H nuclear magnetic resonance, MS, and physical properties. The same applies for redundant assays for analyte purity such as U/HPLC-MS, elemental analysis, inorganic content analysis, and residual solvent analysis. Other analytes such as proteins and nucleic acids should be characterized with appropriate sequencing technologies. Whenever possible, chemical identities identical to the biological analyte should be utilized.

Reference standards are usually derived from three sources: certified reference standards (e.g., USP compendium), commercial-supplied reference standards from reputable sources (e.g., Cerilliant, LGC), and custom-made reference standards. Regardless of the source, LDTs should carefully catalog the lot, batch number, expiration date, certificates of analysis, and characterization data of all reference standards. Maintaining such traceability facilitates troubleshooting, such as discrepant method comparisons or shifts in assay performance with new reagent lots.

The role of the medical laboratory director

There are many guidelines that have been written by domain experts outlining the components and criteria for method validation and verification. However, there are times when the medical laboratory director has to make a clinical assessment on the performance of an assay. There are instances when collecting the recommended number of specimens for performing a method correlation might not be feasible. Examples include precious specimen types like various types of fluids or matrices (e.g., cerebrospinal fluid), and specimens positive for rare bacteria or viruses. The medical laboratory director would have to deem whether the number of specimens tested is acceptable.

In addition, most of the method validation criteria are applicable to quantitative and perhaps semiquantitative assays. Qualitative assays cannot be assessed for linearity nor can be assessed for precision using the CV. It is therefore the medical laboratory director's decision how to evaluate assay performance as well as which levels should be chosen for assessing the reproducibility of a positive or negative result. In addition, the cutoff concentration for either quantitative or qualitative assays should be carefully considered to meet clinical criteria. For example, many assays for prostate specific antigen have an LLOQ of $\sim$0.01 ng/mL, even though the medical decision point for biochemical recurrence is 0.2 ng/mL. Is it then appropriate to use 0.01 ng/mL as the assay cutoff or should results be reported as less than 0.2 ng/mL? Analytes such as cardiac troponin and human chorionic gonadotropin are reviewed frequently by emergency departments to make quick decisions for patient management. In these situations, a "negative" result is just as important as a quantitative level. It may then be important to evaluate a negative patient pool for precision and accuracy during the validation/verification process.

Collaborating with clinical experts and collecting feedback from clinicians are crucial to the method verification or validation process. Being familiar with the intended use of the assay and the medical decision points used by the clinical costumers contribute to the clinical validation of the method. Thus the medical laboratory director is not only responsible for assessing the analytical performance of the assay but also its performance within the appropriate clinical context.

Self-assessment questions

1. The within-run precision of your new assay is 15%. Your analytical goal for total imprecision is 15%. Which of the following is the best next step?
   - **a.** Assess the between-run precision over several days.
   - **b.** Perform the method comparison studies.
   - **c.** Perform the linearity or reportable ranges studies.
   - **d.** Review the data with the manufacturer.
2. The laboratory has been asked to report quantitative results for Hepatitis B surface antibody. Which of the following is NOT an acceptable source for linearity material?
   - **a.** quality control material
   - **b.** commercial linearity material
   - **c.** high patient pools
   - **d.** analyte-spiked samples
3. Your method comparison was done with 50 specimens spanning the medical decision points. Least-squares linear regression gives a slope of 1.20, an intercept of 0.1, and a correlation coefficient of 0.99. Which of the following best describes this analysis?
   - **a.** Additional specimens throughout the linear range are necessary.
   - **b.** The correlation coefficient indicates that the new method should be accepted.
   - **c.** A proportional bias of 20% between the methods exists.
   - **d.** The intercept suggests a significant constant bias between the methods.
4. U.S. federal law requires clinical laboratories to adhere to which of the following guidelines?
   - **a.** The Joint Commission (TJC)
   - **b.** College of American Pathologists (CAP)
   - **c.** Clinical Laboratory Improvement Amendment of 1988 (CLIA '88)
   - **d.** Clinical and Laboratory Standards Institute (CLSI)
   - **e.** Both c and d
5. Qualitative assays must follow the same validation parameters as quantitative assays.
   - **a.** True
   - **b.** False
6. If the laboratory changes the clinically reportable range (CRR) of an FDA-approved assay, it is now considered to be an FDA-modified test and must be validated using LDT parameters.
   - **a.** True, if the new CRR is outside of the manufacturer's defined AMR.
   - **b.** True, if the new CRR is within the manufacturer's defined AMR.
   - **c.** True, if the new CRR is either within or outside the manufacturer's defined AMR.
7. All of the following are examples of potential endogenous interferants EXCEPT _____.
   - **a.** human antimouse antibody
   - **b.** potassium
   - **c.** daratumumab
   - **d.** billirubin
   - **e.** albumin
8. Acceptable matrix effects in a lab developed test are ultimately determined by _____.
   - **a.** CLIA guidelines
   - **b.** CLSI guidelines
   - **c.** Medical Director discretion
9. Which of the following factors can influence analyte stability?
   - **a.** temperature
   - **b.** buffer composition
   - **c.** light exposure
   - **d.** time
   - **e.** all of the above

Chapter 5

Quality control

W. Greg Miller[1] and James H. Nichols[2]

[1]Department of Pathology, Virginia Commonwealth University; Richmond, VA, United States, [2]Department of Pathology, Microbiology and Immunology, Vanderbilt University Medical Center; Nashville, TN, United States

Learning objectives

After reviewing this chapter, the reader will be able to:

- Define the purpose of quality control for laboratory testing.
- Describe the principles of statistical process control.
- Identify the attributes and limitations of quality control materials.
- Explain the role of risk management and individualized quality control plans (IQCPs) for defining potential hazards and reducing errors in the laboratory testing process.
- Discuss the utility of proficiency testing.

Introduction

The total error of a laboratory test must be small enough to reflect changes in the biological condition in order to have value for clinical decision-making. The total error of a result is influenced by a number of factors including biological (physiological) variability within an individual; preanalytical variability in sample collection, transportation, processing, and storage; analytical variability in test performance; and interfering substances such as drugs or metabolic components.

This chapter addresses quality control (QC) of the analytical measurement process to ensure analytical variability meets accuracy and precision requirements that have been established for a measurement procedure and are considered appropriate for patient care. QC of the analytical measurement process is a component of an integrated quality management, or quality assurance, system, as shown in Fig. 5.1. The quality management system integrates good laboratory practices to assure correct results for patient care. Written standard operating procedures (SOPs) should be available to describe test methods that meet the organization's requirements for patient care, and SOPs should be followed by well-trained and competent personnel. Samples must be analyzed on well-maintained equipment that has been verified to meet manufacturer performance specifications, using validated reagents and QC samples that have been stored appropriately before and during use. Process control involves quality management of preanalytical, analytical, and postanalytical processes with documentation and review of results. Additional aspects of a quality management system should include information management (document and results control and record retention), occurrence management (incident response and resolution), assessment of quality benchmarks and process improvement, determination of customer service and satisfaction, and facilities for test performance in a safe manner.

QC is a part of the process control portion of the quality management system. An SOP should include all aspects of the analysis including the selection of QC materials and other monitoring parameters, how frequently to sample the measurement process, how to determine statistical parameters to describe a measuring system's performance, the QC plan and the acceptance criteria for QC results, corrective action when problems are identified, and the documentation and review processes. The SOP should also include who is authorized to establish acceptance criteria for the QC plan and the acceptance of results, who should review performance parameters including statistical QC results, and who can authorize exceptions to or modify an established QC policy or procedure.

The essential components of statistical process control are also shown in Fig. 5.1. The measurement system should be periodically evaluated by sampling its ability to produce the expected results for QC samples. The expected results are predefined and reflect the measurement variability when the system is operating correctly. If the QC results indicate a stable measurement process, then the patient results have a high probability of being correct. If the QC results fail evaluation criteria, then the patient results may not be reliable for clinical use. In the latter case, corrective action must be taken to fix the

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00005-3

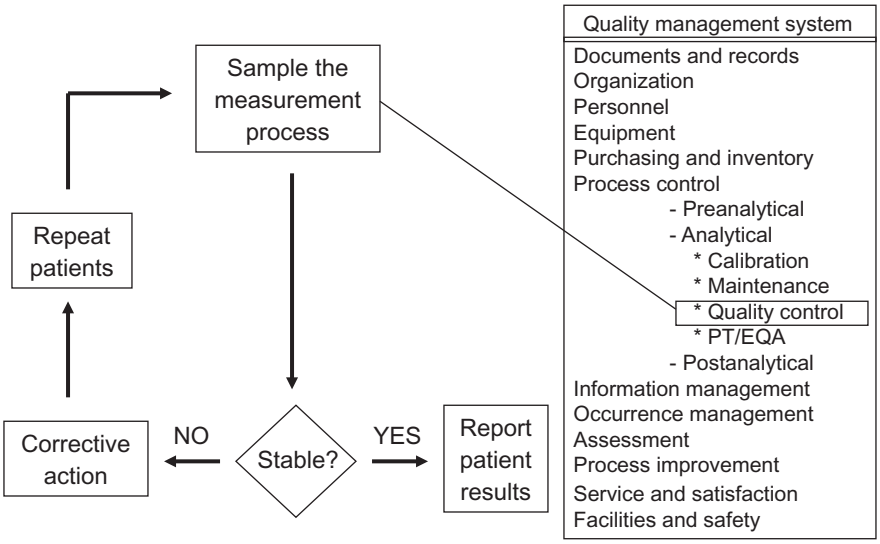

FIGURE 5.1 Overview of statistical process control (quality control) and its integration into a quality management system.

analytical process and patient samples must be reanalyzed for the interval since the last acceptable QC results. Good laboratory practice requires verification that a measuring system is performing correctly anytime patient samples are analyzed and results released to clinicians for management decisions.

Implementing statistical process control

Traditional statistical process control uses stable QC materials as surrogates for patient samples in a measurement process. Reliance on periodic analysis of QC samples does not require a comprehensive knowledge or assessment of potential hazards in the testing process, since this approach evaluates the aggregate effect of all components of the measurement system on the test result. Evaluation of the performance of QC samples provides a good means of detecting systematic errors that persist over time but may not detect random, sporadic errors in test performance. A complementary approach, discussed in a later section, assesses the potential hazards or weak points in each step of the testing process. Frequently occurring hazardous conditions or those with sufficient potential for patient harm require specific controls (that may be in addition to periodic measurement of QC samples) or actions to mitigate risk to the patient. Some devices have built-in checks or controls that monitor portions of the analytic process that may address specific potential hazards. Some of these internal built-in checks are performed with each test and may provide a better means of detecting random errors than reliance only on surrogate QC sample results. The compilation of all of the risk mitigation strategies, both built-in and external control processes, constitutes a QC plan for a specific measurement device that can reduce the residual risk of harm to a clinically acceptable level and ensure quality of test results.

Selection of quality control materials

Generally, two different concentrations of QC materials are necessary for adequate process control and are the minimum required by the Clinical Laboratory Improvement Amendments of 1988 (CLIA) regulations in the United States. For quantitative methods, QC materials should be selected to provide analyte concentrations that adequately monitor the analytical measurement range (also called the measuring interval) of the method. Most quantitative assays have a linear response over the analytical measurement range, and one can be confident that the performance is acceptable if the results near the lower and upper assay limits are acceptable. In the case of nonlinear method response, it may be necessary to use additional controls at intermediate concentrations. Critical concentrations for clinical decisions may also warrant QC monitoring. In the case of analytes that have poor precision at low to normal concentrations, such as bilirubin, the concentration should be chosen to provide an adequate standard deviation (SD) for practical evaluation. For procedures with extraction or pretreatment, at least one QC material should be employed to detect errors in the extraction or pretreatment step.

This chapter is primarily focused on QC procedures for quantitative methods. However, the principles can be adapted to most qualitative procedures. For qualitative tests, for example, urine drugs of abuse testing, both a negative and positive control are necessary, and controls with concentrations near the threshold are recommended to adequately control the method's ability to discriminate between negative and positive. For tests based on

qualitative interpretation of quantitative measurements, for example, drugs of abuse where a concentration is converted into a positive or negative result, it is also necessary to monitor near the threshold/cutoff concentrations to ensure appropriate discrimination between negative and positive responses. For qualitative procedures with graded responses, for example, dipstick urinalysis, a negative, and at least one positive with a value in the intermediate graded response region are appropriate. For qualitative tests based on other properties, for example, electrophoretic procedures and immunofluorescence, the QC procedure should appropriately verify the method's ability to discriminate normal from pathologic conditions.

The QC materials selected must be manufactured to provide a stable product that can be used for an extended time period, preferably 1 or more years. Use of a single lot for an extended period allows reliable interpretive criteria to be established that will permit efficient detection of an assay problem, avoid false alerts due to poorly defined acceptance ranges, and minimize the influence of reagent lot changes on the QC matrix and need for adjustment of target values.

Limitations of quality control materials

There are limitations inherent in currently available QC materials. One limitation is that QC materials are not always "commutable" with native clinical samples. A commutable QC material (or other reference material) is one that reacts in a measuring system to give a result that would be comparable to that expected for a native patient sample containing the same amount of analyte. Commercially available QC materials are typically noncommutable with native patient samples because the serum or other biological fluid matrix has been altered from that of a native patient sample [1]. The matrix alteration is due to processing of the biological fluid during product manufacturing, use of partially purified human and nonhuman analyte additives to achieve the desired concentrations, and various stabilization processes that can alter proteins, cells, and other components. The impact of matrix alteration on the recovery of an analyte in a measuring system is not predictable, is different for different lots of QC material, is different for different analytical methods, and can be different for different lots of reagent within the same analytical method [2].

A second limitation of QC materials is possible deterioration of the analyte during storage. Analyte stability during unopened refrigerated or frozen storage is generally excellent, but slow deterioration eventually limits the shelf life of a product and can introduce a gradual drift in control results. Analyte stability after reconstitution, thawing, vial opening, or exposure to light or air can be important sources of variability in QC results, and stability can vary substantially among analytes in the same vial. Repeated freeze/thaw cycles should be avoided. Users should limit the time spent at room temperature and the time spent uncapped with the potential for evaporation. An expiration time after opening should be established for each QC material and may be different for different analytes in the same control product. For QC materials reconstituted by adding a diluent, the vial-to-vial variability can be minimized by standardizing the pipetting procedure, for example, use the same pipette or filling device (preferably an automated device) and have the same person prepare the controls whenever practical.

Analyte concentrations in multiconstituent control materials may not be at optimal concentration levels for all assays. This limitation is caused by solubility considerations and potential interactions between different constituents, particularly at higher concentrations. Supplementary QC materials may be needed to adequately monitor the entire analytical measurement range when using a multiconstituent QC material to control several analytes at the same time.

Frequency to assay quality control samples

The frequency to assay QC samples is a function of several parameters:

- the analytical stability of the method,
- how much error can be tolerated without impacting patient care,
- the number of results produced in a period of time, and
- the need to verify and document the reliability of clinical results at the time they are reported.

The stability of the measurement system is the fundamental determinant of how frequently a QC sample needs to be assayed. The more stable the system, the less frequently a statistical process control needs to be performed. Minimum laboratory practice, consistent with CLIA Regulations Section 493.1256 [3], is to assay controls at least once per 24 hours, or more frequently if specified by the method manufacturer or if the laboratory determines that more frequent QC analysis is necessary to maintain the performance characteristics of a method. Some tests have more stringent requirements. For example, CLIA Regulations Section 493.1267 requires that blood gas measurements analyze at least one control every 8 hours that includes both high and low levels in the course of 24 hours; in addition, a control must be run with each patient sample unless the instrument automatically calibrates at least every 30 minutes. Methods that have automated built-in control procedures may use less frequent analysis of external QC materials (discussed in a later section).

The need to verify the clinical acceptability of results may support more frequent QC sampling than that based

TABLE 5.1 Common sources of measurement variability.

Source	Time interval for fluctuation	Likely statistical distribution
Pipette volume	Short	Gaussian
Instrument temperature control	Short or long	Gaussian or other
Electronic noise in the measuring system	Short	Gaussian
Calibration cycles	Short to long	Gaussian or shift (periodic step)
Reagent deterioration in storage	Long	Drift
Reagent deterioration after opening	Intermediate	Cyclic, periodic drift/step
Calibrator deterioration in storage	Long	Drift
Calibrator deterioration after opening	Intermediate	Cyclic, periodic drift/step
Control material deterioration in storage	Long	Drift
Control material deterioration after opening	Intermediate	Cyclic, periodic drift/step
Environmental temperature and humidity	Variable	Variable
Reagent lot changes	Intermediate to long	Shift (random step)
Calibrator lot changes	Intermediate to long	Shift (random step)
Instrument maintenance	Variable	Gaussian, cyclic, or shift (periodic step)
Deterioration of instrument components	Variable	Variable

strictly on method stability characteristics or on regulatory minimum requirements. More frequent QC sampling is appropriate with automated systems that release results continuously to minimize the probability to release incorrect results that could initiate inappropriate clinical action before an instrument problem is detected. For example, QC scheduled on a 24-hour cycle might be performed at 09:00 hours. If the QC results indicate a method problem, the erroneous condition could have started at any time during the previous 24 hours. If the problem had occurred at 15:00 hours the previous day, out-of-control results would have been reported for 18 hours, and the risk of harm to a patient from decisions based on those erroneous results must be considered. The cost of a medical error, or simply the cost of repeating the questionable patient samples, could be more expensive than more frequent QC analysis. Analytes, such as whole blood glucose and serum carbon dioxide, are not stable over 24 hours, and more frequent QC may be necessary to ensure sample viability should a specimen need to be repeated.

Establishing quality control target values and acceptance ranges that represent a stable measurement operating condition

QC target values and acceptable performance ranges are established to optimize the probability of detecting a measurement error that is large enough to impact clinical care. QC acceptable ranges should be sensitive enough to detect a problem while minimizing the frequency of false alerts. Prior to establishing QC values and the statistical parameters used to evaluate QC results, the measuring system must be correctly calibrated and operating within acceptable performance specifications. Some sources of measurement variability are listed in Table 5.1. Measurement variability can be affected by factors with short time-interval frequencies, many of which can be described by Gaussian error distributions, as well as intermediate and long time-interval factors that can cause cyclic fluctuations over several days or weeks, gradual drift over weeks or months, and more abrupt shifts in results. Acceptance criteria for QC results must adequately account for all sources of expected variability in results that are likely to occur when the measuring system is performing to specifications.

A QC material must have a reliable target value for an analyte. This requires adequate statistical sampling of both the QC material's vial-to-vial and open-vial stability, as well as the measurement variability during a period of time when the measuring system is calibrated correctly and is exhibiting the expected imprecision associated with a stable measurement condition. The objective to establishing a reliable QC target value is to include all sources of variability in the measurement process that will ensure a representative mean concentration. This objective is rarely met due to long-term variability components and the practical inability to account for all influences at the time of QC target value assignment. A Clinical and

Laboratory Standards Institute (CLSI) guideline for QC recommends the mean value from assaying a QC material on a minimum of 10 different days for an initial target value [4]. Note that it is preferable to use a single bottle of QC material for the expected duration of its open-vial stability in order to account for analyte stability effects rather than a fresh bottle on each day of testing. If a 10-day protocol is not practical, provisional, or temporary, target values can be established with less data but should be updated when additional replicate results are available. When applicable, more than one assay calibration event should be represented in the 10-day period to include the variability associated with the calibration process. The target value should be reassessed after additional QC data are available that include more sources of variability than can be included in 10 days.

Some QC materials are provided with manufacturer-assigned target values and ranges that can be used to confirm that a method meets the manufacturer's specifications. Such assigned values can be used initially by the laboratory, but both the target value and ranges should be reevaluated and adjusted by the laboratory after adequate replicate results have been obtained. Laboratory-defined target values and SDs ensure that the acceptance criteria used by a laboratory adequately reflect performance for the method in that laboratory. The acceptability limits suggested by a manufacturer may reflect sources of variability, such as between instruments and between reagent and calibrator lots, or may represent best-case or worst-case performance that may not be typical for that QC material in an individual laboratory. QC materials with assigned target values are also available from third-party manufacturers (i.e., manufacturers not affiliated with the method manufacturer). Caution should be used when employing assigned values for third-party QC materials, since the target values and ranges may have been established using protocols that do not adequately reflect specific measuring system performance. Noncommutability may further limit applicability of third-party QC values for some methods.

Once a target value has been assigned to a QC material, a range or SD must be established that represents the typical imprecision of the measuring system when it is performing according to its manufacturer's specifications. Although there are non-Gaussian components of variability in QC results, an SD is the conventional way to express method variability because the statistical packages in instrument and laboratory computer systems are designed for QC data analysis based on mean and SD parameters. An SD based on the data from a 10-day target value assignment, or a 30-day monthly summary, has a large uncertainty and cannot reflect all sources of variability that need to be accommodated in the QC result evaluation process [4]. When previous experience with a method exists, the SD or range of QC results for stable measurement performance can be established from the cumulative SD over a 6- to 12-month period, which will include most sources of expected variation. Note that the cumulative SD is not established from the average of monthly QC statistical summaries. Different sources of long-term variability, which occur at different times during the use of a measuring system, may not be represented in a monthly SD for QC results. However, the cumulative SD includes contributions from most sources of variability as they occur and as they are reflected in the individual QC results. Consequently, the cumulative SD will typically be larger than the monthly values and better represent the actual variability of the measuring system. If the imprecision expected during stable operation is underestimated, then the acceptable range for QC results will be too narrow and the false-alert rate will be unacceptably high. If the imprecision is overestimated, then the acceptable range for QC results will be too large and the QC process will be less sensitive to detect a measurement error.

It is important to include all valid QC results in the calculation of a QC range. A valid QC result is one that was, or would have been, used to verify acceptable measuring system performance and reporting of patient results. Only QC results that would have been responsible for holding the release of patient results should be deleted (with documentation) from summary calculations. Selective editing of QC results underestimates the true method of SD, so QC ranges will be too narrow and will generate increased false QC alerts with concomitant reduction in the effectiveness of the statistical process control.

When a method has been established in a laboratory, and a new lot of QC material is being introduced, the target value for the new lot should be used with the cumulative SD from the previous lot to establish an acceptable range for the new lot of QC material. This practice is appropriate because the measurement imprecision is a characteristic of the measuring system. The measuring system imprecision is unlikely to change with a different lot of QC material. If the target values for the old and new lots are substantially different, there may be a different imprecision observed, and an adjustment to the QC SD may be necessary as additional experience with the new lot of QC material is accumulated.

When a new method is introduced for which there is no historical performance information, then the SD for stable performance must be established using data from the method validation and target value assignment of the QC materials. Additional information on expected method performance can be obtained from the method manufacturer, the package insert, and the method's performance in interlaboratory QC and/or proficiency testing (PT)

programs. For a new method, the initial SD and QC range evaluation criteria will need to be monitored closely, and adjustments made after more data have been collected to include intermediate and long-term sources of method variability.

Establishing acceptance criteria to evaluate quality control results

Operating conditions must be established for each measuring system before suitable QC interpretive criteria or rules can be selected. Establishing acceptance criteria to evaluate QC results is a balance between the sensitivity of detecting a significant analytical error condition and the frequency of false alerts. Various statistical models and assumptions regarding distribution of errors have been used to establish interpretive rules for QC results [5–7]. The probability for any interpretive rule to detect a measurement error increases as the magnitude of the error increases. When evaluating interpretive rules, it is common practice to express the magnitude of an error in multiples of the SD for the method (i.e., SD intervals, SDIs, or z-score).

A conventional way to express QC interpretive rules is with an abbreviation nomenclature summarized in Table 5.2. Note that fractional SDIs are permissible, as in the $2_{2.5S}$ rule. For example, consider a 1_{2S} interpretive rule that would be violated if a single QC result was >2 SD from the target value. A power function graph [7] shows that a 1_{2S} rule has a 35% probability to detect a systematic error that is 1 SD in magnitude and a 78% or 98% probability to detect systematic errors that are 2 or 3 SD in magnitude, respectively. However, it is not recommended to use a 1_{2S} rule because, due to the inherent imprecision, a 1_{2S} rule has an almost 10% probability of falsely indicating an error condition when there is zero systematic bias. Trend detection techniques such as cumulative sum or exponentially weighted moving averages are more powerful than rules based on the number of results that exceed a particular SDI and are recommended when computer systems can support their use [5,8].

A combination of interpretive rules applied simultaneously to a set of QC results will optimally detect errors with the lowest false-alert rates [6,7,9]. For example, a $1_{3S}/2_{2S}/R_{4S}$ multirule applied to two QC results identifies an error condition if one control exceeds ±3 SD from the target value, if two controls exceed ±2 SD in the same direction from the target value, or if the range between two controls exceeds 4 SD. In this multirule example, the 1_{3S} component is sensitive to large systematic bias, the 2_{2S} component is sensitive to systematic bias, and the R_{4S} component is sensitive to imprecision. This multirule has a low false-alert rate and a better probability to detect an error condition than the individual components alone. A number of multirule combinations can be used as appropriate for the performance characteristics and clinical requirements of a measuring system.

A challenge when selecting QC interpretive rules is that all sources of variability listed in Table 5.1 occur in most contemporary automated measuring systems and introduce long-term cyclic and step fluctuations in performance. These sources of variability are not adequately described by Gaussian-based QC interpretive rules. Since almost all instrument and laboratory computer system QC software is based on SDI (z-score) interpretation, it is necessary to estimate an SD that approximates the long-term variability from Gaussian and non-Gaussian contributions. Thus data collected over a significant time period are necessary to ensure the SD and QC ranges represent typical

TABLE 5.2 Abbreviation nomenclature to express quality control (QC) rules assuming Gaussian (normal) distribution of imprecision.

Rule	Meaning	Detects
1_{2S}	One observation exceeds 2 SD from the target value	Imprecision or systematic bias
1_{3S}	One observation exceeds 3 SD from the target value	Imprecision or systematic bias
2_{2s}	Two sequential observations, or observations for two QC samples in the same run, exceed 2 SD from the target value in the same direction	Systematic bias
$2_{2.5s}$	Two sequential observations, or observations for two QC samples in the same run, exceed 2.5 SD from the target value in the same direction	Systematic bias
R_{4S}	Range between two observations in the same run exceeds 4 SD	Imprecision
10_m	Ten sequential observations are on the same side of the target value (mean)	Systematic bias and trend (not recommended)
8_{1S}	Eight sequential observations for the same material exceed 1 SD in the same direction from the target value	Systematic bias and trend

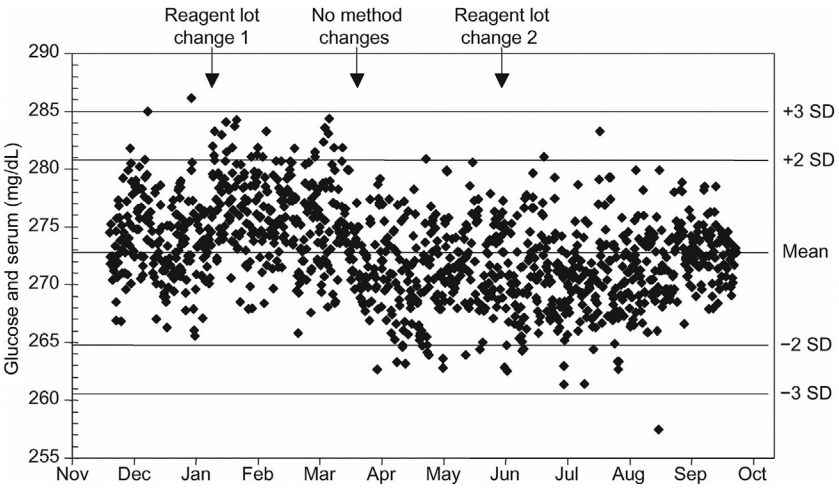

FIGURE 5.2 Levey–Jennings plot of quality control results ($n = 1232$) for a single lot of quality control material used for a 10-month period. The mean and standard deviation are cumulative values from all data.

variability when the method is stable and performing correctly.

Fig. 5.2 shows results for a single lot of QC material over a 10-month period for an automated glucose measuring system. The glucose method stability and performance over the 10 months were considered acceptable for clinical use. If acceptance criteria were based on the SD from the initial 30-day period, the subsequent long-term QC result fluctuations would have caused a large number of false alerts with significant effort and expense for troubleshooting what was actually inherent variability during stable method performance. The SD lines shown in Fig. 5.2 were determined from the entire 10 months of data. Examination of these data shows several fluctuations that cannot be described by a Gaussian statistical model. The first reagent lot change caused a step shift to higher values, but the shift was small enough to not require a target value adjustment (see later section). The second reagent lot change had no effect on the QC results. Between March and April, there was a transition to lower results that did not correspond to any reagent lot change, maintenance, or calibration events. Throughout the 10-month period, there are intervals of several weeks duration when the imprecision was either better or worse than other time periods emphasizing the importance to use a cumulative SD over a sufficient time interval that includes most sources of variability.

An empirical approach is frequently necessary to establish QC interpretive rules that will adequately encompass the observed variability in a measuring system. An example of an empirically developed multirule based on the data in Fig. 5.2 is $1_{3S}/2_{2.5S}/R_{4S}/8_{1.5S}$, in which 1_{3S} detects imprecision or bias, $2_{2.5S}$ detects systematic bias, R_{4S} detects imprecision, and $8_{1.5S}$ detects a trend in bias based on eight consecutive results that exceed 1.5 SD. This multirule was selected based on the clinical requirements for patient care, observed long-term measuring system performance, and the need to identify potential measurement issues with a false-alert rate $<1\%$. This multirule had 0.6% false alerts when applied to the data in Fig. 5.2 with a target value assigned as the mean value from the November-to-January period and the SD for the 10-month period to represent overall imprecision. If a 2_{2S} rule had been used instead of a $2_{2.5S}$ rule (sequential observations in this example), the false-alert rate would have increased from 0.6% to 1.8%. An $8_{1.5S}$ rule was selected to provide detection of bias trends because it had zero false alerts compared to 0.5% false alerts for an 8_{1S} rule. The $8_{1.5S}$ rule value was small enough that a bias trend of this magnitude would not adversely affect clinical interpretation of patient results. A rule that evaluates sequential results on one side of the mean can have a high false-alert rate when a measuring system's actual error distributions are not perfectly Gaussian. For example, a 10_m rule for the data in Fig. 5.2 would have increased the false-alert rate by 10.6%, which is why a 10_m rule is not recommended. Many contemporary analyzers are very stable and may produce QC results on one side of the mean for extended periods of time; however, if the magnitude of the difference from the target value is small, it may not indicate a problem with clinical interpretation of the patients' results.

In practice, empirical judgment is frequently necessary to set QC rules that fit the actual data accumulated over a long enough time period to adequately describe the variability observed when a measuring system is working correctly. Caution should be used when selecting QC interpretive rules based only on Gaussian models of imprecision because the rules may not accommodate all types of variability observed for many measuring systems. Whatever statistical approach is used, the balance between false alerts and the probability of error detection is improved when multiple rules are used in combination. When establishing rules to interpret QC results, statistical

process control can verify that a measuring system is producing results within its expected variability only at a point in time compared to when the system was properly calibrated and in a stable operating condition. QC rules are intended to detect bias and imprecision that is large enough to require correction before patient results are reported. Random events, for example, a temporary clot in a pipette, that do not persist until the next QC sample is measured will not be detected by external surrogate QC sample evaluation.

A laboratory director may determine in the process of reviewing statistical parameters for QC data that a measuring system's variability is too large to meet medical requirements. If the measuring system is performing in a stable condition within its manufacturer's specifications, the observed variability is an inherent property of the current technology. In this case, the only solutions are to improve the measuring system performance or to use a different method. If the measuring system performance cannot be improved and a better method is not available, the laboratory must accept the limitations and communicate them to patient care providers. In this circumstance, the QC ranges or interpretive rules should not be made artificially stringent. This incorrect approach will not improve measuring system performance but will increase the QC false-alert rate and decrease the efficiency and practicality of the statistical QC process.

Corrective action when a quality control result indicates a measurement problem

A QC alert occurs when a QC result fails an evaluation rule, indicating that an analytical problem may exist. A QC alert should occur only when there is a high probability the measuring system is producing results that are unreliable for patient care. When this condition occurs, corrective action should be taken to investigate the cause for the QC alert. Fig. 5.3 presents a generalized troubleshooting sequence. When a QC alert occurs, the first action is to discontinue assaying patient samples. Repeating the QC measurement on the same sample is not recommended, because, with properly designed acceptance criteria, it is more likely that a measurement system problem exists than the QC result was a statistical outlier. However, QC materials can deteriorate after opening due to improper handling and storage or due to labile analytes. Thus repeating the measurement on a new vial of the QC material may establish that the alert was caused by a deteriorated QC material rather than a method problem. In this situation, if the QC alert is resolved, testing of patient samples can resume. One caution is to consider a developing trend. If the repeat result is very near the acceptability limits, it means the measuring system's results are close to unacceptability and may indicate an impending problem that should be investigated as soon as possible. It is important that the multirule sequence include a

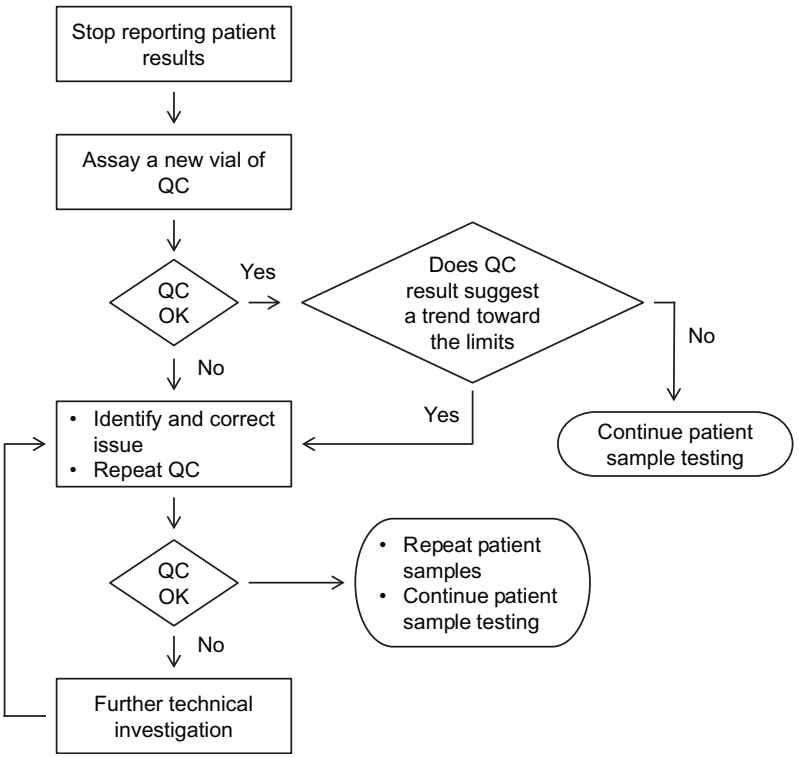

FIGURE 5.3 Generalized troubleshooting sequence following a quality control alert.

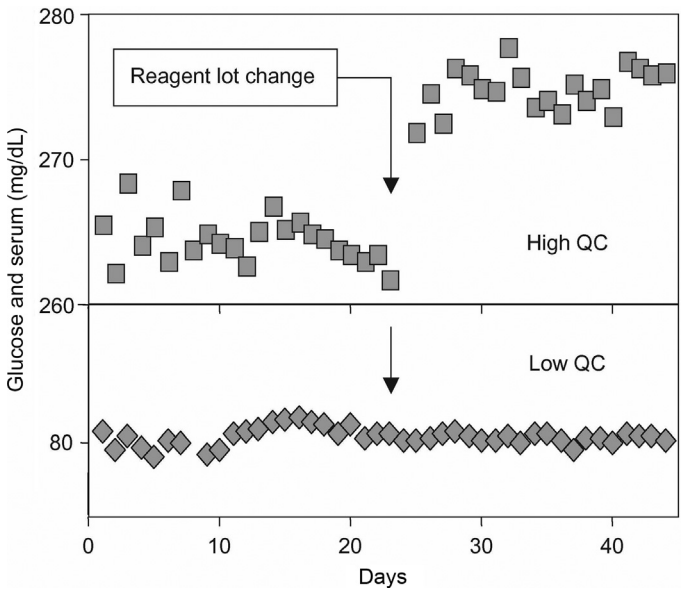

FIGURE 5.4 Levey–Jennings graph showing impact of a reagent lot change on matrix interaction with quality control materials.

trend-detecting QC rule, such as the $8_{1.5S}$ (in the previous example), an exponentially weighted moving average, or a cumulative sum.

When repeat testing of a new QC sample does not resolve the alert situation, the instrument and reagents should be inspected for component deterioration, mechanical problems, or other issues. When the problem is identified and corrected, controls should be measured to verify assay performance has acceptably returned to stable conditions. In many cases, the method will require recalibration before QC results can confirm correct method performance. After confirmation of correction, patient samples since the time of the last acceptable QC results should be repeated. The laboratory director should establish acceptable performance criteria for results from repeat testing of patient samples in order to determine whether the original test results can be reported or whether a corrected result should be reported. The criteria for acceptability of repeated tests are based on measuring system performance, the patient population, and the risk of harm to a patient.

In some cases, there may not be adequate volume left in patient samples (quantity not sufficient; QNS) for repeat testing. In these situations, no results can be reported unless the impact of the error on the original results was small enough to have an insignificant effect on clinical interpretation. One way to evaluate the clinical impact of a measuring system problem is to repeat those patient samples that have adequate volume. The repeated samples must represent the concentration range of the QNS samples, must represent the time span since the previous acceptable QC results, and should include a suitable number of samples originally assayed while the method was in the unacceptable condition to ensure representative assessment of the interval when there was a measurement defect. If the repeat results for this sample group are within established performance criteria for repeat testing of patient specimens, the original results for the QNS samples can be reported. Otherwise, the original results for the QNS samples are considered erroneous, and a corrected report should indicate no results and that the original results were incorrect.

Verifying quality control evaluation parameters following a reagent lot change

Changing reagent lots can have an unexpected impact on QC results. Careful cross-over evaluation of QC target values is necessary. Because the matrix interaction between a QC material and a reagent can change with a different reagent lot, the QC results may not be a reliable indicator of a method's performance for patient samples following a reagent lot change [2]. In the example in Fig. 5.4, the QC values for the high-concentration control shifted following the change to a new lot of reagents, but there was no change in results for the low-concentration control. A comparison of results for native patient samples assayed using the old and new reagent lots demonstrated equivalent patient results using either lot of reagents. Consequently, the change in QC values was due to a difference in matrix interaction between the high-concentration QC material and the two reagent lots.

When changing reagent lots, laboratories should be aware that the target value for a QC material may be affected. Target values for QC materials should be adjusted when a different matrix interaction is observed with a new reagent lot. First, patient sample results measured using the old and new reagent lots should be

compared to verify equivalent results are produced. If a problem is identified, the calibration of the new reagent lot should be investigated and corrected, or the possibility of defective reagents considered. The native patient sample results, not the QC results, are the basis to verify that results using the new reagent lot are consistent with those using the previous reagent lot. CLSI document EP26 provides guidance for verifying reagent lot changes and recommends a minimum of three patient samples or more depending on the number of critical clinical decision values and the imprecision of a measuring system [10]. EP26 also includes guidelines for acceptance criteria related to the magnitude of a difference that is clinically meaningful and the imprecision of a measuring system. CLSI document C24 also includes information on the influence of reagent lot and other changes on QC target values [4].

Once patient results are shown to be equivalent within clinically acceptable limits, the results from QC samples should be evaluated to determine whether the target values have changed with the new lot of reagent. If a QC target value has changed, that value should be adjusted to reflect the new value to be used with the new lot of reagents to keep the QC interpretive rules centered on the appropriate QC target value. This target value adjustment will allow the same QC interpretive rules to be utilized. In making this adjustment, the laboratory is compensating for an altered matrix interaction of the QC material with a different reagent lot. The SD used to evaluate QC results will not typically change when a new lot of reagent is put into service. The SD represents the expected variability when the method is stable and performing according to specifications. In most cases, the variability of a method will be the same with any lot of reagent(s); however, there may be occasional exceptions requiring adjustment of the SD, for example, if the reagent is reformulated and performance changes.

Verifying method performance following use of a new lot of calibrator

When implementing a new lot of calibrator, with no change in reagent, there should be no change in matrix interaction between the QC material and the reagent. In this case, the QC results provide a reliable indication of calibration status with the new lot of calibrator. If the QC results indicate a bias following use of a new lot of calibrator, the problem is caused by the new lot of calibrator and needs to be addressed to ensure consistent results for patient samples.

Some manufacturers package kits that include reagents, calibrators, and QC materials together. In this case, the QC results could fail to identify a calibration shift when a new kit is opened. Native patient samples should be analyzed with the old and new kits to verify consistency of patient results. When possible, QC materials that are independent of the kit lot are recommended. Laboratories should also avoid changing lots of QC material at the same time as changing lots of reagent or calibrators. The analysis of native patient samples, except for unstable analytes, provides a reliable approach to verify the consistency of results following changes in lots of reagents or calibrators.

Calibration issues in quality control

Calibration of the analytical measurement system is a key component to achieve quality results. The principal reason to perform statistical process control is to verify that the calibration and the variability of the analytical system remain within limits expected for stable measuring system performance. Specific techniques for calibration are unique to individual measuring systems and will not be covered here. However, some general principles for implementing calibration procedures, and for verifying calibration uniformity among multiple methods, can contribute to stability and clinical reliability of laboratory results.

Calibration is most often performed by the laboratory using calibrator materials provided by the measuring system manufacturer. In some cases, for example, point-of-care devices, measuring systems are calibrated during the manufacturing process, and the laboratory performs a verification of that calibration. In either situation, traceability of result accuracy to the highest order reference system is provided by the measuring system manufacturer. The measuring system manufacturer's calibrator material and assigned target values are designed to produce accurate results with native patient samples assayed using that particular manufacturer's measuring system. One manufacturer's product calibrator is not intended to be used with other measuring system, and laboratories should not use calibrator materials intended for one measuring system with any other measuring system because the matrix interaction with different reagents will produce a different response. Use of a calibrator with a measuring system for which it was not specifically intended can produce miscalibration and erroneous patient results.

National and international reference materials are available for some analytes. In many cases, these reference materials are intended for use with higher order reference measurement procedures and may not be suitable to use directly with routine clinical laboratory measuring systems. Laboratories should not use national or international reference materials to directly calibrate a clinical laboratory measuring system (or to verify the calibration of a clinical laboratory measuring system) unless

commutability with native patient samples has been verified for that specific reference material and clinical laboratory measuring system (see Chapter 17: Harmonization of results among laboratories, for additional information on calibration traceability and commutable reference materials). The reference material certificate of analysis should be reviewed for commutability documentation. If the reference material is noncommutable, the clinical laboratory measuring system could actually be miscalibrated and produce erroneous results for patient samples [11,12].

Optimal long-term stability of patient results is achieved if recalibration is performed only when the relationship between the analytical measuring system response and specimen concentration has changed. Performing a recalibration when the calibration relationship between measurement signal and concentration has not changed can be a source of imprecision in results. This imprecision occurs because the new calibration will produce a slightly different relationship between analytical system response and specimen concentration. CLIA Regulations Section 493.1255 requires calibration or calibration verification at least every 6 months or more frequently if recommended by the measuring system manufacturer [3]. Recalibration should be performed when necessitated by drift (which can be detected by shifts in QC results or other monitoring parameters), by changes in reagent lots, or after significant instrument maintenance. When there has been no change in measuring system performance, verification of the current calibration may be preferred rather than performing a recalibration.

One common procedure to verify calibration is to analyze the calibrator materials as "unknowns." Recovery of the target values indicates the measuring system calibration has not changed. There is no reason to perform a recalibration because the same relationship would be reestablished between measurement signal and the concentration of analyte in the calibrators. The laboratory must establish criteria for calibration verification (i.e., agreement between the assayed result and the calibrator target value). Conservative criteria for agreement, such as ± 1 SD from the target value, should be considered to avoid misinterpretation of the calibration status of a method. Calibration can also be verified by performing a method comparison using native patient samples measured with another measuring system known to be correctly calibrated.

Another approach to verify calibration is to analyze control materials that are specifically intended for this purpose. Some manufacturers produce control materials, called trueness controls, designed for calibration verification. Such manufacturer-provided materials typically have matrix characteristics and target values specifically designed for the measuring systems claimed in the package insert and cannot be used with any other measuring systems. These calibration verification materials may have target values certified by the manufacturer to be suitable for all reagent lots, or they may be specific for stated reagent lots. Third-party QC materials are usually not suitable for calibration verification. These materials are typically not validated for commutability with native clinical specimens for use with different measuring systems and do not have target values that are traceable to reference systems.

Development of a quality control plan based on risk management

Historically, the quality of laboratory results was ensured by periodic testing of QC samples to verify stability of measuring system performance. QC samples act as surrogates for patient samples and have target values that when recovered upon periodic analysis verify acceptable measuring system performance. Many regulatory agencies have required periodic analysis of QC samples as a means of ensuring quality. For instance, CLIA requires the analysis of at least two levels of controls each day of patient testing (more frequently for blood gas and coagulation devices). This QC strategy is sensitive to changes in the measuring system that persist in time (systematic errors). But, external QC samples do a poor job at detecting random errors that occur sporadically, at one point in time, or for a single patient sample (i.e., hemolysis, clots, and drug interferences).

Newer laboratory instrumentation utilizes a variety of control processes to ensure the quality of patient results. Some of these controls are built-in checks performed by the device to verify instrument function, such as electrical checks, optical checks, and biosensor checks. For example, the control line which develops on a lateral flow pregnancy or drug test evaluates kit storage viability, appropriate sample volume, sample application, and adequate timing. Other devices store on-board QC materials that are analyzed periodically by the measuring system to automate QC sample measurement. Still other devices require the operator to perform an action, like verifying the integrity of a temperature check (a simple device that changes color if frozen or heated during transit) when receiving shipments of reagents and calibrators. Some of these control processes are conducted with each analysis, providing a better means of detecting certain types of random errors than periodic analysis of external QC samples. Each control process is directed at minimizing the probability of certain errors, and devices have different risks for different types of errors. Thus each device may have different control processes to mitigate risk. Consequently, no single QC plan is totally adequate for all devices given

the complexity and variety of laboratory instrumentation that is available on the market today.

Use of risk management principles allows the development of a QC plan that is customized to an individual device, laboratory setting, and clinical application. CLSI guideline EP23 uses risk management to develop a laboratory QC plan [13]. EP23 is intended for clinical laboratories and provides guidance on using the manufacturer-provided information in the package insert, instructions for use and owner's manual, the risk of errors when testing with the device, and engineered control processes available on the instrumentation to develop custom, individualized QC plans (IQCPs).

Fig. 5.5 shows the process for developing a QC plan [13]. The laboratory starts by collecting information about the medical requirements of the test, local and regulatory QC requirements, the measuring system, and the heath care and laboratory settings. This information is processed using a risk assessment to develop a QC plan that will meet patient care needs and local QC regulations. Potential hazards or weaknesses in each step of analysis are identified. These hazards are assessed for frequency of occurrence and potential harm to the patient. Mitigation or control processes are required for those hazards that have greatest risk of harm to the patient or highest frequency of occurrence in order to reduce the residual risk of an error to a clinically acceptable level. The collection of all the control processes that are executed by the laboratory (surrogate QC sample testing plus other risk mitigation procedures) becomes the laboratory specific QC plan for that device or measuring system. The laboratory can never predict every possible hazard that could occur with a laboratory device, so it is never possible to entirely eliminate risk. There will always be some residual risk that the laboratory should manage through its control processes to minimize errors to a clinically acceptable level. Once implemented, the QC plan is monitored for the occurrence of unexpected errors or complaints. When errors or trends are identified, new control processes are defined to further mitigate and minimize risk, and the original QC plan is modified. In this manner, the laboratory responds to issues with corrective and preventive actions and cycles of continuous quality improvement.

The QC plan provides documentation of the reasoning for laboratory QC processes for a specific device. The QC plan defines what potential hazards the laboratory considered, the mitigations that will reduce risk of those hazards to a clinically acceptable level, the frequency of QC processes, and how the QC plan will be monitored (baseline measures for improvement). The QC plan provides a written outline of the laboratory's strategy for controlling the quality of a laboratory method and provides the rationale for control process improvement. Regulatory inspectors will find the QC plan sets laboratory policy for a measuring system's quality by defining how the laboratory will manage hazards, and inspectors can look to specific SOPs to determine whether the laboratory is following the elements of the QC plan.

Under the CLIA interpretive guidelines implemented on January 1, 2016, by the Centers for Medicare and

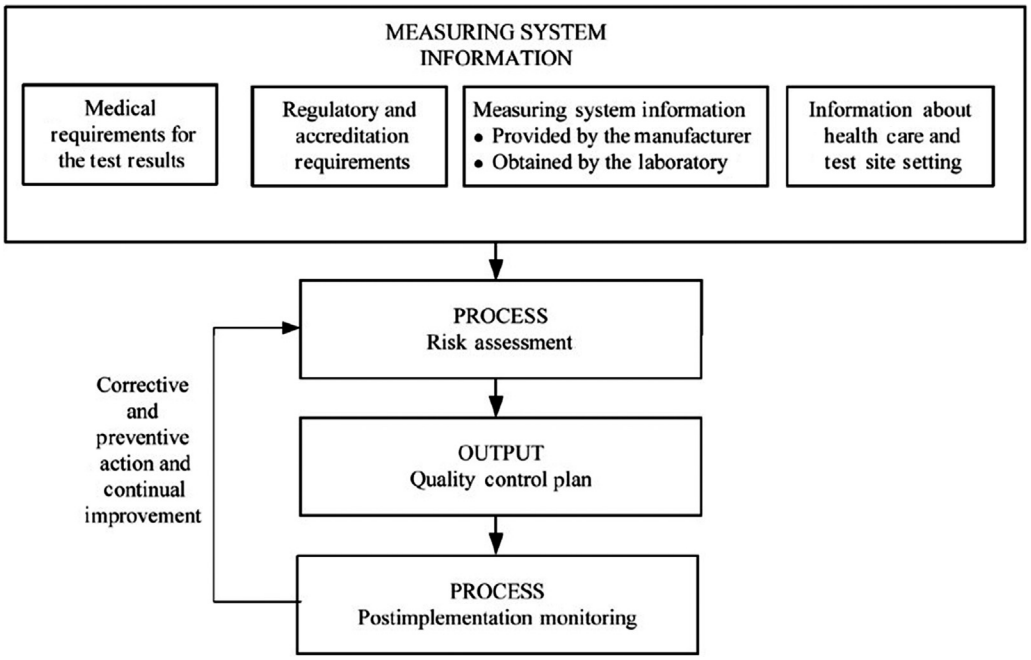

FIGURE 5.5 Process to develop and continually improve a quality control plan. *Reproduced from the EP-23-A Document with permission from the Clinical and Laboratory Standards Institute.*

Medicaid Services (CMS), laboratories in the United States have two options: (1) perform a minimum of two levels of QC for each test daily; or (2) develop an IQCP [14]. CMS is initially requiring an IQCP for CLIA nonwaived tests. IQCPs will allow laboratories to find the right balance of surrogate sample QC frequency with manufacturer built-in QC and control processes engineered into the device. Laboratories will be able to utilize the device control processes to reduce the frequency of surrogate sample QC for measuring systems that have minimal risk. In other situations, laboratories may find that they will need to increase the frequency of surrogate sample QC as well as implement additional control processes for high-risk measuring systems to achieve a clinically acceptable level of risk. Inspectors will be reviewing three items as part of the IQCP inspection process: (1) the laboratory's risk assessment; (2) the IQCP summary; and (3) the laboratory's quality assessment (e.g., the laboratory's quality benchmarks monitored to prove the effectiveness of the IQCP). As the philosophy of risk management is more widely adopted, laboratories can expect to see additional changes to regulations that will allow a variety of QC processes to be utilized in various combinations to manage measuring system quality and more reliance on laboratory specific IQCPs to define a laboratory's QC strategy.

Reviewing the quality control plan

A QC plan should be reviewed at least annually or whenever troubleshooting of QC errors or trends indicates the need to change the QC strategy. To develop a QC plan requires review of the many steps of the testing process looking for potential hazards or weaknesses where errors may occur. In a central laboratory with the analyzers all located in the same space, the analytical process may be more uniform than a point-of-care testing program with dozens of devices spread throughout an institution and hundreds of staff conducting testing. Discussion of the testing process with representative staff can uncover variations that may present the potential for errors in one location that may be less likely in other locations. Consider specimen labeling, for instance. Printing multiple specimen labels in advance before specimen collection may seem to be efficient but also presents the potential to mix-up labels between patient samples compared to on-demand printing of the label at the time of specimen collection. This difference in process requires an extra control step where staff must verify the correct specimen label matches the right patient and the right collection container with suitable preservative when needed. This verification step may be overlooked if printing occurs in advance. Printing labels on-demand during specimen collection has a much lower probability of specimen mix-up and the chance of human error during labeling.

Minor variations in preanalytical practices can occur throughout the testing process. Individual operator technique, specimen processing, aliquotting, dilutions, reagent preparation, and calibration all present a potential for error. QC specimens, if handled in the same manner as patient specimens, may detect some of these operational variations, especially if the technique leads to errors or increased variability in results. However, QC is often handled differently than patient samples and thus may not identify all sources of potential hazards. The management and handling of QC should therefore be considered in developing or revising a QC plan.

Review of the QC plan and discussion of the testing process with those involved is also an opportunity to uncover QC efficiencies that may not have been considered. Many point-of-care devices act as test readers and are simple voltmeters or light photometers with no moving parts. The chemistry of these devices is in the cartridges or test strips. QC can be performed on every device and a representative test cartridge every 24 hours, but with dozens of devices and locations to manage, this frequency may be excessive given the manufacturer control processes that are engineered into each test cartridge/strip. A urine pregnancy test, for example, has a control line that develops with each test. Analyzing a QC sample on these devices verifies the viability of that lot of test cartridges/strips during storage but can be duplicative to the internal control on that cartridge/strip. A QC plan may therefore consider utilizing the internal control on each test as the process for verifying chemical viability while employing the external QC samples as an event-driven process for confirming viability of new shipments, comparability of new lots (together with patient sample correlations), and detection of any deterioration during storage (periodic weekly or monthly analysis).

Testing surrogate sample QC materials cannot be billed to a patient or reimbursed by insurance but is required to manage the quality of the testing process. Large institutions that share a common lot of cartridges/strips might consider performing QC on a subset of analyzers, since the QC is detecting the chemistry of the test while the devices are internally verifying the voltage and photometer readouts when devices are turned on. Table 5.3 shows that an institution that has 20 readers receives quarterly shipments and conducts monthly QC on two lots of cartridges/strips could achieve significant efficiencies versus performing QC for every device and shipment. Such considerations are the heart of strategies for developing a robust QC plan that meets clinical needs but is also cost-effective and optimizes available resources while ensuring high-quality test results.

TABLE 5.3 Example comparing performing quality control (QC) for every point-of-care device versus a subset of devices[a].

QC for every device
20 readers × 4 quarterly shipments × 2 levels of QC = 160 QC tests
20 readers × 12 monthly QC × 2 levels of QC × 2 lots cartridges/strips = 960 QC tests
Total annual = 1120 QC tests
QC for a subset of devices
3 readers × 4 quarterly shipments × 2 levels of QC = 24 QC tests
3 readers × 12 monthly QC × 2 levels of QC × 2 lots cartridges/strips = 144 QC tests
Total annual = 168 QC tests
Savings of 952 QC tests or 85% reduction QC annually

[a]*These estimates assume a shared source of reagents throughout the institution, four quarterly shipments, and monthly two-level QC of no more than two lots of cartridges/strips on a point-of-care reader or simple photometer where the chemistry of the test is in the disposable cartridge/strip, the cartridge/strip includes internal control for the chemical reaction, and the point-of-care reader includes built-in checks of its electronic performance. This example shows one approach that may be utilized to develop a QC Plan that saves analysis of external QC in lieu of internal control processes engineered by the manufacturer into the test system. The actual approach chosen will depend on the device, the manufacturer QC recommendations, the local regulations, and, most importantly, the medical director approval that the QC plan covers the primary risks in the testing process to appropriately meet medical needs.*

Using patient data in quality control procedures

Results from patient samples are used in four principal ways to support the QC processes in the laboratory:

- to verify consistency of patient results when changing lots of reagent or calibrator (discussed in a previous section),
- to perform a delta check with a previous patient result,
- to verify consistency of patient results when an analyte is measured using more than one instrument or method in a healthcare system, and
- to use a statistical process control scheme that tracks the mean (or median) of patient results to monitor method performance.

Delta check with a previous result for a patient

Some types of laboratory errors can be identified by comparing a patient's current test result to a previous result for the same analyte. This comparison is called a "delta check." Mislabeled samples and samples altered by dilution with IV fluid or collected with an incorrect preservative are examples of errors that can be detected using delta checks. The time period between two patient results must be small enough that a significant physiological change in the analyte is unlikely for a delta check to be effective to identify mislabeled or improperly collected samples. This limitation restricts the analytes that can be monitored with a delta check to those with small within-individual variability. The difference between results used for the delta parameter must be sufficiently large to avoid excessive numbers of false alerts; however, as the difference threshold becomes larger, the number of potential problems missed also increases. Kazmierczak [15] has reviewed delta check and other patient data-based QC procedures. CLSI guideline EP33 describes various approaches to using delta checks for quality management [16].

Verify consistency between more than one instrument or method

Another common use of patient results in a QC process is to verify consistency of patient results when an analyte is measured using more than one measuring system within the same health system. Good laboratory practice requires that multiple measuring systems (whether identical or based on different method principles) for the same analyte be calibrated to give clinically equivalent patient results whenever possible. It may be necessary to modify the calibration settings of one measurement system to match another system's results. This strategy allows a common reference interval to be used, provides continuity of results between patient encounters at different locations, and avoids clinical confusion regarding interpretation of laboratory results.

One method or instrument should be chosen to represent the primary comparative method to which others will be adjusted to achieve equivalent results. The primary method should be chosen based on quality and reliability of results with consideration of calibration traceability to national or international standards, performance stability,

selectivity for the analyte, and influence of interfering substances. CLSI guideline EP31 suggests procedures to evaluate the equivalence of patient results within a healthcare system [17]. The number of samples to use when verifying equivalence of patient sample results can be as few as one or more depending on the frequency of the assessment, the magnitude of a difference that is clinically meaningful, and the imprecision of the measuring systems. The laboratory will need to establish the frequency of evaluation and number of samples based on the stability of the methods, the frequency of reagent and calibrator lot changes, and the clinical requirements of the health system. Common practices include splitting one or more individual patient samples, or a small pool from several samples, on a weekly basis for high-volume methods, and a monthly, quarterly, or semiannual basis for lower volume or very stable methods. A larger number of samples are recommended if the monitoring is performed less frequently. When establishing interpretation criteria, the laboratory needs to consider the limited statistical power for the number of results available and utilize trend-monitoring techniques. For example, if one patient sample is tested weekly, the evaluation criteria for agreement will need to allow for the expected imprecision of the methods and rely more on trends to identify a measuring system that may be performing differently than others in the group.

Results for QC materials should not be used for verifying equivalence of patient sample results assayed using different measuring systems. Noncommutability of QC materials with patient specimens is a common occurrence. Even when more than one measuring system from the same manufacturer is used, QC results may show differences between different reagent lots and instrument models.

Using patient data for statistical process control

For a sufficiently large number of patient results, the mean (or median) value can be stable enough to be used as an indicator of measuring system consistency over time. This approach can be used on a periodic basis by extracting data for a time period, for example, 1 month, calculating the mean and SD for the distribution of results, and comparing one time period to another to determine if any changes have occurred. Automated approaches have been described to determine the mean (or median) for groups of sequential patient results for use as a process control parameter. These methods are called "average of normals" (AON) or "moving average" techniques and are suitable for use in higher volume assays in chemistry and hematology [18]. In general, these approaches evaluate sequential patient results over time intervals such as several hours to one or more days. The patients may be grouped by age, gender, and ethnicity to obtain homogeneous subgroups. Results may be trimmed to remove extreme values, so the remaining results are more reflective of patients without disease conditions that influence a particular analyte. However, trimming may remove results that are indicative of a calibration drift reducing the effectiveness of the procedure. The median is minimally influenced by extreme values and is recommended when the computer system can make the calculation. The mean (or preferably median) for a group of results is tracked to monitor trends in method performance using statistical procedures such as cumulative sum or exponentially weighted moving average [5,8]. These approaches can be a useful supplement to traditional surrogate QC materials when monitoring a single measuring system's stability and the calibration uniformity between multiple measuring systems in one or several distributed laboratories. Patient result-based algorithms are useful for high-volume settings but have not been widely adopted due to lack of consensus guidelines for their use and lack of computer support from instrument manufacturers and laboratory information systems.

Proficiency testing

Evaluation of method performance by an external entity is referred to as PT or external quality assessment (EQA). PT/EQA allows a laboratory to verify that its results are consistent with other laboratories using the same or similar measuring systems for an analyte and thus confirms the measuring system is being used correctly [19]. PT/EQA providers circulate a set of samples among a group of laboratories. Each laboratory includes the PT/EQA samples along with patient specimens in the usual assay process. The results for the PT/EQA samples are reported to the PT/EQA provider for evaluation.

Because PT/EQA samples are typically not commutable with native patient specimens, each reported result is compared to the mean result from all laboratories using the same measuring system or closely related ones (called a "peer group"). The report also includes the SD for the peer group distribution of results, the number of laboratories in the peer group, and the SDI or z-score, which expresses the reported result as the number of SD from the mean value. The limits of acceptability may be established by regulation or by the PT/EQA provider for analytes without regulatory criteria. The evaluation criteria are defined as a number of SD, a fixed percent, or a fixed concentration from the peer group mean value. Many QC manufacturers also provide a data analysis service that calculates summary statistics for measuring system peer groups similar to those for PT/EQA providers. This type of interlaboratory QC data allows a laboratory

to verify that it is producing results that are consistent with those of other labs using the same measuring system.

PT/EQA is designed to evaluate the total error of a single measurement. The acceptability limits for PT/EQA include laboratory bias and imprecision components plus other error components that are unique to PT/EQA samples such as between laboratory variation in calibration, variable matrix interaction with different lots of reagent within a peer group, filling imprecision of the PT/EQA material vials, stability variability in storage, shipping, and after reconstitution or opening of PT/EQC materials in the laboratory. Consequently, the acceptability limits for PT/EQA specimens are frequently larger than what might be expected for clinically acceptable total error with patient specimens.

PT/EQA is not offered for some analytes either because the test is new to the clinical laboratory or the analyte stability makes it difficult to include in a PT/EQA material. In these situations, the laboratory should use an alternate approach to verify acceptable performance of the method. CLSI guideline GP27 provides several approaches to assess measuring system performance when formal PT/EQA is not available [20].

Noncommutability of proficiency testing/external quality assessment materials and peer group grading

PT/EQA results are usually evaluated through peer group comparison because of the noncommutability of the materials typically used as PT/EQA specimens. Matrix interference is unique to each combination of measuring system and processed PT/EQA sample (just as for QC or reference materials) and can be quantitatively different for different method, instrument, and material combinations for the same analyte. Several investigations have reported >60% incidence of noncommutable materials for different analytes [1,11].

Fig. 5.6 illustrates the effect of noncommutable materials on interpretation of PT/EQA results. In this example, pooled native patient sera and PT/EQA samples were assayed by the DuPont Dimension analyzer and by the Abell−Kendall reference method for cholesterol [21]. The patient samples showed excellent agreement between the two methods (average bias = 0.2%). However, the PT/EQA materials had a large negative bias (−9.5%) with this measuring system that was due to noncommutability between the PT/EQA samples and the patient specimens with the Dimension measuring system. If the apparent accuracy of the routine method was compared against the reference method based on PT/EQA results, and the calibration was erroneously adjusted, the results for patient specimens would then be incorrect. PT/EQA results were still valuable to judge the performance of

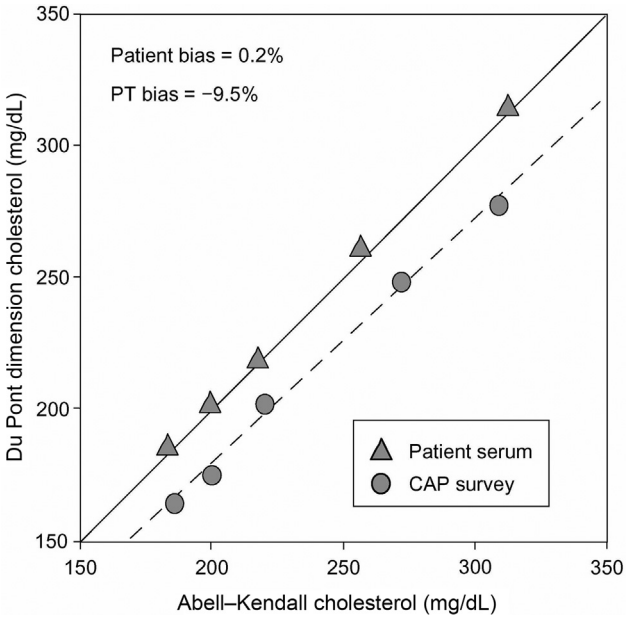

FIGURE 5.6 Example of noncommutability between proficiency testing materials and native patient sample pools for a specific method. *Adapted with permission from H.K. Naito, Y.S. Kwak, J.L. Hartfield, J.K. Park, E.M. Travers, G.L. Myers, et al. Matrix effects on proficiency testing materials: impact on accuracy of cholesterol measurement in laboratories in the nation's largest hospital system. Arch. Pathol. Lab. Med. 117 (1993) 345−351.*

laboratories using the Dimension method because the matrix interference was uniform within this peer group. Thus if an individual laboratory's results agreed with those of the peer group, the individual laboratory could conclude the measuring system was performing as expected. However, the accuracy of the Dimension method for patient specimens could not be evaluated based on the PT/EQA results.

Reporting proficiency testing/external quality assessment results when one method is adjusted to agree with another method

Good laboratory practice that is consistent with CLIA Regulations Section 493.1281 recommends adjusting the calibration of different measuring systems for the same analyte, within a health system, so the results for patient specimens are comparable irrespective of analytical method. In this situation, PT/EQA results must be reported correctly so they can be properly evaluated against the appropriate peer group. The peer group target value reflects the method calibration established by the measuring system manufacturer. For an individual laboratory's method with adjusted calibration, PT/EQA results must be reported to the PT/EQA provider with any user-applied calibration adjustment removed so the reported result can be compared to the manufacturer's calibration. The most convenient way to remove a calibration

adjustment is to first assay the PT/EQA samples with the calibration adjustment applied to the measuring system as would be the usual assay process for patient samples. After analysis, the PT/EQA results are corrected by mathematically removing the calibration adjustment. One should not recalibrate the instrument with a new set of calibrators for the purpose of analyzing PT/EQA specimens because this practice would violate regulations requiring the PT/EQA material to be assayed in the same manner as patient specimens.

For example, a laboratory has performed a native patient specimen comparison between Method A used in the main lab and Method B used in a satellite laboratory. Method B consistently generates results that are 10% higher than Method A, that is, a slope of 1.10 with negligible intercept. Method B can be adjusted to agree with Method A by automatically multiplying Method B's results by $1/1.10 = 0.91$ to lower the results by 10% before reporting (typically performed by the instrument's computer as a post measurement adjustment). When reporting PT/EQA results from Method B, it is necessary to remove the 0.91 factor to allow the reported result to be evaluated against the appropriate Method B peer group mean that will reflect the calibration established by the method manufacturer and allow the laboratory to assess its performance versus the peer group. Removing the 0.91 factor is accomplished by multiplying the reported PT/EQA result from Method B by the factor $1/0.91 = 1.10$ to increase its numeric value by 10%. The numeric result reported to the PT/EQA provider reflects the actual measured result using the manufacturer's recommended calibration settings. This process allows the PT/EQA sample to be assayed in the same manner as the patient specimens and the PT/EQA result to be appropriately evaluated by comparison to its peer group.

Interpretation of proficiency testing/external quality assessment results

When an unacceptable PT/EQA grade is received from a PT program, the measuring system should be investigated for possible causes and corrective action taken as necessary to correct any problems. Even when a PT/EQA grade is within acceptable limits, good laboratory practice recommends investigating any PT/EQA results that are greater than ~ 2.5 SDI from the peer group mean. When the SDI is 2.5, there is only a 0.6% probability of the result being within the expected distribution for the peer group; consequently, there is a reasonable probability of a measuring system problem that needs to be investigated. In addition, PT/EQA results that have been near the failure limit for more than one PT/EQA event, even if the results have passed the PT/EQA acceptance criteria, should initiate a review for systematic problems with the measuring system. These practices support identification of potential problems before they progress to more serious situations.

PT/EQA results are always received several weeks or more after the date of testing. Consequently, a review of QC, reagent, calibration, and maintenance records for the date of the testing and the preceding several weeks or months is necessary. If review of these records suggests a stable operating condition, and review of the PT/EQA material handling and documentation does not identify a cause for the erroneous PT/EQA result, it may be concluded the PT/EQA failure was a random event. The investigative steps, data reviewed, and conclusions from the review must be documented in a written report of the unacceptable PT/EQA result and reviewed by the laboratory director.

PT/EQA providers also include a summary report that includes the mean and SD/range for all the peer groups represented by the participants' results. Similar reports are available from interlaboratory QC programs. Summary reports are useful but must be interpreted with consideration of the limitations of noncommutable samples. The peer group mean and SD can be used to evaluate the uniformity of results between laboratories in the same peer group, to confirm an individual laboratory is using a measuring system in conformance to the manufacturer's specifications, and to evaluate the consistency of an individual laboratory's performance relative to the peer group over extended periods of time from one PT/EQA event to the next (trend monitoring). The summary information also allows evaluation of the imprecision of different types of measuring systems, and the number of users of each peer group reflects the market share for different measuring systems.

Because PT/EQA samples are commonly noncommutable with patient samples, PT/EQA summary reports cannot be used to compare: (1) the agreement or disagreement of patient results among different peer groups; (2) peer group means for different measuring systems to each other; or (3) an individual measuring system peer group mean to a value assigned by a reference method. Noncommutability also prevents any inference of the agreement for patient results among different measuring systems.

Accuracy-based proficiency testing/external quality assessment programs

PT/EQA providers offer programs that use commutable samples for some analytes. Commutable samples are typically prepared by pooling native clinical samples with minimal processing or additives to avoid any alteration of the sample matrix. To achieve samples with abnormal concentrations of analytes, donors can be identified with known

pathologic conditions, or blood and serum units from a general donor population can be prescreened for selected analytes. When commutable PT/EQA samples can be prepared, then the results from all laboratories reflect results that would be expected if native patient specimens were sent to each of the different laboratories. Thus agreement between laboratories (called "harmonization") and between different types of measuring systems can be correctly evaluated. The agreement between an individual laboratory result and a reference measurement result (accuracy), and the agreement between a measuring system mean and a reference method result (called trueness), can be evaluated when a reference method is available for an analyte.

For example, the College of American Pathologists Glycohemoglobin Survey has for many years used fresh, pooled whole blood from both normal and diabetic donors. The target values for the pooled blood are assigned by reference measurement procedures for hemoglobin A1c. In this survey, the accuracy of individual laboratory results, and the trueness of measuring system mean values, can be evaluated because the PT/EQA materials are commutable with native patient specimens. The measuring system trueness can be used by the respective manufacturers to monitor the effectiveness of their calibration processes.

PT/EQA programs have included commutable samples on occasion to evaluate individual laboratories and measuring systems groups for agreement with reference methods and for harmonization of results between laboratories and measuring systems groups [19]. Use of commutable materials adds substantial value to the information available from the results of PT/EQA programs.

Self-assessment questions

1. What is the primary purpose of QC (statistical process control)?
   a. to determine that a method is adequate for clinical requirements
   b. to verify that a method is performing as expected for its stable operating condition
   c. to establish the uncertainty in a laboratory result
   d. to ensure that regulatory requirements are met
2. Which of the following criteria should be used to select materials to use for QC?
   a. analyte stability after opening
   b. analyte concentrations at low and high values relative to the analytical measurement range
   c. a matrix similar to that of clinical samples
   d. number of analytes in the same vial
3. How should the target value for a QC material be assigned?
   a. by assaying one bottle 10 times over 5 days
   b. by assaying 10 bottles on each of 10 days
   c. by assaying several bottles on each of 10 days while allowing the open-vial stability to age
   d. by using the manufacturer's assigned value
4. How is the expected variability for a stable measurement system established?
   a. by calculating the SD after a full month of QC results
   b. by calculating the cumulative SD over a 6-month interval
   c. by averaging the monthly SD over 6 months
   d. by calculating the cumulative SD over a long enough time period that all expected sources of variability have been included in the data
5. Which of the following sources of measurement variability need to be included in the SD used to evaluate a method's performance?
   a. instrument maintenance cycles
   b. reagent and calibrator lot changes
   c. QC material open-vial stability
   d. instrument parameters such as pipette stability, temperature stability, and dirt accumulation
6. Which of the following criteria should be used to select rules for evaluation of QC results?
   a. frequency of false alerts
   b. probability to detect significant bias
   c. probability to detect significant imprecision
   d. probability to detect trends in bias
7. Which of the following are considerations for how frequently to run QC samples?
   a. stability of the measurement system
   b. use of built-in controls
   c. clinical impact of reporting an incorrect result
   d. cost to repeat questionable results following a QC alert
8. Why might it be necessary to adjust QC target values following a reagent lot change?
   a. The calibration could be incorrect.
   b. The matrix interaction between the QC material and the new reagent could be different than with the old reagent.
   c. The method could have changed.
   d. The original target value could have been incorrect.
9. Why are QC or PT results not used to evaluate agreement between different methods?
   a. The concentrations are different in different samples.
   b. The within-peer group SD and CV include calibration variability between laboratories.
   c. The peer groups may not have enough participants for reliable statistics.
   d. The specimens used are frequently noncommutable with native clinical samples.
10. Which of the following components of the QC program are documented in the SOP and review logs?
    a. the specimen target values and SDs used for evaluation
    b. the results for each measurement
    c. troubleshooting performed to resolve a QC alert
    d. the acceptance criteria used to evaluate the QC results

Answers

1. b
2. a, b, c, d
3. c
4. d
5. a, b, c, d
6. a, b, c, d
7. a, b, c, d
8. b
9. d
10. a, b, c, d

Chapter 6

Laboratory calculations

Steven M. Truscott

Department of Pathology and Laboratory Medicine, Oakland University William Beaumont School of Medicine, Beaumont Health, Royal Oak, MI, United States

Learning objectives

After reviewing this chapter, the reader should be able to:

- Perform basic analytical calculations used in the clinical laboratory.
- Perform calculations commonly reported by the laboratory or done by clinicians to inform medical decisions.
- Perform basic method evaluation and laboratory management calculations.

Both clinicians and patients should be able to safely assume that laboratorians are correctly applying mathematical concepts in analytical testing, and that calculated values in patient reports are as reliable as measured values. Developing a lab-developed test (LDT) and assuring the quality of that test require the application of multiple types of calculations, from calibration and quality control to test system−specific operations and ongoing evaluation of method performance. Whether providing consulting service to clinicians or validating test systems, a laboratory director should know which calculations to use, how to assess the appropriate inputs, and how the calculations are done. He or she must understand the clinical impact of the calculations performed by the laboratory.

This chapter reviews important calculations performed in the clinical chemistry laboratory and focuses on the problem-solving aspects of these calculations. While mastery of the equations and mathematical operations is foundational, their application to the clinical laboratory is vital, which is why the calculation-focused portions of board examinations often take a case-based approach to probe one's ability to use the calculations in context. References are made to other chapters for more detailed descriptions of how each calculation is applied in various clinical or laboratory situations. Other laboratory mathematics texts or review texts offer additional opportunities for practice, from fundamental arithmetic to statistical methods [1−5].

Analytical calculations

Dimensional analysis

Dimensional analysis, or the factor-label method, is a useful approach for tracking conversion between units and relationships between physical quantities. Put simply, initial quantities must convert through *unit factors*, or ratios of equivalent or corresponding values, into desired quantities by "canceling units." This concept is demonstrated throughout the chapter for many types of relationships and provides a check on the accuracy of calculations describing chemical or physical relationships.

Example 6.1: *A serum creatinine result of 1.1 mg/dL is equivalent to ____ μmol/L? The molecular weight of creatinine is 113.1 g/mol.*

$$\begin{array}{l}\text{Initial quantity} \times \text{Unit factor} \times \text{Unit factor} \times \text{Unit factor} = \\ \text{Desired quantity}\end{array} \quad 1.1\ \text{m gdL} \times \frac{\text{mol}}{113.1\ \text{g}} \times \frac{1000\ \mu\text{mol}}{1\ \text{m mol}} \times \frac{10\ \text{dL}}{\text{L}} = \frac{97\ \mu\text{mol}}{\text{L}}$$

The same result can be obtained using tabulated factors for interconverting the conventional and SI units for analyte concentrations.

$$1.1\ \text{mg/dL} \times \frac{88.4\ \mu\text{mol}/L}{1\ \text{mg/dL}} = 97\ \mu\text{mol}/L$$

Example 6.2: *The concentration of free testosterone measured for a male patient is 218 pg/mL; total testosterone is 619 ng/dL. What fraction of the total testosterone is free?*

$$\frac{218\ \text{pg/mL}}{619\ \text{ng/dL}} \times \frac{\text{ng}}{1000\ \text{pg}} \times 100\ \text{mLdL} = 0.035 \text{ or } 3.5\%$$

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00006-5

Example 6.3: *A case report describes a patient with a serum urea concentration of 12.4 mmol/L. What is this patient's blood urea nitrogen (BUN) concentration in mg/dL? The molecular weight of urea is 60.1 g/mol.*

The BUN descriptor is historical; current methods measure serum samples and reported values are the concentration of nitrogen mass within urea. Converting between urea and urea nitrogen requires the mass ratio of nitrogen in the urea molecule.

$$12.4 \text{ m mol urea} \text{L} \times 60.1 \text{ gmol} \times \frac{\text{L}}{10 \text{ dL}} \times \frac{28.0 \text{ g N}}{60.1 \text{ g urea}}$$
$$= ? \text{ mg/dL BUN}$$

$$74.5 \text{ mg/dL urea} \times 0.466 \frac{\text{g N}}{\text{g urea}} = 34.7 \text{ mg/dL BUN}$$

Centrifugation

Centrifuges in the clinical laboratory are used to separate plasma or serum from the cellular components of the blood, or to prepare samples for analysis after extraction with solvents. When using different centrifuge equipment, the corresponding centrifugation speed must be determined for consistent separation. Relative centrifugal force (RCF, in units of "$\times$ *g*") is usually provided in published methods and by collection tube manufacturers. RCF is a function of the speed that the centrifuge rotates [*n*, in revolutions per minute (rpm)] and the radius [*r*, in centimeters (cm)] as measured from the center of the centrifuge rotor to the middle of the sample in the tube:

$$\text{RCF} = 1.118 \times 10^{-5} \times r \times n^2$$

Example 6.4: *Another lab in your hospital system has a centrifuge rotor with a 14-cm radius and prepares samples at 8000 rpm. To prepare samples with the same RCF using a 10-cm rotor, what speed in rpm should be used?*

$$\text{RCF}_1 = \text{RCF}_2$$

$$1.118 \times 10^{-5} \times r_1 \times n_1 2 = 1.118 \times 10^{-5} \times r_2 \times n_2 2$$
$$14 \text{ cm} \times (8000 \text{ rpm})^2 = 10 \text{ cm} \times n_2 2$$

$$n_2 = 9466 \text{ rpm}$$

Both centrifuges will operate at $1.118 \times 10^{-5} \times r \times n^2$, or $10{,}017 \times g$.

Concentration

The laboratorian should be adept at calculating reagent and analyte concentrations for common analytical methods and for the specific methods employed in his or her own laboratory. The most common units of concentration in the clinical laboratory are the percent weight/volume ($\%^{\text{w/v}}$) and molarity (mol/L or *M* in italics). Precisely defined, the percent weight/volume is grams of solute per 100.0 mL of total solution, and molarity is moles of solute per liter of total solution. Reagent concentrations may also be described in terms of mass per volume of total solution (e.g., mg/dL). Clinical results may be presented in grams or moles of analyte per volume of biological fluid (serum, plasma, whole blood, urine, or other fluid)—with conventional or SI prefixes as needed to be able to provide a manageable number to clinicians. The following examples review the preparation of simple solutions and interconversion of concentration units.

Example 6.5: *To prepare 0.100 L of a 100.0-mM aqueous stock solution of lactic acid, how many grams must be weighed and transferred to a volumetric flask?*

Start with the volume of solution that is needed and use the molecular weight of lactic acid as one of the unit factors.

$$0.100 \text{ L} \times 100.0 \text{ mmolL} \times \frac{\text{mol}}{1000 \text{ mmol}} \times 90.08 \text{ gmol} = 0.901 \text{ g}$$

Example 6.6: *An LDT method utilizes 1.5% NaCl. How many grams of NaCl are required to prepare 1.00 L? What is the molarity of this solution?*

Assume this is a percent weight/volume solution indicating the number of grams per 100.0 mL.

$$1.00 \text{ L} \times \frac{1.5 \text{ g}}{100.0 \text{ mL}} \times 1000 \text{ mLL} = 15.0 \text{ g}$$

Use the molecular weight of sodium chloride to convert into molarity.

$$\frac{15.0 \text{ g}}{\text{L}} \times \frac{\text{mol}}{58.44 \text{ g}} = 0.257 \text{ mol/L or } 257 \text{ mmol/L}$$

Example 6.7: *Zinc sulfate heptahydrate is used to make up a 5% solution of $ZnSO_4$ in deionized water. How many grams of the heptahydrate are needed to make 500.0 mL?*

One mole of a hydrated salt corresponds to one mole of an anhydrous salt; therefore the ratio of the two molecular weights becomes one of the unit factors.

$$500.0\ \text{mL} \times \frac{5.0\ \text{g}\ ZnSO_4}{100.0\ \text{mL}} \times \frac{287.56\ \text{g/mol}\ ZnSO_4 \bullet 7H_2O}{161.45\ \text{g/mol}\ ZnSO_4}$$
$$= 44.5\ \text{g}\ ZnSO_4 \bullet 7H_2O$$

Electrolyte concentrations may be expressed in terms of *equivalents* (Eq), where one equivalent is equal to one mole of charges [6]. To convert between moles and equivalents, it is helpful to remember the following pattern:

For monovalent ions, 1 mmol = 1 mEq
For divalent ions, 1 mmol = 2 mEq
For trivalent ions, 1 mmol = 3 mEq

Example 6.8: *A patient's serum magnesium concentration is reported as 0.8 mEq/L in another laboratory, but your lab's reference interval is 1.7–2.4 mg/dL. What is the patient's magnesium result in mmol/L? in mg/dL?*

Magnesium is a divalent cation, so 1 mmol Mg^{2+} corresponds to 2 mEq Mg^{2+}. The molarity can be determined first and then converted into mg/dL using the molecular weight of the magnesium ion.

$$\frac{0.8\ \text{mEq}\ Mg^{2+}}{\text{L}} \times \frac{1\ \text{mmol}}{2\ \text{mEq}} \times \frac{24.3\ \text{g}}{\text{mol}} \times \frac{\text{L}}{10\ \text{dL}}$$
$$= ?\ \text{mg/dL}\ Mg^{2+} \quad 0.4\ \text{m mol}\ Mg^{2+}\text{L} \times 24.3\ \text{gmol}$$
$$\times \frac{\text{L}}{10\ \text{dL}} = 1.0\ \text{mg/dL}\ Mg^{2+}$$

Other concentration-related calculations involving the concepts of normality, molality, and other percent solutions [e.g., percent weight/weight ($\%^{w/w}$) and percent volume/volume ($\%^{v/v}$)] are reviewed effectively elsewhere [4]. However, strong acids are usually labeled with percent weight/weight ($\%^{w/w}$), so the pertinent calculations should be reviewed briefly, since these reagents are frequently used in specialized methods and LDTs in clinical laboratories. Percent weight/weight ($\%^{w/w}$) refers to the number of grams of solute dissolved in 100.0 g of total solution. Specific gravity (SG) of the strong acid solution is also given on the chemical label. The SG, a unitless entity, is the ratio of the density of the solution to the density of water, which approaches 1.00 g/mL depending on the temperature. At room temperature, the SG of a solution is approximately the density of the solution in g/mL.

Example 6.9: *How many milliliters of concentrated HCl solution (37.0%$^{w/w}$, SG 1.19) are needed to prepare 500 mL of 0.200 M HCl?*

Start with the volume to be prepared. The desired molar concentration, molecular weight of HCl, percent weight/weight, and density (SG) are used as unit factors.

$$500\,\text{mL} \times \frac{0.200\,\text{mol HCl}}{\text{L}}$$
$$\times \left(\frac{36.46\,\text{g HCl}}{\text{mol HCl}} \times \frac{100.0\,\text{g sol'n}}{37.0\,\text{g HCl}} \times \frac{\text{mL}}{1.19\,\text{g sol'n}} \times \frac{\text{L}}{1000\,\text{mL}} \right)$$
$$= 8.28\,\text{mL}$$

Note that the unit factors indicated in parentheses can be used to determine the molarity of the concentrated HCl solution. One might find the molarity first, then the calculation simplifies to either of the following:

$$500\ \text{mL} \times 0.200\ \text{mol HClL} \times \left(\frac{\text{L}}{12.08\ \text{mol HCl}} \right) = 8.28\ \text{mL}$$

$$500\ \text{mL} \times \frac{0.200\ \text{M HCl}}{12.08\ \text{M HCl}} = 8.28\ \text{mL}$$

Dilutions

The last expression in Example 6.9 is consistent with an algebraic manipulation of the equation, $C_1V_1 = C_2V_2$. The product of concentration and volume of an initial solution (C_1V_1) equals the product of concentration and volume of a new solution (C_2V_2) after dilution or concentration, since the number of moles of solute does not change. In the context of this formula, the *dilution factor* is equal to V_2/V_1, the new total volume divided by the original volume. Laboratory procedures should be written with clear and consistent terminology for preparing dilutions. Potential confusion lies in differentiating among the *ratio to diluent*, the *dilution*, and the *dilution factor*.

Example 6.10: *A patient with bone metastases has a total serum alkaline phosphatase activity outside of the analytical measuring range. The lab procedure for manual dilutions calls for 50 μL of patient sample to be diluted with 150 μL of the approved diluent. Define the ratio to diluent, the dilution, and the dilution factor for this situation.*

Ratio to diluent: 1 to 3; 1 volume of sample (50 μL) to 3 volumes of diluent (3 μL × 50 μL)
Dilution: ¼, or 1 to 4; the ratio of sample volume (50 μL) to total volume of sample plus diluent (200 μL; note that a 1 to 4 dilution is not one part sample to four parts diluent).
Dilution factor: 4; the reciprocal of the dilution, or the total volume of sample plus diluent, divided by the original sample volume: 200 μL/50 μL = 4

When patient results are beyond a method's analytical measuring range and must be diluted, it is the *dilution factor* that should be used to calculate the final result after

reanalysis of the diluted sample. Many automated chemistry analyzers will perform on-board dilutions and calculate a final result. When further manual dilutions are required, the laboratorian should verify that both automated and manual dilution factors are applied correctly to obtain a final result. When serial dilutions are performed, the final dilution is the product of all individual dilutions. Dilution factors may be applied at the instrument, in middleware, or in the laboratory information system (LIS).

Example 6.11: *An automated immunoassay analyzer measures human chorionic gonadotropin (hCG) with an analytical measuring range of 2−1000 mIU/mL. Out-of-range samples undergo an automatic dilution of 1 to 100, and the dilution factor is applied automatically by the instrument. For a certain patient sample, the hCG result was still out of range after autodilution. A manual dilution was prepared using 50 μL of serum and 200 μL of the approved diluent. The hCG result provided by the instrument was 42,700 mIU/mL. What result should be reported to the clinician?*

The first dilution factor of 100 is already applied to the result by the instrument. The manual dilution was 1 to 5, so the final reported result should be

$$42,700\ \text{mIU/mL} \times 5 = 213,500\ \text{mIU/mL}.$$

Equilibrium calculations and pH

In the clinical laboratory, equilibrium calculations describe protein−ligand interactions, including antigen−antibody interactions, as well as acid−base equilibria. For any chemical reaction at equilibrium, the extent or state of equilibrium can be described mathematically using an equilibrium constant, K. For the reaction

$$aA + bB \rightleftarrows cC + dD$$

the equilibrium constant is determined from product and reactant concentrations and their stoichiometry. (Note that activity versus concentration of species in solution is not addressed here.)

$$K = \frac{[C]^c[D]^d}{[A]^a[B]^b}$$

Acid−base equilibria, both analytical and physiological, are among the most commonly encountered in the clinical laboratory. In a relatively dilute solution of weak acid, where changes in the molar concentration of water are insignificant, the equilibrium reaction can be represented as the dissociation of the acid (HA) into hydrogen ion and the conjugate base (A^-)

$$HA \rightleftarrows H^+ + A^-$$

and the equilibrium constant, in this case known as the acid dissociation constant, takes the form:

$$K_a = \frac{[H^+][A^-]}{[HA]}$$

Because hydrogen ion concentrations under physiological conditions are on the order of 1×10^{-7} mol/L, logarithms provide the most practical notation. The convention is to use pH for the negative logarithm of $[H^+]$ and to use pK_a for the negative logarithm of K_a.

$$pH = -\log [H^+]$$
$$pK_a = -\log K_a$$

It is worthwhile to review mathematical concepts involving logarithms [7] and how to use the "log" and "10^x" keys for your model of handheld calculator.

Buffer calculations

Buffer preparation: A buffer is an equilibrium solution, a mixture of a weak acid and its conjugate base (or a base and its conjugate acid), that resists pH changes when strong acid or base is added. For acid−base equilibrium and buffer calculations, one should remember the Henderson−Hasselbalch equation, which is derived from the expression for equilibrium dissociation constant of the acid:

$$pH = pK_a + \log \frac{[A^-]}{[HA]}$$

Buffers are completely specified by stating the volume needed, target pH, and total concentration [Y] of the specific acid/base pair, $[Y] = [A^-] + [HA]$. The ratio of $[A^-]$ / [HA] is determined using the Henderson−Hasselbalch equation based on the target pH.

Example 6.12: *Outline how to prepare 1.00 L of a pH 3.50, 0.200-M fluoride buffer: $pK_a = 3.20$, $K_a = 6.31 \times 10^{-4}$ for hydrofluoric acid.*

First, determine the $[A^-]$ / [HA] ratio using the Henderson−Hasselbalch equation:

$$pH = pK_a + \log \frac{[A^-]}{[HA]}$$

$$3.50 = 3.20 + \log \frac{[A^-]}{[HA]}$$

$$\frac{[A^-]}{[HA]} = 10^{(3.50-3.20)} = 2.00$$

Then, solve for $[A^-]$ and [HA], knowing that $[Y] = [A^-] + [HA] = 0.200\ M$.

$$[A^-] + [HA] = 0.200\ M$$
$$2[HA] + [HA] = 0.200\ M$$
$$[HA] = 0.067\ M$$
$$[A^-] = 0.133\ M$$

To prepare the buffer, add 0.133 mol of a fluoride salt and 0.067 mol of hydrofluoric acid to a 1.00 − L volumetric flask. Alternatively, add 0.200 mol of the fluoride salt and add 0.067 mol of a strong acid, or add 0.200 mol of hydrofluoric acid and add 0.133 mol of a strong base. Check and make minor adjustments to the pH using a pH meter, then dilute to 1.00 L with deionized water.

The carbonic acid buffer system: While buffer calculations involving carbon dioxide species are like other weak acid buffer calculations, there are significant complicating equilibria in the physiological setting, as described in detail in Chapter 35, Laboratory evaluation of kidney function. Carbonic acid (H_2CO_3) is a weak acid in equilibrium with bicarbonate (HCO_3^-), its conjugate base, and hydrogen ion (H^+). Yet carbonic acid is also in equilibrium with water and dissolved carbon dioxide gas, which can be exhaled to raise rapidly blood plasma pH. The key calculation for this buffer system is

$$\text{pH} = \text{pK}' + \log\frac{[HCO_3^-]}{\alpha \times \text{pCO}_2}$$

where pK′ is the apparent pK for carbonic acid, $[HCO_3^-]$ $[HCO_3^-]$ is the bicarbonate concentration in mmol/L, α is the solubility coefficient for CO_2 gas in mmol/L/mm Hg, and pCO_2 is the partial pressure in mm Hg of dissolved carbon dioxide gas. At the normal physiological temperature and ionic strength of human plasma, pK′ and α are 6.1 and 0.03, respectively; therefore:

$$\text{pH} = 6.1 + \log\frac{[HCO_3^-]}{0.03 \times \text{pCO}_2}$$

After measuring plasma pCO_2 and pH, the $[HCO_3^-]$ $[HCO_3^-]$ and total CO_2 (TCO_2) in mmol/L can be calculated. TCO_2 refers to the sum of bicarbonate, carbonic acid, and dissolved CO_2 gas:

$$TCO_2 = [HCO_3^-] + 0.03 \times \text{pCO}_2$$

This calculation is performed on blood gas analyzers and correlates well with total CO_2 methods on automated chemistry analyzers.

Example 6.13: *Blood gas results obtained for a patient with contraction alkalosis and hypokalemia include pH 7.52 and pCO_2 of 51-mm Hg. Determine bicarbonate and TCO_2 concentrations in mmol/L.*

$$\text{pH} = 6.1 + \log\frac{[HCO_3^-]}{0.03 \times \text{pCO}_2}$$
$$7.52 = 6.1 + \log\frac{[HCO_3^-]}{0.03 \times 51}$$
$$[HCO_3^-] = 0.03 \times 51 \times 10^{(7.52-6.1)}$$
$$[HCO_3^-] = 40\ \text{mmol/L}$$

To determine TCO_2, use this bicarbonate concentration.

$$TCO_2 = [HCO_3^-] + 0.03 \times \text{pCO}_2$$
$$TCO_2 = 40 + 0.03 \times 51 = 42\ \text{mmol/L}$$

Buffer capacity: In general, the ability of a buffer to resist pH changes, the buffer capacity, is the highest when the pK_a of the buffer system is near the intended pH and when near-equal concentrations of acid and conjugate base are present. (Interestingly, neither of these is the case for the carbonic acid buffer system, where the pK′ = 6.1 and the $[A^-]$/[HA] ratio is 20:1). Buffer capacity also increases with increasing total buffer concentration. However, depending on the analytical method, one may need to minimize the total buffer concentration. Using a variation of the Henderson−Hasselbalch equation, it is possible to determine how much total buffer concentration (conjugate base plus acid) is needed to resist a specified pH change induced by an added strong acid or base. Given initial pH (pH_i), as well as initial salt ($[A^-]_i$) and acid ($[HA]_i$) concentrations, a known concentration of added strong acid ([X]) will decrease the pH by δ. The added $[H^+]$ will react with the conjugate base, resulting in a higher concentration of undissociated weak acid, so $[A^-]$ will decrease by [X] and [HA] will increase by [X]:

$$\text{pH}_i - \delta = \text{pK}_a + \log\frac{[A^-]_i - [X]}{[HA]_i + [X]}$$

Adding a strong base raises the pH by δ and consumes the undissociated weak acid, resulting in a higher concentration of the conjugate base:

$$\text{pH}_i + \delta = \text{pK}_a + \log\frac{[A^-]_i + [X]}{[HA]_i - [X]}$$

Example 6.14: *An acetate buffer set to pH 4.6 must not allow pH to fall more than 0.2 pH units if up to 5.0 mM strong acid is added. What total buffer concentration is needed? (pK_a for acetic acid = 4.76.)*

Begin by calculating the $[A^-]_i$/$[HA]_i$ ratio from the pK_a and initial pH:

$$\begin{aligned}
\mathrm{pH_i} &= \mathrm{pKa} + \log\frac{[\mathrm{A^-}]_i}{[\mathrm{HA}]_i}\\
4.6 &= 4.76 + \log\frac{[\mathrm{A^-}]_i}{[\mathrm{HA}]_i}\\
\frac{[\mathrm{A^-}]_i}{[\mathrm{HA}]_i} &= 10^{(4.6-4.76)} = 0.692\\
[\mathrm{A^-}]_i &= 0.692\,[\mathrm{HA}]_i
\end{aligned}$$

Use the equation above for pH change upon addition of strong acid:

$$\begin{aligned}
&\mathrm{pH_i} - \delta = \mathrm{pKa} + \log\frac{[\mathrm{A^-}]_i - [\mathrm{X}]}{[\mathrm{HA}]_i + [\mathrm{X}]}\\
&4.6 - 0.2 = 4.76 + \log\frac{[\mathrm{A^-}]_i - 5.0\ \mathrm{m}M}{[\mathrm{HA}]_i + 5.0\ \mathrm{m}M}\\
&\frac{[\mathrm{A^-}]_i - 5.0\ \mathrm{m}M}{[\mathrm{HA}]_i + 5.0\ \mathrm{m}M} = 10^{(4.4-4.76)} = 0.437\\
&[\mathrm{A^-}]_i - 5.0\ \mathrm{m}M = 0.437([\mathrm{HA}]_i + 5.0\ \mathrm{m}M)\\
&0.692\,[\mathrm{HA}]_i - 5.0\ \mathrm{m}M = 0.437([\mathrm{HA}]_i + 5.0\ \mathrm{m}M)\\
&[\mathrm{HA}]_i = 28.2\ \mathrm{m}M\\
&[\mathrm{A^-}]_i = 19.5\ \mathrm{m}M
\end{aligned}$$

The total acetate buffer concentration should be at least 28.2 + 19.5 = 47.7 m*M*.

An alternative approach to buffer capacity calculations does not require the $\mathrm{pK_a}$ value if $[\mathrm{A^-}]_i$ and $[\mathrm{HA}]_i$ are known. Consider subtraction of the first two equations below:

$$\begin{aligned}
&\mathrm{pH_i} + \delta = \mathrm{pKa} + \log\frac{[\mathrm{A^-}]_i + [\mathrm{X}]}{[\mathrm{HA}]_i - [\mathrm{X}]}\\
&\mathrm{pH_i} = \mathrm{pKa} + \log\frac{[\mathrm{A^-}]_i}{[\mathrm{HA}]_i}\\
&\delta = \log\frac{[\mathrm{A^-}]_i + [\mathrm{X}]}{[\mathrm{HA}]_i - [\mathrm{X}]} - \log\frac{[\mathrm{A^-}]_i}{[\mathrm{HA}]_i}\\
&\delta = \log\frac{\dfrac{[\mathrm{A^-}]_i + [\mathrm{X}]}{[\mathrm{HA}]_i - [\mathrm{X}]}}{\dfrac{[\mathrm{A^-}]_i}{[\mathrm{HA}]_i}}\\
&10^{\delta} = \frac{\dfrac{[\mathrm{A^-}]_i + [\mathrm{X}]}{[\mathrm{HA}]_i - [\mathrm{X}]}}{\dfrac{[\mathrm{A^-}]_i}{[\mathrm{HA}]_i}}\\
&10^{\delta} \times \frac{[\mathrm{A^-}]_i}{[\mathrm{HA}]_i} = \frac{[\mathrm{A^-}]_i + [\mathrm{X}]}{[\mathrm{HA}]_i - [\mathrm{X}]}
\end{aligned}$$

This equation holds for the addition of a strong base, where the pH change is positive ($\delta > 0$). For the addition of strong acid, the pH change is negative ($\delta < 0$), and the equation becomes

$$10^{\delta} \times \frac{[\mathrm{A^-}]_i}{[\mathrm{HA}]_i} = \frac{[\mathrm{A^-}]_i - [\mathrm{X}]}{[\mathrm{HA}]_i + [\mathrm{X}]}$$

Example 6.15: *A phosphate buffer set to pH 7.4 is made with 190-mM Na_2HPO_4 and 50-mM NaH_2PO_4. What concentration of strong acid can be added before the pH drops by 0.5 pH units? (Three pK_a values apply to the triprotic phosphate buffer system, and they vary slightly in the literature; however, pK_a is not needed when the $[A^-]_i/[HA]_i$ ratio is known.)*

In this problem, $\delta = -0.5$, for a decrease in pH. Conjugate base will be converted into undissociated weak acid, so the correct calculation is

$$10^{\delta} \times \frac{[\mathrm{A^-}]_i}{[\mathrm{HA}]_i} = \frac{[\mathrm{A^-}]_i - [\mathrm{X}]}{[\mathrm{HA}]_i + [\mathrm{X}]}$$

$$10^{-0.5} \times \frac{190\ \mathrm{m}M}{50\ \mathrm{m}M} = \frac{190\ \mathrm{m}M - [\mathrm{X}]}{50\ \mathrm{m}M + [\mathrm{X}]}$$

$$(50\ \mathrm{m}M + [\mathrm{X}]) \times 1.202 = 190\ \mathrm{m}M - [\mathrm{X}]$$

$$[\mathrm{X}] = 59\ \mathrm{mM}\ \text{strong acid may be added}$$

Ionic strength

Ionic strength is a unitless quantity that accounts for the charge and concentration of all ions in a solution. It is used to estimate the difference between the activity (e.g., as measured by an ion-selective electrode) and the calculated concentration of the ion. The formula for calculating ionic strength (I) in any solution is

$$\mathrm{I} = \frac{1}{2}\sum c_i z_i^2$$

where c_i is the molar concentration of each individual ion, and z_i is the charge of each ion.

Example 6.16: *Determine the ionic strength of a 0.10 M solution of $MgCl_2$ at pH 7.0.*

The concentrations of each ion in this solution are

$$\begin{aligned}
[\mathrm{Mg^{2+}}] &= 0.10\ M\\
[\mathrm{Cl^-}] &= 0.20\ M\\
[\mathrm{H^+}] &= 1.0 \times 10^{-7}\ M\\
[\mathrm{OH^-}] &= 1.0 \times 10^{-7}\ M
\end{aligned}$$

Considering the hydrogen and hydroxide concentrations to be negligible in this case, use the concentrations and charges for $\mathrm{Mg^{2+}}$ and $\mathrm{Cl^-}$ to calculate *ionic strength*:

$$\mathrm{I} = \frac{1}{2}\left[(0.1)(+2)^2 + (0.2)(-1)^2\right] = 0.30$$

Photometry calculations

Photometric measurements are the basis of a majority of analytical systems in the clinical laboratory. The analytical requirements and biochemistry of absorbance spectrophotometry are described in Chapter 7, Spectrophotometry. Transmittance (T) and absorbance (A) of a solution are described mathematically in terms of either fraction or percentage of transmitted light intensity (I) relative to that of a blank solution (I_o).

$$\mathrm{T} = \mathrm{I}/\mathrm{I_o} \quad \text{or} \quad \mathrm{T} = \mathrm{I}/\mathrm{I_o} \times 100\%$$

$$\mathrm{A} = -\log \mathrm{T} \quad \text{or} \quad \mathrm{A} = 2 - \log \%\mathrm{T}$$

The Beer–Lambert law states that the absorbance of monochromatic light by a solution is directly proportional to the concentration of the absorbing species in the solution and to the path length and is expressed as

$$A^{\lambda} = \varepsilon^{\lambda} \times l \times c$$

where A^{λ} is the absorbance at wavelength λ, ε^{λ} is the *molar absorptivity* in liter/mol·cm at wavelength λ, l the length (cm) of the light path through the solution, and c the molar concentration of the solution. For a given analytical system, on measuring the absorbance of a solute over a range of concentrations, a plot of absorbance versus concentration is expected to form a straight line with an intercept of zero and a slope equal to the product of $\varepsilon^{\lambda} \times l$. The practical application of the Beer–Lambert law is to find the value for molar absorptivity ε from the slope of a plot of calibrator absorbances and from which the concentration of unknown samples can be determined from observed absorbance readings. Automated analyzers will record changes in absorbance over time in enzymatic reactions that are monitored continuously.

Using an extension of Beer's Law, the concentrations of mixtures of absorbing species can be determined. Thus it is possible to report multiple analyte concentrations from the same patient sample or to compensate mathematically for interfering substances that may be present at analytical wavelengths. For example, in a mixture with three absorbing compounds x_1, x_2, and x_3, the total absorbance at a single wavelength λ_1 would be expressed as

$$\mathrm{A}^{\lambda_1}_{\mathrm{total}} = \mathrm{A}^{\lambda_1}_{\mathrm{x_1}} + \mathrm{A}^{\lambda_1}_{\mathrm{x_2}} + \mathrm{A}^{\lambda_1}_{\mathrm{x_3}} = \varepsilon^{\lambda_1}_{\mathrm{x_1}} l c_{\mathrm{x_1}} + \varepsilon^{\lambda_1}_{\mathrm{x_2}} l c_{\mathrm{x_2}} + \varepsilon^{\lambda_1}_{\mathrm{x_3}} l c_{\mathrm{x_3}}$$

Absorbance measurements at multiple wavelengths (absorbance spectra) enable deconvolution of the contributions of each compound, and individual concentrations can be determined. Modern cooximeters can measure absorbance at >100 wavelengths simultaneously using diode arrays.

Electrophoresis

The migration of charged particles through liquid under an applied electric field is influenced by several factors (e.g., charge, size, and shape of solute; viscosity of the medium; ionic strength of the buffer; and strength of the electric field); see Chapter 8, Chromatography and electrophoresis. The electrophoretic rate of migration or migration velocity (v) is equal to the distance traveled (l, cm) per time of migration (t, s) and can be calculated as a function of the electrophoretic mobility (μ, $\mathrm{cm^2/Vs}$) and the field strength (E/d, V/cm). In electrophoretic theory, the electrophoretic mobility is found to be directly proportional to charge of the solute (Q) and inversely proportional to solute radius (r) and viscosity of the medium (η) [8].

$$v = \frac{l}{t} = \mu\frac{E}{d} = \left(\frac{Q}{6\pi r\eta}\right)\frac{E}{d}$$

For a given electrophoretic system, the electrophoretic mobility is the characteristic of the individual solute and can be used to estimate the migration rate when applied voltage is changed.

Example 6.17: *A voltage of 250 V is applied across a 5-cm gel, and a serum protein migrates 3 cm in 8 minutes. What is the electrophoretic mobility (μ)? How long will it take for this protein to migrate 3 cm if the voltage is reduced to 200 V?*

$$v = \frac{l}{t} = \mu\frac{E}{d}$$

$$\mu = \frac{l}{t} \times \frac{d}{E} = \frac{3\ \mathrm{cm}}{8\ \mathrm{min} \times 60\ \mathrm{s/min}} \times \frac{5\ \mathrm{cm}}{250\ \mathrm{V}}$$

$$= 12.5 \times 10^{-5}\ \mathrm{cm^2/Vs}$$

One "mobility unit" is defined as $10^{-5}\ \mathrm{cm^2/Vs}$, so the answer can also be stated as 12.5 mobility units. To find the new migration time, solve for t and substitute the new voltage:

$$t = \frac{l}{\mu} \times \frac{d}{E} = \frac{3\ \mathrm{cm}}{12.5 \times 10^{-5}\ \mathrm{cm^2/Vs}} \times \frac{5\ \mathrm{cm}}{200\ \mathrm{V}}$$

$$= 600\ \mathrm{s\ or}\ 10\ \mathrm{min}$$

The migration rate is proportional to the applied voltage.

Electrochemistry

The most common electrochemical method in the clinical laboratory is potentiometry, which can be applied to the measurement of pH, as well as sodium, potassium, chloride, lithium, and magnesium ion concentrations. As described in Chapter 9, Electrochemistry, the Nernst equation can be derived and simplified to a form that is most readily used for determining the electrical cell potential as a function of ion activity (presuming the cell has been designed to be selective for the ion of interest). This equation is:

$$E_{cell} = E^{\circ} + \left(0.0592/n\right) \times \log a$$

where E_{cell} represents the measured voltage for the cell, E° is the standard potential, n is the charge of the ion, and a is the activity of the ion of interest. A further simplifying assumption can be made, where the molar concentration is used for the ion activity. Note that the measurement of cell potential must be quite accurate and precise, as the change in potential is only 0.0592 V for a 10-fold change in ion concentration, for ions with a plus or minus one charge. For the divalent cations (calcium, magnesium) where the value for n is 2, the sensitivity is lowered to 0.0592/2 or 0.0298 V for a 10-fold concentration change.

Coulometric titration is the most precise method available for quantification of chloride ions and is used for sweat chloride measurements (see Chapter 27, Testing in alternative matrices: CSF and body fluid analysis). A constant current of silver ions reacts with the dissolved chloride ions in a sample to form insoluble silver chloride. The reaction is timed to detect a threshold concentration of excess silver ions. Using a blank sample, the time for threshold detection in the absence of chloride ions can be measured and subtracted. Total charge (Q) transferred is proportional to the number of moles of chloride present in the sample. The relationship is described by Faraday's law

$$Q = It = znF$$

where Q is charge in coulombs, I is current in amperes, t is time in seconds, z is number of charges transferred (per reaction), n is the number of moles reacted, and F is the Faraday constant (96,485 coulombs per mole). Remember that an ampere is one coulomb per second, A = C/s or C = A s.

Example 6.18: *A 100-μL sample has a titration time of 17.5 seconds on a chloridometer operating at 48 mA. The blank time was 1.2 seconds. What is the chloride concentration in this sample in mmol/L?*

Subtract the blank time to determine how long chloride ions from the patient sample were reacting with the silver ion current: 17.5−1.2 = 16.3 s. Solve for number of moles and divide by the volume of the sample to determine chloride concentration.

$$Q = It = znF$$

$$n = It/zF$$

$$n = \frac{48 \text{ m C/s} \times 16.3 \text{ s}}{1 \times 96485 \text{ C /mol}} = 8.1 \times 10^{-3} \text{ mmol Cl}^{-}$$

$$\frac{8.1 \times 10^{-3} \text{ mmol Cl}^{-}}{100 \text{ μL}} \times \frac{10^{6} \text{ μL}}{\text{L}} = 81 \text{ mmol/}L \text{ Cl}^{-}$$

This concentration of chloride in a sweat sample is consistent with a diagnosis of cystic fibrosis.

Enzyme kinetics

A single-substrate enzymatic reaction can be described by the equation

$$E + S \rightleftarrows \text{ES} \rightarrow E + P$$

where E is the enzyme, S is the substrate, ES is the enzyme−substrate complex, and P is the product of the reaction. The Michaelis−Menten equation describes the relationship between the rate of enzymatic activity and the initial substrate concentration:

$$v = \frac{V_{max}[S]}{K_m + [S]}$$

where v is the enzyme-catalyzed reaction rate, V_{max} the maximum reaction rate, $[S]$ the substrate concentration, and K_m the Michaelis−Menten constant, which is equal to $[S]$ at ½ V_{max}. When enzymes are used as analytical reagents to determine *substrate concentration* in a patient sample, the enzyme is added in large excess of the expected substrate concentration. This establishes the first-order kinetics in which the $[S]$ is very low compared with the K_m, and the Michaelis−Menten equation reduces to

$$v = \left(\frac{V_{max}}{K_m}\right)[S] = k\,[S].$$

The first-order rate constant is k, and the reaction rate is directly proportional to the substrate concentration. When the intent is to measure *enzyme activity* in a patient sample, the substrate is added in large excess of the expected enzyme concentration. This establishes zero-order kinetics, in which $[S]$ is much larger than the K_m, and the Michaelis−Menten equation reduces to $v = V_{max}$. The enzyme activity is measured directly as the rate of substrate depletion or product formation over time.

One of the first steps in developing an enzyme assay is to determine the kinetic constants K_m and V_{max} for the assay conditions. For the most part, this is now done by importing kinetic data into software applications. However, a Lineweaver–Burk plot provides a straightforward example of the basis of these calculations. The Lineweaver–Burk plot is a linear transformation of the hyperbolic Michaelis–Menten curve. The reaction velocity (e.g., μmol/min) is measured at multiple substrate concentrations (e.g., μmol/L), and reciprocal velocity ($1/v$) is plotted versus reciprocal substrate concentration ($1/[S]$). The Lineweaver–Burk equation takes the basic form of a linear equation ($y = mx + b$). The slope equals K_m/V_{max}, and x- and y-intercepts correspond to $-1/K_m$ and $1/V_{max}$, respectively.

$$\frac{1}{v} = \left(\frac{K_m}{V_{max}}\right)\left(\frac{1}{[S]}\right) + \frac{1}{V_{max}}$$

Example 6.19: *Determine K_m and V_{max} from the following kinetic data for enzyme activity.*

v (μmol/min)	$[S]$ (μmol/L)
8	5
15	10
28	20
48	40
73	80
94	160
100	240
104	320
106	400

Using a spreadsheet, calculate $1/v$ and $1/[S]$ for each data pair. Regular linear regression of $1/v$ versus $1/[S]$ gives a slope (m) and intercept (b):

$$m = 0.5894 = \frac{K_m}{V_{max}};\ K_m = 83\ \mu mol/L$$

$$b = 0.0071 = \frac{1}{V_{max}};\ V_{max} = 141\ \mu mol/min$$

Under conditions of zero-order kinetics, one can determine enzyme concentration using photometric data and the molar extinction coefficient ε for the optically active component of the reaction, as determined by calibration. The following equation accounts for the dilution of a patient sample (V_{sample}) into the total reaction volume (V_{total}) and utilizes both the Beer–Lambert law and the definition of an international unit of enzyme activity (IU = μmol $_{substrate}$/min). The change in absorbance ΔA is determined for a reaction time t in a reaction vessel of path length l.

$$[E] = \left(\frac{\Delta A/\varepsilon l}{t}\right)\left(\frac{10^6\ \mu mol}{mol}\right)\left(\frac{V_{total}}{V_{sample}}\right)$$

Example 6.20: *Aspartate aminotransferase (AST) activity is determined photometrically using a coupled reaction (which is not rate-limiting) that oxidizes NADH at a rate proportional to AST activity. In this test system, the cuvette path length is 0.2 cm and ε for NADH is 6.22×10^3 L mol^{-1} cm^{-1}. When 10 μL of patient serum is added to 50 μL of reagents at 37°C, the absorbance change (ΔA) is −0.032 over a monitored reaction time of 5 minutes. What is the AST concentration in IU/L?*

The absorbance change is negative, because NADH absorbance decreases when it is oxidized to NAD^+ at 340 nm. Using the equation above

$$[E] = \left(\frac{0.032\ /\ \left[\left(6.22 \times 10^3\ \text{L mol}^{-1}\ \text{cm}^{-1}\right)(\ 0.2\ \text{cm}\ )\right]}{5\ \text{min}}\right)$$

$$\left(10^6\ \mu\text{molmol}\right)\left(\frac{60\ \mu\text{L}}{10\ \mu\text{L}}\right)[E] = 31\ \mu\text{mol/min/L} = 31\ \text{IU/L}$$

Chromatography

Calculations related to chromatography are applicable to many mass spectrometry-based LDTs (see Chapter 8, Chromatography and electrophoresis, and Chapter 10, Mass spectrometry). This section reviews basic calculations describing chromatographic peaks and the extent of their separation by column chromatography. The retention factor (k') quantifies how long a compound is retained on a column, the retention time (t_r), relative to the column void time (t_o). For isocratic separations, k' is independent of the flow rate of the mobile phase. This factor can also be calculated in terms of volumes.

$$k' = \frac{t_r - t_o}{t_o} = \frac{v_r - v_o}{v_o}$$

The selectivity factor (α) describes the relative retention of two compounds. For this formula, the retention time for the compound that elutes later is given the subscript of 2.

$$\alpha = \frac{k'_2}{k'_1} = \frac{t_{r2} - t_0}{t_{r1} - t_0} = \frac{v_{r2} - v_o}{v_{r1} - v_o}$$

Calculating the chromatographic resolution (R_s) of two peaks accounts for both retention and the widths of two chromatographic peaks. It is the difference in retention times (or volumes), divided by the average of the baseline widths of the two peaks.

$$R_s = \frac{t_{r2} - t_{r1}}{\left(\frac{(w_{b1} + w_{b2})}{2}\right)}$$

Clinical calculations

Physicians from the various medical specialties will perform calculations based on numeric results provided by the laboratory in order to interpret the data and make medical decisions. In some cases, the laboratory performs these calculations in the LIS and reports the calculated results automatically. The College of American Pathologists requires verification of calculated values that appear with patient results, biennially or whenever a change in the test systems or information systems could affect the calculations. Examples of several clinical calculations are given below. Note that these kinds of calculations have assumptions and limitations that should be considered and must be interpreted in the context of the whole clinical picture.

Electrolytes

Anion gap: This calculation is used in the differential diagnosis of metabolic acidosis (see Chapter 36, Blood gas and critical care testing). The anion gap (AG) is the difference in mmol/L between the measured cations and the measured anions in serum and is traditionally calculated as

$$AG = [Na^+] - [Cl^-] - [HCO_3^-]$$

although some laboratories include potassium.

$$AG = [Na^+] + [K^+] - [Cl^-] - [HCO_3^-]$$

The anion gap is 8−16 mmol/L in healthy individuals (12−20 mmol/L, if K^+ is included). An elevated anion gap indicates the presence of unmeasured anions (e.g., lactate, acetoacetate, and β-hydroxybutyrate) in the serum that may be involved in the acidosis. As shown in Example 6.29, the imprecision of the anion gap calculation is considerable, because the variances of all individual measurands contribute. In fact, for any of the following clinical calculations, the imprecision will increase with the number of and with the individual imprecisions associated with component measurands used for the calculation.

Delta ratio: For an uncomplicated metabolic acidosis, one would expect the increase in unmeasured anions to be reflected in a decrease in the base, HCO_3^-. The increase is calculated as the anion gap minus 12 (an average normal anion gap). The decrease is calculated as 24 (an average normal bicarbonate concentration) minus the patient's measured $[HCO_3^-]$. The ratio of these differences is the delta ratio.

$$\frac{AG - 12}{24 - [HCO_3^-]}$$

Significant deviation from a delta ratio of 1 suggests the presence of a mixed acid−base disorder (again see Chapter 36, Blood gas and critical care testing).

Example 6.21: *A diabetic patient in ketoacidosis had the following results for a basic metabolic panel. Calculate the anion gap and delta ratio. What type of additional acid−base disorder is suggested by these results?*

Na^+	139	mmol/L
K^+	4.7	mmol/L
Cl^-	92	mmol/L
HCO_3^-	16	mmol/L
Glucose	378	mg/dL
BUN	29	mg/dL
Creatinine	1.7	mg/dL

$$\text{Anion gap} = [Na^+] - [Cl^-] - [HCO_3^-] = 139\text{-}92\text{-}16 = 31 \text{ mmol/L}$$

$$\text{Delta ratio} = \frac{AG - 12}{24 - [HCO_3^-]} = \frac{31 - 12}{24 - 16} = \frac{19}{8} = 2.4$$

The increase of 19 mmol/L in the anion gap is more than twice the decrease in bicarbonate concentration. There is an additional metabolic alkalosis, which in this case was due to loss of acid by vomiting associated with a viral gastroenteritis.

Osmolality and osmolal gap

Osmolality is the number of moles of dissolved particles (charged or uncharged solutes) per kilogram of solution. Most laboratories use freezing point depression to measure this colligative property in serum or urine. The primary clinical utility is to detect osmotically active substances that may not be rapidly measured in the laboratory, such as toxic alcohols or mannitol. Osmolality measurements are also used to assess the kidney's ability to concentrate urine. It is possible to predict serum osmolality based on measurements of serum sodium, BUN, and glucose:

$$\text{Calculated serum osmolality} = 2 \times [Na^+](\text{mmol/L}) + \frac{[\text{Glucose}](\text{mg/dL})}{18} + \frac{[\text{BUN}](\text{mg/dL})}{2.8}$$

If ethanol is measured in the serum, its osmolality can be added to the calculated value as [EtOH] (in mg/dL)/4.6. If the difference between the measured and calculated osmolality (osmolal gap) is more than 10 mOsm/kg for a particular serum sample, other osmotically active

substance(s) must be present (see Chapter 37, Water and electrolyte balance).

Renal function calculations

Renal function testing has been a challenge for the clinical laboratory, as the kidney has substantial reserve capacity, such that substances cleared from the blood do not show a marked increase in concentration until the reserve is nearly exhausted. Various methods have been combined with patient demographics in calculations that estimate renal function in terms of glomerular filtration rate (GFR).

Renal clearance: The classic method for estimating GFR is creatinine clearance, which is calculated from the serum creatinine concentration (C_s, mg/dL) and the urine creatinine concentration (C_u, mg/dL) of a urine sample collected over a known time interval (t, minute), usually 24 hours, and the measured urine volume (V_u, mL).

$$\text{Creatinine clearance}\quad (\text{mL/min}) = \frac{C_u}{C_s} \times \frac{V_u}{t}$$

The test relies on creatinine as an endogenous marker for GFR and requires a reliable urine collection, which is difficult to obtain, especially outside of the hospital environment.

GFR estimating equations: Laboratorians should be familiar with equations used to calculate estimated GFR (eGFR). Each is based on serum creatinine measurement and does not require urine collection. Cockcroft–Gault, Modification of Diet in Renal Disease study (MDRD), and Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equations, in order of increasing accuracy relative to measured GFR, pertain to estimates in adults. The 2009 modification of the Schwartz equation, also known as the "Bedside Schwartz" equation, is appropriate for children ages 1–18 years old [9]. Note that even the currently recommended CKD-EPI equation still provides estimates that differ significantly from measured GFR in many adult patients. All of these equations are limited by the inherent physiology of creatinine. Details pertaining to the clinical application of these equations are described more fully in Chapter 35, Laboratory evaluation of kidney function. The Cockcroft–Gault equation, first described in 1976, is

$$\text{eGFR}_{CG} = \frac{(140\text{-age}) \times \text{weight}}{72 \times [S_{Cr}]} \times 0.85\ [\text{if female}]$$

where age is in years, weight in kilograms, and $[S_{Cr}]$ is the serum creatinine concentration in mg/dL. The 0.85 constant is applied if the patient is female; similar constants are applied in the MDRD and CKD-EPI equations where applicable to the patient's sex and race. Cockcroft–Gault estimates are not adjusted for body surface area (BSA) and are inconsistent with current automated creatinine methods, which have been standardized to the isotope dilution mass spectrometry (IDMS) reference method.

The MDRD equation derives from the 1999 Modification of Diet in Renal Disease study:

$$\text{eGFR}_{MDRD} = 175 \times ([S_{Cr}])^{-1.154} \times \text{age}^{-0.203} \times 0.742\ [\text{if female}] \times 1.210\ [\text{if African American}]$$

Again, $[S_{Cr}]$ is in mg/dL and age in years. The initial constant of 175 is appropriate for current, IDMS-standardized creatinine assays.

The CKD-EPI equation was published in 2009 by the Chronic Kidney Disease Epidemiology Collaboration:

$$\text{eGFR}_{CKD\text{-}EPI} = 141 \times \min([S_{Cr}]/\kappa, 1)^{\alpha} \times \max([S_{Cr}]/\kappa, 1)^{-1.209} \times 0.993^{\text{age}} \times 1.018\ [\text{if female}]\ \times 1.159\ [\text{if African American}]$$

- $[S_{Cr}]$ is IDMS-standardized serum creatinine in mg/dL.
- κ is 0.7 for females and 0.9 for males.
- α is −0.329 for females and −0.411 for males.
- Min indicates the minimum of $[S_{Cr}]/\kappa$ or 1.
- Max indicates the maximum of $[S_{Cr}]/\kappa$ or 1.

Further revisions of the CKD-EPI equation have been published, which incorporate serum cystatin C concentration [10], but these equations have not yet been widely adopted. Cystatin C is discussed further in Chapter 35, Laboratory evaluation of kidney function.

The modified Schwartz equation is at present the best creatinine-based GFR estimate for children and is also adjusted for the IDMS-traceable creatinine methods currently in use:

$$\text{eGFR}_{\text{modified Schwartz}} = \frac{0.41 \times \text{height}}{[S_{Cr}]}$$

The result of this calculation has units of mL/min/1.73 m^2, as for CKD-EPI; the height of the patient should be entered in centimeters (cm), and in this version of the equation, serum creatinine in mg/dL.

Except for the historical Cockcroft–Gault calculation, eGFR results are reported as normalized values, adjusted to the average adult BSA, which is why eGFR is reported in units of mL/minute/1.73 m^2. For patients with a significantly larger or smaller than average BSA, the adjustment may be removed to obtain an eGFR specific to the patient [11]. To do this, multiply the eGFR by the patient's BSA in m^2, then divide by 1.73:

$$\text{eGFR} = (\text{eGFR, mL/min/1.73m}^2) \times \text{BSA}_{\text{patient}}, \text{m}^2/1.73$$

Online calculators and original references for the GFR estimating equations are available from the National Kidney Foundation [12] and the National Institute of Diabetes and Digestive and Kidney Diseases [13].

Example 6.22: *Determine the eGFR (CKD-EPI) for an African American female, age 57, whose serum creatinine is 1.30 mg/dL. BSA for this patient is 1.95 m^2.*

Enter the serum creatinine. For a female, κ is 0.7 and α is -0.329. For the second term, the minimum is 1, and for the third term, the maximum is 1.30/0.7 or 1.86. Enter the age in years as the exponent for 0.993. On most models of handheld calculator, the [y^x] key should be used to apply the exponent to the base, which key is not the same as the [EXP] key to program scientific notation ($\times 10^x$). Both of the constants for sex and race are applied to obtain the calculated eGFR.

$$\begin{aligned}
&\mathrm{eGFR_{CKD\text{-}EPI}} \\
&= 141 \times \min\left([S_{Cr}]/\kappa,\ 1\right)^{\alpha} \times \max\left([S_{Cr}]/\kappa,\ 1\right)^{-1.209} \times 0.993^{\mathrm{age}} \\
&\quad \times 1.018\ [\text{if female}] \times 1.159\ [\text{if African American}] \\
&= 141 \times \min\left(1.30/0.7, 1\right)^{-0.329} \times \max\left(1.30/0.7, 1\right)^{-1.209} \\
&\quad \times 0.993^{57} \times 1.018 \times 1.159 \\
&= 141 \times (1)^{-0.329} \times (1.86)^{-1.209} \times 0.993^{57} \times 1.018 \times 1.159 \\
&= 52.6\ \mathrm{mL/min/1.73\ m^2}
\end{aligned}$$

To remove the normalization for BSA, use the equation above.

$$\mathrm{eGFR} = 52.6\ \mathrm{mL/min/1.73\ m^2} \times 1.95\ \mathrm{m^2}/1.73 = 59.3\ \mathrm{mL/min}$$

Fractional excretion of sodium: This calculation requires sodium and creatinine measurements in both blood and urine. It is used in patients with acute kidney disease to determine the fraction of sodium excreted by the kidneys, using creatinine as a marker to adjust for urine concentration.

$$\mathrm{Fe_{Na}} = \frac{[\mathrm{Na^+}]_{\mathrm{urine}} \,/\, [\mathrm{Na^+}]_{\mathrm{serum}}}{[\mathrm{Cr}]_{\mathrm{urine}} \,/\, [\mathrm{Cr}]_{\mathrm{serum}}} \times 100\%$$

$\mathrm{Fe_{Na}} < 1\%$ is an indication of prerenal disease, or decreased blood flow to the kidneys. $\mathrm{Fe_{Na}} > 1\%$ indicates renal damage. As with each clinical calculation, there are certain limitations in the application of $\mathrm{Fe_{Na}}$, and the calculation should be interpreted in clinical context (see Chapter 37, Water and electrolyte balance).

Iron calculations

Serum iron and iron-binding capacity calculations are helpful in the differential diagnosis of iron deficiency or overload conditions (see Chapter 47, Trace elements). Serum iron concentration should be interpreted in the context of the total iron-binding capacity (TIBC) of transferrin and percent saturation of transferrin (Tf); the clinical laboratory should report these results together. TIBC is measured directly by some methods, or TIBC can be calculated by first measuring unbound iron-binding capacity (UIBC) of transferrin, then adding the serum iron concentration:

$$\mathrm{TIBC}\ (\mu\mathrm{g/dL}) = \mathrm{UIBC}\ (\mu\mathrm{g/dL}) + [\mathrm{Fe_{serum}}]\ (\mu\mathrm{g/dL})$$

The percent saturation of transferrin calculation is

$$\text{Tf saturation}\ (\%) = \frac{[\mathrm{Fe_{serum}}](\mu\mathrm{g/dL})}{\mathrm{TIBC}\ (\mu\mathrm{g/dL})} \times 100\%$$

Example 6.23: *Determine the percent transferrin saturation for a sample with serum iron concentration of 90 μg/dL and a UIBC of 330 μg/dL.*

$$\mathrm{TIBC} = 330\ \mu\mathrm{g/dL} + 90\ \mu\mathrm{g/dL} = 420\ \mu\mathrm{g/dL}$$

$$\text{Tf saturation}\ (\%) = \frac{90\ \mu\mathrm{g/dL}}{420\ \mu\mathrm{g/dL}} \times 100\% = 21.4\%$$

To determine the percent saturation of transferrin on a molar basis after direct measurement of serum transferrin, an alternate calculation can be performed based on the molar ratio of iron to transferrin. Note that two moles of iron bind to one mole of transferrin and that the constant 0.673 is applicable when units of measure for iron and transferrin are conventional:

$$\begin{aligned}
&\text{Molar Tf saturation}\ (\%) \\
&= \frac{[\mathrm{Fe_{serum}}]\ (\mu\mathrm{g/dL})}{[\mathrm{Tf_{serum}}]\ (\mathrm{mg/dL})} \times \frac{\mathrm{mg}}{1000\ \mu\mathrm{g}} \\
&\quad \times \frac{\text{mol Fe}}{55.84\ \mathrm{g}} \times 75{,}200\ \text{gmol Tf} \\
&\quad \times \frac{1\ \text{mol Tf}}{2\ \text{mol Fe}} \times 100\% = \frac{[\mathrm{Fe_{serum}}]}{[\mathrm{Tf_{serum}}]} \times 0.673 \times 100\%
\end{aligned}$$

Transferrin is the major iron transport protein in plasma; therefore the percent saturation calculations should be relatively close, since other serum proteins bind iron to a lesser extent than transferrin.

Example 6.24: *Determine the molar percent transferrin saturation for a serum iron concentration of 90 μg/dL and transferrin of 310 mg/dL.*

$$\text{Molar Tf saturation}\ (\%) = \frac{90\ \mu\mathrm{g/dL}}{310\ \mathrm{mg/dL}} \times 0.673 \times 100\% = 19.5\%$$

Lipid calculations

Chapter 28, Lipoprotein disorders, describes the pathophysiology and biochemical measurements of cholesterol and serum lipoproteins. Cholesterol present in low-density

lipoprotein (LDLC) is fundamental to assessment of cardiovascular risk. LDLC can be measured directly or calculated using the Friedewald equation, which requires three other lipid measurements, each in mg/dL, taken on the same fasting sample:

$$\text{LDLC} = \text{TC-HDLC-}\frac{\text{TG}}{5}$$

Note that the overall error in the LDLC calculation depends on the error in measurements of total cholesterol (TC), high-density lipoprotein cholesterol (HDLC), as well as triglycerides (TG). For this relationship to be valid, chylomicrons must be absent, as is the case in normal fasting samples, and TG must be less than 400 mg/dL. The serum triglyceride result is divided by a factor of 5 to estimate the cholesterol found in very-low-density lipoprotein particles (VLDLC). Recently, adjustable factors for estimating VLDLC have been proposed, but consensus guidelines have not yet recommended these calculations for routine use [14].

The non-HDLC fraction, which includes cholesterol in all lipid fractions thought to contribute to cardiovascular risk, is not dependent on fasting or triglyceride levels and should be calculated automatically in the LIS and reported with lipid panels. Non-HDLC is simply the difference between TC and HDLC in mg/dL:

$$\text{Non-HDLC} = \text{TC-HDLC}$$

For patients with highly elevated levels of lipoprotein (a) [Lp(a)], LDLC may appear to be refractory to therapy, since Lp(a) cholesterol is a subfraction of the LDLC. In such cases, recent guidelines have suggested calculation in mg/dL of Lp(a)-corrected LDLC [14].

$$\text{Lp(a)-corrected LDLC} = \text{TC-HDLC-}\frac{\text{TG}}{5}\text{-[Lp(a)} \times 0.30\text{]}$$

This approach may help clinicians with treatment decisions, since Lp(a) is known not to respond to statin therapy.

Statistics

Statistical calculations are used extensively in the clinical laboratory to evaluate method performance. Spreadsheet programs and software packages are helpful with calculations, but the laboratorian must establish the quality of the input data, determine which statistical calculations are appropriate, and interpret the calculated statistics properly (see Chapter 2, Statistical methods in laboratory medicine). This section will review basic statistical operations used in the clinical laboratory that can readily be performed with a handheld calculator.

Mean

The most commonly used measure for the central tendency of a set of values, the mean ($\bar{x}$) is calculated by finding the sum of the data set and dividing by the number of values in the set. For large data sets, especially when values are repeated within the set, calculators that have a "statistics" mode can be used to enter the set more efficiently.

$$x = \frac{\sum_{i=1}^{n} x_i}{n}$$

Example 6.25: *Determine the mean for the following data set: 63, 68, 69, 63, 65, 66, 65, 67, 61, 65.*

$$\bar{x} = \frac{652}{10} = 65.2$$

Median

The median is a measure of central tendency that is less susceptible to outliers. More often used for non-Gaussian data, it is independent of assumptions about the distribution pattern of the data set and requires only inspection of the set, once the set is arranged in numerical order. The arrangement can be either ascending or descending, and the middle value for the set is the median.

Example 6.26: *Determine the median for the following values: 63, 68, 69, 63, 65, 66, 65, 67, 61, 65.*

Arrange the set and find the middle value: 61, 63, 63, 65, **65, 65**, 66, 67, 68, 69. There is an even number of values in the set; in which case, the average of the two central values is the median. In this example, both central values are the same, 65, so no further calculation is needed.

Standard deviation

The "SD" or *s* statistic is used to describe the logical concept of the spread of values for a normally distributed (Gaussian) data set. While the range for a set also gives an idea of the spread, the SD is an improvement, in that all of the data enter into the calculation. While the concept is straightforward, the calculation of standard deviation (SD) is not. When the data set is a sample of the population, the formula is

$$s = \sqrt{\frac{\sum_{i=1}^{n} (x_i - \bar{x})^2}{n-1}}$$

where the difference between each of the individual values (x_i) and the mean ($\bar{x}$) is squared, the squared differences are summed, and this sum is divided by the number of values in the set, less one. The SD is the square root of the quotient and has the same units as the individual data points. The mean is determined before the SD calculation is done. When calculating the SD by hand, it is helpful to construct a table to track the individual values for the squares of the differences. In practice, the calculation of SD is performed in a software package, middleware, or the LIS and is most often used to evaluate method imprecision.

Example 6.27: *Determine the SD for the following data set: 63, 68, 69, 63, 65, 66, 65, 67, 61, 65.*

Creating a table as described above, or using a handheld calculator or spreadsheet program, the SD calculates to 2.4. Some calculators have an option of σ_n or σ_{n-1} for this calculation. The latter (sample SD) is appropriate for a data set that is a sample of a complete set, as is the case for precision studies.

Coefficient of variation

While the SD is usually used to describe precision, comparing SDs for two data sets can be complicated when the means or the units for each set differ. For example, a comparison of the SD for creatinine and BUN data sets would not determine which method is more precise, without knowing the means. To facilitate such comparisons, the coefficient of variation (CV) is calculated and reported as a percentage, using the equation

$$\mathrm{CV} = s\bar{x} \times 100\%$$

Example 6.28: *A control was tested 10 times to validate within-run precision for an FDA-approved method. Mean ($\bar{x}$) was 65.2 mg/dL, and SD (s) was 2.4 mg/dL. Determine the CV.*

$$\mathrm{CV} = \frac{2.4}{65.2} \times 100\% = 3.7\%$$

The CV is not presented in units of the assay, so the amount of variation can be readily compared with other methods or concentrations. However, the utility of this statistic is reduced as the mean approaches zero.

Variance

When combining independent components of measurement imprecision, it is not appropriate to add SDs. The variance, s^2, or square of the SD, is the additive statistic. Given three data sets x, y, and z, the total variance is calculated as the sum of squared SDs.

$$\left(s_{TOTAL}\right)^2 = {s_x}^2 + {s_y}^2 + {s_z}^2$$

This concept applies to estimates of uncertainty when a reported result is calculated from the sum of or the difference between independent measurements. Consider anion gap in the following example [15].

Example 6.29: *The SDs for sodium, potassium, chloride, and bicarbonate measurements are found to be 1.2, 0.1, 1.3, and 1.2 mmol/L, respectively. What is the imprecision in the anion gap?*

$$\begin{aligned} s^2_{\mathrm{AG}} &= s^2_{\mathrm{Na+}} + s^2_{\mathrm{K^+}} + s^2_{\mathrm{Cl^-}} + s^2_{\mathrm{HCO_3^-}} \\ s^2_{\mathrm{AG}} &= (1.2)^2 + (0.1)^2 + (1.3)^2 + (1.2)^2 \\ s^2_{\mathrm{AG}} &= 4.58 \\ s_{\mathrm{AG}} &= 2.14\ \mathrm{mmol/L} \end{aligned}$$

This is relatively imprecise, as calculated anion gap results would be expected to vary as much as $\pm 2s_{\mathrm{AG}}$ or ± 4 mmol/L (at the 95% confidence interval) on repeated measurements of the same patient sample.

If a calculated clinical result is a product or quotient of independent measurements, then the overall imprecision must be calculated from relative SDs, or CVs:

$$(\mathrm{CV_{TOTAL}})^2 = \mathrm{CV}_x^2 + \mathrm{CV}_y^2 + \mathrm{CV}_z^2$$

Standard error of the mean

Replicate measurements of control materials are actually samples taken from the larger population of possible measurements. For a parametric data set, how close is a mean of sample measurements ($\bar{x}$) to the true mean (μ) of all possible measurements? For this one computes the standard error of the mean (SEM), or s-subscript $\bar{x}$, calculated as

$$s_{\bar{x}} = \frac{s}{\sqrt{n}}$$

where s is the SD of the sample set and n is the number of data points in the set. The more data collected, the smaller the standard error, and the more precise the estimate of μ. Standard error can be calculated for other statistics, not just the mean, and is used to calculate the confidence intervals based on tabulated t-values (see Chapter 2, Statistical methods in laboratory medicine). As an approximation, for a large data set, the true mean μ lies within ± 2 SEM from the sample mean $\bar{x}$ at the 95% confidence level.

Method evaluation

The statistical calculations described above, as well as several other calculations presented here, are used to evaluate the analytical and clinical performance of laboratory methods. The companion concepts for these calculations are discussed in more detail in Chapter 4, Method evaluation.

Accuracy: regression analysis of method comparison data

To evaluate bias in a quantitative method, the usual data treatment is to plot the results for the method being evaluated on the *Y*-axis versus the results from the same patient samples tested by a reference method (or best comparative method) on the *X*-axis of a scatter plot. Linear regression analysis determines the best fit line by providing the slope and the intercept, which indicate proportional bias and constant bias, respectively. An ideally accurate comparison has a slope of 1.00 and an intercept of zero. The regression slope and intercept are heavily influenced by outlier data at concentration extremes, so the data should be evenly distributed across measurable concentrations. How well the individual data points fit the line is given by the correlation coefficient, *r*, where the perfect fit of all the points gives an *r* value of 1.00. However, this value is not useful for determining bias; two methods may have excellent correlation but still have significant bias.

The laboratorian should be aware of the strengths and weaknesses of three types of linear regression. Regular linear regression minimizes differences in one direction, so it is easily calculated. However, this mathematical approach assumes no error (imprecision) in the *X*-direction (comparative method), and is therefore not often appropriate for real method evaluations. Deming regression accounts for imprecision in both methods, but is still affected when data sets are not evenly distributed. Passing−Bablok regression, a nonparametric calculation, makes no assumptions of data distribution. Method evaluation software will perform any of these regression types. However, for a small data set, the Passing−Bablok slope and intercept can be approximated with a basic calculator. The principle is to determine the slope and intercept for all combinations of *X*−*Y* data points in the data set and then determine the medians.

Example 6.30: *Determine the Passing−Bablok slope and intercept for the following comparison data set:*

	X	Y
1	*24*	*26*
2	*50*	*48*
3	*72*	*74*
4	*97*	*93*

Complete the data table below with the slope (change in *Y* divided by change in *X*) for each data pair and then calculate the intercept for each pair from the equation $b = Y - m\ X$, substituting the *X* and *Y* values from the larger of the two data sets in the pair.

Pair combination	ΔY	ΔX	Slope	Intercept
1−2	22	26	0.846	5.69
1−3	48	48	1.000	2.00
1−4	67	73	0.918	3.97
2−3	26	22	1.182	− 11.09
2−4	45	47	0.957	0.13
3−4	19	25	0.760	19.28
Median	**−**	**−**	**0.938**	**2.99**

The Passing−Bablok slope is 0.938 and intercept is 2.99. For comparison, Deming regression analysis gives a slope of 0.943, an intercept of 2.9, and a correlation coefficient of 0.997.

Accuracy: recovery studies

An evaluation method may be checked for accuracy by adding a known amount of analyte to a sample, then testing the sample to determine if the added amount is recovered. When a nonaqueous solvent must be used as a spiking solution, a blank with the same solvent should be incorporated into the study design to account for matrix differences. Since a recovery study requires manipulation of native samples, this assessment of accuracy may be considered secondary to a correlation study that includes a range of patient samples. The prepared samples may not match native samples for matrix differences, such as the presence of metabolites and protein binding. This limitation actually turns out to be useful when recovery studies can demonstrate that a method provides comparable results within allowable error for different sample matrices, for example, in a nonstandard body fluid. The fundamental calculation for any recovery study is to determine accurately the expected value for the analyte concentration in the prepared samples, allowing for dilution and for analyte initially present. This is an application of the equation used above in the "Dilutions" section:

$$C_1V_1 = C_2V_2$$

The product of the initial concentration and volume (C_1V_1) for the analyte should equal the product of the final concentration and volume (C_2V_2) after the sample has been manipulated. If the analyte is present in both the original sample and a spiking sample, then the C_1V_1 for both samples must be added and this sum is divided by the new total volume (V_2) to determine the expected concentration (C_2).

Example 6.31: *A laboratory is validating a glucose method in the testing of pleural fluid using serum/fluid admixtures. The glucose concentration in a serum pool is 103 mg/dL, and the glucose concentration in a pleural fluid sample is 164 mg/dL. An admixture of 1.2 mL of serum and 0.8 mL of fluid has a measured glucose concentration of 124 mg/dL. Calculate the percent recovery of glucose in the admixture.*

First calculate the expected concentration of glucose in the admixture.

$$C_{1(\text{serum})}V_{1(\text{serum})} + C_{1(\text{fluid})}V_{1(\text{fluid})} = C_{2(\text{admixture})}V_{2(\text{admixture})}$$

$$103\ \text{mg/dL} \times 1.2\ \text{mL} + 164\ \text{mg/dL} \times 0.8\ \text{mL} = C_{2(\text{admixture})} \times 2.0\ \text{mL}$$

$$C_{2(\text{admixture})} = 127\ \text{mg/dL}$$

Then calculate the recovery as a percentage of the expected concentration.

$$\frac{124\ \text{mg/dL}}{127\ \text{mg/dL}} \times 100\% = 97.6\%$$

Depending on matrix effects on a given method and the assay precision, it is possible to recover greater than 100%.

Precision: repeatability and within-lab precision studies

For the initial assessment of method precision, a within-run study of replicate measurements, usually $n = 20$, will provide the data to determine the mean, SD, and CV for a single run (see the "Statistics" section above). If this is acceptable, then a more extensive within-lab precision study is carried out over several days to address additional sources of variability that will be encountered in routine use of the method. Analysis of variance calculations performed by statistical software requires a data set of several smaller ($n = 2$ or 3) within-run tests of relevant control materials, two runs per day, each day for 20 days. The various contributions to the overall imprecision are calculated from this data set, and total imprecision is estimated for routine testing of quality control materials.

Total error

Error in an analytical method consists of both bias (inaccuracy) and imprecision, and a clinician has no way of determining to what extent either contributes to the error in a given patient result. Therefore the laboratorian must combine both sources of error and assure that the *total error* (TE) does not exceed allowable error. At the 95% confidence interval, TE is calculated in units of the method as

$$\text{TE} = \text{Bias} + 1.96 \times \text{SD}$$

TE is calculated at specified analyte concentrations, usually at medical decision levels (MDL). SD is determined from precision studies at the MDLs, and bias is calculated from the regression statistics (slope and intercept) determined from method comparisons. The analyte concentration corresponding to the MDL is entered as the X value in the regression equation ($Y = m\,X + b$), and the bias is the difference between Y and X. That is,

$$\text{Bias}_{\text{MDL}} = (mX_{\text{MDL}} + b)\text{-}X_{\text{MDL}}$$

Example 6.32: *Determine the TE for a method at the MDL of 200 mg/dL. Regression statistics for the method comparison study gave a best fit of $Y = 1.034X - 2.2$ and the within-lab precision studies indicated an SD of 1.2 mg/dL at 200 mg/dL.*

$$\text{TE} = \text{Bias} + 1.96 \times \text{SD}$$

$$\text{TE} = [(mX_{\text{MDL}} + b) - X_{\text{MDL}}] + 1.96 \times \text{SD}$$

$$\text{TE} = [(1.034\ (200) - 2.2) - 200] + 1.96 \times 1.2$$

$$\text{TE} = 4.6 + 1.96 \times 1.2 = 7.0\ \text{mg/dL}$$

TE is compared with allowable error for the method. Allowable error is determined by the laboratory director, who considers primarily clinical but also regulatory requirements for method performance characteristics.

Detection limits

Calculating detection limits for an evaluation method is done by measuring imprecision at very low concentrations over multiple days. So again, the mathematical approach aligns with the "Statistics" section. The lowest quantitative estimate of detection limit is *limit of blank* (LoB). A zero concentration sample is measured in replicate and the SD is calculated from these data. The LoB may be estimated as 2 × SD of blank replicates; thus 2.5% of blank sample measurements would still fall above this threshold. The *limit of detection* (LoD) is quantitatively greater than LoB. Replicate samples of known very low concentration are measured and, as an approximation, 2 × SD of these replicates is added to the LoB. For LDTs, the most important estimate of the detection limit is the *limit of quantitation* (LoQ), which defines functional sensitivity and the lower limit of the measuring interval, below which quantitative values should not be reported.

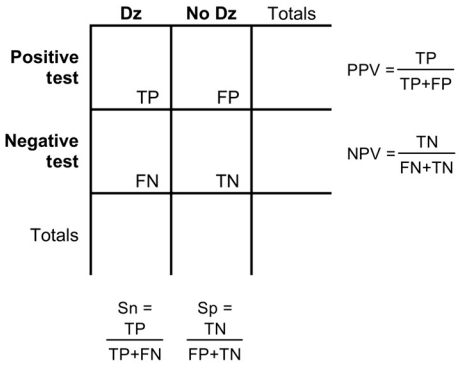

FIGURE 6.1 Example template for predictive value theory calculations. To calculate sensitivity, specificity, or predictive values, divide the true tests in the row or column by the total for that row or column. Prevalence of the disease in a given cohort or population equals the total of the first column divided by the total number of individuals. *Dz*, Individuals with disease; *FN*, false negative; *FP*, false positive; *No Dz*, individuals without disease; *NPV*, negative predictive value; *PPV*, positive predictive value; *Sn*, sensitivity; *Sp*, specificity; *TN*, true negative; *TP*, true positive.

The LoQ is the lowest value that can be measured within stated acceptability limits for accuracy and precision. Repeated measurements at low concentrations define the analyte concentration at which the method is accurate (e.g., $<10\%$ bias from a comparative method) and precise (e.g., $<20\%$ CV). Detailed descriptions of the LoB, LoD, and LoQ calculations, both parametric and nonparametric, are described in CLSI EP17 [16].

Clinical performance of laboratory tests: predictive value theory

Either the manufacturer (for FDA-approved systems) or the laboratory (for LDTs) must validate that a diagnostic test is clinically useful. The calculations of predictive value theory evaluate how well a method classifies patients into diagnostic categories. Test results produced by the evaluation method are compared either to a gold standard method performed on the same patient cohort or to a reliable clinical diagnosis assigned to each member of the cohort. Depending on quantitative cutoffs selected, each test result is designated as true positive (TP), true negative (TN), false positive (FP), or false negative (FN). Here, we review how to calculate sensitivity (Sn), specificity (Sp), positive predictive value (PPV), negative predictive value (NPV), and diagnostic efficiency. These quantities are usually calculated as percentages. To avoid confusion, it is helpful to keep a consistent approach to these types of problems by drawing a simple grid the same way for each scenario (Fig. 6.1). Then, depending on what information is available, expect the starting values for the grid to differ. The reader is encouraged to draw and fill in a grid by hand for each example below.

Example 6.33: *In a prostate cancer study, 5000 men were screened by measuring serum PSA concentration. Two hundred and fifty of the men had a PSA above 4.0 ng/mL and were given a biopsy. Two hundred out of the 250 had a negative biopsy result, and 50 had positive biopsy findings. Follow-up studies on the 4750 men who had PSA ≤ 4.0 ng/mL showed that 75 had prostate cancer at the time of screening. Calculate diagnostic performance statistics for this PSA test in this study group, including Sn, Sp, PPV, and NPV, and diagnostic efficiency.*

A total of 5000 tests were performed, 250 of which were positive and 4750 of which were negative at this PSA cutoff. These are entered as the totals for each row. The biopsy result is the gold standard, so we know that 50 of the men with positive tests had the disease (TP) and 200 did not (FP). Seventy-five of the PSA-negatives actually did have the disease (FN). Thus far, solely from the given data, the grid should look like this:

	Dz	No Dz	Totals	
Positive test	50	200	250	PPV = %
Negative test	75		4750	NPV = %
Totals			5000	
	Sn = %	Sp = %		

Now complete the grid by calculating the missing values. FNs plus TNs must add up to the total of all negative tests ($75 + TN = 4750$); therefore $TN = 4675$. A total of 125 subjects had prostate cancer (Dz) and 4875 were cancer-free (No Dz). Enter these totals for the columns. The grid is now complete, and the diagnostic statistics are calculated from the true results divided by the total in each row or column. Diagnostic efficiency is the sum of true results divided by the total number of tests: $(50 + 4675) / 5000 = 0.945$ or 94.5%. Note that Sn cannot be calculated from testing healthy subjects, nor can Sp from testing diseased/unhealthy subjects.

	Dz	No Dz	Totals	
Positive test	50	200	250	PPV = 20%
Negative test	75	4675	4750	NPV = 98%
Totals	125	4875	5000	
	Sn = 40%	Sp = 96%		

Sn and Sp can be considered unchanging characteristics of the test, independent of the population being tested, as long as the quantitative cutoff is not changed. (Lowering the cutoff value will increase Sn, but at the expense of decreased Sp.) Predictive values, however, are highly dependent on the prevalence of the disease in the population being studied. In the cohort in Example 6.33, the prevalence of prostate cancer was 125/5000, the number with disease divided by total subjects, or 2.5%. If a broader population of men is considered, in which prostate cancer prevalence is lower, and the same test is used for screening, then the predictive values can be recalculated.

Example 6.34: *Given the Sn and Sp of the PSA screening test in the previous example, what would the PPV and NPV be for a population in which the prevalence of prostate cancer was 0.25%?*

Draw a grid as before, and consider what is known about this new population. To obtain the predictive values, one can assume a convenient number (e.g., 100,000) for the total population. Based on the prevalence in this population, 0.25% of 100,000 or 250 will have the disease:

	Dz	No Dz	Totals	
Positive test				PPV = ?
Negative test				NPV = ?
Totals	250		100,000	
	Sn = 40%	Sp = 96%		

Individuals without disease can be found by subtraction: 250 + No Dz = 100,000; therefore the total of No Dz = 99,750. All of the other entries in the grid can be calculated from the Sn and Sp of the test. Forty percent of diseased individuals will test positive: 0.40 × 250 = 100 TP; the rest (150) will be FN. Ninety-six percent of healthy individuals will test negative: 0.96 × 99,750 = 95,760 TN; the rest (3990) will be FP. Row totals are calculated, and PPV and NPV are calculated from the number of true results divided by totals in each row:

	Dz	No Dz	Totals	
Positive test	100	3990	4090	PPV = 2.4%
Negative test	150	95,760	95,910	NPV = 99.8%
Totals	250	99,750	100,000	
	Sn = 40%	Sp = 96%		

In this broader population, the PPV is much lower. Even though the Sn of the test is still 40%, the probability that a patient with a positive test actually has the disease is only 2.4%.

Another mathematical approach to describe Sn and Sp is to calculate likelihood ratios (LR). These are defined in terms of the likelihood of obtaining a positive or negative test result *in a person with the disease*. The LR answers the question, "Assuming disease is present, what is the likelihood of a positive result (LR +) or negative result (LR −)?" This is distinct from PPV and NPV, which predict presence or absence of disease, given a test result. The positive LR is calculated as LR + = Sn/(1 − Sp), and the negative LR is calculated as LR − = (1 − Sn)/Sp. A higher LR + or lower LR − indicates a more useful test, and as with Sn and Sp, LRs are not affected by prevalence of the disease.

Laboratory management

Management of a clinical laboratory involves not only analytical and medical considerations, but also multiple aspects of business and healthcare administration [17]. Laboratorians should be familiar with several key financial calculations.

Budget justification

Creating and monitoring a budget do not require complicated mathematics per se, but the volume of calculations may be daunting depending on the complexity of budget categories. Budgets describe the expected revenue and expenditures for a given timeframe, according to the institutional fiscal year. Budgets for an upcoming fiscal year are justified based on historical trends, expected contractual changes, marketing studies, supply costs, and staffing needs. After detailed review, the upcoming year's budget figures may be established based on an absolute or

percent change from the current year, with clear written justification for each budget category. Annual budgets may be broken down to monthly revenue and expenditures to account for seasonal or short-term variations. Significant increases or decreases from expected budget figures, or variances, must be accounted for. Corrective action may be needed, for example, when the laboratory is able to control supply purchases or finalize delinquent payments.

Full-time equivalent

The full-time equivalent (FTE) represents the typical workload of 40 hours per week and 52 weeks per year. FTE expenses include both salary and benefits, often approximated as an additional 20%−30% of the salary. In laboratory management, the work unit of FTEs is used to allocate the workforce to various sections of the lab, individual instrument systems, or workstations. In such allocations, full work efficiency is not assumed, as factors such as vacations, shifts, illness, breaks, training, etc. need to be considered. Finally, actual staffing requires whole people, so calculated FTEs may need to be rounded up to the next integer, unless part-time employment can be used.

Cost per reportable result

The apparent cost of a lab test can vary by over 10-fold, depending on how it is calculated. The lowest cost per test comes from the simple estimate of the reagent cost to perform one test, but that value by itself has little utility in laboratory cost management. The *cost per reportable* result, or CPR, comes from a more complex calculation, but provides a basis for making important decisions such as whether an assay should be performed in-house or by a reference laboratory. The CPR is calculated by summing all costs allocated to the test (total cost) and dividing by the number of test results reported out to a patient record (reportable results). The number of reportable results in the denominator excludes QC or calibration samples, test repeats, or losses due to outdated reagents. However, the costs associated with these excluded tests are included in the numerator, along with other expenses. Note that a reportable result may not be equivalent to a *billable test*, which may consist of a panel or test group billed as a single item, even though it may contain several reportable results. The numerator of the total cost estimate includes both *direct* (reagents, QC materials, instrument costs, operator costs, etc.) and *indirect* costs (hospital overhead, clerical staff, and management), as allocated to the assay. An alternative approach is to consider costs as either *fixed* or *variable*. Here, costs that change with the number of tests reported (e.g., reagents and operator cost) are variable, while fixed costs are independent of the number of reported tests (instrument costs, calibration, and overhead). By dividing costs into fixed and variable, changes in CPR can be readily made as a function of changes in the test volume. Note that the CPR will go down as the test volume goes up, since the fixed costs are being allocated over a larger number of reportable results. This calculation can be used to determine the "break-even" test volume, the threshold number of tests where in-house costs would equal the send out cost for a given period of time. Beyond this point, all tests performed in-house would represent savings for the lab.

Example 6.35: *Determine the cost per reportable result for a test system with the following costs: instrument annual maintenance contract of $35,000, and annual cost of $65,000 based on 5-year depreciation. Operator costs are 0.2 FTE at $80,000/year per FTE. Reagent costs are $1.24 per test. Total annual tests are estimated at 14,000, of which 23% are not reportable (QC, calibrators, external proficiency samples, etc.).*

The total cost per year is the sum of instrument maintenance ($35,000), instrument cost ($65,000), allocated operator cost (0.2 × $80,000), and reagent cost ($1.24 × 14,000). This sum is divided by the number of reportable results per year (77% of 14,000).

$$\begin{aligned}\text{CPR} &= \frac{\text{Total cost}}{\text{Reportable results}} \\ &= \frac{\$35,000 + \$65,000 + (0.2 \times \$80,000) + (\$1.24 \times 14,000)}{0.77 \times 14,000} \\ &= \frac{\$133,360}{10,780} = \$12.37\end{aligned}$$

Example 6.36: *Plasma vitamin E costs $32 for each sample sent to a reference laboratory. To perform the test in-house, the total fixed costs, including a new HPLC detector, would be $22,000. Variable costs, including reagents, supplies, and a portion of an FTE, are estimated at $7.75 per reportable test. What would be considered a break-even test volume?*

Determining the break-even test volume (v) requires breaking down the total cost per reportable to separate components of fixed and variable costs as they approach the cost of sending out the test to the reference laboratory.

$$\text{Fixed} + \text{Variable} = \text{Sendout cost}$$

$$\$22,000 + v \times (\$7.75 \text{ per test}) = v \times (\$32 \text{ per test})$$

$$v = \frac{\$22,000}{(\$32\text{-}\$7.75)} = 907 \text{ tests}$$

Capital equipment justification

The laboratory can improve the quality of service to patients, decrease the turnaround times, and avoid the higher sendout costs by investing in improved instrumentation for in-house testing. Large capital expenditures may be justified by evaluating return on investment (ROI), which is calculated either in terms of monetary gain after the initial investment is recovered or in terms of a percentage of the initial investment.

$$\text{ROI}_{5\text{year}} = \frac{(\text{Cost avoidance} + \text{New revenue})_{5\text{year}} - \text{Investment}}{\text{Investment}} \times 100\%$$

Consider a 5-year ROI to justify acquisition of two liquid chromatography/mass spectrometry (LC/MS) systems to be used as open platforms for LDTs. The cost difference between sendout testing and in-house testing (cost avoidance), and additional revenue obtained by developing novel tests on LC/MS instrumentation, considered cumulatively over 5 years, constitute gains attributable to the initial investment. While new revenue may be difficult to predict, the cost of sendouts is known and the cost of in-house testing can be estimated in an objective manner. The initial investment includes not only the instruments but also construction costs or other costs not included in the in-house cost per reportable test. For the purpose of capital equipment justification, the instrument cost should not be included in the in-house cost per reportable calculation.

Example 6.37: *The combined cost of two LC/MS systems is $1,000,000. Construction costs are estimated at $27,000. Three tests X, Y, and Z will be developed to replace corresponding sendout tests, and in-house CPRs are given below:*

Test	Annual test volume	Reference lab cost	In-house CPR
X	*600*	*$150*	*$5.35*
Y	*700*	*$125*	*$4.65*
Z	*4200*	*$35*	*$4.65*

A novel diagnostic Test N will be developed as well. Based on a market study, $50,000 in additional annual revenue should be attainable by offering Test N. Assuming development and validation of all tests requires 1 year before savings can be realized, and calculate the 5-year ROI.

First, calculate the annual cost avoidance by finding the difference between the sendout and in-house costs for Tests *X*, *Y*, and *Z*. No savings or revenue will occur in the first year during validation, so multiply by 4 years.

Cost avoidance
= Annual volume × (Sendout cost per test—In-house CPR)
Test *X* $600 \times (\$150 - \$5.35) = \$86,790$ per year
Test *Y* $700 \times (\$125 - \$4.65) = \$84,245$ per year
Test *Z* $4200 \times (\$35 - \$4.65) = \$127,470$ per year

Cost avoidance over four years post validation =
$4 \times (\$86,790 + \$84,245 + \$127,470) = \$1,194,020$

After Test *N* is developed and validated, four years of new revenue are expected ($4 \times \$50{,}000 = \$200{,}000$). Thus the 5-year ROI calculation is

$$\text{ROI}_{5\text{year}} = \frac{(\text{Cost avoidance} + \text{New revenue})_{5\text{year}} - \text{Investment}}{\text{Investment}} \times 100\%$$

$$= \frac{(\$1,194,020 + \$200,000) - \$1,027,000}{\$1,027,000} \times 100\% = 36\%$$

Chapter 7

Spectrophotometry

Lorin M. Bachmann and W. Greg Miller
Department of Pathology, Virginia Commonwealth University, Richmond, VA, United States

Learning objectives

After reviewing this chapter, the reader will be able to:

- Explain the principles of spectrophotometric measurement.
- Describe the sources of error in spectrophotometric measurement.
- Discuss the calibration of spectrophotometric methods.
- Explain the principles of related optical measurement technologies such as fluorescence, chemiluminescence, and atomic emission.

Principles of light absorption and emission

Spectrophotometry is the measurement of the absorption of electromagnetic radiation, in the wavelength range of ultraviolet (UV), visible, and near-infrared (IR) light, by an atom or a molecule to determine the quantity or identity of the substance present. In clinical chemistry, this analytical technique is used to measure the quantity of an analyte present in a body fluid sample. In most cases, an analyte of clinical interest participates in a chemical reaction resulting in the formation of a product, called a chromogen (or chromophore), which absorbs light at a specific measuring wavelength. The measuring wavelength is selected based on the wavelength, or wavelength range, at which the chromogen exhibits peak absorbance. The quantity of chromogen produced in the reaction is proportional to the quantity of analyte, and therefore the amount of light absorbed by the chromogen is proportional to analyte concentration in the clinical sample. Spectrophotometry measures the amount of light absorbed to quantitate the chromogen. A related analytical technique measures the light emitted as fluorescence. In fluorescent measurement techniques, a specific wavelength of light is absorbed by a chromogen, called a fluorophore, and the subsequent emission of a longer wavelength of light is measured. Other complimentary photometric techniques measure light emitted from atoms when stimulated by nonelectromagnetic energy sources (e.g., a gas flame or plasma) or from molecules that emit light when stimulated by a chemical reaction (chemiluminescence).

The energy state of the molecular orbitals of the organic molecules can be represented as illustrated in Fig. 7.1. At typical laboratory temperatures, the electrons are in the ground (lowest energy) state, but the energy is distributed among several vibrational and rotational energy levels. A molecule can transition to an excited-state electron orbital distribution if sufficient energy is available for the transition. For molecules with an appropriate molecular orbital electron distribution, absorption of radiation in the 200−1000-nm wavelength range can cause a transition to a stable higher energy orbital. Such a transition is illustrated in Fig. 7.1. The arrows represent electrons going from ground-state energy levels to excited-state levels. Absorption of radiation is quantized between specific electronic, vibrational, and rotational energy levels, which means that only the exact quantity of energy required for a transition to a given higher energy level will be absorbed. Because of quantized absorption, a molecule absorbs specific wavelengths corresponding to the energy required for a transition. The individual quantized transitions are not resolved at typical laboratory temperatures, because there are many transitions with similar energy because of multiple vibrational and rotational states. For this reason, it is typical to observe relatively broad chromogen absorption bands (absorbance of multiple wavelengths within a given wavelength range) in liquids at ambient temperatures.

After absorption of radiation, the excited-state molecule can dissipate the energy in several ways. One is for the excited state to undergo a photochemical reaction with another molecule to produce a new compound; this process is not discussed in this chapter. In spectrophotometric applications, thermal transfer primarily dissipates the energy through collision with other molecules in the liquid solution. Therefore no energy in the form of photons is emitted. In fluorescence applications, the excited state emits radiation at a longer wavelength

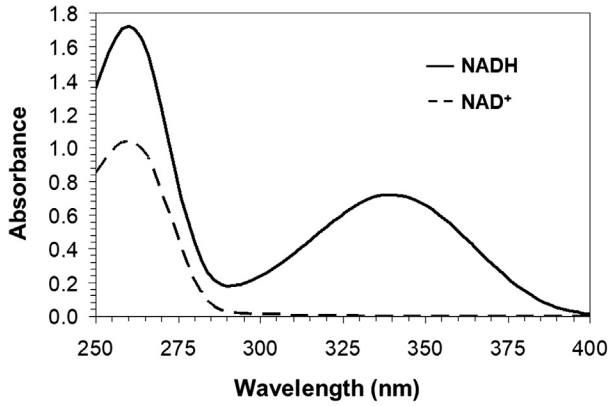

FIGURE 7.2 Absorption spectrum of the NAD^+/NADH chromogens.

(lower energy), as it relaxes to the ground state. Not shown in Fig. 7.1, and infrequently used in clinical chemistry, is the possibility for singlet excited-state electrons to undergo further electronic orbital transitions to a triplet excited state and emit radiation at a longer wavelength, called phosphorescence, which persists for a longer time interval.

Typical chromogens that are absorbed in the UV−visible−IR wavelength range are organic molecules with highly conjugated C = C, C = O, C = N, and other double bonds and/or aromatic rings that have molecular orbital electron distributions that can transition to an excited state at the energies available in these wavelength ranges. Metallic atoms can also absorb energy in this wavelength range to produce excited-state electronic orbitals.

The absorption spectrum describes chromogen absorbance vs. the wavelength range of light passing through a cuvette that contains a solution of the chromogen. Fig. 7.2 shows an absorption spectrum for the oxidized and reduced forms of nicotinamide adenine dinucleotide (NAD^+ and NADH, respectively). Many spectrophotometric assay reaction mechanisms utilize the absorptive properties of the NAD^+/NADH redox pair. In this reaction scheme, an analyte-specific chemical reaction results in product formation that is coupled to the reduction of NAD^+ to NADH or oxidation of NADH to NAD^+. As shown in Fig. 7.2, NAD^+ and NADH absorb light at 250−280 nm because of absorption by the adenine base. However, an absorbance specific for NADH also occurs at approximately 340 nm because of the orbital distribution of the electrons in the dihydronicotinamide ring of NADH. In contrast, NAD^+ exhibits minimal absorbance at 340 nm. An example of an analyte reaction with the NAD^+/NADH redox pair is the hexokinase method for measuring glucose.

Hexokinase:

$$\text{Glucose} + \text{ATP} \rightarrow \text{glucose-6-phosphate} + \text{ADP} \qquad (7.\text{i})$$

Glucose-6-phosphate dehydrogenase:

$$\text{Glucose-6-phosphate} + NAD^+ \rightarrow \text{6-phosphogluconate} + \text{NADH (absorbance at 340 nm)} \qquad (7.\text{ii})$$

During the second step of the reaction, enzymatic conversion of glucose-6-phosphate to 6-phosphogluconate is coupled to the reduction of NAD^+ to NADH, and absorbance is measured at 340 nm. The resulting increase in absorbance due to NADH formation is directly proportional to the concentration of glucose in the sample. It is important to note that consumption of a chromogen is also utilized in some spectrophotometric reactions. If the reaction mechanism results in the oxidation of NADH to NAD^+, the chromogen (NADH) is converted into a nonchromogenic product at 340 nm (NAD^+), as shown in a method for measuring lactate dehydrogenase (LDH) activity.

LDH:

$$\text{Pyruvate} + \text{NADH (absorbance at 340 nm)} \rightarrow \text{lactate} + NAD^+ \qquad (7.\text{iii})$$

In this case, absorbance decreases in proportion to pyruvate concentration conversion to lactate by LDH.

Other methods of chromogen production include dye-binding reactions, chemical conversion of an analyte to a chromogen, and enzyme-mediated conversion of an analyte to a chromogen. In the dye-binding methods, direct binding of an analyte to a precursor compound in the reagent leads to the formation of a colored complex that absorbs light at a specific wavelength. An example of a dye-binding reaction is a commonly used method for measuring total calcium.

$$Ca^{2+} + \text{arsenazo III} \rightarrow \text{Ca:arsenazo III complex (absorbance at 660 nm)} \qquad (7.\text{iv})$$

Dye-binding reactions are used for many analytes, including orthocresolphthalein complexone for calcium,

pyrogallol red and Coumassie brilliant blue for total serum protein, and bromcresol green and bromcresol purple for serum albumin.

For quantitation of analytes using spectrophotometric procedures, it is typical to select a single wavelength to measure the amount of light energy absorbed by the chromogen. The wavelength corresponding to the maximum absorbance is usually used to optimize the analytical sensitivity of the measurement. However, the influence of interfering substances is a consideration when selecting a measuring wavelength as discussed in a later section.

Principles of spectrophotometric measurement

Fig. 7.3 illustrates a spectrophotometric measurement system. Light of the desired wavelength impinges on a photodetector that converts the light energy into an electrical signal. A container, called a cuvette, is placed in the light path of the spectrophotometer. The cuvette is filled with a blank solution that, ideally, contains all reaction components except the chromogen, and the amount of light hitting the photodetector is measured (called I_0). The cuvette is then filled with a solution that contains all reaction components, including the chromogen, and the light hitting the photodetector is measured again (called I). The amount of light hitting the photodetector is reduced by the absorbance of light by the chromogen. The amount of chromogen produced by the reaction and the corresponding magnitude of absorbance are proportional to the amount of analyte present in the cuvette. A spectrophotometric measurement is the ratio of I to I_0 and is called the transmittance (T) or the percent transmittance ($\%T$) when the ratio is multiplied by 100. The formula is

$$T = I/I_0 \tag{7.1}$$

The transmittance ratio has an inverse, semilogarithmic relationship to the concentration of the chromogen. The transmittance is more commonly converted into absorbance (A), which has a linear relationship to concentration to make it more convenient to use. It should be noted that transmittance is the parameter actually being measured and that the corresponding absorbance is a calculated value. The formula is

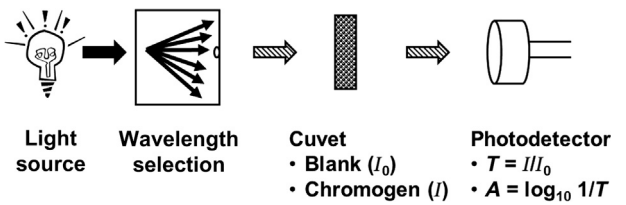

FIGURE 7.3 Diagram showing major components and configuration of a typical single-beam spectrophotometric system.

$$A = \log_{10}(1/T) = -\log_{10} T \tag{7.2}$$

Beer's law describes the linear relationship between absorbance and concentration.

$$A = (\varepsilon)\ (b)\ (C) \tag{7.3}$$

where A is absorbance, ε is molar absorptivity [L/(mol•cm)] of the chromogen, b is path length (cm) of light through the cuvette, and C is concentration (mol/L) of the chromogen in the solution in the cuvette. The molar absorptivity is a physical property of the chromogen. This property is defined as the amount of light, at a specified wavelength, that a 1 mol/L concentration of the chromogen absorbs assuming the cuvette path length is 1 cm. The molar absorptivity can be affected by the temperature, pH, and matrix of the solution containing the chromogen. Variations in temperature, pH, and matrix (e.g., ionic strength, protein content, and surfactants), as well as errors in wavelength and bandpass, can cause an error when calculating concentration using Beer's law. For these reasons, many methods correct for such variations by calibration, which will be discussed in more detail later in the chapter.

It is important to remember that a spectrophotometric measurement is a ratio of I to I_0, because it is the intensity of light hitting the photodetector that limits the measuring range for a chromogen concentration. An absorbance of 0.0 is 100%T; an absorbance of 1.0 corresponds to 10%T, which means the chromogen has absorbed 90% of the incident light energy. Similarly, an absorbance of 2.0 corresponds to 1%T, which means the chromogen has absorbed 99% of the incident light energy. Consequently, the concentration change that causes an absorbance change from 0 to 1 will use 90% of the measurement range of the spectrophotometer; doubling the concentration will cause the absorbance to change from 1 to 2 but will only use 9% of the measurement range of the spectrophotometer. The progressively smaller change in the ratio of I to I_0 as concentration increases and the corresponding increasing contribution of noise sources to the signal become a limiting factor in the ability of a spectrophotometer to measure accurately the concentration of a chromogen. For this reason, the optimal measurement range for most spectrophotometers is between 0 and 1.0A. Some instruments can make acceptable measurements at larger A values, but there will be a progressive decrease in precision and accuracy at higher values.

Configuration of spectrophotometers

Figs. 7.3 and 7.4 show two common configurations for a single-beam spectrophotometric measurement system. A wavelength selection device can be placed before the cuvette as in Fig. 7.3 or after the cuvette as in Fig. 7.4,

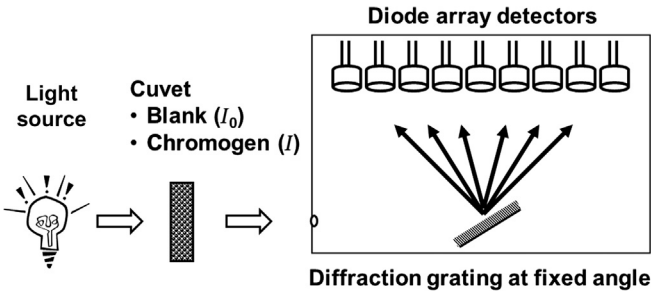

FIGURE 7.4 Diagram showing the configuration of a diode array spectrophotometric system.

depending on the design of the spectrophotometer. In Fig. 7.3, the specific wavelength of interest is isolated, passes through the cuvette, and hits the detector. This configuration can use a monochromator or an interference filter to isolate the wavelength of interest. In Fig. 7.4, the broad spectrum of wavelengths passes through the cuvette, is diffracted by a grating monochromator, and hits a series of individual diode detectors (called a diode array configuration). Each diode in the array is impinged by a very narrow band of wavelengths such that many different wavelengths can be measured simultaneously. The diode array configuration has no moving parts to go out of alignment. Diode array configurations are common in automated analyzers because of their stability and the ability to measure simultaneously multiple wavelengths. Research-grade diode array spectrophotometers can measure in wavelength increments of 1 nm. However, many clinical laboratory instruments are restricted to specific intervals of wavelengths that may limit flexibility for development of new assays.

Absorbance is measured by placing a cuvette containing the solution without chromogen in the light path measuring I_0. The solution in the cuvette is then replaced with a solution containing the chromogen and I is measured. Alternatively, the chromogen-containing solution could be in a separate cuvette with a path length identical to that of the one used for I_0 measurement. This configuration can easily be incorporated into a typical random access automated analyzer in which a single reference cuvette is used for the I_0 measurement. A series of cuvettes that contain the analyte-specific chromogens is measured to obtain I for a series of clinical samples. The ratio of I/I_0 for each cuvette/reference combination is then used to determine the absorbance for each sample. In addition to providing an I_0 value for a specific set of measurements, the reference channel can also be used to monitor the stability of the spectrophotometric system over time and to correct for optical or electronic signal drift.

Another common configuration for a spectrophotometer is called a double-beam system, in which the light path is split with mirrors and is directed alternately through each of two cuvettes, one used for the I_0 and one for the I measurements. The frequency of the light alternating between the two cuvettes is typically fast enough to permit the measurement of transmittance over a range of wavelengths to obtain an absorption spectrum.

Critical operating parameters: accuracy

Bandpass

Spectral bandpass (bandwidth) refers to the range of wavelengths that pass through the cuvette when the monochromator precedes the cuvette or can be isolated to impinge on an individual detector in a diode array configuration. The intensity of light isolated at a specific wavelength will be most intense at the nominal selected wavelength, but a range of wavelengths with progressively decreasing intensity will also be transmitted. The bandpass is defined as the range of wavelengths at the point of half-intensity of transmitted light. Consequently, a range of wavelengths is actually measured by the detector. If the molar absorptivity of the chromogen changes over the bandpass of the instrument, which is common, there will be less absorbance observed than expected for the concentration of chromogen present. This condition results in a lower than expected absorbance, because the observed absorbance is the integral of absorbance over the band of wavelengths passing through the cuvette and hitting the detector. If the conversion of absorbance to concentration is based on the molar absorptivity (e.g., in methods that measure enzyme activity), there will be an error in the concentration measured unless the molar absorptivity is corrected for the actual bandwidth of a specific spectrophotometer.

For example, the NADH chromogen shown in Fig. 7.2 exhibits a change in absorbance vs. wavelength. If a spectrophotometer with a wavelength bandpass of 1 nm was used to measure NADH, there would be little absorbance error, because 1 nm is small enough to isolate functionally the peak absorbance at which the molar absorptivity was determined. However, if a spectrophotometer with 10-nm bandpass was used, some of the wavelengths would not be measuring the peak absorbance, the integrated absorbance over the bandpass would be less than that expected, and the concentration calculated from the molar

absorptivity would be erroneously low. For NADH, a 10-nm bandpass would produce an absorbance that is approximately 1% lower than the correct value and a 20-nm bandpass would produce an absorbance that is approximately 3% lower than the correct value. Bandpass has a greater influence for chromogens with a narrower absorption spectrum and a smaller influence for those with a broader absorption spectrum. A bandpass of <8 nm has been recommended when measuring NADH in enzyme assays that determine activity on the basis of molar absorptivity [1].

When a relatively wide bandpass instrument is used, it is necessary to correct for the condition by determining a functional molar absorptivity value specific for that instrument. Instrument manufacturers have various names (e.g., filter factor) for such instrument-specific molar absorptivity values. When interference filters are used, the instrument-specific molar absorptivity values must be verified periodically, because the devices are subject to deterioration over time. Alternatively, an instrument-specific calibration can be established using a calibrator with known concentration (or activity) to establish the relationship between absorbance and concentration (or activity) for that instrument.

Stray light

Stray light is the light at wavelengths other than the measuring wavelength that reaches the detector and is not absorbed by the chromogen. Stray light causes the measured absorbance to be lower than it would be in the absence of the stray light. Consider the equation for transmittance when a stray light component (I_S) is present.

$$T = \frac{I + I_S}{I_0 + I_S} \tag{7.4}$$

The intensity of light hitting the detector has the stray light added to it. I_S is usually an insignificant fraction of I_0, but as I gets small due to large absorbance by the chromogen, I_S becomes a significant fraction of I, which causes T to be larger (and A to be lower) than what would be expected based on the concentration of chromogen. Consequently, the relationship between absorbance and concentration becomes nonlinear, as stray light becomes a greater percentage of the total light hitting the detector. For example, if stray light is 0.1% of the total hitting the detector, the absorbance will have a 1% error at approximately 1.5A, and if stray light is 0.5%, the absorbance will have a 1% error at approximately 0.6A.

Stray light can be caused by light leaks in the instrument, degradation of the source lamp, and, rarely, fluorescence or phosphorescence from endogenous substances or drug metabolites in the sample. However, the most common source of stray light is undesired wavelengths originating from the monochromator or wavelength isolation device because of optical defects. Contemporary holographic grating monochromators have reduced stray light to insignificant levels for many applications, but this source of error can be an issue when interference filters are used. Some spectrophotometric systems have incorporated automated multiwavelength stray light correction algorithms, which are effective for some types of optical defects.

Stray light can be measured as residual absorbance when measuring a solution or a filter that absorbs $>4A$ (0.01 %T) at the wavelength of interest but passes most other wavelengths. A signal observed in these conditions is due to stray light reaching the detector. Note that only potential stray light at wavelengths that are not blocked by the filter or solution used to detect stray light will be identified by this procedure. Two or more test filters or solutions are typically needed to cover a range of wavelengths. Therefore stray light checks should be performed as part of routine instrument performance assessment. Use of a pulsed-frequency xenon lamp as the spectrophotometer source lamp is a common technique used to reduce the effects of light leaks. The light from the xenon lamp is pulsed at a frequency much faster (e.g., 1000 Hz) than that of the overhead fluorescent lights (60 Hz) and is synchronized with the photodetector. This approach reduces the error contribution of minor amounts of environmental light contamination.

Wavelength accuracy

The wavelength selected by the monochromator or other device must be verified to be correct as indicated. If the wavelength is not as indicated, the molar absorptivity used to calculate concentration will be incorrect for the actual wavelength in use, corrections for interfering substances may not be accurate, or the analytical sensitivity of the measurement may not be as expected. Wavelength accuracy can be verified by scanning and identifying the peak absorbances for known substances such as holmium oxide in solution [National Institute of Standards and Technology Standard Reference Material (NIST SRM) 2034] or in glass, or by removing wavelength-isolating filters from an instrument and scanning them in a calibrated spectrophotometer. Some spectrophotometers have a provision to use sharp line emissions from deuterium or mercury lamps used as UV light sources. Verifying wavelength accuracy is the responsibility of the clinical chemist for a stand-alone spectrophotometer, but is the responsibility of the manufacturer for a spectrophotometer built into a diagnostic instrument.

Absorbance accuracy

The absorbance measured by the spectrophotometer must be verified to be correct whenever results are based on

molar absorptivity. Verification of absorbance accuracy can be accomplished by measuring a set of certified absorbance standards. Liquid solutions with a known concentration of chromogen with a known molar absorptivity can be used. A set of liquid solutions for the range 302−678 nm (SRM 931h) and solid potassium dichromate (SRM 136f) can be obtained from NIST to create liquid solutions for use at wavelengths 235−350 nm. Another approach (useful for automated analyzers for which it is difficult to add solutions directly into cuvettes) is to generate quantitatively NADH, for which the molar absorptivity is known at 340 nm, from pure glucose (NIST SRM 917c) using the hexokinase reaction. Verifying absorbance accuracy is the responsibility of the clinical chemist for a stand-alone spectrophotometer but is the responsibility of the manufacturer for a spectrophotometer built into a diagnostic instrument.

Chromogen limitations

The measured chromogen is usually generated by a chemical reaction that converts the amount of analyte present in a biological sample into a proportional amount of the chromogen. The proportionality of the chemical conversion can be affected by defects in the reagents or by an inadequate amount of one or more reagents that may limit the completeness of the chemical reaction(s). The chromogen, at higher concentrations, may form complexes or adducts with itself or with other components of the reaction that can change the molar absorptivity and thus the ability to transform accurately the absorbance to the concentration of the analyte.

Calibration of spectrophotometric measurements

Calibration establishes the mathematical relationship between the analytical response and the chromogen concentration in the solution in the cuvette. The concentration of the analyte in the biological sample is typically directly proportional to the analytical response of the chromogen. Spectrophotometric measurements are based on the molar absorptivity of the chromogen or on a calibration relationship established by a calibrator that compensates for the unique conditions of an instrument. It is a common practice to calibrate a spectrophotometric assay using the calibration solutions of known analyte concentration, which are assayed in the same manner as the clinical samples, in which case the calculated concentration of an analyte in an unknown sample is not reliant on knowing the molar absorptivity. However, spectrophotometric assays for enzyme activity typically use the molar absorptivity of a chromogen to calculate the activity as the rate of substrate consumption. Errors related to the molar absorptivity are important to control when Beer's law is used to calculate enzyme activity or analyte concentration.

Molar absorptivity

When concentration is calculated from the molar absorptivity, it is imperative that the pipette, absorbance, wavelength and temperature accuracy, bandpass, and stray light have been verified. Each of these variables can affect the chemical reaction(s) and the observed molar absorptivity of the chromogen in the cuvette. Any variable that can influence the matrix of the solution in the cuvette (e.g., pH, ionic strength, surfactants, and temperature) must be controlled to ensure the chromogen is in the same matrix conditions as when the molar absorptivity was determined. Note that it is acceptable and recommended to establish the molar absorptivity of the chromogen for the unique conditions of a specific method and spectrophotometric system. Note that some automated analyzers may not permit the user to make changes to molar absorptivity settings. A measurement system-specific molar absorptivity can be established by preparing a series of solutions containing various amounts of pure chromogen dissolved in the reaction buffer for the method. The molar absorptivity is calculated as the absorbance per mole per liter of chromogen in the cuvette for a range of concentrations.

Calibration relationship

A calibration relationship can be established by measuring a series of concentrations of calibrators (also called standard solutions) and establishing the mathematical relationship between the absorbance and concentration of analyte in the calibrator solutions. The calibrator solutions are measured in the same manner as the clinical samples and must have a matrix that is appropriate for the clinical samples that will be quantitated using the calibration relationship. The term "standard curve" or "calibration curve" is used to refer to a calibration relationship even when the relationship is a straight line. For most spectrophotometric assays, the relationship between absorbance and concentration is linear, although the relationship between transmittance (the actual measured quantity) and concentration is semilogarithmic. If the absorbance relationship is not linear, several concentrations of the calibrator are required to describe accurately the calibration relationship over the analytical measurement range.

Establishing a calibration relationship eliminates or substantially reduces the influences of biases in pipette, wavelength, and absorbance accuracy, bandpass, and stray light, because these variables are compensated for by having the calibrators measured at the same spectrophotometric conditions as the unknown samples. These variables remain important for the measurement and must be at

settings appropriate for the reactions involved, but nominal differences from specifications can be tolerated as long as they remain constant for calibrators and unknown samples. The need for temperature accuracy is eliminated as far as its effect on the molar absorptivity of the chromogen but the role of temperature on the chemical reaction that generates the chromogen may still be important.

Precision of the various steps in the assay remains an important variable to control. The matrix of the calibrator solutions must be appropriate for the clinical samples to be assayed to ensure there is no bias introduced by a difference in the extent of the chemical reactions involved in generating the chromogen or in the final matrix of the solution in the cuvette that might differently affect the molar absorptivity of the chromogen, depending on whether it originated from the calibrator or from the clinical sample. The matrix should also be taken into consideration when diluting a sample. The selected diluent should possess matrix characteristics similar to the sample to avoid measurement biases due to matrix differences.

One of the critical factors affecting measurement accuracy is the target value assignment of the calibrator materials. The calibrator value assignment should be traceable to a higher order reference measurement procedure, if one is available, or to a commutable certified reference material when available and no reference measurement procedure exists. Reference measurement procedures and reference materials can be found in the database of the Joint Committee on Traceability in Laboratory Medicine (JCTLM) [2]. Many of the reference materials listed by JCTLM are intended for use as trueness controls with reference measurement procedures and are not commutable with clinical samples when used with routine clinical laboratory methods. Use of noncommutable reference materials as calibrators for routine clinical laboratory methods can cause miscalibration and erroneous results for clinical samples [3,4]. See Chapter 17, Harmonization of results among laboratories, for additional information on calibration traceability.

Critical operating parameters: precision

The precision of a spectrophotometric measurement varies with design of the instrument system. At low absorbance (high $\%T$), the precision is limited by mechanical, optical, and electronic stabilities. At high absorbance (low $\%T$), the precision is also limited by stray light and detector background electronic noise, as these sources of error become a larger fraction of the measured signal. Maximum precision is generally obtained when the absorbance is $0.1-1.0A$. Contemporary automated spectrophotometers typically make multiple independent absorbance measurements and average the results to reduce the effects of imprecision. Precision improves proportional to the square root of the number of independent measurements (e.g., the mean of nine measurements reduces imprecision by a factor of 3; 100 measurements reduces imprecision by a factor of 10).

The precision of a spectrophotometric measurement can be validated in several ways depending on the accessibility of the cuvette. A dye can be measured in replicate in a single cuvette or in multiple cuvettes. When multiple cuvettes are used, minor differences in path length among cuvettes will be included in the imprecision value. For automated systems, it is frequently adequate to measure the combined effects of pipette and absorbance variation on the precision using a dye (which removes any influence of a chemical reaction) or with a chemical reaction to generate a chromogen that may also include reagent formulation variability and temperature effects.

Interferences

The absorbance of a substance other than the chromogen derived from the analyte of interest will cause interference in the measurement, unless the signal from the interfering substance is removed from the total absorbance. Absorbance from the reagents used in a reaction can be measured before adding the sample and subtracted from the total absorbance of the reagent plus chromogen. This process is called a reagent blank correction. Clinical samples such as serum or urine frequently contain substances that may absorb light at the wavelength used to measure the analyte-specific chromogen and cause spectral interference. The effects of spectral interferences can be reduced in several ways, including the use of a sample blank, use of a kinetic reaction-rate method, and correction using wavelengths at which the interfering substances absorb.

Measurement of a sample blank can correct for spectral interferences in spectrophotometric end-point methods. In an end-point reaction (Fig. 7.5), the absorbance value is obtained at a time point after the reaction has proceeded to completion (when all of the analyte has reacted with the reagents to produce a chromogen). To correct for spectral interferences, a "sample blank" absorbance reading at the measuring wavelength is taken after mixing the sample with all of the reagents, except those that cause chromogen production. The reagent that triggers production of chromogen is added, and the reaction is allowed to proceed to completion. The total absorbance is measured at the completion of the reaction. The absorbance of the sample blank, corrected for the volume of the added second reagent, is then subtracted from the total absorbance to yield the corrected chromogen-specific absorbance. This method of correction is subject to error if the absorbance of the spectral interferant is of such a large magnitude that the chromogen-specific contribution

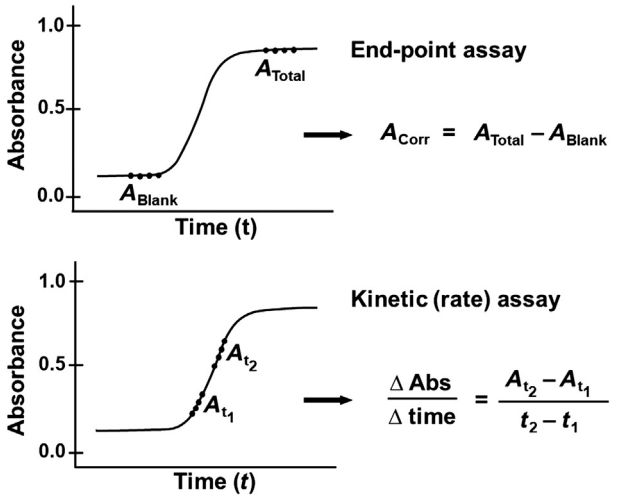

FIGURE 7.5 Spectrophotometric end-point and rate reactions. The first inflection on each graph represents the addition of reagents required for chromogen production. *Note*: Equations are simplified examples; automated instruments typically include polychromatic corrections for interfering substances, sample volume corrections, and averaging of many measurements to improve precision.

to the total absorbance is small. It also is important to note that sample or reagent blanks can only correct for interfering absorbances that remain constant during the reaction. The magnitude of the correction will be erroneous if an absorbing interferant reacts with any component of the reaction mixture.

Another procedure to correct for spectral interferences is by utilization of a kinetic (rate) reaction (Fig. 7.5). Rather than calculating the analyte concentration on the basis of total absorbance at the end of a reaction, the absorbance is measured at multiple time points during the reaction. The change in absorbance vs. time is then used to calculate analyte concentration. Measurement of the change in absorbance over time corrects for the absorbance of interfering substances that do not change during the course of the reaction. As is the case with sample blanking, this correction method will not work if the interfering substance causes a large absorbance, such that the change in absorbance due to the analyte-specific chromogen cannot be accurately measured.

An important limitation to the preceding correction techniques occurs when the absorbance from an interfering substance changes during the time of the reaction. Examples of dynamic absorbance interference include clearing of turbidity due to dispersion of triglyceride by surfactants and reaction of an interfering chromogen such as bilirubin in peroxide-coupled reactions as shown in the following example:

Glucose oxidase:

$$\text{Glucose} + O_2 \rightarrow H_2O_2 + \text{products} \qquad (7.v)$$

$$H_2O_2 + \text{dye} \rightarrow \text{chromogen (analyte-specific absorbance)} \qquad (7.vi)$$

$$H_2O_2 + \text{bilirubin} \rightarrow \text{nonchromogen (decrease in total absorbance)} \qquad (7.vii)$$

Note that the interference from bilirubin has two mechanisms. First, some H_2O_2 that would otherwise be available to react with the dye to produce chromogen instead reacts with bilirubin and is not converted into the analyte-specific chromogen, thus resulting in a falsely low absorbance. Second, bilirubin itself can absorb light and may contribute to the total absorbance. The interfering absorbance from bilirubin decreases in magnitude over the time course of the reaction. As the bilirubin reacts with H_2O_2, the absorbance from bilirubin no longer contributes to the total absorbance. Dynamic interferences must be controlled by modifying the reaction system to remove the interfering substance independently from the reaction that generates the analyte-specific chromogen. For example, inactivating agents such as sodium dodecyl sulfate (SDS) or potassium ferricyanide can be added to the reagent to reduce the interference of bilirubin for reaction methods that use peroxide to produce the chromogen such as those based on the Trinder reaction. In some instances, the interfering substance exhibits different reaction kinetics than the reaction of the analyte. In these cases, the time points at which absorbance readings are obtained can be modified to reduce the effect of the interference.

Another limitation in the spectrophotometric methods, as in all methods, is caused by the nonspecificity of the reaction for the analyte of interest. In this case, interfering substances react to produce the same chromogen that is produced from the analyte of interest. For example, acetoacetic acid can react with alkaline picrate used in some creatinine methods to produce a chromogen that cannot be discriminated from that produced from creatinine. Method nonspecificity must be corrected by modifying the method to include additional separation steps to remove interfering substances or to change the chemical mechanism to be more specific for the analyte. When interferences exist in a method, they must be documented as limitations in method specificity.

Bichromatic and polychromatic measurements

Measuring absorbance at a second wavelength at which no change in absorbance occurs during the reaction can be used as a reference point to correct the spectrophotometric system for drift in the measurement signal. Two or

more wavelengths can also be used to correct for some types of absorbance interferences. A simple case occurs when an interfering substance absorbs light at the same wavelength as the analyte-specific chromogen (primary wavelength) but also absorbs light at a second wavelength at which the analyte-specific chromogen does not absorb. The ratio of molar absorptivities of the interfering substance at the two wavelengths can be used to predict the absorbance due to the interfering substance at the primary wavelength from its absorbance at the second wavelength. This value can then be subtracted from the total absorbance at the primary wavelength to obtain the net absorbance due to the analyte-specific chromogen. This correction approach has been referred to as the Allen correction.

A more complex situation occurs when the analyte-specific chromogen and an interfering substance both absorb light at all wavelengths available for measurement. This situation is shown in Fig. 7.6. When the molar absorptivities of the analyte-specific chromogen and the interfering substance(s) are different and are known at two wavelengths, two equations with two unknowns can be written to describe the total absorbance at each of the two wavelengths. This correction method has been referred to as bichromatic correction. A is the absorbance; λ_1 and λ_2 are the two respective wavelengths; ε_1 and ε_2 are the molar absorptivities of substances 1 and 2, respectively, at each of the two wavelengths; and C_1 and C_2 are the concentrations of substances 1 and 2, respectively.

At wavelength 1:

$$A_{(\lambda 1)} = \left(\varepsilon_{1(\lambda 1)} \times C_1\right) + \left(\varepsilon_{2(\lambda 1)} \times C_2\right) \tag{7.5}$$

At wavelength 2:

$$A_{(\lambda 2)} = \left(\varepsilon_{1(\lambda 2)} \times C_1\right) + \left(\varepsilon_{2(\lambda 2)} \times C_2\right) \tag{7.6}$$

All arguments in the two equations are known or can be measured except C_1 and C_2. Thus the two equations can be simultaneously solved for C_1 and C_2, one of which is the concentration of the analyte of interest.

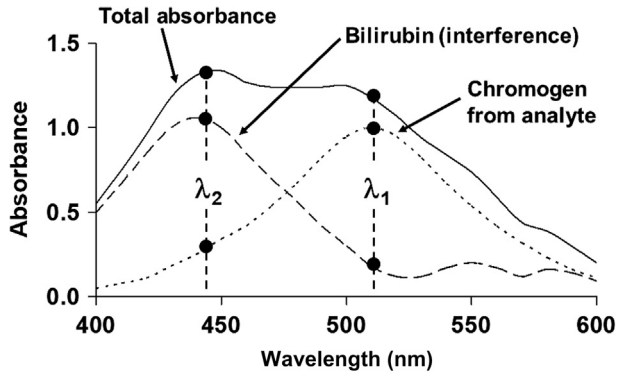

FIGURE 7.6 Absorption spectra illustrating bichromatic measurement to correct for an interfering substance that has absorption at all wavelengths available to measure a chromogen.

Note that more than one interfering substance can be corrected using a bichromatic (two wavelengths) technique as long as the substances have similar molar absorptivities at the two wavelengths used. For example, bilirubin and hemoglobin have very similar absorbance spectra at several wavelengths and can frequently be adequately corrected using bichromatic measurements. However, interfering substances that have different molar absorptivity ratios at the two wavelengths cannot be corrected using bichromatic measurements. For example, turbidity from triglyceride-rich lipoproteins has a very different absorption spectrum than bilirubin and hemoglobin; thus a bichromatic technique cannot simultaneously correct for each of these sources of spectrophotometric interference. Three (trichromatic) or more wavelengths can be used to correct for more complex interferences or to measure simultaneously multiple analytes, such as in cooximetry (COOX) determination of hemoglobin species. Imprecision of a final result will increase as more individual absorbance measurements are used and must be accommodated in the total error budget of the measurement.

Other applications of spectrophotometric or light emission measurements

Cooximetry

COOX is the measurement of blood total hemoglobin and the relative percentages of hemoglobin derivatives including oxyhemoglobin (O2Hb), deoxyhemoglobin (HHb), carboxyhemoglobin (COHb), and methemoglobin (MetHb). COOX instrumentation may be integrated with routine blood gas analyzers or function as stand-alone analyzers. O2Hb, HHb, COHb, and MetHb each exhibit characteristic spectrophotometric absorbance profiles over the wavelength range of 422−695 nm. The absorbances at the measuring wavelengths are obtained for venous or arterial whole blood samples, and a series of algorithms based on the absorbance spectrum for each molecule is used to identify and quantify each hemoglobin derivative. Total hemoglobin is quantified using conductivity or the sum of the spectrophotometric measurements of O2Hb, HHb, COHb, and MetHb. Due to similar absorbance spectra, sulfhemoglobinemia from medications containing sulfonamides can cause interference with MetHb measurements and fetal hemoglobin can cause interference with COHb measurements. Therefore COOX instruments employ additional algorithms for qualitative spectrophotometric detection of sulfhemoglobin and fetal hemoglobin to alert the user of elevated concentrations of these derivatives. Although different combinations of instrument

optics and measuring wavelengths are used to reduce the effects of interferences, high concentrations of bilirubin, intralipid, or methylene blue can also cause errors in COOX measurements. More information on the use and interpretation of COOX measurements can be found in Chapter 35, Contemporary practice in clinical chemistry: blood gas and critical care testing.

Reflectance spectrophotometry

Reflectance refers to a configuration in which the incident light impinges on the chromogen contained in a thin coating on a surface, and the light is reflected from the rear surface of the coating support to make a second pass through the chromogen matrix. Examples include dry slide chemistry analyzers and urinalysis dipstick readers. In these applications, the path length is small and measurement precision is influenced by the uniformity of the coating containing reagent(s) and chromogen. Reflectance is characterized by increased influence of scatter at each reagent layer surface that has a change in the index of refraction. Consequently, a diffuse reflectance measurement typically has a nonlinear relationship with concentration and appropriate calibration algorithms are used.

Densitometry

Densitometry measures absorbance by passing light through a solid support material on which the chromogen is contained by absorption or adsorption to the solid (or gel) layer. Thin-layer chromatography and electrophoresis are typical examples. Accuracy and precision are limited by variations in path length due to inconsistent thickness of the medium, scatter from components in the solid medium, and exceed the limited dynamic range of the detector caused by too high of a concentration of the chromogen in the medium.

Turbidimetry and nephelometry

Turbidimetry and nephelometry are the techniques to measure concentration on the basis of light scatter, as illustrated in Fig. 7.7. Conventional spectrophotometers measure light transmitted at 180 degrees from (or in line with) the incident light source. Turbidity is measured in this configuration as absorbance, because scattered light does not reach the photodetector and causes a decrease in I_0 (increase in absorbance), just as does absorbance by a chromogen. This mechanism is the reason for which turbidity causes interference in spectrophotometric measurements. Nephelometry measures the intensity of light scattered at an angle away from the incident light path. Nephelometry is not a measurement of the ratio of light intensity in the absence and presence of scattering molecules but is a measure of absolute intensity of light caused by scattering molecules. Nephelometry is capable of measuring orders of magnitude lower concentrations of scattering molecules than turbidity. Nephelometers frequently use laser light sources, because the increased intensity can produce increased intensity of scattered light and lower detection limits. In addition, optics and optical filters are used to focus the scattered light and reduce the contribution of stray light to improve the analytical sensitivity of the measurement.

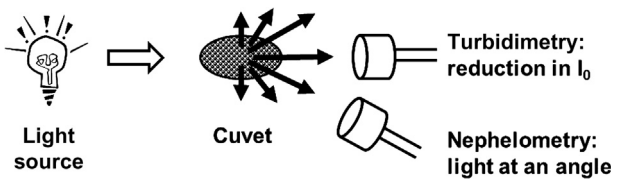

FIGURE 7.7 Configuration used to measure light scatter by turbidimetry or by nephelometry.

Light is scattered by molecules large enough that their hydrated diameter is of similar magnitude to the wavelength of the incident light [5]. Light scatter is typically used to quantitate antibody complexes of protein analytes, because these complexes are large enough to scatter light. Light scatter is a complex process that depends on the size and index of refraction of the scattering molecular complex. Light scatter is typically greater at shorter wavelengths, with the intensity being approximately proportional to the inverse of the wavelength to the fourth power ($1/\lambda 4$). Light scatter is not symmetrical; the intensity of scatter at a given angle from incident varies with the size of the complex. As the scattering complex gets larger, a greater proportion of light is scattered at angles >90 degrees from the incident (called forward scatter). Nephelometers typically measure scatter at forward angles from the incident to improve sensitivity for immune complexes and similar sized molecular aggregates. It is common to control the size of immune complexes by the use of surfactants and polymers (e.g., polyethylene glycol) to optimize conditions for quantitation of complexes of different sizes that may be produced by analytes at different concentrations. Measurement of light scatter can be used to measure amylase and lipase hydrolysis of starch or triglycerides, respectively, and for assays based on the aggregation of latex particles coated with various substances, including antibodies. Flow cytometry measures scatter of light by cells (typically larger than the molecular aggregates) at small forward angles to determine the size and concentration of the cells.

The response of turbidimetry and nephelometry is not linear with the concentration of analyte because of the variable size of scattering complexes formed at different analyte concentrations. When the scattering complexes are formed by the classical antibody–antigen reaction,

the complex size is susceptible to antigen-excess conditions. Antigen excess may cause falsely low results at very high concentrations of analyte (called the "high-dose hook effect" or "prozone effect"). To detect a high-dose hook effect, the absorbance of the undiluted sample is compared with the absorbance of a sample that has been diluted. If the absorbance of the diluted sample is greater than the undiluted sample, a prozone effect is present. Most modern spectrophotometers and nephelometers automatically analyze the kinetics of antigen−antibody complex formation to increase the probability of prozone effect detection and alert the user.

Nephelometry and turbidimetry are sensitive to interferences from light scatter due to triglyceride-rich lipoproteins (lipemia). The effects of interfering lipoproteins may be partially reduced by ultracentrifugation and removal of the lipid particles. Because turbidimetric methods are based on the measurement of transmitted light, they are also sensitive to the absorbance of colored substances such as hemoglobin and bilirubin in the sample. Antibodies are often utilized as detection reagents, and therefore the presence of cross-reacting substances or interfering antibodies (e.g., rheumatoid factor or heterophile antibodies) can be a source of measurement error.

Atomic absorption

Atomic absorption is a special application in which ground-state atoms of metals absorb light at very specific wavelengths corresponding to the energy needed to cause electronic transitions in their electron orbitals. Fig. 7.8 shows the configuration of an atomic absorption spectrophotometer. The atoms are created by heating the sample in an acetylene gas flame or a cylindrical graphite tube furnace to a temperature that burns off most of the organic matrix and produces ground-state atoms of the metal to be measured. The "cuvette" is the flame or the center of the graphite tube, and the atoms are in the gas state. The population of atoms is relatively short-lived in the light path, and rapid measurements are necessary. The thermal energy must be carefully controlled and ionization of metals must be avoided maintaining the atoms in the ground state.

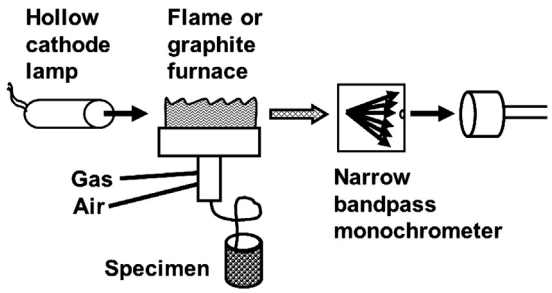

FIGURE 7.8 Diagram showing major components and configuration of an atomic absorption spectrophotometer.

Atomic electron transitions have very narrow bandwidths that require specialized light sources with very narrow bandpass (a few angstroms or tenths of nanometers). Hollow cathode lamps have an electrode coated with the metal to be measured and use an electronic discharge to generate an emission wavelength from the metal that is at the correct wavelength to be absorbed by the ground-state atoms in the cuvette. A high intensity of stray light is produced by incandescence of sample materials in the flame or furnace that necessitates placing the monochromator after the cuvette in the light path to the detector. A very narrow bandpass monochromator is used to isolate the wavelength of interest for the metal from the stray light. Because of the stray light, linearity of atomic absorption is frequently limited to a small range of absorbance (e.g., 0−0.3). Background absorbance and light scatter from sample components can also interfere and can be corrected by specialized bichromatic (Zeeman effect) or polychromatic (deuterium lamp or Hieftje) techniques. Atomic absorption can be used for accurate assay of many metals in body fluid and tissue samples, because most sample interferences can be eliminated by correct choice of instrument and thermal conditions.

Atomic emission

Atomic emission is a photometric technique in which thermal energy is used similarly to atomic absorption, except that, in this technique, the thermal energy is adequate to create excited-state atoms, which then emit light as they relax back to the ground state. Atomic emission offers the possibility to measure simultaneously several different atomic species and can have lower limits of quantitation than atomic absorption. The emitted light is at wavelengths specific to the metals present. Flame photometry using propane gas provides the reference measurement procedures for sodium, potassium, and lithium in clinical samples. An inductively coupled argon ion plasma (ICP) can be used to create excited-state atoms for many metals. The ICP is much hotter than propane or acetylene flames and thus produces more complete combustion of potential interfering organic substances. The hotter plasma also produces more emission lines from metals and requires a more sophisticated optical system to isolate wavelengths of interest. ICP methods are used for toxic and trace metal measurements from body fluid and tissue samples.

Fluorescence

Fluorescence is the light emitted from an excited-state molecular orbital as it relaxes to the ground state by

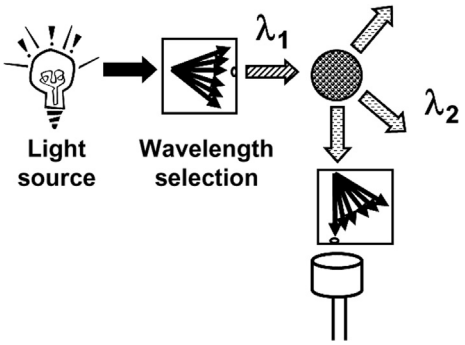

FIGURE 7.9 Diagram showing major components and typical configuration to measure fluorescence.

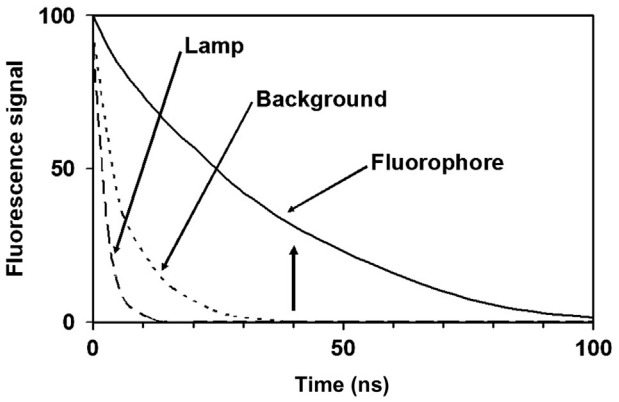

FIGURE 7.10 Time course of fluorescence emission after a pulse of excitation light.

emitting a photon of light. Fluorescent molecules, called fluorophores, are characterized by the extended conjugation of double bonds with aromatic resonance that allows the lifetime of the excited state to persist long enough for relaxation to occur by the emission of light. The excited state is produced by the absorption of light that has greater energy (shorter wavelength) than that of the emitted light. The emitted light is always at a longer wavelength (lower energy), because the excited-state electrons rapidly lose thermal energy to reach a minimal energy excited state before the emission of light to relax to the ground state. The difference in wavelength between the excitation and emission wavelengths is called the Stokes shift. Fig. 7.9 shows a fluorescence measurement configuration. Fluorescent light is emitted with equal intensity in all directions, which allows for various optical configurations. Fluorescence intensity is measured at an angle and using a wavelength selection device that excludes the excitation light. The fluorescence intensity is directly proportional to the concentration of a fluorophore in the cuvette. The quantum yield is the fraction of absorbed energy that is emitted by the fluorophore and is a measure of the efficiency of molecular fluorescence.

Fluorescence typically provides a 100-fold to 1000-fold increase in concentration sensitivity compared with absorbance measurements. For maximum sensitivity, the detection system must be able to measure the fluorescence emission without any background signal from the excitation light (i.e., measure the signal against a zero background). Potential interferences are from substances in the sample that can quench the excited-state molecule before fluorescent light is emitted or that can absorb the emitted light in the cuvette before it reaches the detector (called an inner filter effect).

Fluorescence lifetime

Fluorescence emission typically persists for 10−100 ns after excitation to the excited state, depending on the fluorophore, until all of the excited-state molecules have returned to the ground state. When longer lifetime fluorophores are used, this characteristic can be exploited to eliminate interferences from substances that contribute background fluorescence emission and to improve the limit of quantitation. Fig. 7.10 illustrates a time-resolved fluorescence measurement when a relatively long-lifetime fluorophore is used. A pulse of light is used for excitation; when the pulse ends, the background fluorescence decays to 0 in 30 ns, but the fluorescence from the long-lifetime fluorophore persists and can be measured against a zero-signal background at 40 ns.

Fluorescence polarization (depolarization)

If a fluorescent molecule absorbs polarized light (i.e., all electromagnetic waves are oriented in the same direction) to produce the excited state, then the fluorescence emission will have the same polarization as long as the fluorophore does not rotate during the lifetime of the excited state. If the fluorophore rotates before the fluorescence emission takes place, the emission will be depolarized proportional to the degree of rotation before the light emission. This property has been the basis for fluorescence polarization (more correctly depolarization) immunoassay for low-molecular-weight haptens. In this application, a fluorescent analog of the analyte and the analyte from the sample are mixed and compete for analyte-binding sites on a fixed number of antibodies. If analyte is absent, the fluorescent analog binds to the antibodies and rotates in solution at the rate of the antibodies. Because an antibody is a large protein, it rotates relatively slowly compared with the low-molecular-weight fluorescent analyte analog, such that there is little change in position during the lifetime of the excited state. Consequently, the fluorescence polarization of the emitted light is not changed from that of the excitation light. If analyte is present, it binds to some of the antibody molecules, which leaves some of the fluorescent analog unbound to antibodies and free in solution. Because the

fluorescent analog is small, it rotates relatively quickly, such that its orientation changes during the lifetime of the excited state before fluorescent light is emitted. Consequently, the fluorescence polarization of the emitted light is randomized or depolarized. The amount of depolarization or the ratio of polarized to depolarized signal is the basis to quantitate the analyte. Historically, the fluorescence polarization approach was used in several immunoassay instruments but is not used in current practice.

Chemiluminescence

Chemiluminescence is related to fluorescence in that light emitted from a molecular orbital excited state is measured and is proportional to the concentration of the chemiluminescent substance. In this technique, the excited state is produced by a chemical reaction rather than by absorption of light, as in fluorescence excitation. The excited chemiluminescent compound emits light as it relaxes to a ground electronic energy state. Many precursor compounds used in chemiluminescent reactions (e.g., acridinium ester, luminol, and luciferin analogs) are activated to emit light upon oxidation. In the presence of an oxidizing agent, metal ions or enzymes (e.g., horseradish peroxidase or alkaline phosphatase) mediate oxidation of the precursor compounds. Chemiluminescent reactions often have a wide dynamic range and can have greater sensitivity to low concentrations than absorption or fluorescence, because the measurements are made against a zero-signal background.

The most common applications for chemiluminescent measurement are immunoassay methods, in which the chemiluminescent compound or enzyme mediator functions as part of the detection label. Light emission is detected by a luminometer, in which emitted photons are detected to produce a measurement signal. The analytical sensitivity of chemiluminescent reactions is improved by the inclusion of a second molecule (sometimes called an intensifier agent) that can amplify the intensity of emitted light by a nonradiative energy transfer mechanism or stabilize the excited state to optimize light emission. Common sources of error in clinical practice include the development of light leaks in the luminometer and insufficient removal of unbound chemiluminescent label because of defects in the wash system. Like fluorescence, potential interferences include molecules that can quench the excited state before light emission and molecules that can absorb the emitted light in the cuvette before it reaches the detector.

Self-assessment questions

(More than one answer may be correct for each question.)

1. What is actually measured to determine the absorbance of a chromogen?
   - **a.** light energy hitting a detector
   - **b.** decrease in light intensity hitting a detector
   - **c.** increase in light intensity hitting a detector
   - **d.** ratio of light intensity hitting a detector between the chromogen and the blank
2. Which of the following reaction types can be used to produce chromogens that absorb light?
   - **a.** redox reactions
   - **b.** chemiluminescent reactions
   - **c.** dye-binding reactions
   - **d.** enzyme-mediated reactions
3. What can cause the relationship between absorbance and concentration to be nonlinear?
   - **a.** stray light
   - **b.** too large of a bandpass
   - **c.** chromogen complexation
   - **d.** wavelength calibration error
4. Why is 0.1−1.0 the most precise measurement range for absorbance?
   - **a.** Effects of stray light are minimized.
   - **b.** The proportion of light intensity change with concentration decreases at larger *A* values.
   - **c.** The noise of the detector becomes dominant at low *A* values.
   - **d.** The noise of the detector becomes dominant at high *A* values.
5. What can cause the apparent molar absorptivity to be different from theoretical?
   - **a.** too large of a bandpass
   - **b.** stray light
   - **c.** inner filter effect
   - **d.** miscalibrated wavelength
6. What type of calibration can make molar absorptivity unimportant?
   - **a.** calibration relationship using calibrator solutions
   - **b.** correct wavelength calibration
   - **c.** bracketing with standards
   - **d.** use of a filter factor
7. What sources of bias or error can be corrected for by calibration?
   - **a.** wavelength inaccuracy
   - **b.** autopipettor imprecision
   - **c.** absorbance inaccuracy
   - **d.** spectrophotometric interferences
8. How can the absorbance from an interfering substance be corrected?
   - **a.** sample blank before final reagent addition
   - **b.** kinetic measurement
   - **c.** bichromatic measurement for a sample with hemoglobin and turbidity
   - **d.** rapid absorbance measurement
9. What type of interference cannot be corrected with a bichromatic measurement?
   - **a.** bilirubin
   - **b.** turbidity
   - **c.** bilirubin and turbidity in the same sample
   - **d.** nonchromogenic drugs
10. What is the relationship between turbidimetric and nephelometric measurements?
    - **a.** Nephelometry is the inverse of turbidimetry.
    - **b.** Turbidimetry is more sensitive.
    - **c.** Nephelometry can be measured with a conventional spectrophotometer.
    - **d.** Both measure light scatter.
11. How can the presence of a prozone effect in an immunoturbidimetric assay be detected?
    - **a.** measuring the absorbance after ultracentrifugation
    - **b.** measuring the absorbance after concentrating sample
    - **c.** measuring the absorbance after diluting the sample
    - **d.** measuring the absorbance after treating the sample with SDS
12. How does atomic absorption spectrophotometry differ from solution-phase measurements?
    - **a.** The chromogen has broad absorbance bands in atomic absorption.
    - **b.** Stray light is more significant in atomic absorption.
    - **c.** The chromogen is short-lived in atomic absorption.
    - **d.** The flame or furnace in atomic absorption produces a more stable chromogen.
13. How does fluorescence polarization immunoassay discriminate between free and bound fluorescent analogs?
    - **a.** The bound fluorescent analog emits polarized light in all directions.
    - **b.** The bound fluorescent analog emits polarized light with the same orientation as that of the light absorbed.
    - **c.** Free fluorescent analog rotates during the lifetime of fluorescence and depolarizes the emitted light.
    - **d.** Fluorescent-labeled analog and native analyte compete for antibody-binding sites.

Chapter 8

Chromatography and electrophoresis

David S. Hage
Department of Chemistry, University of Nebraska, Lincoln, NE, United States

Learning objectives

After reviewing this chapter, the reader will be able to:

- Define "chromatography" and describe common ways of categorizing different types of this method.
- Discuss the terms that are used to describe retention, band-broadening, and peak separations in chromatography.
- Explain the significance of the van Deemter equation and the general factors that affect the resolution of a separation in chromatography.
- Discuss the general concepts of gas chromatography and liquid chromatography, including the types of mobile phases, elution methods, supports, and stationary phases that are used in these techniques.
- Describe the design and applications of common detectors and detection systems that are used in gas chromatography and liquid chromatography.
- Define "electrophoresis" and describe general formats for this method.
- List the various factors that can affect the migration and band-broadening of chemicals in electrophoresis.
- Discuss the general concepts of gel electrophoresis and capillary electrophoresis, including the types of supports, application methods, and formats that are used in these techniques.
- Describe common detectors or detection systems that are used in gel electrophoresis and capillary electrophoresis.

Introduction to chromatography

General terms and concepts

The complexity of clinical samples such as blood, serum, and urine typically necessitates some separation prior to analysis. Chromatography is a method that is frequently employed for this purpose. Chromatography is a separation technique in which the components of a sample are separated based on how they distribute between two chemical or physical phases, a stationary phase and a more mobile phase that is allowed to travel through the separation system. This method is illustrated in Fig. 8.1, in which a sample is applied to the top of a tube, known as the "column." This column contains a fixed surface or layer, known as the "stationary phase," that is held in place by a solid support and that can interact with the various components of the sample. A second phase (called the "mobile phase") is used to apply samples to the column and pass their components through to the other end. Those substances that have the weakest interactions with the stationary phase will travel through more quickly than those with strong interactions, resulting in a separation of these chemicals [1–4].

There are many different types of chromatography. The main way of categorizing these techniques is based on their mobile phase. If a gas is used as the mobile phase, the method is called gas chromatography (GC); if the mobile phase is a liquid, the technique is known as liquid chromatography (LC). Both GC and LC can be divided into further subcategories based on their separation mechanism, which is determined by the type of stationary phase in the column. For instance, the use of underivatized solid particles in GC or LC as the stationary phase produces the methods of gas–solid chromatography (GSC) and liquid–solid chromatography (LSC).

Another way chromatographic methods can be grouped is according to the type of chromatographic bed or support that is present. A method in which a column contains the support and stationary phase is known as column chromatography. If the column is packed with support particles, this method is called packed bed chromatography. If the stationary phase is instead placed directly onto the interior wall of the column, the technique is known as open-tubular chromatography. It is also possible to have the support and stationary phase present on a flat plane, giving the technique of "planar chromatography." Specific examples of planar chromatography include paper chromatography, which uses paper as a support, and thin-layer chromatography, which generally uses a stationary phase coated on a glass or plastic sheet.

One way that chromatography can be utilized is for the isolation of a given chemical prior to its analysis by a

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00008-9

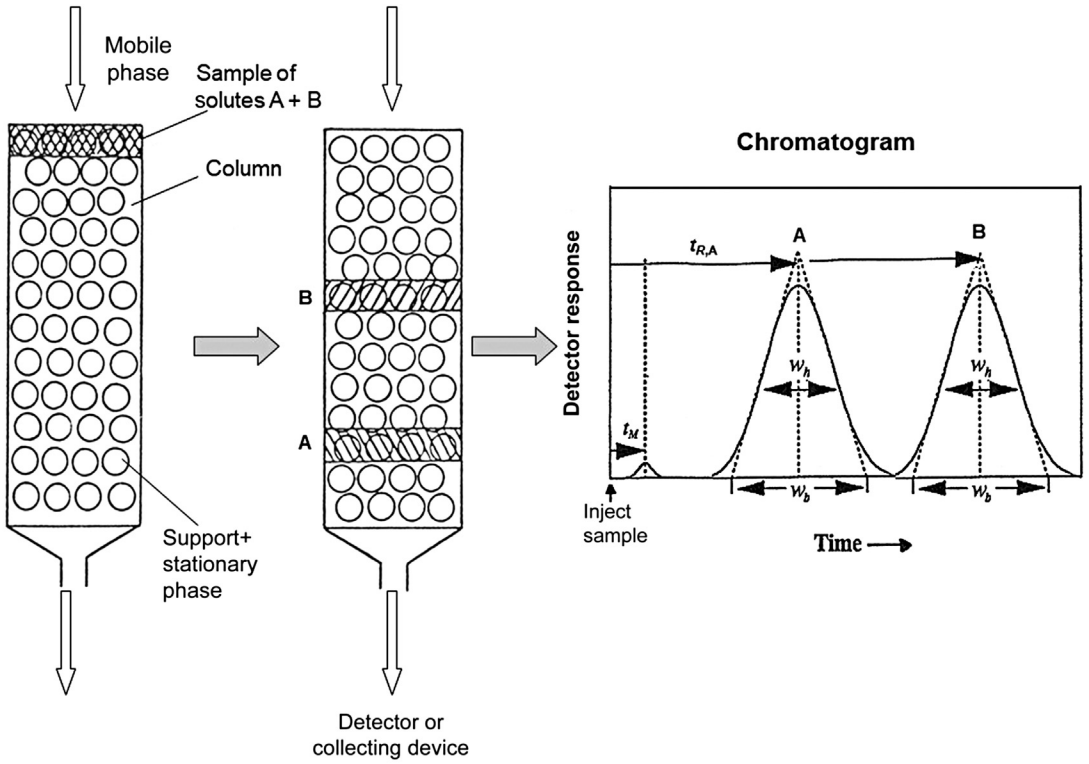

FIGURE 8.1 (A) General scheme for the separation of chemicals by chromatography and (B) a typical chromatogram for such a separation.

different method. However, chromatography can also be used directly for the identification and measurement of sample components if it is used along with a detector that can monitor these chemicals as they pass through the chromatographic system. The result is usually plotted by making a graph of the response measured by this detector as a function of the time or volume of mobile phase needed for the elution of each injected chemical. This plot, as shown in Fig. 8.1, is known as a "chromatogram."

Theory of chromatography

In chromatography, there is always a minimum amount of time required for any substance to pass through the system. This is known as the column "void time" (t_M). If a compound is bound (or "retained") by the stationary phase, it will travel more slowly through the column and exit at some later time. The average time required for this is known as that compound's "retention time" (t_R) (see Fig. 8.1). The length of this retention time is determined by the eluting substance's structure, as well as the type and composition of stationary and mobile phases being used in the chromatographic system. Elution volume can also be used to describe the movement of substances in chromatography. The average volume of mobile phase it takes to move a compound through the column is called that compound's "retention volume" (V_R). Similarly, the volume of mobile phase it takes to elute a totally nonretained substance is known as the column "void volume" (V_M).

Another way the retention of substances in chromatography can be described is by using the retention factor (k). The retention factor can be calculated by using one of the following relationships.

$$k = \frac{(t_R - t_M)}{t_M} \quad \text{or} \quad k = \frac{(V_R - V_M)}{V_M} \tag{8.1}$$

The retention factor is a more fundamental measure of retention than t_R and V_R, because it is related directly to the amount of stationary phase in the column and the extent to which solutes are interacting with this phase. As an example, Eq. (8.2) is another way of describing the retention factor for a chromatographic system in which a solute is partitioning between the mobile phase and the stationary phase.

$$k = K_D\left(\frac{V_S}{V_M}\right) \tag{8.2}$$

In this equation, (V_S/V_M) (i.e., the phase ratio) is the relative volume of stationary phase versus the volume of mobile phase in the column, and K_D is the distribution equilibrium constant for the solute in these two phases. Eq. (8.2) indicates that the degree of retention in chromatography will be related to both the degree of that

compound's interactions with the stationary phase (K_D) and the relative amount of stationary phase in the column (V_S/V_M).

As chemicals travel through a chromatographic system, the width of the region that contains each compound (i.e., the compound's peak or band) gradually becomes broader. This process is known as "band-broadening" and occurs even for substances that have little or no binding to the stationary phase. One way of describing band-broadening in chromatography is to measure the width of a peak at its baseline level (w_b) or its width at half-height (w_h) (Fig. 8.1). However, these values are highly dependent on the retention time or retention volume used for measurement. To compare the band-broadening for substances with different retention times, the "number of theoretical plates" or "plate number" (N) is utilized. The value of N can be calculated from w_b or w_h by one of the expressions given in Eq. (8.3) for a peak with a Gaussian shape.

$$N = 16\left(\frac{t_R}{w_b}\right)^2 \quad \text{or} \quad N = 5.545\left(\frac{t_R}{w_h}\right)^2 \tag{8.3}$$

A large value for N makes it easier for a chromatographic system to separate compounds. One way this parameter can be viewed is by having the value of N represent the number of times a substance will equilibrate between the mobile phase and stationary phase as it travels through the column. If a compound is able to undergo more of these equilibration steps, it becomes possible for the system to distinguish between compounds with smaller differences in their retention.

Although N is useful for describing band-broadening in columns, it does have the disadvantage of being dependent on the column length. This problem can be overcome by using a related value known as the "height equivalent of a theoretical plate" or "plate height" (H). The value of H is calculated from N by using Eq. (8.4), where L is the length of column.

$$H = \frac{L}{N} \tag{8.4}$$

The value of H gives the length of column that corresponds to one theoretical plate, or one equilibration step of the analyte with the stationary phase. Because a large number of theoretical plates are desirable to provide a small degree of band-broadening, a small plate height is also desirable.

Plate heights are used not only to describe band-broadening and column efficiency, but also to evaluate how a particular experimental factor impacts band-broadening. One well-known relationship developed for this purpose is the van Deemter equation, which shows how a change in linear velocity (u, which is directly proportional to flow-rate) alters the measured plate height for a column (H).

$$H = A + \frac{B}{u} + Cu \tag{8.5}$$

In this equation, the terms A, B, and C are constants that represent the contributions to band-broadening due to several processes that occur as a solute passes through the column. These processes are eddy diffusion (A), longitudinal diffusion (B), and stagnant mobile phase mass transfer plus stationary phase mass transfer (C), where the effect of each process on H has a different dependence on the flow-rate. Eddy diffusion is produced by the presence of the large number of flow paths around support particles, with each path having a slightly different length. Longitudinal diffusion refers to the broadening of a compound's peak due to the diffusion of solutes along the length of the column. Stagnant mobile phase mass transfer is related to the rate of movement of solutes as they go from the outside of the support to the region in the support's pores or near the support's surface. Stationary phase mass transfer is related to the rate at which an analyte transfers between the stationary phase and the mobile phase.

A plot of the van Deemter equation gives a "U"-shaped curve in which there is a distinct linear velocity where H has its lowest optimum value. This type of graph is helpful in finding the flow-rate or linear velocity that gives the best possible efficiency for a column. Another way a van Deemter plot can be used is to compare the plate heights of columns that contain different supports or that are prepared by different processes. This information is useful in the development of new columns or in comparing existing columns.

Evaluating and optimizing chromatographic separations

The final success of any chromatographic separation will depend on how well the peaks of interest are separated. There are a number of ways to evaluate the extent of this separation. One way is to use the separation factor (α, also known as the "selectivity"). The separation factor is a measure of the relative difference in retention of two solutes as they pass through a column. The value of α is calculated as shown below, where k_1 is the retention factor for the solute exiting first from the column and k_2 is the retention factor for the second.

$$\alpha = \frac{k_2}{k_1} \tag{8.6}$$

The separation factor becomes larger as the relative difference in retention increases between two peaks. This

feature makes α useful in describing the effectiveness of a separation in chromatography. The separation factor can also be used to indicate whether it is feasible to resolve two compounds by a given column, in which a value for α greater than one is needed for any separation to occur.

Another approach for describing the separation of two peaks is to use the peak resolution (R_s). The value of R_s for two adjacent peaks can be calculated through the following formula.

$$R_s = \frac{t_{R2} - t_{R1}}{(w_{b2} + w_{b1})/2} \tag{8.7}$$

In this relationship, t_{R1} and w_{b1} are the retention time and baseline width (both in units of time) for the first eluting peak, while t_{R2} and w_{b2} are the retention time and baseline width of the second peak. An important advantage of using peak resolution instead of the separation factor to describe the extent of a separation is that R_s considers both the difference in retention between two compounds (as represented by $t_{R2} - t_{R1}$) and the degree of band-broadening (as represented by w_{b1} and w_{b2}), while α only considers the difference in retention for these substances.

The lowest possible value for R_s is zero, which occurs when two peaks have exactly the same degree of retention and are not separated. A value for R_s greater than zero represents some degree of separation between peaks, with the extent of this separation becoming larger as R_s increases. Ideally, it is desirable to have no significant overlap between two neighboring peaks. This situation usually occurs when R_s is greater than 1.5, a condition said to represent "baseline resolution." In some separations, peak resolution values between 1.0 and 1.5 are also adequate. The latter often occurs if the peaks are about the same size and can be measured by using peak heights, which are less affected by overlap than peak areas.

Because the resolution between two peaks is a measure of both the difference in compound retention and band-broadening, any items that affect retention or peak width will also affect R_s. This relationship is demonstrated in Eq. (8.8),

$$R_S = \frac{\sqrt{N}}{4}\frac{(\alpha - 1)}{\alpha}\frac{k_2}{(1 + k_2)} \tag{8.8}$$

where k_2 is the retention factor for the second peak, α is the separation factor between the first and second peaks, and N is the number of theoretical plates for the column. Eq. (8.8) is called the "resolution equation" of chromatography. This equation shows that the degree of a separation in chromatography will be affected by three factors: (1) the extent of band-broadening in the column (N); (2) the overall degree of peak retention (k); and (3) the selectivity of the column's stationary phase in binding to one compound versus another (α).

Some ways the band-broadening of a chromatographic system can be lowered to improve resolution include the use of a longer column, operation at a flow-rate producing a smaller plate height, or the use of a support with better mass transfer properties (e.g., smaller diameter support particles). An improvement in resolution by increasing the degree of retention generally involves changing the mobile phase or stationary phase. Altering the selectivity of the chromatographic system is usually performed last and is the most difficult of the options for improving resolution, because this requires more complete knowledge of the types of interactions that are taking place between the injected compounds and the stationary phase.

Gas chromatography

General terms and concepts

One of the most common types of chromatography is the method of GC [2–7]. As stated earlier, GC is a type of chromatography in which the mobile phase is a gas. Fig. 8.2

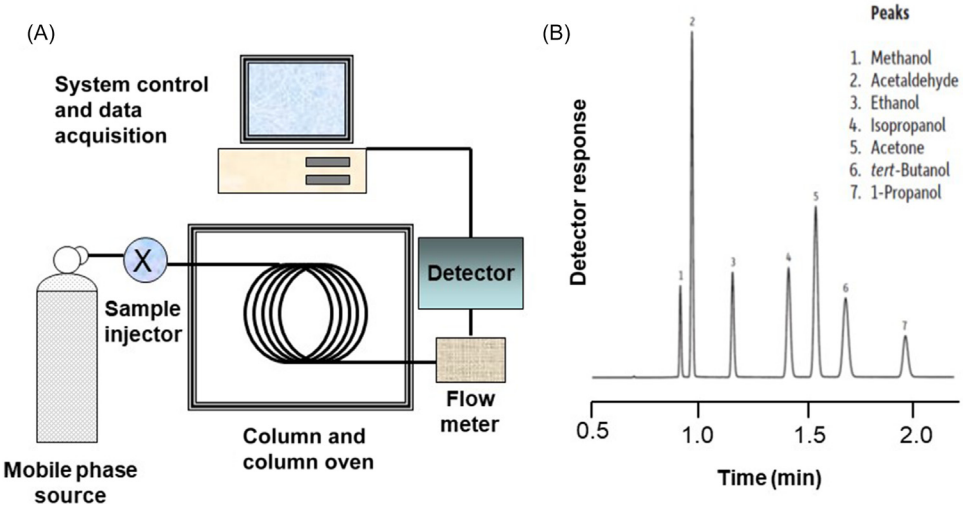

FIGURE 8.2 (A) A system for performing gas chromatography and (B) a typical separation performed by gas chromatography, using the separation of components in a blood alcohol standard as an example. *The chromatogram in (B) is adapted with permission from Restek.*

shows a typical GC system, which is known as a "gas chromatograph." The first major component of this system is the gas source that supplies the mobile phase. This source is usually a gas cylinder equipped with pressure regulators to deliver the mobile phase at a controlled rate. The second part of the gas chromatograph is the injection system, which usually consists of a heated loop or port into which the sample is placed and converted into a gaseous form. The next part of the system is the column, which contains the stationary phase and the support material. It is here that sample components are separated. This column is usually held in an enclosed area known as the "column oven" that keeps the temperature of the column and its surroundings at a well-defined level. The last part of the GC system is the detector (along with its recording device), which monitors the sample components as they leave the column.

One limitation of GC is that all analytes to be examined by this method must either be naturally volatile or capable of forming a volatile derivative. This requirement is needed so the analyte can be injected and passed through the GC system using a gas as the mobile phase. The volatility of a chemical will depend on such things as the temperature of the compound's surroundings, the size of the compound, and the types of functional groups in the compound's structure. As a rule, chemicals with molecular masses of below 600 g/mol and boiling points of below 500°C−550°C at a pressure of 1 atmosphere are usually suitable for GC. Along with good volatility, an analyte must also have good thermal stability, so that it does not decompose at the high temperatures often present in GC systems.

A common approach for increasing the volatility and thermal stability of analytes for GC is to use derivatization. This approach usually involves replacing one or more polar groups on an analyte (such as alcohol or amine groups) with less polar groups that have only weak interactions with their surrounding molecules. The result is a compound that is more volatile and easier to place into the gas phase. The same changes tend to make chemicals more thermally stable. The reaction between an alcohol-containing compound and the reagent trimethylchlorosilane is one example of derivatization. This particular reaction results in a product known as a "trimethylsilyl (TMS)-derivative" in which the hydrogen on the alcohol group is replaced with a bulkier and less polar TMS group.

Like any chromatographic method, the retention of a compound in GC will be determined by how much time this substance spends in the mobile phase versus the stationary phase. Due to the low density of gases, compounds passing through a GC column generally have no significant interactions with the mobile phase. As a result, the volatility of these chemicals is the main item that causes them to stay in the mobile phase during a GC separation. The most volatile compounds in a sample will tend to spend the most time in the mobile phase and elute most quickly from a GC column. Temperature also plays an important role in GC, because the volatility of a chemical will increase as the temperature of its surroundings increases. This is the reason why GC systems contain a column oven to maintain and control temperature during the separation process. Using a lower column temperature will produce longer retention times, because a lower temperature will cause the injected compounds to be less volatile and spend less time in the mobile phase. Increasing the temperature produces the opposite effect, with analytes becoming more volatile and passing through the column more quickly as they spend more time in the mobile phase.

Gas chromatography mobile phases and elution methods

One benefit of using a gas as the mobile phase in GC is it provides a chromatographic system with low band-broadening and narrow peaks. These narrow peaks make it easy to measure small quantities of analytes and allow GC to separate a large number of compounds in a single run. There are several reasons for the low band-broadening of GC systems. For instance, the low density of gases makes it possible for compounds in these gases to quickly move about by diffusion, which reduces many band-broadening processes. Another useful feature of gases is their low viscosity. A low viscosity for the carrier gas leads to small back pressures across GC columns, allowing the use of long columns for separations. The use of a longer column, in turn, provides a greater number of theoretical plates and better resolution.

Given that the main purpose of the mobile phase in GC is to simply move solutes through the column, the mobile phase in this technique is often referred to as the "carrier gas." Examples of common carrier gases used in GC are hydrogen, helium, nitrogen, and argon. All of these gases are relatively inexpensive, easy to obtain, inert (with the exception of hydrogen), and safe to use. These gases are usually provided by a standard gas cylinder, but sometimes they are supplied by a gas generator connected to the GC system. The carrier gas should always have high purity to avoid contamination or damage to the column and the GC system. Impurities like water, oxygen, organic substances, and particulate matter can be removed by passing the carrier gas through a series of traps and filters before it enters the column. The carrier gas source should also be equipped with regulators for pressure and flow-rate control. In some cases, it is necessary to use special devices to maintain a constant flow-rate as the temperature or pressure of the system is varied.

If a single temperature is used throughout a GC separation, this approach is called an "isothermal method." Similarly, if a constant pressure is being used, the technique is known as an "isobaric method." These elution methods work well if a sample is relatively simple or has only a few known compounds. However, these methods may not be feasible for complex samples that contain chemicals with a wide range of volatilities and/or interactions with the stationary phase. Such a situation causes some analytes to elute too quickly and others too slowly from the chromatographic system. This problem can be addressed by varying the elution conditions over time, giving an approach known as "gradient elution."

The most common way of performing gradient elution in GC is to vary the temperature of the column over time; this method is called "temperature programming." This elution method begins with a relatively low column temperature, which allows the most volatile compounds in an injected sample to better interact with the column for improved separation. Next, there is a step known as the "temperature ramp," during which the column temperature is gradually increased over time. It is during this step that analytes with intermediate volatilities are separated and eluted from the column. At the end of this ramp, the temperature is sometimes held at a high value for a short period of time to ensure that there are no low volatility substances remaining on the column from one sample injection to the next. There is then a cooling-down period in which the column is returned back to its initial temperature prior to the next sample injection.

Another type of gradient elution in GC is flow programming. In this method, the flow-rate of the carrier gas is changed during the separation. Because a change in pressure of the carrier gas is used to control its flow-rate, flow programming is sometimes referred to as "pressure programming." This method begins with a relatively slow flow-rate, which allows weakly retained components to have more time to contact the stationary phase and become better resolved. The pressure and the flow-rate are then increased to elute strongly retained compounds from the column. At the end of the elution program, the pressure and the flow-rate are adjusted back to their initial levels, and the next sample is injected. The result is a method that, like temperature programming, gives better resolution and shorter analysis times than can be obtained under constant chromatographic conditions.

Gas chromatography supports and stationary phases

GC columns can be placed into one of two major categories based on the type of support they employ: packed columns and open-tubular columns. A packed column is made up of a glass or metal tube that is usually 1−2-m long and a few millimeters in diameter; this tube is filled with small support particles that act as an adsorbent or are coated with the desired stationary phase. Packed GC columns are useful when a large amount of a sample must be separated, such as in preparative applications. This type of column can also be employed in analytical applications, but it typically has greater band-broadening than columns based on open-tubular supports. As a result, packed columns tend to be used only when a limited number of compounds are to be separated.

An open-tubular column (or "capillary" column) is used in most analytical applications of GC, including those used in clinical testing. This type of column generally ranges from 10 to 100 m in length, has an inner diameter of 0.1−0.75 mm, and possesses a stationary phase that is coated on or attached to its interior surface. A polymer such as polyimide is coated on the outside of the column to give it better strength and flexibility for handling and storage. The low band-broadening of this column allows it to provide better resolution, lower limits of detection, and/or faster rates of separation than a packed column. Three types of stationary phases are used with GC columns: (1) solid adsorbents; (2) liquids coated on solids; and (3) chemical phases bonded to a support. If a solid adsorbent is used as the stationary phase in GC, the resulting method is referred to as GSC. This technique involves the use of the same material as both the support and the stationary phase, with retention being based on the adsorption of analytes to the support's surface. An example of a support that is often used in GSC is a molecular sieve, which contains pores with well-defined sizes and binding regions. Molecular sieves are useful in retaining such things as small hydrocarbons and gases like hydrogen, oxygen, carbon monoxide, and nitrogen. Several other supports can also be used in GSC. These include organic polymers such as porous polystyrene and inorganic substances such as silica or alumina. The extent to which an analyte will bind to these materials will be determined by the support's total surface area, the size of pores in the support, and the functional groups located on the support's surface.

Another group of GC columns are those in which a chemical coating or layer is placed onto the support and used as the stationary phase. This format gives a technique known as gas−liquid chromatography (GLC), which is the most common type of GC. As shown in Table 8.1, there are many liquids used as stationary phases in this method. A common feature of all these liquids is they have high boiling points and low volatilities, which allows them to stay within the column even when high temperatures are used for sample injection and elution. Most of these stationary phases are based on polysiloxanes, which consist of a backbone of silicon and

TABLE 8.1 Typical stationary phases for gas–liquid chromatography.

Chemical name	Relative polarity[a]
100% Dimethylpolysiloxane	16 (Nonpolar)
5% Phenyl–95% methylpolysiloxane	33
14% Cyanopropylphenyl–86% methylpolysiloxane	67
50% Phenyl–50% methylpolysiloxane	119
50% Trifluoropropyl–50% methylpolysiloxane	146
50% Cyanopropylmethyl–50% phenylmethylpolysiloxane	228
Polyethylene glycol	322 (Polar)

[a]*These data are from Ewing [4]. The relative polarity is based on the McReynolds constant for benzene (X′) as a measure of stationary phase polarity.*

oxygen atoms attached in long strings of Si–O–Si bonds. The remaining two bonds on each silicon atom are bound to side groups that can have a variety of structures, ranging from nonpolar methyl groups to polar cyanopropyl groups. By altering the amount and type of these groups, it is possible to produce polysiloxanes with a variety of polarities.

One difficulty with using a liquid stationary phase is that the elevated temperatures often employed in GC will eventually cause this liquid to decompose or vaporize and leave the column over time. This process is known as "column bleeding" and changes the binding characteristics of the column. One approach for minimizing column bleeding is to use a stationary phase that is covalently attached to the support. The resulting material is known as a "bonded phase." One way a bonded phase can be produced is by reacting groups on the stationary phase with groups on the surface of the support. An alternative route is to cross-link the stationary phase to give a larger and more thermally stable structure. Either approach gives a column with less bleeding and that can be used at higher temperatures than columns that contain liquid stationary phases. It is for this reason that bonded phases are preferred in most clinical applications of GC.

Gas chromatography detectors

There are many detectors available for GC (see Table 8.2). These detectors can be divided into two categories: general detectors and selective detectors. The thermal conductivity detector (TCD) is a general detector that can be used for both organic and inorganic compounds. It produces a signal by measuring the thermal conductivity of the carrier gas/analyte mixture leaving the GC column. Hydrogen and helium are the two carrier gases that work best with a TCD, because they have the greatest difference in thermal conductivities from most analytes. The main advantage of a TCD is its ability to respond to any compound, provided that this substance is different from the carrier gas and is present in a sufficient quantity for monitoring. A disadvantage of a TCD is it will respond to impurities in the carrier gas, to stationary phase bleeding from the column, or to air leaking into the GC system. The TCD is also highly sensitive to changes in flow-rate, such as might occur during temperature programming or flow programming. Another disadvantage of a TCD is it has a relatively poor lower limit of detection compared with other common GC detectors.

The flame ionization detector (FID) is another general GC detector. An FID detects organic compounds by measuring their ability to produce ions when they are burned in a flame. The flame in the FID is usually formed by burning the eluting compounds in a mixture of hydrogen and air. Positively charged ions produced by the combustion of organic compounds in the flame are collected by an electrode and produce a current that allows these compounds to be detected. An advantage of using an FID for the GC analysis of organic compounds is it gives little or no signal for many inorganic compounds, including carrier gases (e.g., He, Ar, and N_2) and common carrier gas contaminants (O_2, CO_2, and H_2O). The FID is also less sensitive to flow-rate changes than the TCD, which makes it easier to use with temperature programming and flow programming. One disadvantage of the FID is it is a destructive detector, which breaks down analytes during the process of their measurement, preventing this detector from being connected directly to other devices or techniques for compound analysis.

A nitrogen–phosphorus detector (NPD) is a selective detector used in GC for nitrogen- or phosphorus-containing compounds. The NPD is similar to an FID in that both are based on the measurement of ions produced from eluting compounds. The main difference from an FID is that, instead of a flame, an NPD uses thermal heating at or above a rubidium surface to form ions. This process is particularly efficient for nitrogen- or phosphorus-containing compounds, which makes the NPD selective for such chemicals. The greatest strength of the NPD is its good selectivity and low limits of detection for nitrogen- and phosphorus-containing compounds. Like an FID, the NPD does not detect many common carrier gases or impurities. It is necessary when using an NPD to periodically change the heated material, because it will slowly degrade over time.

The electron capture detector (ECD) is another selective detector used in GC. This device detects compounds

TABLE 8.2 Common detectors for gas chromatography.

Detector name	Compounds detected	Detection limit[a]
Thermal conductivity detector	General: all compounds	1 ng
Flame ionization detector	All organic compounds	1 pg
Nitrogen–phosphorus detector	N- and P-containing compounds	0.01–0.1 pg
Electron capture detector	Chemicals with electronegative groups	1–100 fg
Mass spectrometry	General: full-scan mode	0.1–1 ng
	Selective: SIM mode	1–10 pg

SIM, Selected ion monitoring.
[a]*This information is from Poole and Poole [2], Ewing [4], and manufacturers of these detectors.*

that have electronegative atoms or groups in their structure, such as halogen atoms (I, Br, Cl, and F) and nitro groups (NO_2). An ECD detects compounds based on the capture of electrons by such atoms or groups. These electrons are usually produced by a radioactive source, such as ^{3}H or ^{63}Ni, and in the presence of argon or nitrogen as the carrier gas. Although an ECD is selective and has good limits of detection, it does require a radioactive source that must be changed from time to time (now commonly done by a specially trained technician from the manufacturer of this device).

Another common detector used in GC is a mass spectrometer. This combination is known as gas chromatography/mass spectrometry (GC/MS). This is a powerful tool for both measuring and identifying a compound. For instance, this approach can provide information on a chemical's molecular mass (by using its molecular ion) or its structure (through the use of its fragment ions). Common ionization methods used in GC/MS are electron impact ionization and chemical ionization. The resulting ions are separated according to their mass and/or charge by using a device such as a quadrupole mass analyzer or ion trap. One way of viewing this information is to make a plot of the number of ions measured at each elution time, giving a mass chromatogram. Another way this information can be viewed is by looking at the mass spectrum for all ions that are produced for analytes eluting at a particular retention time.

A big advantage of GC/MS is it can be used to either universally or selectively detect compounds as they leave the column. When used as a universal detector, the total number of measured ions is used to plot the mass chromatogram. This method involves using the mass spectrometer to quickly scan through a wide range of mass-to-charge ratios while collecting information on each ion that occurs within this range. This detection format is also known as the "full-scan mode" of GC/MS. This mode is useful when the goal is to look for a broad range of compounds in a single analysis (e.g., during drug screening) or when a mass spectrum is desired to determine the identity of an unknown compound (e.g., determining the drug taken by a patient suffering from an overdose). A more selective mode for performing GC/MS is selected ion monitoring (SIM). In this approach, only a few ions characteristic of the compounds of interest are examined. This mode is employed when low detection limits are desired and when it is known in advance what compounds are to be analyzed.

Methods for sample injection and pretreatment in gas chromatography

Because GC requires that analytes be in the gas phase, gaseous analytes and samples are natural candidates for this technique. If the gaseous analytes are present at moderate-to-high concentrations, direct sampling and injection onto a GC system is possible. Direct injection can be performed by passing the sample through a gas-tight valve. Alternatively, a gas-tight syringe can be used to inject a known volume of gas into the GC system. For trace components in gases, it is often necessary to collect and concentrate these analytes for separation and measurement by GC. One way this collection and concentration can be accomplished is by passing a large volume of samples through a solid-phase extraction cartridge, a cold trap, or a liquid in which the analytes will dissolve.

Liquids are the type of sample most frequently encountered in GC. When using packed columns or wide-bore open-tubular columns, it is possible to use direct injection to place this liquid into the GC system. This direct injection involves the use of a calibrated microsyringe to apply the desired volume of liquid to the system through a gas-tight septum and into a chamber where it is vaporized for analysis. However, the volumes of liquid delivered by most microsyringes are too large for the

open-tubular columns used in many clinical applications of GC. This problem can be overcome by using split injection, in which only a small portion of the vaporized sample (0.01%−10%) is allowed to go into the column.

It is quite common for some pretreatment to be required before a liquid sample can be analyzed by GC. An example is the derivatization of a fatty acid or amino acid into a more volatile or thermally stable form prior to an analysis by GC. Another example is the transfer of analytes from their original sample into a solvent that is more suitable for testing by GC. The injection of water into most GC columns creates problems with the long-term behavior and reproducibility of these columns. These problems occur because water tends to bind strongly to such columns, changing their chromatographic properties from one injection to the next. In addition, the water may contain dissolved solids, salts, or other nonvolatile compounds that are not suitable for injection into a GC system. Because of these problems, aqueous-based samples are usually extracted before GC analysis. Either liquid−liquid or solid-phase extraction can be used to remove analytes from water and place them into a more volatile solvent, as well as to remove them from nonvolatile substances present in the sample. The use of solvent evaporation with these two methods also makes it possible to greatly reduce the sample volume, which allows a larger mass of analyte to be injected for easier detection.

Headspace analysis is another technique used to avoid the introduction of water and nonvolatile compounds into a GC system. This technique is based on the fact that volatile chemicals in a liquid or solid sample will also be present in the vapor phase located above the sample. By sampling this vapor (known as the "headspace"), a portion of the volatile substances can be collected without interference from other less volatile compounds. This approach can be performed in one of two ways: the static and dynamic methods. In the static method, the sample is placed in a closed container, and its contents are allowed to distribute between the sample and its vapor phase. After equilibrium has been reached, a portion of the vapor phase is injected into the GC system. In the dynamic method, an inert gas is passed through the liquid sample, which carries away volatile compounds. This gas is then passed through a cold trap or solid adsorbent, which collects and concentrates the volatile solutes for later analysis.

GC is not limited to gas and liquid samples but can be adapted for work with chemicals adsorbed or held within a solid sample. A common way of handling this type of analysis is to first extract the compounds of interest from the solid material by using liquid−liquid extraction, with the extracted analytes and their solvent then being treated as a liquid sample. It is also possible to analyze some solids without performing an extraction. For instance, headspace analysis might be used to examine the volatile compounds that are present in a solid. Another approach for examining solids is to use pyrolysis−GC. This approach is useful in forensic testing for solid substances like plastics and polymers that are not volatile and cannot be easily derivatized into a volatile form. Pyrolysis involves heating a solid sample in a controlled fashion to very high temperatures in order to break the solid apart into smaller, more volatile fragments that can be examined by GC. The result is a gas chromatogram which provides a fingerprint of the volatile compounds that are given off as the test substance is heated.

Liquid chromatography

General terms and concepts

LC is a chromatographic technique in which the mobile phase is a liquid [2−4,7−9]. There are many ways LC can be performed, but most LC methods for clinical analysis use a system like the one shown in Fig. 8.3. This

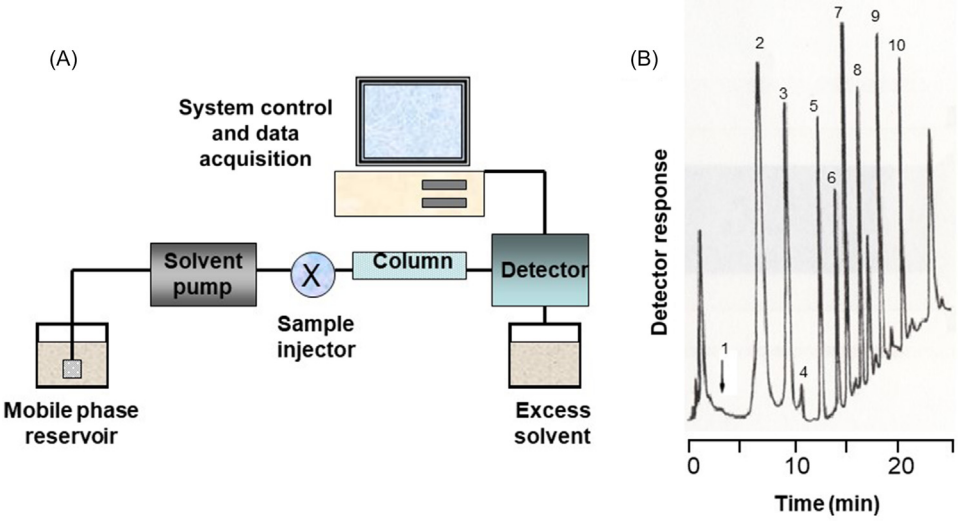

FIGURE 8.3 (A) A system for performing high-performance liquid chromatography and (B) a typical separation performed by high-performance liquid chromatography, using the analysis of basic drugs (peaks 1−10) in blood as an example. *The chromatogram in (B) is reproduced with permission from W.E. Lambert, D. Meyer, A.P. De Leenheer, Systematic toxicological analysis of basic drugs by gradient elution of an alumina-based HPLC packing material under alkaline conditions, J. Anal. Toxicol. 19 (1995) 73 [9]; courtesy Oxford University Press.*

system is known as a "liquid chromatograph," which includes a support and stationary phase enclosed in a column and a liquid mobile phase that is delivered to the column by means of a pump. An injection device is used to apply samples to the column, and a detector is usually present to detect and measure analytes as they leave the column.

Although LC and GC have many things in common, they also have some differences in terms of their sample and analyte requirements, their formats, and the role played by the mobile phase in these methods. The first requirement that must be met before a chemical can be examined by LC is that it must be possible to place this chemical into a liquid that can be injected into the mobile phase. This is a much less stringent requirement than the one presented in GC, where analytes must be naturally volatile or convertible to a volatile form. This feature makes LC valuable in separating many large biological compounds (e.g., proteins, peptides, and nucleic acids) that cannot be easily placed into the gas phase. The use of a liquid as the mobile phase also allows LC to be performed at much lower temperatures than GC, making it better suited for compounds that are thermally unstable.

A second requirement in LC is that there must be a difference in retention between the analytes to be separated. Although retention is altered in GC by adjusting the temperature and type of stationary phase within the column, retention in LC can also be varied by changing the mobile phase due to the higher density of liquids compared with gases. As a result, solute retention in LC depends on the interactions of sample components with both the mobile phase and the stationary phase, making LC more flexible than GC when optimizing a separation.

One disadvantage of LC is it tends to have greater band-broadening than GC. This greater band-broadening is due to the much slower diffusion coefficients of solutes in liquids versus gases. Thus, if it is possible to separate a series of chemicals by either LC or GC, GC is often the better choice, because it will provide narrower peaks and better separations. However, as discussed previously, the use of GC requires that the analytes be volatile or capable of being converted into a volatile derivative, which is not needed in LC. The greater density and viscosity of liquids compared with gases means that higher pressures are needed in LC than in GC to deliver mobile phase to the column. As a result, columns in LC are often much shorter than those used in GC, which also tends to make the number of theoretical plates lower for LC columns than for GC columns.

One result of the greater band-broadening and shorter columns in LC is that more emphasis is placed on obtaining more efficient supports with less band-broadening. Prior to the mid-1960s all LC columns contained supports made of relatively large and irregularly shaped particles. The use of such supports created broad peaks and separations with low resolution. This approach is sometimes called "classical LC" and is still commonly used for sample pretreatment because of its low cost and ease of use. However, a shift then occurred in LC toward the use of smaller and more uniform and rigid supports. This shift led to a technique known as high-performance liquid chromatography (HPLC). The presence of a more efficient support in this method produces narrower peaks, which in turn gives rise to better separations and lower limits of detection. These features make HPLC the current LC method of choice for clinical analysis. One consequence of using smaller support particles in HPLC is the need for greater pressures to pass the mobile phase through the column. Most modern HPLC columns require operating pressures of a few hundred to a few thousand pounds per square inch. This calls for special pumps and other system components that can be operated at such pressures (see Fig. 8.3). The sample in HPLC analysis is applied by using a closed system (e.g., an injection valve), and detection is typically performed by using an on-line detector.

Liquid chromatography mobile phases and elution methods

An important difference between LC and GC is that the retention of solutes in LC depends on interactions involving both the mobile and stationary phases. To describe how solutes are retained on an LC column in the presence of a given liquid, the terms "weak mobile phase" and "strong mobile phase" are used. A strong mobile phase is a solvent or a solution that quickly elutes a solute from a column. This situation occurs when the mobile phase is very similar to the stationary phase in the types of interactions that each can have with solutes. A weak mobile phase is a solvent or solution that elutes solutes slowly from a column, which occurs if the mobile phase is very different from the stationary phase in its interactions with solutes. It is important to note that whether a liquid is a weak or strong mobile phase will depend on the type of stationary phase in the column. For instance, a nonpolar solvent (such as hexane) will be a weak mobile phase on a polar stationary phase but a strong mobile phase for a nonpolar stationary phase. Thus it is the stationary phase that determines what liquids are strong or weak mobile phases for a given LC column.

Analytes can be eluted from an LC column by using either constant conditions or by using gradient elution. If a constant mobile phase composition is used for elution, this technique is referred to as "isocratic elution." Although this type of elution is simple and inexpensive, it does make it difficult to elute all solutes with good

resolution and in a reasonable amount of time. An alternative approach is to change the composition of the mobile phase with time. This approach is known as "solvent programming." This method is conducted by starting with a weak mobile phase, which allows early eluting solutes to be more strongly retained by the column. A switch is then made to a stronger mobile phase to allow highly retained solutes to come out in a reasonable amount of time. Solvent programming can be performed in one or more steps and by using a linear or nonlinear change in the mobile phase content, with linear gradients between two solvents being the most common method.

Temperature programming can also be used in LC, but it is much less common here than in GC. Temperature programming does improve resolution in some types of LC, such as size-exclusion chromatography (SEC) and ion-exchange chromatography (IEC). However, this method gives only marginal improvements in other types of LC and can cause degradation for some solutes. Flow programming can be used in LC as well. Advantages of flow programming include its ability to more quickly get the LC system ready for the next injection than solvent or temperature programming. A disadvantage of using flow programming in LC is the increased pressure across the column that occurs with an increase in flow-rate.

Types of liquid chromatography

Adsorption chromatography

A common way of grouping LC techniques is according to the mechanisms by which they separate solutes. The first of these is adsorption chromatography, which is a chromatographic technique that separates solutes based on their adsorption to the surface of a support. This method is also known as LSC. This technique is similar to GSC in that it uses the same material as both the stationary phase and the support. In fact, many of the supports used in GSC are also used in LSC.

The solid supports used in adsorption chromatography may be either polar or nonpolar in nature. Silica is the most popular support for adsorption chromatography and is a polar material with slightly acidic properties. Because silica is polar in nature, it will have the highest retention for polar compounds and will have a strong mobile phase that is polar in nature. Alumina is another popular support employed in adsorption chromatography. It is also polar and has the highest retention for polar compounds. Charcoal is also sometimes used as a support in adsorption chromatography. Unlike silica or alumina, charcoal is nonpolar and most strongly retains nonpolar solutes. The strong mobile phase on a charcoal column will also be nonpolar.

Adsorption chromatography is particularly useful in separating compounds with polar groups but that are soluble in nonpolar solvents; examples include steroids such as estrogens and testosterone. This method is also valuable in the separation of geometrical isomers and structurally similar chemicals. There are, however, problems in the use of adsorption chromatography. These problems include the heterogeneous nature of the surface on silica or alumina and the ability of these surfaces to act as catalysts for some chemical reactions. These supports can also give rise to nonreproducible retention for polar compounds and require the use of good quality solvents to give consistent mobile phase strengths.

Partition chromatography

The second major type of LC is partition chromatography. This is a chromatographic technique in which solutes are separated based on their partitioning between a liquid mobile phase and a stationary phase coated on a solid support. The support used in partition chromatography is usually silica but can also be other materials. Originally, partition chromatography involved coating the support with a liquid stationary phase that was immiscible with the mobile phase. However, most modern columns for partition chromatography employ stationary phases that are chemically bonded to the support.

There are two main types of partition chromatography. The first of these is normal-phase chromatography [also called "normal-phase liquid chromatography" (NPLC)], which is a type of LC in which the stationary phase is polar. These stationary phases contain polar regions based on cyano, amino, or diol groups that can form hydrogen bonds or undergo dipole interactions with solutes. Because NPLC has a polar stationary phase, it has the strongest retention for polar compounds. However, it may also be used for separating nonpolar compounds. The weak mobile phase in NPLC is a nonpolar liquid, such as an organic solvent, which is used as the injection solvent. A strong mobile phase is a polar liquid, such as water or methanol.

Reversed-phase chromatography [also known as "reversed-phase liquid chromatography" (RPLC)] is the second type of partition chromatography. It uses a nonpolar stationary phase, which is opposite or "reversed" in polarity from that utilized in normal-phase chromatography. This stationary phase usually consists of an alkane like an octyl group (C_8) or octadecyl group (C_{18}). RPLC is currently the most popular type of LC. The main reason for its popularity is that its weak mobile phase is a polar solvent, such as water. This feature makes RPLC ideal for the injection and separation of solutes in aqueous-based systems, such as drugs in clinical samples.

NPLC has similar applications to adsorption chromatography performed with silica or alumina supports. These applications typically involve the use of NPLC for separating chemicals in organic solvents and that contain polar functional groups. Examples include steroids, pesticides, terpenoids, nonionic detergents, sugars, and metal complexes. RPLC is used to separate a broad range of substances in aqueous samples, including its use for both small molecules (such as drugs) and macromolecules (such as proteins).

Another type of partition chromatography is hydrophilic interaction liquid chromatography (HILIC). Like NPLC, HILIC uses a polar stationary phase. However, in HILIC, the components of a sample now distribute between an organic-rich region in the mobile phase and a more polar water-enriched layer located at or near the surface of the support. The polar groups on the support's surface, which can be neutral or charged, may also interact with chemicals as they enter the water-enriched layer on the support. HILIC has been of particular interest for the analysis of polar compounds in fields such as proteomics and glycomics.

Ion-exchange chromatography

Another major type of LC is IEC. This is a chromatographic technique in which solutes are separated by their adsorption onto a support containing fixed charges on its surface. IEC is a fairly common technique used for the removal or replacement of ionic compounds in samples. It is also used for the separation and analysis of charged compounds, including inorganic ions, organic ions, and biological compounds, such as amino acids, proteins, and nucleic acids.

There are two types of stationary phases used in IEC. The first type is a cation-exchanger, which has a negatively charged group and is used to separate positively charged ions. The second type is an anion-exchanger, which has a positively charged group and is used to separate negatively charged ions. These two types of stationary phases are used in the methods of cation-exchange chromatography and anion-exchange chromatography, respectively. There are several types of stationary phases used in these methods. For cation-exchange chromatography, the charged groups consist of either: (1) the conjugate base of a strong acid (e.g., a sulfonic acid group), which is ionized over a broad pH range; or (2) the conjugate base of a weak acid (e.g., a carboxylate group), which has a net charge over a moderate pH range that is above the pK_a of the weak acid. For anion-exchange chromatography, the stationary phase is either: (1) the conjugate acid of a strong base (e.g., a quaternary amine), which is ionized over a broad pH range; or (2) the conjugate acid of a weak base (e.g., a tertiary amine), which has a net charge over a moderate pH range that is below the pK_a of its conjugate acid.

Several supports can be used with these cation- or anion-exchange groups. One common support used in IEC for small inorganic and organic ions is polystyrene. Carbohydrate-based gels are another common type of support used in IEC. Examples of these include agarose, cross-linked dextran, and cellulose gels. Silica can also be used as a support in IEC. Each of these supports is modified prior to placing appropriate charged groups on their surface. The high efficiencies and rigid structure of silica make it useful for HPLC-based IEC. The main limitation of silica in these applications is the narrower range of pH values over which it is stable compared with polystyrene- or carbohydrate-based supports.

A strong mobile phase in IEC is a solution with a high concentration of competing ions. A change in ion concentration is the most common way of altering the retention of sample ions in IEC. However, the retention of charged analytes will also be affected by the type of competing ion, the type of ion-exchange site being used and the mobile phase pH, the latter of which can alter the charge on some analytes, competing ions, or ion-exchange sites. Adding a complexing agent to the mobile phase can also affect the charge of an analyte and alter its retention. For instance, complexation of the cation Fe^{+3} with excess Cl^- can be used to form a negatively charged $FeCl_4^-$ complex, which can then be retained and analyzed by anion-exchange chromatography.

As a preparative tool, IEC has been used for many years in biochemistry for purifying proteins, peptides, and nucleotides. Ion-exchange supports are also frequently employed for concentrating small inorganic and organic ions from food and environmental samples. In addition, IEC has been used for many years for direct chemical analysis. One common example in clinical chemistry is the use of IEC to separate amino acids and amines to look for metabolic disorders in patients, as illustrated in Fig. 8.4.

The use of a high concentration of competing ions makes it difficult to detect cations or anions as they leave ion-exchange columns. A way to overcome this problem is to use a special type of IEC known as "ion chromatography" (IC). In this method, the background signal due to competing ions is reduced by using a low number of charged sites for the stationary phase. The result is that a lower concentration of competing ions will be needed to elute sample ions. This method is often used with a second column or membrane separator (of opposite charge to the first ion-exchange column), in which competing ions that have high conductivity are replaced with chemicals or ions that have lower conductivity. The result is a lower signal due to the competing ions, providing better limits of detection for analyte ions.

Sato, Simultaneous determination of urinary creatinine and UV-absorbing amino acids using a novel low-capacity cation-exchange chromatography for the screening of inborn errors of metabolism, J. Chromatogr. B 816 (2005) 333 [10]; courtesy Elsevier.*

Size-exclusion chromatography

The fourth general type of LC is size-exclusion chromatography (SEC). This is a liquid chromatographic technique that separates substances according to their size. This technique is based on the different ability of analytes to access mobile phase within the pores of a support. No true stationary phase is present in this system. Instead, the mobile phase in the pores acts as the stationary phase. SEC uses a support that has a certain range of pore sizes. As solutes travel through this support, small molecules can enter the pores while large molecules cannot. Larger molecules can enter a smaller volume of the column, so they elute before smaller molecules. The result is a separation based on size or mass.

The ideal support in SEC consists of a porous material that does not interact directly with the injected solute. Carbohydrate-based supports like dextran and agarose can be used in SEC for biological compounds and aqueous-based samples. Polyacrylamide gel can also be employed for such samples. Similarly, polystyrene can be used for SEC when working with samples in organic solvents, and silica containing a diol-bonded phase can be utilized with aqueous samples.

The mobile phase in SEC can be either a polar or nonpolar solvent. Because there is no true stationary phase, there is also no weak or strong mobile phase in this method. Instead, the selection of mobile phase depends mostly on the solubility of the analytes and the support's stability. If an aqueous mobile phase is used in SEC, the technique is called "gel filtration chromatography." If an organic mobile phase is used, the technique is known as "gel permeation chromatography." As a preparative tool, SEC is often used with biological samples to remove small solutes from large agents like proteins. It can also be used to transfer large analytes from one solution to another or to remove salts from a sample. This approach can further be used to estimate the molecular weight of an analyte like a protein by comparing the retention of such an analyte to that of similar standard compounds with known masses.

Affinity chromatography

The fifth type of LC is affinity chromatography (AC). This method is based on biologically related interactions, like the binding of an enzyme with its substrate, or the binding of an antibody with an antigen. These reactions are used in AC by immobilizing one of a pair of interacting molecules onto a solid support and placing it into a column. This immobilized molecule is known as the "affinity ligand," and it is this agent that acts as the stationary phase in this method. The column containing the immobilized ligand can then be employed as a selective adsorbent for the complementary molecule.

The sample in AC is often applied to the column in the presence of an application buffer during an adsorption step. Because of the strong and selective nature of most biological interactions, the affinity ligand will bind to the analyte of interest during this step while allowing most other sample components to pass through as a nonretained peak. After these nonretained components have been washed from the column, an elution buffer is applied to release the retained analyte. This analyte is then detected as it leaves the column or collected for later use. The column and affinity ligand are then placed back into the application buffer, allowing them to be regenerated prior to injection of the next sample.

There are several types of ligands employed in AC, but all can be classified into one of two categories: (1) high-specificity ligands and (2) general (group-specific) ligands. High-specificity ligands are compounds that bind to only one or a few very closely related molecules. Examples include antibodies for binding to foreign agents (i.e., antigens) and single-stranded nucleic acids for separating and binding to complementary strands. General, or group-specific, ligands are molecules that bind to a family or class of related molecules. Examples of these include boronates for binding compounds with diol groups, and lectins for retaining compounds that have carbohydrate groups.

Several types of supports are utilized in AC. Carbohydrate gels like agarose or cellulose are commonly

used with affinity ligands for the purification of biological molecules. Silica can also be used by first converting this support into a diol-bonded form. The affinity ligand is then attached to these supports by using an immobilization method. This process usually involves coupling the affinity ligand to the support through amine, carboxyl, or sulfhydryl groups. If appropriate immobilization conditions are not used, the ligand may be denatured or attached in a way that blocks its binding to the analyte. For the immobilization of small molecules, placement of a spacer arm between the ligand and the support may be necessary to reduce steric hindrance in the binding of larger molecules to this ligand.

A weak mobile phase in AC is one that allows strong binding between the analyte and the ligand. This weak mobile phase is usually a solvent that mimics the pH, ionic strength, and polarity of the affinity ligand in its natural environment. This mobile phase is known as the "application buffer." It is this solvent that is typically used during the application, washing, and regeneration steps. A strong mobile phase in AC is a solvent that can readily remove the analyte from the ligand. This is called the "elution buffer." This strong mobile phase is selected to either lower the association equilibrium constant for the analyte−ligand interaction or to displace the analyte from the affinity ligand through the use of a competing agent.

AC is frequently used as a large-scale purification method for enzymes and proteins. This application involves the use of columns that contain immobilized agents that can selectivity bind to and retain such substances in the presence of other sample components. However, AC is also commonly used as a method for sample preparation. Examples include the use of affinity columns containing antibodies for the isolation of cellular proteins or the use of immobilized metal ions to isolate recombinant proteins containing histidine tags as part of their structure. The selectivity of AC has also made it appealing for use in the direct analysis of complex biological samples. One example is the use of boronate affinity columns in the measurement of glycated hemoglobin, an indicator of long-term blood sugar levels in diabetes. Affinity columns have also been used with HPLC for the measurement of hormones, proteins, drugs, and other agents in clinical and biological samples.

Liquid chromatography detectors

As shown in Table 8.3, there are several types of detectors available for LC. These can again be classified as either general or selective detectors. An absorbance detector is an example of a general detector for LC. This type of device is similar to those used for other absorbance measurements but includes a special sample cell (known as a "flow cell"), which allows the mobile phase and analytes to pass through in a continuous manner. The simplest type of absorbance detector for LC is a fixed-wavelength absorbance detector. This device is set to always monitor a specific wavelength (usually 254 nm). A variable-wavelength absorbance detector has a more flexible design and allows the monitored wavelength to be varied over a wide range (e.g., 190−900 nm). A third design is a photodiode array detector, which uses an array of small detector cells to measure the change in absorbance at many wavelengths simultaneously. This array makes it possible to record an entire spectrum for an eluting compound. Absorbance detectors can detect any compound that absorbs light at the wavelength(s) monitored. They can also be used with gradient elution, provided that the weak and strong mobile phases do not have significant

TABLE 8.3 Common detectors for liquid chromatography.

Detector name	Compounds detected	Detection limit[a]
Refractive index detector	General: all compounds	0.1−1 μg
UV−vis absorbance detector	Compounds with chromophores	0.1−1 ng
Evaporative light scattering detector	Nonvolatile compounds	0.1 μg
Fluorescence detector	Fluorescent compounds	1−10 pg
Conductivity detector	Ionic compounds	0.5−1 ng
Electrochemical detector	Electrochemically active compounds	0.01−1 ng
Mass spectrometry	General: full-scan mode	0.1−1 ng
	Selective: SIM mode	

SIM, Selected ion monitoring.
[a]*This information is from Poole and Poole [2] and manufacturers of these detectors.*

differences in their absorbances at the detection wavelengths. The main disadvantage of these devices is they require a compound to have a chromophore that can absorb at the wavelengths being monitored or that can be derivatized into a form that does absorb.

A refractive index (RI) detector is one of the most universal detectors available for LC. This detector measures the ability of the mobile phase and analytes to refract or bend light. This property varies as the composition of the mobile phase changes, such as when analytes elute from a column. An RI detector will respond to any compound that has a different RI from the mobile phase, provided that enough solute is present to give a measurable signal. This property makes an RI detector useful in work where an analyte cannot be easily measured by other devices or where the nature or properties of an analyte are not yet known. However, an RI detector does not have limits of detection as low as absorbance detectors or other LC detectors. In addition, its signal is sensitive to changes in the mobile phase composition and temperature, making it difficult to use with gradient elution.

A third type of general detector for LC is an evaporative light scattering detector (ELSD). This device can be used for any solute that is less volatile than the mobile phase and detects analytes by first converting the eluting mobile phase into a spray of small droplets. As the solvent in these droplets evaporates, small particles of the nonvolatile sample components are left behind that can scatter light. The extent of this scattering will depend on the number and size of these particles and the original concentration of nonvolatile solutes in the mobile phase. An ELSD has a better limit of detection than an RI detector and can be used with gradient elution. Although absorbance detectors have better limits of detection, an ELSD does not require that a chromophore be present in the analyte. This feature gives an ELSD the ability to examine substances that cannot be easily detected based on their absorbance, such as lipids and carbohydrates.

An example of a selective detector for LC is a fluorescence detector. This device measures the ability of solutes to absorb and emit light at a particular set of wavelengths. Fluorescence can also be used to detect compounds that are first converted to a fluorescent derivative, as is often used for analytes such as alcohols, amines, amino acids, and proteins. Although fluorescence detectors can be used with gradient elution, extremely pure mobile phases must be employed, because even trace impurities can affect the background signal or quench the fluorescence of solutes.

A conductivity detector can monitor ionic compounds in LC. This detector measures the ability of the mobile phase and its contents to conduct a current when placed in an electrical field. Conductivity detectors can be used to detect any compound that is ionic, making them useful in IC. This device can be used with gradient elution as long as the ionic strength (and possibly pH) of the mobile phase is kept constant. It is also necessary that the background conductance of the mobile phase be sufficiently low so that sample ions can be detected.

An electrochemical detector is another device used to monitor specific compounds in LC. This combination is known as "LC/electrochemical detection" (LC/EC). An electrochemical detector can be used to measure the ability of an analyte to undergo either oxidation or reduction. Examples of compounds that may be detected by reduction in such a detector include aldehydes, ketones, esters, unsaturated compounds, and aromatics. Compounds that may be detected by their oxidation include phenols, mercaptans, aromatic amines, diamines, purines, and dihydroxy compounds, such as some carbohydrates. The response of an electrochemical detector depends on the extent of oxidation or reduction that occurs at the given potential of the electrode. For such compounds, the limit of detection can be quite low due to the accuracy with which electrical measurements (especially current) can be made.

Another type of detector that can be employed in LC is a mass spectrometer. The result is a technique known as "liquid chromatography/mass spectrometry" (LC/MS). The use of mass spectrometry with LC can be used to both measure the amount of a chemical and identify this chemical based on its molecular ion and/or fragment ions. By looking at all ions that are produced in the mass spectrometer (i.e., the full-scan mode), LC/MS can be used as a general detection method. If LC/MS is instead used to look at a few ion characteristics of a particular set of analytes (i.e., the SIM mode), this approach can also be used for selective detection.

The most common way of performing LC/MS is to use electrospray ionization (ESI). This combination can examine substances ranging from small polar compounds to proteins. It can also be utilized with gradient elution methods. The use of LC/MS with ESI is particularly useful in the analysis of proteins and peptides, which tend to give ions with mass-to-charge ratios that are outside the range of most common mass analyzers. In ESI, this problem is overcome by the fact that many charges are often placed on one biomolecule, giving ions with lower mass-to-charge ratios. One difficulty associated with this process is that a single protein or peptide can give rise to many molecular ions. However, this issue can be addressed by using computer programs that are designed to analyze such spectra and determine the true molecular masses from such information.

Introduction to electrophoresis

General terms and concepts

Another separation method often used in clinical testing is electrophoresis [11]. This is a technique in which

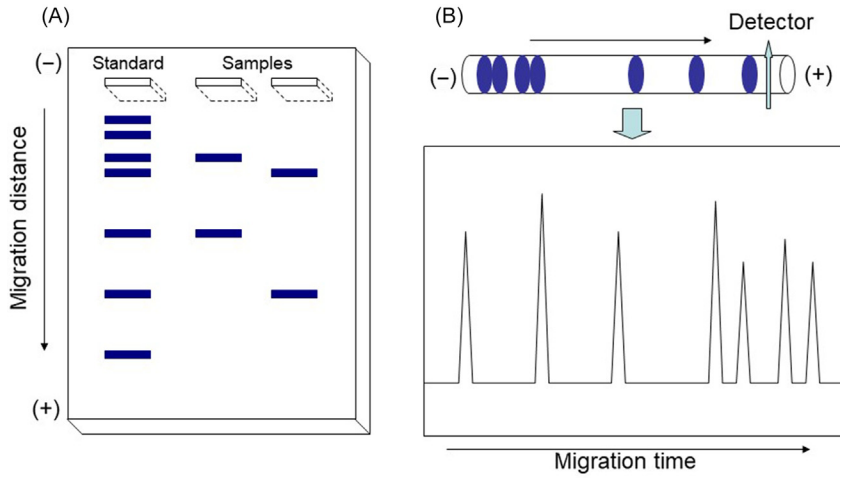

FIGURE 8.5 General scheme for the separation of chemicals by (A) gel electrophoresis and (B) capillary electrophoresis.

solutes are separated by their different rates of migration in an electric field. This concept is illustrated in Fig. 8.5, in which a sample is first placed in a container or support that also contains a background electrolyte (or "running buffer"). When an electric field is applied to this system, ions in the running buffer will flow from one electrode to the other and provide the current needed to maintain the applied voltage. At the same time, positively charged ions in the sample will move toward the negative electrode (the cathode), while negatively charged ions will move toward the positive electrode (the anode). The result is a separation of these ions based on their charge and size. Many biological compounds have charges or ionizable groups (e.g., DNA and proteins), which makes electrophoresis a common tool in clinical laboratories and medical research.

Electrophoresis can be performed in a variety of formats. One way is to apply small amounts of a sample to a support (usually a gel) and allow analytes to travel in a running buffer through the support when an electric field is applied. This approach is known as "gel electrophoresis." It is also possible to separate the components of a sample in a narrow capillary filled with a running buffer and placed into an electric field. This second method is called "capillary electrophoresis" (CE).

Depending on the type of electrophoresis being performed, the result of the separation can be viewed in one of two ways. In the case of gel electrophoresis, the separation is stopped before the analytes have traveled off the support. The result is a series of bands in which the migration distance characterizes the extent these substances have interacted with the electric field. Because the migration distance of an analyte through an electrophoresis gel will depend on the exact voltage and time used for the separation, it is common to include standard samples on the support to help in analyte identification. The intensities of the resulting bands are then used to measure the amounts of analytes in the sample.

In CE, all analytes travel the same distance, from the point of injection to the opposite end, where a detector is located. However, the analytes now differ in the time it takes to travel this distance. In this case, it is the migration time for each analyte that is measured and recorded. The resulting plot of detector response versus migration time is called an "electropherogram." This migration time is used for analyte identification, while the peak height or peak area is utilized for measurement. An internal standard is usually injected along with the sample to correct for variations during injection or for small fluctuations in the experimental conditions during the separation.

Theory of electrophoresis

The separation of analytes by electrophoresis requires two items. First, there must be a difference in how the analytes will interact with the electric field. This requirement means the analytes must have a difference in their migration times or migration distances. The second requirement is that the bands or peaks for the analytes must be sufficiently narrow to allow them to be resolved.

The overall rate of travel of a charged solute in electrophoresis will depend on two opposing forces. The first of these is the attraction of a charged solute toward the electrode of opposite charge. This force depends on the strength of the applied electric field (E) and the charge on the solute (z). However, the solute will also experience resistance to its movement by the surrounding medium. The force of this resistance depends on the size of the solute (as described by the solvated radius r), the viscosity of the medium (η), and the velocity of the solute (v). When an electric field is applied, a solute will accelerate toward the electrode of opposite charge until these two

opposing forces become equal in size but opposite in direction. At this point, a steady-state situation is produced in which the solute moves at a constant velocity, as given by Eq. (8.9).

$$v = \frac{(Ez)}{(6\pi r\eta)} \tag{8.9}$$

To see how this velocity will be affected by only the strength of the electric field, other terms in Eq. (8.9) can be combined to give a single constant (μ),

$$v = \mu E \tag{8.10}$$

where $\mu = z/(6\pi r\eta)$. This combination of terms is known as the "electrophoretic mobility." The value of μ is constant for a given analyte under a particular set of temperature and solvent conditions. However, this value will depend on the apparent size and charge of the solute, as represented by the ratio z/r in Eq. (8.9). As a result, any two solutes with different charge-to-size ratios can, in theory, be separated by electrophoresis.

It is also possible to have movement of the running buffer in an electric field. This movement can occur if there are any fixed charges present within the system, such as on the surface of a support. The presence of these fixed charges attracts ions of opposite charge from the running buffer and creates an electrical double layer at the support's surface. In the presence of an electric field, this double layer acts like a piston that causes a net movement of the buffer toward the electrode of opposite charge to the fixed ionic groups. This process is known as "electroosmosis" and results in a net flow of the buffer within the system.

The extent to which electroosmosis affects the buffer and analytes in electrophoresis is described by the electroosmotic mobility (μ_{eo}). This term depends on such things as the size of the electric field, the type of running buffer, and the charge on the support. Depending on the direction of buffer flow, electroosmosis can work either with or against the natural migration of an analyte through the electrophoretic system. The overall observed electrophoretic mobility (μ_{Net}) for an analyte will equal the sum of its own electrophoretic mobility (μ) and the mobility of the running buffer due to electroosmotic flow (μ_{eo}).

$$\mu_{Net} = \mu + \mu_{eo} \tag{8.11}$$

In gel electrophoresis, electroosmotic flow is usually small compared with the inherent rate of analyte migration. However, this is not usually the case in CE, where the support has a relatively large charge and high surface area compared with the volume of running buffer.

The same terms used to describe band-broadening in chromatography (e.g., the number of theoretical plates N and the height equivalent of a theoretical plate H) can be used in electrophoresis. However, chromatography and electrophoresis differ in which processes are most important in producing this band-broadening. For instance, one important band-broadening process in many types of electrophoresis is *Joule heating*. This is heating that occurs whenever an electric field is applied to the system. According to *Ohm's law*, placing a voltage V across a medium with a resistance of R requires that a current of I be present to maintain this voltage.

$$V = IR \tag{8.12}$$

However, as current flows through the system, heat is generated. This heat production depends on the voltage, current, and time t that current passes through the system, as shown below.

$$\text{Heat} = VIt \tag{8.13}$$

As heat is produced, the temperature of the electrophoretic system will begin to rise and increase the rate of diffusion. In addition, if the heat is not distributed uniformly, the temperature will not be the same throughout the system. This effect leads to regions with different densities, which causes mixing and results in even more band-broadening.

One way Joule heating can be decreased is by using a lower voltage for the separation. However, using a lower voltage will also lower the migration velocities of analytes and give longer separation times. An alternative approach is to use more efficient cooling, which allows higher voltages to be employed and provides shorter separation times. A third possibility is to add a support to minimize the effects of uneven heat distribution and density gradients in the running buffer. Another factor that affects Joule heating is the ionic strength of the running buffer, where a lower ionic strength buffer will decrease heat production.

Wick flow is a source of band-broadening that occurs in gel electrophoresis. In such a system, the gel is kept in contact with the electrodes and buffer reservoirs through the use of wicks. The gel is often open to air, which means Joule heating will cause evaporation of solvent in the running buffer at the surface of this support. As this solvent is lost, it is replenished by the flow of more solvent through the wick and from the buffer reservoir. This process leads to a net movement of buffer toward the center of the support. Because the rate of this flow depends on the rate of evaporation, it increases with high voltages and high currents.

Gel electrophoresis

General terms and concepts

One of the most common types of electrophoresis is the method of gel electrophoresis. This is an electrophoretic method that is performed by applying a sample to a gel

support that is then placed into an electric field. In this type of system, several samples are usually applied to the gel and allowed to migrate in the presence of an electric field. The separation is stopped before analytes leave the gel, with the location and intensities of their bands then being determined.

Supports and sample application in gel electrophoresis

A system for performing gel electrophoresis may involve a support held in either a vertical or horizontal position. The type of support used will depend on the analytes and samples being examined. Cellulose acetate and filter paper are valuable for work with small molecules like amino acids and nucleotides. Starch is also sometimes used as a support in electrophoresis. However, a more common support is agarose. In addition to its low nonspecific binding for many biological compounds and its low inherent charge, agarose gels have relatively large pores. This property makes agarose useful in dealing with large molecules like DNA, as occurs in DNA sequencing.

Probably, the most common support used in gel electrophoresis is polyacrylamide. This combination is often referred to as "polyacrylamide gel electrophoresis" (PAGE). Polyacrylamide is a synthetic polymer that can be made with a variety of pore sizes. These pores are generally smaller than those in agarose and of a size more suitable for the separation of proteins and peptide mixtures. Like agarose, polyacrylamide has low nonspecific binding for many biological compounds and does not have any inherent charged groups in its structure.

The samples in gel electrophoresis are applied by a micropipette to small wells that are made in the gel during its preparation. This process usually involves applying sample volumes in the range of 10−100 μL. These sample volumes help provide a sufficient amount of analytes for later detection and collection. However, there is also a danger of introducing band-broadening by creating a large sample band at the beginning of the separation. A common approach to create narrow sample bands is to employ two types of gels in the system: a stacking gel and a running gel. The stacking gel has a low degree of cross-linking (giving it large pores) and is located in the section of the support in which the sample wells are located. The running gel has a higher degree of cross-linking (i.e., smaller pores) and is used during the actual separation of analytes. After a sample has been placed in the wells in the stacking gel, analytes will travel quickly through this medium until they reach its boundary with the running gel. These substances will then travel much more slowly, allowing other parts of the sample to catch up and form a narrower, more concentrated band that can then be separated into its components as they travel through the running gel.

Detection in gel electrophoresis

There are several ways in which analytes can be detected in gel electrophoresis. This detection is performed after the analytes have been separated either by looking at their location on the gel or by transferring these substances to a different support for detection. In some cases, it is possible to perform direct detection of analytes on a gel. Direct detection can sometimes be conducted visually when dealing with intensely colored proteins, like hemoglobin, or by using absorbance measurements and a scanning device called a densitometer. However, direct detection requires that an analyte be present at a relatively high level in a sample or concentrated by a pretreatment step prior to the separation.

The most common approach for detection in gel electrophoresis is to treat the support with a stain or reagent that makes it easier to see analyte bands. Examples of stains used for proteins are Amido black, Coomassie Brilliant Blue, and Ponceau S. Silver nitrate, giving rise to a method known as "silver staining," is also used when looking at low concentration proteins. DNA bands are often detected by using ethidium bromide. When separating enzymes, the natural catalytic ability of these substances can be used for their detection (e.g., detecting production of the fluorescent compound NAD(P)H by enzymes that generate this substance in their reactions). Sometimes biological ligands are used to react with analytes on a gel for detection. This approach is used in rocket immunoelectrophoresis, where antibodies are used to form precipitation bands that help identify and measure specific proteins in a sample.

A third approach for detection in gel electrophoresis is to transfer a portion of the analyte bands to a second support (e.g., nitrocelluose), where they are reacted with a labeled agent. This approach is known as "blotting." There are several different types of blotting methods. A Southern blot is used to detect specific sequences of DNA by having these sequences bind to an added, known sequence of DNA containing a radioactive tag (^{32}P) or other easily detected label. A Northern blot is similar in format but is instead used to detect specific sequences of RNA by using a labeled DNA probe. A Western blot is used for detecting a given protein by reacting this protein with labeled antibodies that can bind to such analytes.

Special types of gel electrophoresis

Whenever there is a porous support in an electrophoretic system, it is possible that analytes may be separated by size as well as their electrophoretic mobilities. This effect

is used for proteins in a technique known as "sodium dodecyl sulfate polyacrylamide gel electrophoresis" (SDS-PAGE). In SDS-PAGE, the proteins in a sample are first denatured and their disulfide bonds are broken through the use of a reducing agent. This pretreatment converts the proteins into a set of single-stranded polypeptides. These polypeptides are then treated with sodium dodecyl sulfate (SDS). This is a surfactant with a nonpolar tail and a negatively charged sulfonic group at the other end. The nonpolar end of this surfactant coats the protein, forming a roughly linear rod with a layer of negative charges on the outside. The result for a mixture of proteins is a series of rods with different lengths but similar charge-to-mass ratios. Next, these protein rods are passed through a porous polyacryamide gel in the presence of an electric field. The negative charges on these rods from the SDS coating cause them all to move toward the positively charged electrode, while the pores of the gel cause small rods to travel more quickly than larger ones. At the end of the run, the positions of the protein bands from a sample are compared with those obtained in a protein ladder for a series of protein standards with known molecular masses and applied to the same gel, as illustrated in Fig. 8.5A. This comparison can be performed either qualitatively or by preparing a calibration curve by plotting the log of the molecular masses for the protein standards versus their migration distances.

Another type of electrophoresis that often makes use of supports is isoelectric focusing (IEF). This is a method used to separate zwitterions (i.e., substances with both acidic and basic groups) based on differences in their isoelectric points. This type of separation is accomplished by having the zwitterions migrate in an electric field across a pH gradient. In this pH gradient, each zwitterion will migrate until it reaches a region where the pH is equal to its isoelectric point (pI). Once this situation has occurred, the zwitterion will no longer have any net charge, and its electrophoretic mobility will become zero, causing the analyte to stop migrating. This results in a series of tight bands, where each band appears at the point where the pH is equal to the pI for a given analyte. IEF is useful in separating proteins with similar properties but slightly different amino acid compositions. A common example is its use in separating the isoforms of an enzyme. To obtain a separation in IEF, it is necessary to have a stable pH gradient. This pH gradient is produced by placing in the electric field a mixture of small reagent zwitterions known as "ampholytes." These are usually polyprotic amino carboxylic acids with a range of pK_a values. When these ampholytes are placed in an electric field, they will travel through the system and align in the order of their pK_a values. The result is the formation of a pH gradient. This gradient can be used directly or by first cross-linking the ampholytes to a support to keep them stationary in the system.

Another way gel electrophoresis can be utilized is in a method known as "two-dimensional electrophoresis." This is a high-resolution technique used to look at complex protein mixtures. In this method, two types of electrophoresis are performed on a single sample. The first of these separations is usually based on IEF, and the second is based on SDS-PAGE. The fact that two different characteristics of each protein are used in this separation (pI values and size) makes it possible to resolve a much larger number of proteins than is possible by either IEF or SDS alone. This method is popular in the analysis of large protein libraries, as is used for finding new disease biomarkers or in studying disease pathology.

Capillary electrophoresis

General terms and concepts

Another type of electrophoresis is the method of CE. This is a technique that separates analytes by electrophoresis that is carried out in a capillary. This method is typically conducted in capillaries with inner diameters of 20−100 μm and lengths of 20−100 cm. The use of these narrow bore capillaries allows efficient removal of Joule heating, which helps decrease band-broadening and provides much more efficient and faster separations than gel electrophoresis.

If there is no appreciable Joule heating present and no interactions between the analytes and the capillary, the main source of band-broadening in CE will be longitudinal diffusion. Under these conditions, an increase in applied voltage results in less band-broadening, because shorter times are allowed for analytes to undergo diffusion along the length of the capillary. Besides providing efficient separations, the ability to use high electric fields also reduces the time needed for a separation. This combination of good efficiency and speed has made CE of interest for the analysis of complex biological samples like urine and blood.

An example of a CE system is shown in Fig. 8.6. In addition to the capillary, this system includes a power supply and electrodes for applying the electric field, two buffer containers that supply a contact between these electrodes and the solution within the capillary, an on-line detector, and a means for injecting samples onto the capillary. Most CE instruments can supply voltages up to 25−30 kV. To prevent injury to laboratory workers, these instruments have safety features that isolate the region of high voltage from the user and that turn off this voltage when the system is opened for maintenance or for the insertion of samples and reagents.

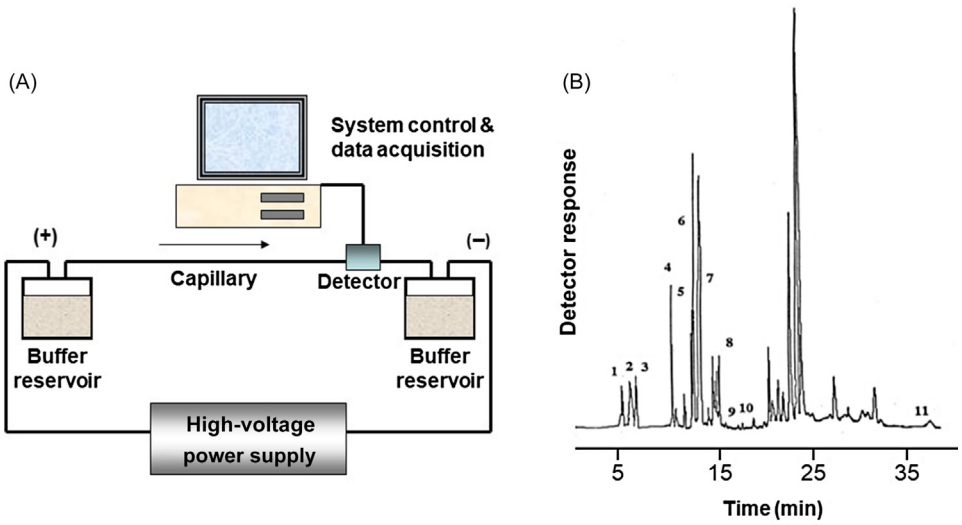

FIGURE 8.6 (A) A system for performing capillary electrophoresis and (B) a typical separation performed by capillary electrophoresis, using the analysis of biogenic amines (peaks 1–11) in urine. *The electropherogram in (B) is reproduced with permission from H. Siren, U. Karjalainen, Study of catecholamines in patient urine samples by capillary electrophoresis, J. Chromatogr. A 853 (1999) 527 [12]; courtesy Elsevier.*

Supports and sample application in capillary electrophoresis

The capillary in a CE system is usually fused silica. A fused silica capillary is often used directly, but it can also be modified to place various coatings on its interior surface. With a fused silica capillary, flow of the buffer due to electroosmosis can have a significant impact on the overall mobility of analytes. This electroosmosis is created by the negative charge present on surface of silica at a neutral or basic pH. The presence of these negatively charged groups creates an electrical double layer that causes movement of the running buffer toward the negatively charged electrode.

One useful feature of electroosmosis is it causes most analytes, regardless of their charge, to travel in the same direction through the CE capillary. This effect means that a sample containing many types of ions can often be injected at one end of the capillary (at the positively charged electrode), with electroosmosis then carrying these through to the other end (to the negatively charged electrode) and past a detector. This format is referred to as the "normal polarity mode" of CE. It is important to remember in this situation that a separation of ions will still occur but that the observed mobility will now be the sum of the inherent electrophoretic mobility for an analyte plus the mobility due to electroosmosis. The observed migration time for the analyte and the efficiency and resolution obtained for the separation are also affected.

Although many analytes will travel in the same direction as electroosmotic flow through a CE system, it is possible for some to have migration rates faster and in the opposite direction from electroosmosis. The analysis of these ions in a silica capillary is performed by injecting them by the negatively charged electrode and allowing them to migrate toward the positively charged electrode against electroosmotic flow. This format is referred to as the "reversed polarity mode" of CE. In addition, electroosmotic flow can be altered by changing the pH, which changes the charge on silica, or by placing a coating on the support surface. In this latter case, a neutral coating helps to reduce or eliminate electroosmosis while a positively charged coating will reverse the direction of this flow toward the positively charged electrode.

There are two features of CE that place special demands on how samples can be injected in this method. First, the small volume of this device must be considered. For instance, a typical 50-μm I.D. × 25-cm-long capillary for CE will contain only 0.5 μL of running buffer. This type of capillary requires the use of much smaller injection volumes to allow samples to be separated into their individual components. Another factor to consider is the high resolution of CE, which further restricts the sample sizes that can be employed. In practice, this factor generally requires the use of samples that are $<2\%$ of the capillary's internal volume, or <10 nL for a 0.5-μL volume capillary.

Sample volumes of nanoliters or less cannot be easily delivered by the types of injection valves used for LC. Thus alternative means for injection must be employed. One is hydrodynamic injection, which uses a difference in pressure to deliver a sample to the capillary. Hydrodynamic injection can be performed by placing one end of the capillary into a sample in an enclosed chamber and applying a pressure to this chamber for a fixed period of time. The amount of injected sample will depend on the size of the pressure difference and the amount of time this pressure is applied to the capillary. A similar effect occurs if a vacuum is pulled at the other end of the capillary. Once the sample has entered the capillary, the capillary is placed back into contact with the running buffer and electrodes, and the separation is begun.

Another technique frequently employed in CE is electrokinetic injection. This method again begins by placing the capillary into the sample; however, an electrode is also now placed into the sample. When an electric field is placed across the capillary, electroosmotic flow causes analytes to enter the capillary. The amount of each analyte that is injected will depend on the rate of electroosmotic flow, the analyte's inherent electrophoretic mobility, the applied electric field, and the time over which this field is applied. The capillary is then placed back into a container of the running buffer, and another electric field is applied to separate the sample components. One disadvantage to this approach is it favors the injection of analytes with electrophoretic mobilities that move them into the capillary over those that are applied only through the presence of electroosmotic flow.

Like traditional gel electrophoresis, there are various methods for concentrating samples and providing narrow analyte bands in CE. Sample stacking is one approach for accomplishing this goal and occurs when the ionic strength (and therefore the conductivity) of the sample is less than that of the running buffer. When an electric field is applied, analytes will migrate quickly through the sample matrix until they come to the boundary between the sample and the running buffer. Because the running buffer has a higher ionic strength, this situation causes the rate of migration to slow down and the analytes to concentrate as they enter the running buffer.

Detection in capillary electrophoresis

Many of the same detection techniques used for LC are also used in CE. However, one important difference between detection in LC and CE is the need in CE for methods that can work with very small sample sizes. This difference is a result of the small injection volumes that are required in CE to avoid adding excessive band-broadening. Selective detection methods that work particularly well for this purpose are electrochemical and fluorescence detection. However, UV−vis absorbance, conductance, and mass spectrometry detection are also employed.

Special types of capillary electrophoresis

One useful feature of gel electrophoresis is the ability of some supports in this method to separate analytes based on size, as occurs for proteins in SDS-PAGE. The same effect can be obtained in CE by including an agent in the CE system that sieves the analytes, or separates them based on size. There are several ways of doing this. The first way is to place a porous gel in the capillary, like the polyacrylamide gels employed in SDS-PAGE. This approach is called "capillary gel electrophoresis." However, these gels are not always stable in the high electric fields used in CE and must frequently be replaced. A second approach is to add a large polymer to the running buffer that is not immobilized but that can entangle with analytes and alter their rate of migration. This technique provides a system with better reproducibility and stability than those using gels, because the polymer is continuously renewed as the running buffer passes through the capillary.

The approach using polymers to entangle and separate analytes based on their size is often used when performing DNA sequencing by CE. The process of DNA sequencing by CE typically makes use of the Sanger method, in which the DNA template sequence to be examined is mixed with a smaller DNA primer that binds to part of this sequence. This mixture is then combined with: (1) nucleotides that contain the bases cytosine (C), guanine (G), adenine (A), or thymine (T); (2) the enzymes that are needed to add these nucleotides to the primer and extend it to match the template; and (3) small amounts of labeled nucleotides (also containing C, G, A, or T) that will stop this extension. The DNA strands that have been formed are then separated by CE based on their size, or strand length. The type of labeled nucleotide that ends each sequence is then determined and used to provide the sequence of the original template.

Ordinary CE works well for separating cations and anions, but it cannot be used to separate neutral substances, which migrate as a single peak that travels with the electroosmotic flow. However, CE can be extended to such compounds by placing in the running buffer a charged agent that can interact with these substances. One way of accomplishing this is to employ micelles as additives, giving a method known as "micellar electrokinetic chromatography." A micelle is a particle formed by the aggregation of a large number of surfactant molecules, such as SDS. As indicated earlier, SDS has a long nonpolar tail attached to a negatively charged sulfate group. When the concentration of a surfactant like SDS reaches a certain threshold level (i.e., the critical micelle concentration), some of the surfactant molecules come together to form micelles. If this situation occurs in a polar solvent like water, the nonpolar tails of the surfactant will be on the inside of the aggregate (giving a nonpolar interior), while the charged groups at the other end will be on the outside by the solvent.

When micelles based on SDS are placed into the running buffer of a CE system, they will be attracted toward the positively charged electrode. If a sample with several neutral compounds is now injected, some of these neutral substances may enter the micelles and interact with their nonpolar interior. Although these neutral compounds normally travel with electroosmotic flow through the capillary, while they are in the micelles they travel with the

micelles in the opposite direction. This effect gives a separation of neutral compounds based on the degree to which they enter the micelles. Micelles can also alter the migration times for charged substances through a combination of partitioning and charge interactions between the analytes and the micelles.

Self-assessment questions

1. Which part of a chromatographic system interacts with the components of a sample and delays the rate at which they travel through the system?
   a. the mobile phase
   b. the stationary phase
   c. the support material
   d. the detector
2. Which of the following statements is false?
   a. The retention factor is related to the retention time of a compound.
   b. The van Deemter equation shows how the retention of a compound changes with linear velocity.
   c. The resolution between two peaks will increase with their degree of retention.
   d. The retention factor is affected by the amount of stationary phase in the column.
3. Which of the following items is NOT desired for a good separation in chromatography?
   a. a large value for the number of theoretical plates, N
   b. a large value for the peak resolution, R_s
   c. a large value for the plate height, H
   d. a large value for the separation factor, α
4. What is the most common type of column used in clinical applications of GC?
   a. a packed column with a bonded stationary phase
   b. a packed column with a liquid stationary phase
   c. an open-tubular column with a bonded stationary phase
   d. an open-tubular column with a liquid stationary phase
5. A GC detector that is selective for compounds with electronegative groups is _____.
   a. a thermal conductivity detector
   b. a flame ionization detector
   c. a nitrogen−phosphorus detector
   d. an electron capture detector
6. Liquid chromatography is different from gas chromatography in that _____.
   a. it has less band-broadening
   b. it has a liquid mobile phase that affects analyte retention
   c. it requires volatile analytes
   d. it can use a gas or liquid as the mobile phase
7. Which type of liquid chromatography uses a nonpolar stationary phase?
   a. normal-phase chromatography
   b. reversed-phase chromatography
   c. ion-exchange chromatography
   d. size-exclusion chromatography
8. Which type of liquid chromatography uses a support with fixed charges to separate chemicals?
   a. reversed-phase chromatography
   b. ion-exchange chromatography
   c. size-exclusion chromatography
   d. affinity chromatography
9. Which of the following detectors might be used in LC to record an absorbance spectrum?
   a. photodiode array detector
   b. evaporative light scattering detector
   c. conductivity detector
   d. electrochemical detector
10. Separations in electrophoresis are based mainly on _____.
    a. interactions of analytes with a stationary phase
    b. the different volatilities of analytes
    c. the migration rates of analytes in an electric field
    d. the use of radioactive labels for detection
11. Which term is used to describe the pH at which a zwitterion has no net charge?
    a. electrophoretic mobility
    b. size or mass
    c. isoelectric point
    d. amino acid composition
12. Which of the following is NOT an advantage of capillary electrophoresis?
    a. It has low band-broadening due to effective removal of Joule heating.
    b. It can provide faster separations than gel electrophoresis.
    c. It can be used with large sample volumes.
    d. It can be used with an on-line detector.

Chapter 9

Electrochemistry

William Clarke[1] **and Paul D'Orazio**[2]

[1]*Department of Pathology, The Johns Hopkins University School of Medicine, Baltimore, MD, United States,* [2]*Instrumentation Laboratory, Bedford, MA, United States*

Learning objectives

After reviewing this chapter, the reader will be able to:

- List the major categories of electrochemical analysis.
- Describe the basis for ion-selective electrodes.
- Discuss the most widely used electrochemical methods in laboratory medicine.

Introduction

Electrochemistry is the area of chemistry that deals with the interconversion of chemical and electrical energy. Electrochemical methods of measurement used in clinical analysis can be divided into four major categories: potentiometry, amperometry (voltammetry), conductometry, and coulometry. In-depth fundamental reviews of these techniques can be found in textbooks dedicated to electrochemistry and electrochemical methods [1–3]. The routine use of electrochemical methods in the clinical laboratory can be traced to the introduction of modern blood gas analyzers in the 1950s [4]. During this time, Stow and Severinghaus developed the first practical sensor to measure the partial pressure of CO_2 in blood [5]; this discovery was followed closely by the development of the first pO_2 sensor by Clark to follow oxygenation of blood [6]. Electrochemical methods are advantageous because they can be adapted for sensor technologies to measure specific analytes rapidly, directly, and nondestructively in a complex sample matrix, such as whole blood. Because of this, there are several current clinical methods based on electrochemical analysis—a summary of these can be found in Table 9.1.

Potentiometric methods in clinical chemistry

Potentiometry is defined as the measurement of electrical potential (also designated electromotive force) between two electrodes when the cell current is zero. One electrode is typically designated as a reference electrode, while the second electrode is the indicator electrode (Fig. 9.1). The overall potential of a potentiometric cell is found by adding all the potential gradients that exist between different phases within the cell. It is possible to design a cell in such a way that all potential gradients (e.g., oxidation–reduction potential, membrane potential, diffusion potential) except for one are constant—the measured potential can then be related to the concentration of a specific analyte in the sample of interest. Potentiometry is by far the most utilized electrochemical method in clinical laboratories. Electrolytes and the partial pressure of carbon dioxide (pCO_2) can be measured directly in blood using potentiometric ion-selective electrodes (ISEs). At the core of the potentiometric cell shown in Fig. 9.1 is the silver–silver chloride (Ag/AgCl) electrode. The Ag/AgCl electrode is a specific type of potentiometric electrode known as a redox electrode, described briefly in the following section.

Redox electrodes

Redox potentials are the result of chemical equilibria involving transfer of electrons:

$$\text{Oxidized form(Ox)} + ne^- \leftrightarrow \text{Reduced form(Red)} \quad (9.i)$$

where n is the number of electrons involved in the reaction. The electrical potential generated by the redox couple is given by the Nernst equation:

$$E = E^o - 2.303\left(\frac{RT}{nF}\right) \times \log\left(\frac{a_{Red}}{a_{Ox}}\right) \quad (9.ii)$$

where E represents the half-cell potential, E^o the standard electrode potential when $a_{Red}/a_{Ox} = 1$, R the ideal gas constant (8.31 J K^{-1} mol^{-1}), T the absolute temperature (in Kelvin), n the number of electrons in the reaction, F the Faraday constant (96,487 coulomb/mol), and a the

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00009-0

activity. The term 2.303(R*T*/*n*F) equals 0.0592 V for a one electron transfer. The Ag/AgCl electrode is an example of a metal electrode that participates as a member of a redox couple. The Ag/AgCl electrode consists of a silver wire or rod coated with $AgCl_{(s)}$. This electrode is in contact with a solution of constant chloride activity, which sets the half-cell potential.

$$AgCl(s) + e - \leftrightarrow Ag^{\circ}(s) + Cl_{-} \qquad (9.iii)$$

and the equation governing the potential of the electrode is written as:

$$E = E^{o} - 0.0592 \times \log\left(\frac{a_{Ag} \times a_{Cl^-}}{a_{AgCl}}\right) \qquad (9.iv)$$

Since AgCl and Ag are solids, their activities are equal to 1, and the potential of the electrode is controlled by the activity of chloride ion contacting the electrode. The Ag/AgCl electrode is used both as an internal electrode in potentiometric ISEs and as a reference electrode half-cell of constant potential, required to complete a potentiometric cell (see Fig. 9.1).

TABLE 9.1 Clinical laboratory applications of electrochemical methods.

Methodology	Applications
Potentiometry	ISEs for pH, Na^+, K^+, Li^+, pCO_2 (internal element), Ca^{2+}, Mg^{2+}, and Cl^-
Amperometry	pO_2 electrode and H_2O_2 electrode (glucose biosensor internal element)
Conductometry	Measurement of hematocrit
Coulometry	Electrochemical titration of Cl^-

Ion-selective electrodes

ISEs are designed to respond selectively to one ionic species in a solution; a schematic of a potentiometric cell used to measure ion activity is shown in Fig. 9.1. The cell is composed of two half-cells: a reference electrode and an ISE. The ISE has a thin membrane that separates the sample from an internal electrolyte at constant activities for Cl^- and for the ion of interest. The potential for the entire cell (E) can be separated into several components (from Fig. 9.1):

- E_{ref} represents the potential at the internal Ag/AgCl element of the reference electrode.
- E_j represents the liquid junction potential at the interface of the concentrated electrolyte and sample.
- E_{int} represents the potential at the internal Ag/AgCl element of the ISE.
- E_{MEM} represents the potential developed across the ion-selective membrane.

The reference, internal, and liquid junction potentials can all be held constant, such that the only change in potential that occurs is across the ion-selective membrane (E_{MEM}), as a function of the activity of the ion of interest in the sample. Ion-selective membranes are typically composed of glass, crystalline, or polymeric materials, with either ion-exchange or ion-sequestering properties and high, but reversible, affinity for the ion of interest over other ions in the sample.

This electrochemical process can be described mathematically in the following manner—the potential generated across the ISE membrane consists of two potentials: one at the outer surface (E_{M1}) and one at the inner surface (E_{M2}). The membrane potential can be expressed as the difference between these two potentials:

$$E_{mem} = E_{M1} - E_{M2} \qquad (9.v)$$

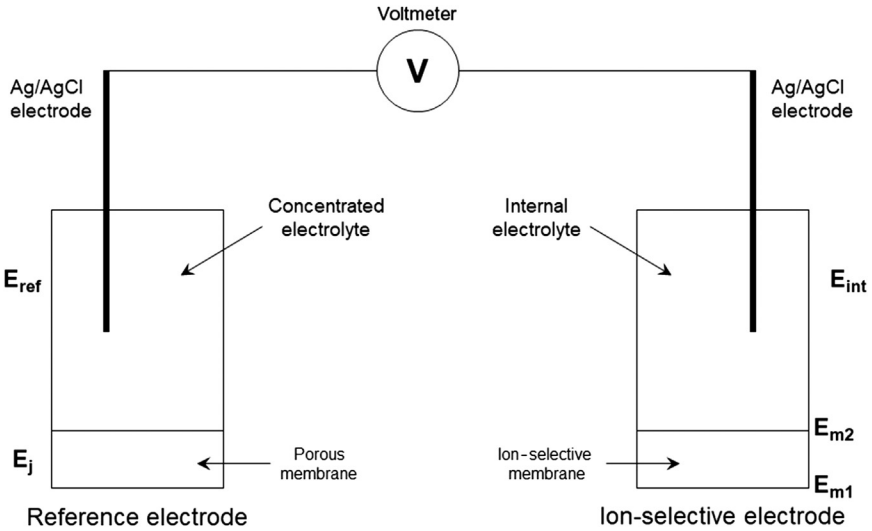

FIGURE 9.1 Schematic of a potentiometric cell using an ISE.

Both of the surface potentials are related to ion activities by Nernst-like relationships:

$$E_{M1} = j_1 - (0.0592/n) \times \log(a_1'/a_1) \quad (9.vi)$$

$$E_{M2} = j_2 - (0.0592/n) \times \log(a_2'/a_2) \quad (9.vii)$$

where j_1 and j_2 are constants, a_1 and a_2 are the activities for the ion of interest in solution, for the external and internal solutions with respect to the membrane, and n is the charge number for the ion of interest. The terms a_1' and a_2' are the ion activities *within* the membrane at the external and internal surfaces, respectively. If the two membrane surfaces have an equal number of ion-binding sites (which is typically the case), then j_1 and j_2 are identical, and so are a_1' and a_2'. By substituting Eqs. (9.vi) and (9.vii) into Eq. (9.v) and utilizing the fact that $j_1 = j_2$ and $a_1' = a_2'$, we arrive at the following equation:

$$E_{mem} = E_{M1} - E_{M2} = \left(\frac{0.0592}{n}\right) \times \log\left(\frac{a_1}{a_2}\right) \quad (9.viii)$$

This relationship shows that the membrane potential depends only on the ion activities of the solutions on either side of the membrane. However, recall that the ion activity for the internal solution is held constant, so the equation reduces to:

$$E_{mem} = E^{\circ} + \left(\frac{0.0592}{n}\right) \times \log a_1 \quad (9.ix)$$

where

$$E^{\circ} = \left(\frac{-0.0592}{n}\right) \times \log a_2 + E_{ref} + E_j + E_{int} \quad (9.x)$$

Therefore, when all other potentials in the cell are constant, the membrane potential is proportional to the ion activity in the external solution, or sample. It is important to note that this is not a potential generated directly by a redox reaction, but it is a phase boundary potential derived from transfer of the ion of interest across a concentration gradient—no oxidation or reduction reaction occurs. Sensitivity is determined by the change in potential corresponding to change in log units of activity for the ion of interest ($\Delta E/\Delta \log a$)—this corresponds to the Nernst slope (RT/nF). The theoretical value for the slope is 0.0592 V/concentration decade at 25°C for monovalent ions and 0.0296 for divalent ions.

TABLE 9.2 Ion selective electrodes in the clinical laboratory.

Electrode type	Clinical application
Glass membrane	pH (H^+) and Na^+
Ion exchange	K^+, Na^+, Cl^-, Ca^{2+}, Li^+, and Mg^{2+}
Gas sensing	pCO_2, pO_2, and pNH_3

The following are several important requirements for ISEs to be practical for the measurement of electrolytes in clinical specimens:

- Must have a Nernstian response to the ion of interest over the activity or concentration range of interest.
- Must have high selectivity for the ion of interest over other ions present in the sample.
- Must have a rapid response time.
- Must exhibit minimal drift over time.

The selectivity is dependent on analytical conditions; if the membrane has some affinity toward other ions present in the sample, then a complex diffusion potential arises that is not determined solely by the ion of interest. The Nicolsky equation [Interference section, Eq. (9.xxi)] can be used to describe the interference in terms of the activities of the ion of interest and the interfering ion.

There are three main categories of ISEs used today in clinical laboratories: glass membrane electrodes, ion-exchange or ion-sequestering electrodes based on polymer membranes, and gas-sensing electrodes; a list of clinically important electrolytes measured by ISEs can be found in Table 9.2.

Glass membrane electrodes

Glass electrodes are made from specially formulated melts of silicon dioxide with added oxides from various metals including aluminum and oxides of alkaline earth or alkali metal cations. Glass membranes range in thickness from 10 to 100 μm, and their electrical resistance is very high. Variation of the glass composition can change the selectivity of the membrane—glass electrodes for H^+, Na^+, Li^+, K^+, Rb^+, Cs^+, Ag^+, Tl^+, and NH_4^+ have been developed. However, glass electrodes for Na^+ and H^+ (pH) are the only ones with enough selectivity with respect to interfering ions to allow their use in the clinical laboratory.

Glass electrodes selective for H^+ (pH electrodes) were historically manufactured using silicon dioxide, sodium oxide, and calcium oxide in a molar ratio of 72.2:21.4:6.4 (Corning 015 glass). This glass has been shown to produce significant error for the measurement of pH when Na^+ is present at a physiological concentration and sample pH is more alkaline than 8, so other compositions have been tried and found to be more selective for H^+ ions. Presently, commercially available glass pH electrodes have sufficient selectivity for H^+ to allow error-free measurements between pH 7.0 and 8.0 in the presence of more than 0.1 mol/L Na^+. Glass electrodes can be made

selective for Na^+ by using a composition of silicon dioxide, sodium oxide, and aluminum oxide in the ratio of 71:11:18. These electrodes are insensitive to H^+ in the pH range of 6−10 [7]. Glass electrodes for pH and Na^+ are robust and require little maintenance—the main requirement being that the glass membrane requires occasional etching with a dilute solution of ammonium bifluoride to remove a stagnant layer of hydrated glass. This stagnant layer of glass can lead to a slowing of response time if allowed to build up over time.

Polymer membrane electrodes

Polymer membrane ISEs are used to measure a wide variety of clinically important ions directly in blood, including H^+, Na^+, K^+, Ca^{2+}, Cl^-, Li^+, and Mg^{2+}. There are two types of ISEs in this category: charged ion-exchanger type and ion-sequestering type based on neutral ion carriers, or ionophores. Both types typically use poly (vinyl chloride) (PVC) as a membrane matrix, an ion-exchanger or ionophore with selectivity for the ion of interest, a plasticizer to allow mobility of the ion-exchanger or ionophore within the membrane phase, and other additives in low concentration. An early ion-exchange-type ISE for Ca^{2+} used the calcium salt Ca^{2+}-bis(di-p-octylphenyl phosphate) in a PVC matrix [8]. An anion exchange-based electrode employing a lipophilic quaternary ammonium salt in PVC is still used for determination of Cl^- in blood. This type of electrode shows significant interference from ions in the sample which are more lipophilic in character than Cl^-, for example, thiocyanate and salicylate. A significant event in the development and application of polymer membrane ISEs occurred when Simon et al. discovered that the antibiotic valinomycin (Fig. 9.2) could be incorporated into a PVC membrane to yield a highly selective potassium electrode membrane [9,10]. Valinomycin is a neutral carrier (ionophore) that binds K^+ in the center of a ring of oxygen atoms. Other membranes of this type include those for NH_4^+, containing a mixture of the antibiotics nonactin and monactin, and several synthetic ionophores, for Ca^{2+}, Na^+, Li^+, and Mg^{2+} [11].

Gas-sensing electrodes

Gas electrodes are specially designed electrochemical cells for the measurement of specific gases in a gas mixture or in solution. The main examples of gas-sensing electrodes are those for carbon dioxide (CO_2) or ammonia (NH_3), both of which are based on a potentiometric pH electrode. (Electrochemical measurement of oxygen will be discussed in the next section.) Typically, a pH electrode is separated from the sample by a thin, permeable membrane (~20 μm) that only allows gases and water vapor to diffuse into the cell. The membranes can be made of polyethylene, Teflon, silicone rubber, or other microporous polymer materials. A diagram of a pCO_2 gas-sensing electrode can be seen in Fig. 9.3.

The carbon dioxide electrode is a self-contained electrochemical cell. The gas-permeable membrane is separated from the glass surface of a pH electrode by a thin layer of weakly buffered electrolyte solution, in this case a dilute sodium bicarbonate salt and a chloride salt. When placed in contact with the test solution, CO_2 diffuses through the membrane and rapidly dissolves into the electrolyte solution until equilibrium is reached. This process forms carbonic acid according to the chemical equation:

$$CO_2 + H_2O \Leftrightarrow H_2CO_3 \Leftrightarrow H^+ + HCO_3^- \qquad (9.xi)$$

and this shifts the pH of the internal electrolyte layer. The change in pH is a function of pCO_2 in solution and can be described by rearrangement of the Henderson−Hasselbalch equation:

$$pH = -s \times \log pCO_2 - \log a + pK' + \log cHCO_3^- \qquad (9.xii)$$

where s is the relative sensitivity of the electrode, a is the solubility coefficient of CO_2 (which varies with temperature), and K' is the first dissociation constant of carbonic acid. Therefore the change in pH is proportional to the change in log pCO_2. An ammonia electrode works the same way as the CO_2 electrode, except that the bicarbonate solution is replaced with an ammonium chloride solution. The measured pH of the ammonium chloride solution is linearly related to log pNH_3.

Ion-selective electrodes—units of measure and reporting for clinical application

Most analytical methods for electrolytes measure and report total ion concentration (c) usually expressed in millimoles per liter of sample (mmol/L). However, potentiometric measurements in undiluted blood, serum, or plasma (direct potentiometry) are sensitive to molality (m), millimoles of ion per mass of water in the sample (mmol/kg). The relationship between concentration and molality using the sodium ion as an example is:

$$cNa^+ = mNa^+ \times \rho H_2O \qquad (9.xiii)$$

where ρH_2O is the mass concentration of water in solution (kg/L). In aqueous solution, ρH_2O approximates 1 kg/L, while in normal plasma, ρH_2O is closer to 0.93 kg/L. In samples with elevated proteins or lipids, ρH_2O value may be as low as 0.80 kg/L. In these abnormal samples, the difference between concentration and molality may be as great as 20%, with concentration being the lower value. An advantage of direct potentiometry is that the technique is sensitive to molality and not affected by variations in the concentration of protein or lipids in the sample.

Methods that measure concentration, such as flame photometry, photometric methods, and potentiometric methods requiring sample dilution, report concentration and are affected by the level of proteins and lipids in the sample and may report falsely low electrolyte results (e.g., pseudohyponatremia) in cases of extremely elevated protein and lipid concentrations.

In addition to the difference between concentration and molality, direct potentiometry provides another unit of measurement known as activity (a). Potentiometric methods do not detect the concentration of complexed ions or ions that are "shielded" by other ions in solution (this can occur in solutions with high ionic strength). Ion activity is related to concentration with the following equation (using calcium as an example):

$$a\mathrm{Ca}^{2+} = \gamma\mathrm{Ca}^{2+} \times m\mathrm{Ca}^{2+} \tag{9.xiv}$$

where γ is the activity coefficient, and m is the molality of Ca^{2+} (moles Ca^{2+} per kg of water in the sample). The activity coefficient is primarily dependent on ionic strength of the solution, described by the Debye−Hückel equation:

$$\log \gamma = \frac{-\left(\mathrm{A} \times z^2 \times I^{1/2}\right)}{\left(1 + \mathrm{B} \times a \times I^{1/2}\right)} \tag{9.xv}$$

where A and B are temperature-dependent constants, z is the charge number of the ion, a is the ion size parameter for the specific ion, and I is the ionic strength of the solution.

$$I = \frac{1}{2}\sum m \times z^2 \tag{9.xvi}$$

While ionic activity is the appropriate parameter to discuss when considering biological equilibria and processes, most reference intervals and medical decision points for electrolytes are reported in molar concentration (or in equivalence units). This issue is addressed by using calibrator solutions with ionic strengths and compositions approximating normal human plasma. In this manner, the activity coefficient of each ion in the calibration solution is approximately the same as in the sample matrix, and the calibration can be performed in concentration units [12]. Unfortunately, the difference between molarity and molality cannot be calibrated out because water content [ρH_2O from Eq. (9.xiii)] in an aqueous calibrating

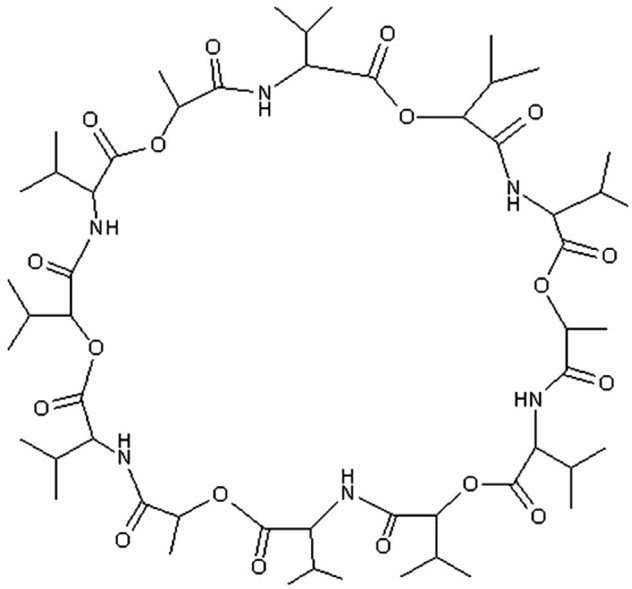

FIGURE 9.2 Chemical structure of valinomycin.

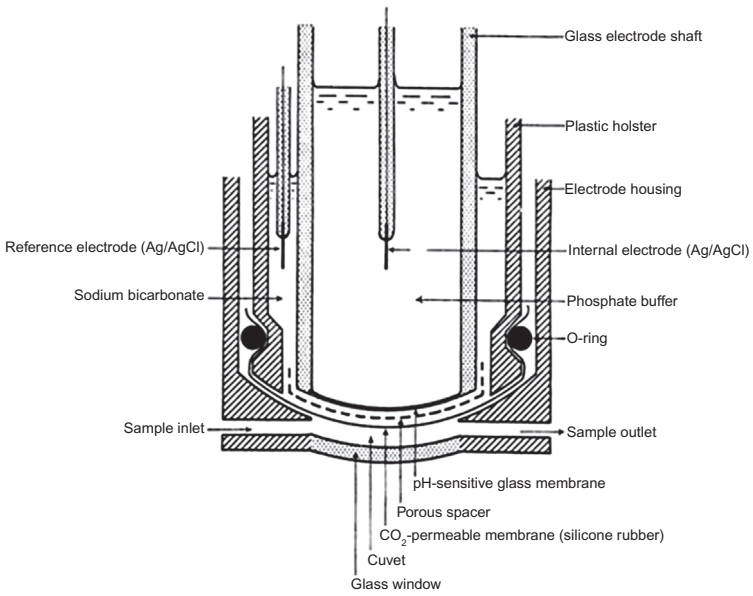

FIGURE 9.3 Schematic of a pCO_2 gas-sensing electrode.

solution (~0.99 kg/L) is much different than normal blood plasma (~0.93 kg/L). Direct potentiometry will report results approximately 6% greater than methods reporting concentration for normal samples because of this difference in water content between sample and calibrator (0.99/0.93 = 1.06). Most manufacturers of electrolyte measurement systems have addressed this problem in a practical way using correlation factors to standardize results from direct potentiometric measurements to units of concentration (mmol/L). However, when there is a significant deviation from typical water content of plasma (0.93 kg/L) due to hyperlipidemia or hyperproteinemia, the electrolyte concentration can be falsely reported as lower than the actual value (e.g., pseudohyponatremia) by indirect potentiometry. This is discussed in further detail in Chapter 36, Contemporary practice in clinical chemistry: blood gas and critical care testing.

Amperometric methods in clinical chemistry

Voltammetric measurements are used to study analytes based on the current−potential relationship when the electrochemical potential is varied. This approach takes advantage of the fact that certain molecules may be oxidized or reduced at an inert metal electrode when driven by an applied potential. When the redox reaction takes place, a current is generated in the cell; if the oxidation or reduction is limited by diffusion of the analyte to the electrode, the measured cell current is proportional to the amount of substance in the cell and will give a quantitative measurement of the analyte in solution. It is important to note that voltammetric methods measure concentration, not activity, and that the analyte of interest is consumed (at least partially) in the cell reaction.

Amperometry is a voltammetric technique where the applied potential is held constant, and the resultant current is used to quantitate the analyte of interest in solution. An amperometric cell typically consists of three electrodes: a *working* electrode, the *reference* electrode, and a third *counter (or auxiliary)* electrode. During amperometric measurements, the potential is measured and controlled between the working and reference electrodes, and the cell current is measured between the working and counter electrodes. This system avoids a possible error that may occur in a two-electrode system, as current passing between the working and reference electrodes could lead to a shift in the reference electrode potential, which would affect the applied cell potential during the measurement.

The most widely used application of amperometry in the clinical laboratory is for the determination of pO_2 in arterial and capillary blood. The Clark electrode [6] is a complete electrochemical cell consisting of a platinum working electrode (cathode) and a Ag/AgCl reference electrode (anode) (Fig. 9.4). In commercial instruments, the cathode is very small (~25 μm diameter) resulting in current levels in the picoampere (pA) range—when currents are this low, a counter electrode is generally not needed. The platinum cathode is covered by a thin film of electrolyte and separated from the test solution by a gas-permeable membrane. The cathode potential is adjusted to ~ −0.65 V relative to the anode, resulting in the following reactions:

$$\text{Cathode reaction: } O_2 + 2H_2O + 4e^- \rightarrow 4OH^- \quad (9.\text{xvii})$$

$$\text{Anode reaction: } Ag^+ + Cl^- \rightarrow AgCl + e^- \quad (9.\text{xviii})$$

Oxygen diffuses from the sample into the electrolyte layer, where it can be reduced at the platinum cathode. When no oxygen is present, the current is almost zero; when oxygen is present in the sample, the flow of current is directly proportional to the pO_2 in solution. It is important to remember that in order for this proportionality to hold true, the signal must be dependent on diffusion of oxygen to the cathode (diffusion-limited). The permeability and

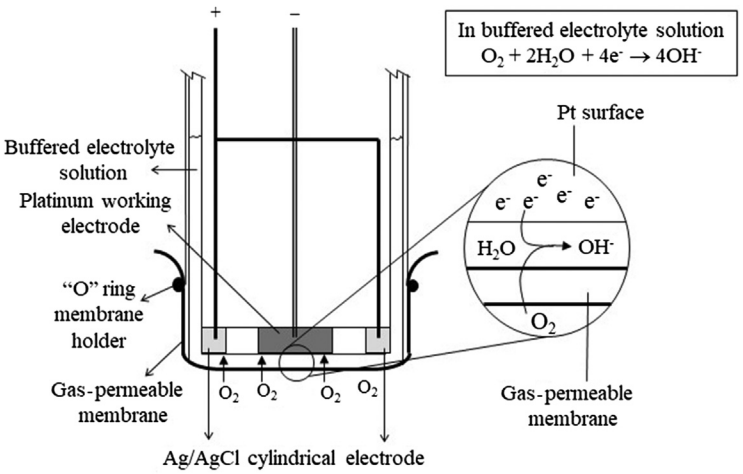

FIGURE 9.4 Diagram of a Clark pO_2 electrode.

thickness of the membrane are chosen to limit the diffusion of oxygen into the electrolyte layer and minimize variability in the diffusion coefficient of oxygen in the test solution. The membrane also functions as a barrier to keep proteins and other dissolved species from reaching the cathode and affecting the result.

Conductometric methods in clinical chemistry

Conductometric analyses are based on the ability of ions in solution to carry a current at a constant applied potential (conductivity). A potential is applied between two electrodes and then the current is measured; a decrease in resistance results in an increase in conductivity and thus an increased current occurs. The measured current is directly proportional to the sample conductivity.

Conductivity was first used to measure hematocrit in whole blood in the 1940s [13] and is still used today in many blood gas or critical care instruments. The basis for the measurement is that erythrocytes are natural electrical insulators because of their lipid-based membranes. As the proportion of red blood cells (RBCs) to plasma volume changes, so does the conductivity of the specimen. RBCs are less conductive than plasma, so as the volume fraction of RBCs increases, the conductivity decreases. This phenomenon can be described by Eq. (9.xix):

$$G_b = \frac{a}{1} + \left[\frac{H}{100} - H\right]c \qquad (9.xix)$$

where G_b represents the conductivity of whole blood, a the plasma conductivity, H the % hematocrit, and c the a factor for RBC orientation. In clinical practice, plasma conductivity must be corrected for effects from Na^+ and K^+ concentration in the sample; most clinical analyzers that measure hematocrit in this manner also measure these ions in conjunction with the whole blood conductivity, and correct for their effects prior to the hematocrit calculation. There are some significant limitations to hematocrit determination by conductivity. Dilution of clinical specimens with protein-free buffers, such as those used as plasma expanders during cardiopulmonary bypass surgery, lead to falsely low hematocrit values by conductivity, and pathologic conditions that lead to abnormally high serum protein levels may result in falsely high hematocrit values.

Coulometric methods in clinical chemistry

Coulometric methods consist of measuring the amount of charge (in coulombs) that passes between two electrodes in a fixed amount of time; the amount of charge is directly proportional to the oxidation or reduction of an analyte at one of the electrodes. Charge can be calculated from measured current because current is simply the amount of charge that passes per unit time (coulombs/second). The amount of charge can be related to the amount of electroactive substance (in moles) using Faraday's Law:

$$Q = z \times n \times F \qquad (9.xx)$$

where Q is the amount of charge passed during the reaction (coulombs), z is the number of electrons transferred in the redox reaction, n is the amount of analyte oxidized or reduced (in moles), and F is the Faraday constant.

Coulometry can be used in the clinical laboratory for the determination of chloride in serum (or plasma). Automatic coulometric titration instruments are available for this type of measurement. The instrument consists of a silver anode working electrode (silver is oxidized) and a platinum cathode reference electrode (hydrogen ion is reduced). A third indicator electrode is present (polarized at a negative potential) for detection of Ag^+ in solution—as Ag^+ is reduced by this electrode, a current is produced. As a constant current is applied to the working and reference electrodes, Ag^+ is produced, which combines with Cl^- in solution to form insoluble AgCl; as long as there are excess Cl^- ions, the Ag^+ concentration in solution will be low. When all the Cl^- in solution has been complexed, the Ag^+ in solution rapidly increases and produces a current at the indicator electrode (amperometry); when the current exceeds a set value, the titration is stopped. From the value of the constant applied current and the amount of time for the titration, charge can be calculated—from this value, the absolute number of Ag^+ ions produced may be calculated using Eq. (9.xx). Knowing that silver and chloride ions combine in a 1:1 stoichiometric ratio, the absolute number of Cl^- ions in the specimen can be determined. Thus, using the known volume of the original serum (or plasma) sample, it is possible to calculate the concentration of Cl^- in the sample. In the absence of interfering substances, coulometry is considered one of the most accurate electrochemical methods because the method measures the absolute amount of electroactive substance in the sample and is not dependent on steady-state or equilibrium processes. It is important to note that this is not a high-throughput technique, and it is typically used for sweat chloride measurement in the evaluation for cystic fibrosis. For general chemistry measurements in a high-throughput setting, chloride is typically measured by ISE.

Interferences for potentiometric and amperometric sensors

Potentiometric ISEs and amperometric sensors are the primary electrochemical methods used in clinical laboratory

applications. It is therefore appropriate to consider some specific types of interferences for these methods.

Some ISEs are subject to interference from other ions present in the sample. The response of an ISE in a solution consisting of the primary and interfering ion is described by the Nicolsky equation [a variation of the Nernst equation, Eq. (9.ix)].

$$E_{mem} = E^{\circ} + \left(\frac{0.0592}{n}\right) \times \log\left(a_i + K_{i/j} a_j^{zi/zj}\right) \quad (9.xxi)$$

where $K_{i/j}$ is the selectivity coefficient for the primary over interfering ion, determined experimentally [14], a_i and a_j are the activities of the primary and interfering ions, respectively, zi is the charge of primary ion, and zj is the charge of interfering ion. With knowledge of the selectivity coefficient and activity (or concentration) of the interfering ion, the concentration of the primary ion may be calculated from the measured cell potential.

Consider a practical example of interference with an ISE. The selectivity of an ISE for a primary ion (e.g., Ca^{2+}) over an interfering ion (e.g., Na^{+}) is given by the selectivity coefficient, expressed as $K_{Ca/Na}$ in this case. The selectivity coefficient is a quantitative measurement of the degree to which presence of an interfering ion will affect accuracy for measurement of the primary ion. Reciprocal of selectivity coefficient is a quantitative estimate of the extent to which the ISE will "favor" the primary ion over the interfering ion. Oesch et al. [15] have published an equation (derived from the Nicolsky equation) to calculate required selectivity coefficient for any ISE based on a tolerable level of interference due to presence of an interfering ion:

$$K_{i/j} = \frac{a_{i,\min}}{\left(a_{j,\max}\right)^{z_i/z_j}} \cdot \frac{p_{i/j}}{100} \quad (9.xxii)$$

where $K_{i/j}$ is the required value of the selectivity coefficient, $a_{i,\min}$ is the lowest expected activity of the primary ion, $a_{j,\max}$ is the highest expected activity of the interfering ion, $p_{i/j}$ is the highest tolerable error for measurement of the primary ion due to interference (in %), and z_i and z_j are charges of the primary and interfering ions, respectively

For example, measurement of Ca^{2+} at a concentration of 1.10 mmol/L in the presence of 160 mmol/L Na^{+}, with a maximum tolerable error of 1%, requires a sensor with $K_{Ca/Na} = 4.3 \times 10^{-4}$, which is equivalent to a preference for Ca^{2+} over Na^{+} of 2325:1. Older Ca^{2+} sensor designs utilizing charged calcium ion-exchangers, such as didecylphosphoric acid or related compounds, exhibit a preference for Ca^{2+} over Na^{+} no better than 200:1 and do not meet the above selectivity requirements [16]. Newer Ca^{2+} sensors, based on neutral carriers for calcium ion, generally meet the selectivity requirements with preference for Ca^{2+} over Na^{+} of 3000:1 or better [17]. However, even these sensors may be challenged in their selectivity over Na^{+} at very low Ca^{2+} concentrations, depending on other additives in the Ca^{2+} sensing membrane and other sources of imprecision or bias in the analyzer, such as surfactants present in calibrating, rinse, or quality control solutions which can produce deterioration in selectivity [18].

Potentiometric and amperometric gas electrodes are particularly sensitive to temperature and barometric pressure (BP) in the lab. When gas electrodes are calibrated, the partial pressure of the gas is dependent on the BP, percentage of gas in the mixture, and the partial pressure of water vapor as described by the following equation:

$$pX = (\mathrm{BP} - 47)\left(\frac{\%\ \text{of gas } X}{100}\right) \quad (9.xxiii)$$

where BP is the ambient barometric pressure in mm Hg, and 47 is the partial pressure of water vapor at 37°C. It is obvious from the equation that changes in humidity or temperature can significantly affect the calibration of the instrument and lead to erroneous results. Temperature in the analyzer must be controlled to tenths of degree celsius in order to meet precision requirements for blood gas analyzers. In addition, the inherent drift of electrochemical gas sensors means that frequent calibration is required—2-point calibrations every 2−4 hours and a 1-point calibration every 15−20 minutes. Most commercial blood gas analyzers are programmed to automatically perform these calibrations during the day at predetermined intervals. Because gas electrodes for pO_2 and pCO_2 are isolated from the sample by gas-permeable membranes, they are largely free of chemical interfering substances from the sample matrix. Early generation pO_2 sensors were reported to show interference from anesthetic gases such as nitrous oxide present in the sample [4]. These substances are electrochemically active and have the ability to diffuse across the gas-permeable membranes used in early pO_2 sensors. However, newer polymeric membranes found in later generations of blood gas electrodes have mostly eliminated this interference.

Biosensors based on electrochemical methods

A biosensor is a specific type of sensor consisting of a biological recognition element and a chemical transducer. The recognition element interacts selectively with an analyte of interest in the sample. This interaction results in a measurable change in a solution property, such as formation of a product or consumption of a reactant. The chemical transducer converts the solution property into a quantifiable electrical signal. Using enzymes as

recognition elements in combination with potentiometric or amperometric sensors has allowed the development of practical electrochemical sensors for analytes, which are electrochemically inactive. Biosensors for the measurement of analytes such as glucose, lactate, urea and creatinine directly in blood are used today in combination with sensors for blood gases and electrolytes in systems for critical care testing.

Enzyme-based biosensors with amperometric and potentiometric detection

Enzyme-based biosensors using electrochemical transducers, specifically amperometric electrodes, are the biosensors most commonly used for clinical analyses. The majority of today's blood glucose meters use enzyme-based biosensors with amperometric detection, with glucose sensors produced in single-use formats. Clark and Lyons developed the first amperometric biosensor; it was used to measure glucose in blood and was based on immobilizing glucose oxidase on the surface of an amperometric pO_2 sensor [6] (see diagram of pO_2 sensor in Fig. 9.4). A solution of glucose oxidase was physically entrapped between the gas-permeable membrane of the pO_2 electrode and an outer semipermeable membrane. The outer membrane was of a low-molecular-weight cutoff to allow substrate (glucose) and oxygen from the sample to pass, but not proteins and other macromolecules. In this way, the enzyme could be concentrated at the sensor's surface. Oxidation of glucose, catalyzed by glucose oxidase as follows:

$$\text{Glucose} + O_2 \xrightarrow{\text{glucose oxidase}} \text{gluconic acid} + H_2O_2 \tag{9.xxiv}$$

consumes oxygen near the surface of the sensor. The rate of decrease in pO_2 is a function of the glucose concentration and is monitored by the pO_2 electrode. A steady-state reduced partial pressure of oxygen can be achieved at the surface in a short period of time, yielding a steady-state current value that is inversely proportional to glucose concentration in the sample. If the polarizing voltage of the pO_2 electrode is reversed, making the platinum electrode positive (anode) relative to the Ag/AgCl reference electrode, and if the gas-permeable membrane is replaced with a hydrophilic membrane containing immobilized glucose oxidase enzyme, it is possible to oxidize the H_2O_2 produced in Eq. (9.xxiv) as follows:

$$H_2O_2 \xrightarrow{\text{applied voltage}} 2H^+ + O_2 + 2e^- \tag{9.xxv}$$

In practice, a sufficiently high voltage must be applied to the platinum anode to drive the oxidation of the hydrogen peroxide. An applied voltage of +0.7 V or greater (relative to Ag/AgCl) is typically used. In this case, the steady-state current produced is directly proportional to the concentration of glucose in the sample. Substitution of other oxidase enzymes in Eq. (9.xxiv) allows practical biosensors for other analytes of clinical interest such as lactate [19] and creatinine [20].

Substances found in blood, which are oxidizable at the applied potential shown in Eq. (9.xxv), are potential interfering substances for amperometric biosensors, particularly amperometric biosensors based on oxidation of hydrogen peroxide. Direct oxidation of the interfering substance at the anode produces the interfering signal. Such substances include ascorbic acid, uric acid, acetaminophen, and other therapeutic drugs [21]. Elimination of interfering substances from altering biosensor response often requires an additional membrane between the enzyme and the electrode surface. A low-molecular-weight cutoff membrane such as cellulose acetate may be used to prevent diffusion of the interfering substance to the electrode surface while maintaining permeability toward hydrogen peroxide. A combination of other techniques such as a second correcting electrode without enzyme to compensate for the signal from oxidation of interferences, the incorporation of anionic sites in the outer membrane to reject negatively charged interfering substances, and the use of lower applied potentials have all been successfully used to reduce the effect of interfering substances on amperometric biosensor response.

ISEs have been used as transducers for potentiometric biosensors. An example is the commercially available biosensor for urea based on an ISE for ammonium ion [22]. The enzyme urease is immobilized at the surface of the ISE and catalyzes the hydrolysis of urea to NH_3 and CO_2.

$$\text{Urea} \xrightarrow{\text{urease}} 2NH_3 + CO_2 \tag{9.xxvi}$$

Ammonia is hydrolyzed to form NH_4^+, which is sensed by the ammonium ISE. The ammonium ISE is based on the ionophore nonactin and suffers interference from Na^+ and K^+. These ions are typically measured simultaneously with urea and used to correct the output of the urea sensor using the Nicolsky equation [see Eq. (9.xxi)]. The selectivity coefficients for NH_4^+ over K^+ and Na^+ must be known or determined as part of the calibration process.

Enzyme-based electrochemical biosensors require another key element to assure practical use in blood. An outer membrane is commonly used to restrict diffusion of substrate to the enzyme layer, avoiding saturation of the enzyme and providing extended linearity toward the analyte of interest at substrate concentrations substantially higher than the K_m of the enzyme. This membrane also mechanically protects the enzyme layer and screens out macromolecules and RBCs from contact with the enzyme.

Track-etched polycarbonate membranes are commonly used. Hydrophobic coatings with lipids or silanes have been used to improve the biocompatibility of the polycarbonate membrane surface. Membranes based on polyvinylchloride, polyurethane, and silicone emulsions have also been used.

Affinity biosensors with electrochemical detection

Affinity sensors are a special class of biosensors in which the immobilized biological recognition element is a binding protein, an antibody (immunosensors), or an oligonucleotide (DNA sensors) that have high binding affinity and high specificity toward a clinically important analyte. Such sensors have been developed as alternatives to conventional binding assays to enhance the speed and convenience of a wide range of assays that would be typically run on sophisticated immunoassay analyzers. Ideally, direct binding of the immobilized species to its target in a clinical sample should yield a sensor signal proportional to the concentration of the analyte. However, "direct" sensing affinity biosensors at analyte concentrations that would cover the full range of clinical applications are very difficult to achieve. Further, high affinity of such binding reactions, required to achieve optimal sensitivity, limits the reversibility of such devices. Affinity sensors-based electrochemical transduction are typically single-use devices, thus obviating the need for some type of regeneration step (pH change, etc.) to dissociate the tight binding between the recognition element and the target.

The number of research reports related to affinity biosensors continues to increase. However, commercialization has lagged behind research output, and movement of these types of biosensors from the research laboratory to the clinical laboratory has been slow. Affinity biosensors with promise of clinical utility are typically based on labeled reagents such as enzymes and electrochemical tags; hence, they function more like traditional binding immunoassays, except that one recognition element is immobilized on the surface of an electrochemical transducer. For example, electrochemical pO_2 sensors have been employed to perform heterogeneous enzyme immunoassays (sandwich or competitive type), using catalase as a labeling enzyme (catalyzes H_2O_2 $2\,H^+$, and O_2). Capture antibodies are immobilized on the outer surface of the gas-permeable membrane. After binding equilibration between antigen and capture antibody, followed by a washing step, a second, catalase-labeled reporter antibody interacts with surface-bound antigen. The activity of bound enzyme is detected by adding the substrate (H_2O_2) and following the increase in current generation caused by local production of oxygen near the surface of the sensor. Some commercial examples of immunosensors do exist, primarily in the unit-use, disposable format designed for point-of-care testing. One successful commercial example is a cartridge-based device for cardiac troponin I on the i-STAT handheld analyzer (Abbott Point of Care) [23]. This sensor uses a sandwich immunoassay format with electrochemical detection. Capture antibody is immobilized on a gold electrode for recognition and capture of troponin in the blood sample. A second, reporter antibody is labeled with alkaline phosphatase and binds with surface-captured troponin antigen. Following incubation and washing steps, the substrate p-aminophenyl phosphate is introduced and product of the enzymatic reaction (p-aminophenol) is detected amperometrically by oxidation at the gold electrode. Magnitude of the oxidative current is proportional to the concentration of troponin in the sample.

Affinity biosensors based on oligonucleotide binding (DNA sensors or "gene" sensors) in which a segment of DNA complementary to a target strand is immobilized on a suitable electrochemical sensor have been demonstrated. These devices operate in either direct (based on electrochemical oxidation of guanine in target DNA) or indirect (with exogenous electrochemical markers/labels) transduction modes. Although most of the proposed electrochemical DNA biosensors require amplification methods, such as PCR, to multiply small amounts of DNA into measurable quantities, some are sensitive enough to eliminate the need for target amplification. Nanotechnology has been proposed, in an indirect format, for signal amplification. For example, a capture probe DNA is immobilized on a gold electrode. Reporter probes with electrostatically bound ruthenium complexes $[Ru(NH_3)_6]^{3+}$ are loaded onto gold nanoparticles (AuNP) and are capable of hybridizing with one of two sequences on target DNA. The other sequence on the target DNA is capable of hybridizing with the immobilized capture probe. Hybridization events on the electrode surface bring multiple reporter probes for each AuNP. Electroactive $[Ru(NH_3)_6]^{3+}$ is reduced at the electrode surface, and the coulometric signal is proportional to the concentration of target DNA [24]. A commercial example of electrochemical DNA sensing, along with AuNP probes without need for PCR amplification, is the Verigene system (Luminex), capable of detecting single-nucleotide polymorphisms related to common genetic disorders, such as thrombophilia, alterations of folate metabolism, cystic fibrosis, and hemochromatosis.

Another example of an electrochemical "gene" sensor array uses electrochemical probes that are selectively inserted into hybridized DNA duplexes. In one approach, after the immobilized capture of oligo anchored to the electrode surface is allowed to bind a target sequence, hybridization is detected by exposing the surface of the

electrode to an exogenous electroactive species (Co[III] tris-phenanthroline, ruthenium complexes, etc.) that intercalates within the duplex, but not to single-stranded DNA. After unbound electroactive species are removed by washing, the presence of hybridization is readily detected by voltammetry, scanning the potential of the underlying electrode to oxidize or reduce any intercalated electroactive species, with the measured current being proportional to the number of duplex DNA species on the surface of the electrode.

Self-assessment questions

1. Which of the following describes the cathode in an electrochemical cell?
   a. loss of electrons occurs; reduction
   b. gain of electrons occurs; reduction
   c. loss of electrons occurs, oxidation
   d. gain of electrons occurs; oxidation
2. Potentiometric analysis involves measurement of:
   a. potential while as current is varied
   b. conductance of material under an applied potential
   c. magnitude of current at a fixed potential
   d. electromotive force while current is zero
3. Which of the following is routinely measured using conductometry?
   a. hematocrit
   b. lipid content of blood
   c. sodium ion concentration
   d. bone density
4. Potassium can be measured using which of the following techniques?
   a. glass membrane ion-selective electrode
   b. coulometric titration
   c. gentamicin-based ion-exchange electrode
   d. none of the above
5. The Nernst equation is used to:
   a. determine current under nonstandard conditions
   b. determine variance from standard potentials under nonstandard conditions
   c. calculate activity coefficient from the ionic strength of solution
   d. calculate hematocrit from conductance measurements
6. Which of the following can be a potential source of error for potentiometric measurements in plasma?
   a. hyperlipidemia
   b. multiple myeloma
   c. dilution of specimen with water
   d. all of the above
7. In potentiometric gas-sensing electrodes, measurement of the partial pressure of the gas is described by:
   a. partial pressure is directly proportional to pH
   b. partial pressure is directly proportional to measured current
   c. pH is directly proportional to the log of partial pressure
   d. partial pressure is directly proportional to the log of pH
8. Successive measurements with a pCO_2 electrode will be continuously lower due to consumption of the analyte during the analytical process. True or False?
   a. True
   b. False

Answers

1. b

8. b

Chapter 10

Mass spectrometry

Stefani N. Thomas

Department of Laboratory Medicine and Pathology, University of Minnesota Medical School, Minneapolis, MN, United States

Learning objectives

After reviewing this chapter, the reader will be able to:

- List the basic components of a mass spectrometer.
- Compare and contrast the various methods for ionization and mass analysis.
- Explain the concept of tandem mass spectrometry.
- Summarize the advantages and limitations of mass spectrometry for use in the clinical laboratory.

In 1910 Thompson [1] built the first instrument used to measure mass-to-charge (*m/z*) values of gaseous ionized atoms: a mass spectrometer. Soon thereafter, mass spectrometry (MS) became essential for the study of various molecules, and from 1913 to 1945 MS was predominantly used for the analysis of isotopes and atomic weights [2]. The applications of MS have since expanded to include a myriad of qualitative and quantitative applications in many fields, including forensics, basic and translational research, environmental science, pharmaceutical science, geology, astronomy, and, of course, laboratory medicine.

Initial applications of MS were relegated to highly specialized laboratories staffed with individuals with considerable technical expertise due to the knowledge base required to effectively operate the complex MS instrumentation. However, recent advances in MS instrumentation have occurred concomitantly with relatively decreased levels of complexity from the standpoint of instrument operation. Hence, MS now is among the routinely used cadre of instrumentation in many clinical laboratories. Applications of MS in the clinical laboratory include therapeutic drug monitoring, testing for inborn errors of metabolism, steroid analysis, and elemental analysis. Indeed, MS is gradually transforming the practice of laboratory medicine, largely due to its analytical sensitivity and specificity [3].

Understanding the fundamental tenets of this powerful technology is a requisite step toward the effective application of MS, particularly in the clinical laboratory. This chapter addresses the basic concepts and definitions of MS with a particular emphasis on instrumentation. Brief mention is made of some of the clinical applications of MS; for a more thorough review of this topic, the readers are encouraged to refer to Chapter 21, Applications of mass spectrometry in the clinical laboratory.

Basic mass spectrometry concepts

MS is a powerful analytical technique that can be used to identify and quantify analytes using the *m/z* of ions generated from a sample. Small molecules, peptides, and proteins are among the clinically relevant analytes that are routinely analyzed by MS. The analysis of such analytes by MS can be performed using systems that exist in several different instrument configurations; however, most MS systems comprise five main components: (1) an ionization source; (2) a vacuum system; (3) a mass analyzer; (4) a detector; and (5) a processor (Fig. 10.1).

MS analysis requires an initial ionization step in which an ion, defined as an atom or molecule with a net electric charge due to the loss or gain of one or more electrons, is produced from a neutral atom or molecule. These ions must be present in the gas phase prior to mass analysis.

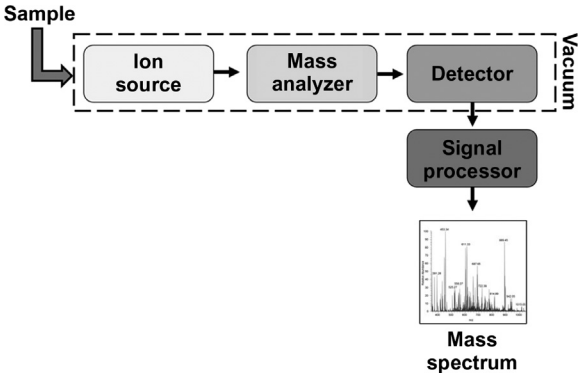

FIGURE 10.1 Overview of the components of a mass spectrometry instrument.

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00010-7

Ion separation requires that the ions do not collide with other molecules, as they traverse the ion path inside of the mass spectrometer, which occurs under vacuum. The magnitude of the vacuum pressure (10^{-3}–10^{-9} torr) varies based on the type of mass analyzer. Whereas Fourier-transform ion cyclotron resonance (FTICR) analyzers require a low pressure of $\sim 10^{-9}$ torr, ion trap mass analyzers operate under higher pressure of 10^{-3}–10^{-5} torr. Vacuum pumps with higher pumping capacities are generally associated with lower detection limits. Mass analyzers separate ions based on their *m/z* ratio prior to their delivery to the detector. The function of the detector is to sense ions, as they travel from the mass analyzer, to increase the signal from the ions (often by several orders of magnitude), and then to convert the charge from the ions to a current. Finally, the signal processor converts current into a peak on the mass spectrum. The "Detectors and processors" section below addresses these concepts in further detail.

A mass spectrum represents the relative abundance or signal intensity of each ion plotted as a function of *m/z* (Fig. 10.2). The accurate interpretation of mass spectra requires an understanding of the concept of molecular mass (also known as molecular weight), which is measured in units of daltons, where 1 dalton (Da) is equivalent to 1/12 of the atomic mass of the most abundant isotope of a carbon atom in its lowest energy state (^{12}C). Small molecules (<1000 Da) typically only carry one charge; thus the *m/z* value is identical to the mass of the molecular ion. However, larger molecules such as peptides or proteins often carry multiple ionic charges, which translates to the *z* value being an integer >1 and the *m/z* value being less than the molecular mass of the analyte.

In a mass spectrum, the peak representing the intact ion from the original molecule is referred to as the molecular ion peak. The ion present in the greatest amount is termed the base peak and is assigned a relative value of 100%. The ability of a mass spectrometer to separate nearby masses from each other is known as resolution, which is defined as $(m/z)/(\Delta m/z)$, where $\Delta m/z$ is the width of the mass spectral peak that is typically measured at 50% of the peak height and is referred to as the full width half height (FWHH) or full width half maximum (FWHM) resolution. FWHH and FWHM are measures of resolution based on a single peak. A definition of resolution that applies to two adjacent, symmetric peaks is based on the 10% valley, which defines $\Delta m/z$ as the distance between two peaks of equal intensity that are separated, such that the valley between the peaks is 10% of the peak height. Another important parameter when interpreting mass spectra is mass accuracy, which refers to how close a measured mass is to its expected (true) mass. Mass accuracy is defined as the difference between the measured and expected masses divided by the true mass. Resolution and mass accuracy vary greatly among different types of MS systems.

In addition to the detection of intact ions, mass spectrometers can also be used for the detection of fragment ions that are generated as a result of energy that is imparted into the ionized analyte, causing internal bonds to break and resulting in fragmentation. The fragment ions can then be used for the purpose of the structural determination of the intact ion. Fragmentation can occur in the ion source as well as in a separate dissociation, or collision, cell inside a tandem mass spectrometer. Tandem mass spectrometers will be addressed in a subsequent section of this chapter.

Any discussion of mass spectra interpretation warrants mention of the influence of isotopes. Chemical elements can be composed of a single or multiple isotopes. In the context of MS, isotopes can reveal the charge state of a peak, the types of elements that could be contained in a particular molecule, and they can indicate the elemental composition of a molecule via accurate mass determination. The monoisotopic mass in a mass spectrum refers to the mass of the isotopic peak whose elemental

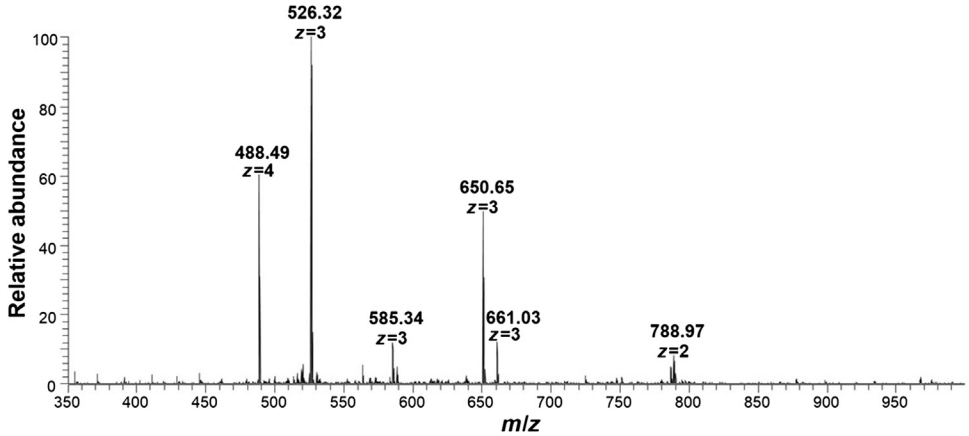

FIGURE 10.2 Representative mass spectrum of complex peptide mixture.

composition comprises the most abundant isotope of the constituent element, whereas the average mass is the average of the isotopic masses weighted by the isotopic abundances. Among the many strengths of MS as an analytical method is the ability to distinguish between ions with the same chemical formula that have different masses due to the difference in their isotopic composition. A comprehensive discussion of the interpretation of mass spectra is provided by McLafferty and Tureek [4].

Sample introduction

Sample preparation is essential for MS analyses that yield useful and reliable data. Given that mass spectrometers are considered close to being universal detectors based on their ability to detect a broad array of ionizable molecules, particular attention must be given to the physical and chemical properties of the analyte of interest in the context of its background matrix when determining the specific protocol for sample preparation prior to MS analysis. Clinical specimens such as plasma, serum, and urine contain background analytes with a wide dynamic range of abundance, which can complicate MS analysis if suboptimal sample preparation is performed.

Ion suppression or enhancement can occur due to the presence of sample constituents such as salts, phospholipids, surfactants, and ion-pairing agents that suppress or enhance ionization of the analyte of interest, which can significantly confound the interpretation of MS data. For example, in applications entailing liquid chromatography coupled with MS, nonvolatile or less volatile components found in a sample can reduce droplet formation and the efficiency of solvent evaporation in the ionization source, resulting in reduced ion formation. Ionization efficiency is a measure of how well gas-phase ions are formed from analyte molecules and it is impacted by the analyte itself, the concentration of the analyte, and the type of ionization process used. Several techniques for determining the degree of ion suppression and enhancement have been described [5,6].

Among the common sample preparation methods that are undertaken for clinical MS analysis are protein precipitation followed by centrifugation, solid-phase extraction, liquid−liquid extraction, derivatization, and affinity enrichment. The buffer into which the sample is extracted should be compatible with the downstream chromatographic and ionization conditions.

Sample complexity must be taken into consideration when determining the method by which a sample is to be introduced into a mass spectrometer. Liquid and gas chromatographs are versatile analytical instruments that can be readily coupled with mass spectrometers. The resolving capabilities of these instruments combined with the specificity of MS have rendered liquid chromatography-mass spectrometry (LC-MS) and gas chromatography-mass spectrometry (GC-MS) powerful analytical techniques for clinical analysis. Broad spectrum molecular weight polar and nonpolar compounds that can be readily dissolved in liquid, such as proteins, vitamins, and certain drugs, can be analyzed using LC-MS, whereas GC-MS analysis is particularly suitable for the analysis of low molecular weight and nonpolar or volatile analytes such as organic acids, cholesterol, steroid hormones, and xenobiotic compounds [7].

Ion sources

Regardless of the method of sample introduction to the mass spectrometer, the generation of gas-phase ions is required for MS detection. When gas-phase molecules are introduced directly into an ionization source from a gas chromatography (GC) system, electron ionization (EI) and chemical ionization (CI) are the most commonly used techniques. When a liquid chromatography (LC) system is coupled with a mass spectrometer for the introduction of liquid-state analytes, ionization under atmospheric or near-atmospheric conditions is conducted using methods such as electrospray ionization (ESI), atmospheric pressure chemical ionization (APCI), or atmospheric pressure photoionization (APPI). Other commonly used ionization techniques include inductively coupled plasma (ICP), matrix-assisted laser desorption ionization (MALDI), desorption electrospray ionization (DESI), rapid evaporative ionization (REI), and thermal desorption (TD).

Electron ionization

EI is the most common form of sample ionization used for GC-MS applications. It occurs in a gas-phase reaction described by the following equation:

$$M + e^- \rightarrow M^{+\cdot} + 2e^- \qquad (10.i)$$

where M is the neutral molecule undergoing ionization, e^- is the electron, and M^+ is the resulting charged radical cation. Uncharged molecules in the gas phase are bombarded with a stream of electrons that are accelerated through an electric field at an ion energy of 70 eV. The potential difference energizes the electron source, such that collision with neutral molecules results in the ejection of two electrons and the formation of a charged radical cation.

This process frequently causes numerous cleavage reactions that give rise to fragment ions, which can convey structural information about the analyte of interest. Consequently, EI is often referred to as a "hard ionization" method due to the extensive fragmentation that occurs. The fragment ions can then be compared with

curated libraries of established EI fragmentation patterns to aid in structural identification.

Chemical ionization

CI is another ionization method that is commonly used for GC-MS applications; however, it is considered a "soft ionization" method due to the formation of primarily molecular ions. In CI, a proton is transferred to, or abstracted from, a gas-phase molecule such as methane, ammonia, or isobutane. The transfer results in protonated ions that carry a net positive charge (MH^+). An example of this reaction using methane as the CI reagent gas is as follows:

$$CH_5^+ + M \rightarrow CH_4 + MH^+ \qquad (10.ii)$$

Negative ions can also be produced by CI wherein protons are extracted from basic gases. These negative ions are formed when thermalized electrons are captured by electronegative functional groups, such as fluorine or chlorine atoms, within the molecule of interest. Negative ion CI is commonly used for the quantification of benzodiazepines and other drugs.

Electrospray ionization

The development of ESI greatly facilitated the broadening of the applications to which MS can be applied. ESI enables the delivery of ions from liquid solutions into the gas phase, including ions from large nonvolatile molecules such as proteins. A solution containing ionic analyte molecules dissolved in a volatile liquid is pumped through a charged capillary to which a 1−5 kV voltage is applied, and it is emitted as an aerosol comprising small droplets, ~10 μm in diameter. The aerosol is thought to be produced by a process involving the formation of a Taylor cone. A gas such as nitrogen facilitates the nebulization of the liquid and the evaporation of the solvent in the droplet. As the solvent evaporates, the analyte molecules are drawn closer together, repel each other, and cause the droplets to break into smaller droplets in a process known as Coulombic fission. This is an iterative process that results in the formation of desolvated analytes, which are then drawn into the orifice of the mass spectrometer. The ESI process is illustrated schematically in Fig. 10.3.

ESI is a soft ionization method wherein molecules are largely spared from fragmentation during the ionization process. Multiply charged ions ($M + nH^{n+}$) are often observed, which is particularly advantageous for the analysis of large macromolecules such as peptides and proteins. The multiple charging reduces the *m/z* value of the molecule to a value that falls within a range that is acceptable to mass analyzers such as quadrupoles and ion traps. In 2002 Fenn [8] was awarded the Nobel Prize in Chemistry for the development of this revolutionary technique. Fenn shared the Nobel Prize with Tanaka who was recognized for the development of laser desorption ionization, which is discussed in a subsequent section of this chapter.

Atmospheric pressure chemical ionization and atmospheric pressure photoionization

APCI is a mode of ionization that is similar to ESI in that ionization takes place at atmospheric pressure, entails nebulization and desolvation, and incorporates an interface design, which is similar to that of ESI. A key difference between APCI and ESI is that ESI is based on ions that are formed in solution, whereas APCI uses ions that are formed in the gas phase. In APCI, instead of high voltage being applied to the inlet capillary, mobile phase from the separation device is evaporated within a heater, and the vapor passes a needle with an applied current, which generates a corona discharge for the formation of stable reaction ions. These ion−molecule reactions involve several patterns such as proton-transfer reactions and electrophilic addition reactions. The high heat (400°C) used with APCI can cause pyrolysis, resulting in

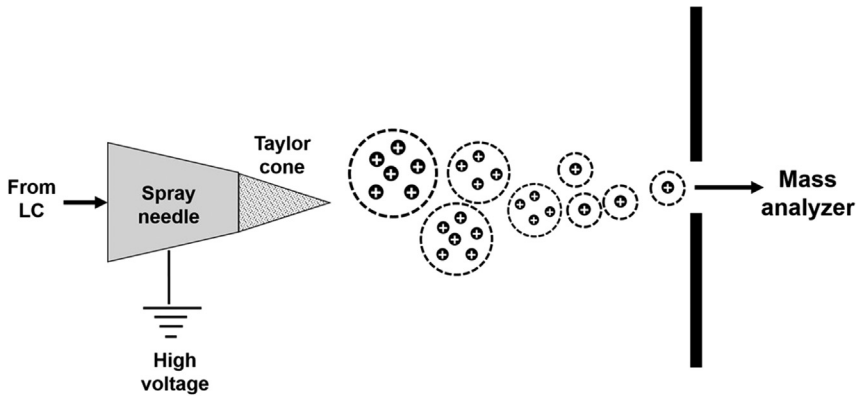

FIGURE 10.3 Electrospray ionization.

the loss of metabolically induced modifications to the analytes of interest. Hence, APCI is best suited for the analysis of small, heat-stable molecules.

APPI is not a mode of ionization that is used frequently in clinical chemistry; however, it is a complementary ionization approach to ESI or APCI. Instead of using a corona discharge needle to generate ions in the gas phase, an ultraviolet (UV) light is used as the source of ionization. To increase the efficiency of analyte ionization, toluene or acetone can be infused coaxially to the nebulizer to provide a source of ions that participate in charge or proton transfer to the analyte molecules. Similar to APCI, ionization occurs after the liquid sample is heated to a gaseous state, which has the benefit of greatly reducing possible matrix effects. Compared with APCI, APPI is more useful for the analysis of compounds with very low polarity.

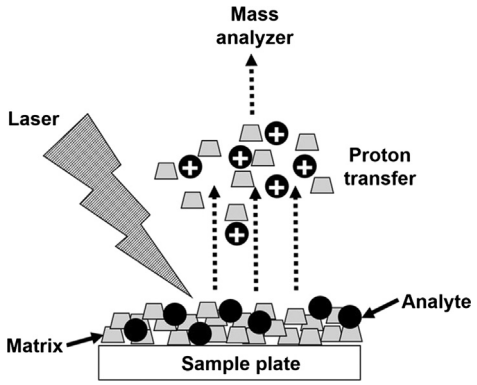

FIGURE 10.4 Matrix-assisted laser desorption ionization. Matrix and analyte are cocrystallized onto a solid support surface. The matrix absorbs at or near the laser wavelength, which causes the matrix molecules to sublime from the surface. Analyte molecules are carried with them, and ionization takes place in the gas phase by proton transfer. The ions are then sampled into the mass analyzer.

Inductively coupled plasma ionization

ICP is an atmospheric pressure ionization method, but unlike the previously mentioned atmospheric pressure ionization methods (ESI, APCI, and APPI), ICP is a hard ionization method, which results in complete sample atomization during sample ionization. An ICP source consists of a sample introduction system (nebulizer and spray chamber that provides the means by which the sample is transmitted into the instrument), an ICP torch, and a radio frequency (RF) coil for the generation of argon plasma, which serves as the ion source, and an interface, which connects the source to the mass spectrometer. In the clinical laboratory, ICP is commonly used for trace element analysis. Among the advantages of ICP are a wide dynamic range and the ability to detect elements at a level of parts per trillion.

Matrix-assisted laser desorption ionization

MALDI is a soft ionization technique that enables the analysis of large, nonvolatile molecules, including proteins, peptides, carbohydrates, and oligonucleotides, from a solid-state phase directly into the gas phase. The first reports of high mass ions $>10{,}000$ m/z that were recorded using MALDI MS were published by two groups in 1988 who reported the detection of molecular ions at m/z 34,529 from carboxypeptidase-A and the detection of molecular ions from bovine serum albumin at m/z 66,750 [9,10]. Tanka [11] was awarded the Nobel Prize in Chemistry in 2002 for his development of laser desorption ionization. As mentioned in a previous section, Tanaka shared this award with Fenn.

The steps entailed in MALDI are as follows: (1) the analyte of interest is suspended or dissolved in a matrix; (2) the analyte cocrystallizes with the matrix as the solvent evaporates; (3) a UV laser (typically a nitrogen laser) irradiates the surface; (4) the matrix absorbs the UV light and ionization occurs; and (5) ions are accelerated and introduced into the mass spectrometer (Fig. 10.4). Several types of matrices are available for use with MALDI. Most matrices are small organic compounds that are able to absorb the energy from UV lasers and gently transfer the energy to the sample, preventing decomposition and promoting the ionization process. Most matrices are mixed with samples at molar ratios of 1000:1 to 10,000:1 matrix:sample.

Laser pulses are targeted at specific areas on the sample plate, containing the matrix cocrystallized sample. Time-of-flight (TOF) mass analyzers are typically used with MALDI ionization sources, because each laser pulse generates a set of ions that can be delivered to the mass analyzer in discrete groups, hence providing distinct start events for the timing of ion flight for each group of ions.

Desorption electrospray ionization and direct analysis in real time

DESI and direct analysis in real time (DART) are ionization methods that enable the generation of ions from surfaces at atmospheric pressure. Before the development of these methods, samples analyzed by MS were not in the free ambient environment nor could they be subjected to processing actions or conditions, while mass spectra were being recorded [12]. In DESI applications, ionization occurs by spraying the sample with an electrically charged aqueous mist. The ions are then released from the surface, and they are transported through air at atmospheric pressure prior to reaching the atmospheric interface of the mass spectrometer. In contrast to the liquid

spray used by DESI, the ionizing gas from the DART ion source contains a dry gas stream with excited state species [13].

Minimal sample preparation, relative ease of operation, and low cost are primary advantages of ambient ionization methods such as DESI and DART. These methods have several clinical applications including dried blood spot testing for therapeutic drug monitoring and lipid profile-based identification of cancerous tissues. Although there are challenges related to sensitivity and matrix effects, novel developments in ambient ionization techniques have created the potential for MS to be included in point-of-care diagnosis.

Emerging ionization methods of interest

Considerable advances in direct sampling methods and ambient analysis have been made in recent years. A few of these advances are highlighted here. Rapid evaporative ionization mass spectrometry (REIMS) allows the direct characterization of biological tissues, food, and environmental samples without the requirement for sample preparation in near real time. In this technique, the aerosol generated from the evaporation of the sample by Joule heating or laser irradiation is introduced into the inlet of a mass spectrometer. REIMS has been demonstrated to have promise in the fields of intrasurgical tissue classification, bacterial identification, and the rapid profiling of cell lines [14].

The intelligent knife (iKnife) was developed by Takats, and it is based on REIMS technology [15]. The iKnife is intended to be used as an alternative to frozen section histology by enhancing near real-time intraoperative decision-making based on surgical margin characterization. By combining a tissue dissection tool (handheld electrosurgical device) with an identification system (MS and a spectral database) via the analysis of the smoke from evaporating tissue during resection, the iKnife has a potential clinical use for patient diagnosis. A clinical trial in the United Kingdom is ongoing to test the iKnife's discriminatory ability and to establish whether the improved accuracy of tissue detection could have a positive impact on progression-free survival and overall survival in breast cancer patients [16].

The MasSpec Pen was developed by researchers at the University of Texas at Austin for use as a clinical and intraoperative device for ex vivo and in vivo cancer diagnosis [17]. Similar to REIMS, it is based on ambient ionization, but it differs from the iKnife method in that it is a nondestructive technique, and biomolecules are extracted from tissues and delivered to the inlet of the mass spectrometer using discrete water droplets as opposed to smoke.

Paper spray MS was developed as a direct sampling ionization method for the MS analysis of complex mixtures, including dried blood spots for therapeutic drug monitoring applications and illicit drug detection in raw urine specimens [18,19]. The method of ionization in paper spray applications is based on electrospray. Ions from the analyte of interest are generated by applying a high voltage to a paper triangle wetted with a small volume ($<10\,\mu L$) of solution. Parameters such as paper thickness, mechanical resistance, surface chemistry, and fiber morphology influence the performance of paper spray, and various functionalized types of paper have been developed for the analysis of specific targets. The potential benefits of paper spray MS in a clinical laboratory include rapid point-of-care analysis.

Coated blade spray (CBS) MS is a solid-phase microextraction-based technology that can be directly coupled to MS to enable the rapid qualitative and quantitative analysis of complex matrices [20]. Combining microsample preparation with ambient ionization, CBS MS uses a polymeric adsorbent particle-coated stainless steel sheet, which functions as a solid-substrate ESI source. Contrary to paper spray MS, analytes of interest are extracted or enriched from a sample in CBS applications.

Laser diode thermal desorption (LDTD)-MS is another direct sampling technique. It was developed primarily to increase analytical throughput by eliminating the need for chromatographic separation prior to MS detection. In this method, a small volume of sample ($\sim 2\,\mu L$) is pipetted into a well of a specially designed 96- or 384-well metallic plate. An infrared laser thermally desorbs the analytes by evaporation of an organic solvent. The desorption process releases neutral gas-phase molecules, which are carried by nitrogen gas through an ion transfer tube into an atmospheric pressure ionization source where they are ionized. In addition to its current applications in the characterization of illicit drugs, explosives, and pesticides, LDTD-MS is being applied to the quantification of trace active pharmaceutical ingredients and their metabolites in blood [21].

Mass analyzers

The operation of mass spectrometers is based on the dynamics of charged particles, or ions, in electric and magnetic fields in a vacuum. These charged particles are separated as a function of their mass and charge in the mass analyzer component of the mass spectrometer. Following their separation, the ions are delivered to the detector.

There are several types of mass analyzers, and they can be broadly classified into two groups: beam-type instruments and trapping-type instruments. In beam-type mass analyzers, ions are delivered from the ion source to

the mass analyzer and then to the detector in a single beam. Comparatively, in trapping-type mass analyzers, ions are retained in a spatially confined region of the mass analyzer for a defined period of time (which can be as short as several milliseconds) prior to being sent to the detector.

The main beam-type mass analyzers are the quadrupole and TOF. Although magnetic sector mass analyzers are also beam-type mass analyzers, they are seldom used in the clinical laboratory and will consequently only be mentioned briefly in this section. The primary trapping-type mass analyzers are the quadrupole ion trap, linear ion trap, ion cyclotron resonance (ICR), and orbitrap.

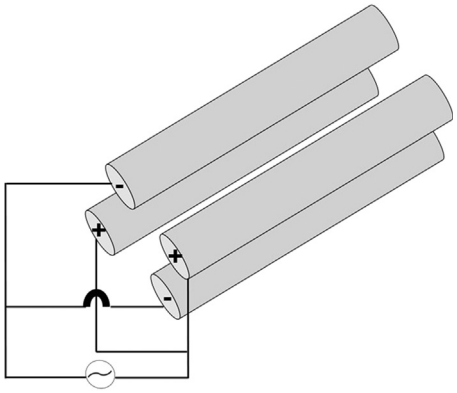

FIGURE 10.5 Quadrupole mass analyzer.

Beam-type design

Magnetic sector

A magnetic sector mass analyzer utilizes an electric or magnetic field to alter the direction of the paths of ions that are accelerated through the mass analyzer. As the ions are deflected toward a detector located at a 90-degree angle from the ion source, the extent of their deflection is based on their *m/z* ratios with lighter ions being deflected to a greater extent compared with heavier ions. Ion separation in magnetic sector analyzers can be described by the following equation:

$$m/z = \frac{B^2 r^2}{2V} \tag{10.1}$$

where B is the strength of the magnetic field, r is the radius, and V is the voltage. Either a narrow range of *m/z* values can be selected by the mass analyzer or a broad range of *m/z* values can be scanned before the ions are transmitted to the detector. The high resolution and mass accuracy of these detectors correlate with their high cost and complex operating principles.

Quadrupole

Quadrupole mass analyzers are sometimes referred to as mass filters due to their ability to select ions of a single *m/z* value for analysis. Although they are inferior to magnetic sector instruments in terms of sensitivity, resolution, and upper mass range, their ease of use, relative affordability, compact size, and ability to be readily interfaced with GC or LC systems have rendered them the most widely used mass spectrometers in the clinical laboratory. As their name suggests, quadrupole mass analyzers comprise four parallel cylindrical metal rods (electrodes with a hyperbolic interior surface) that are positioned equidistant from a center axis. The rods are charged by direct current (DC) and RF voltages, with the opposite pairs of rods carrying like charges (Fig. 10.5). Oscillating electrical fields are used to selectively stabilize or destabilize ions, as they pass through an RF quadrupole field. Each opposing rod pair is connected electrically, and an RF alternating current voltage is applied between the rods. A DC voltage is then superimposed on the RF voltage, which causes the ions to adopt an irregular, oscillatory trajectory, as they travel through the 3-D channel between the rods in a corkscrew path. Only ions with a selected *m/z* value are able to achieve a stable trajectory, which allows them to reach the detector. Ions with other *m/z* values have an unstable trajectory and consequently collide with the rods, or are expelled radially from the analyzer. The selection of ions with a specific *m/z* ratio is achieved by changing the polarity and the voltages that are applied to the rods.

The resolution (R) of quadrupole mass analyzers is directly proportional to the number of RF cycles (n) that an ion undergoes. It therefore follows that increasing the RF frequency is a means by which quadrupole resolution can be optimized. R is defined as follows:

$$R = n^2 = \frac{mf^2L^2}{\mathrm{qV}} \tag{10.2}$$

where m is the mass, f is the RF voltage frequency, L is the rod length, and qV is the kinetic energy (KE) of the ions.

Time of flight

TOF mass analyzers are often used in conjunction with MALDI ionization sources. TOF MS is known as a scanning technique wherein a full mass spectrum is acquired as a snapshot instead of by sequentially stepping through a series of *m/z* values while acquiring the data.

When KE, or force, is imparted to a group of ions with various *m/z* values by the application of an electric field, the ions traverse a path from the ion source to the detector in a flight tube in an amount of time that is

directly related to their *m/z*. Ion velocity (v) is inversely related to the square root of the *m/z*:

$$v = \sqrt{(2V)(z/m)} \tag{10.3}$$

where V represents the voltage. If an equivalent amount of KE, or force, is imparted to all ions, ion velocity will depend only on ion mass:

$$\mathrm{KE} = \frac{mv^2}{2} \tag{10.4}$$

The resolution of early TOF mass analyzers was relatively poor, as the KE for ions with identical *m/z* values was not always equivalent. The development of delayed extraction and the reflectron greatly increased the resolving power of TOF mass analyzers [22]. In the context of MALDI-TOF, delayed extraction involves the inclusion of a short interval between ion creation by the laser and ion acceleration by the application of an electric field, which permits the dense plume of MALDI-generated ions to dissipate before it is accelerated out of the ion source. Consequently, the broadening of ion velocity distribution from collisional processes in the ion source is reduced. In addition, ion arrival time distributions at the detector are narrower, and mass resolution is enhanced. The reflectron compensates for the broadening in the range of flight times of ions with identical *m/z* values by focusing the ion packets in space and time at the detector.

Trapping mass spectrometers

Quadrupole ion trap

Quadrupole ion trap mass analyzers operate based on the same physical principles as quadrupole mass analyzers, but the ions are trapped in stable orbits in a 3-D chamber and are then sequentially ejected. The quadrupole ion trap mass analyzer consists of three hyperbolic electrodes: a donut-shaped ring electrode, an entrance endcap electrode, and the exit endcap electrode (Fig. 10.6—quadrupole ion trap). These electrodes form a cavity in which it is possible to trap (store) and analyze the ions. Both endcap electrodes have a hole in their center through which the ions can travel, and the ring electrode is located midway between the two endcap electrodes.

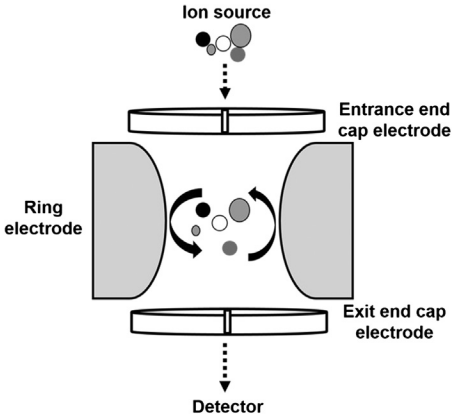

FIGURE 10.6 Quadrupole ion trap mass analyzer.

Ions enter the quadrupole ion trap through the entrance endcap electrode. The ions are then trapped in the space between the electrodes by AC (oscillating, nonstatic) and DC (nonoscillating, static) electric fields. Various voltages are applied to the electrodes to trap and eject ions based on their *m/z*. The ring electrode RF potential produces a 3D quadrupolar potential field within the trapping cavity, which traps ions in a stable oscillating trajectory that is confined within the trapping cell. The exact nature of the trajectory depends on the trapping potential and the *m/z* value of the ions. Then, the electrode system potentials are altered to produce instabilities in the ion trajectories, causing the ions to be axially ejected in order of increasing *m/z* value and focused by the exit lens prior to detection. An important distinction between quadrupole mass analyzers and quadrupole ion trap mass analyzers is that quadrupole mass analyzers separate and detect masses by allowing oscillating ions to pass through the quadrupole to reach the detector (beam-type mass analyzer), whereas quadrupole ion trap mass analyzers separate and detect masses by discharging ions with unstable oscillations from the system (trapping-type mass analyzer).

Quadrupole ion trap mass analyzers are versatile instruments that are routinely used for exploratory studies, structural characterization, and qualitative identification. Their advantages include the ability to conduct tandem MS analysis (see the "Tandem mass spectrometers" section) and high sensitivity. However, quadrupole ion traps are not well suited for quantitative analysis due to the possibility of space-charge (ion−ion repulsion) effects resulting from the limited number of charged species that can fit within the trap, which reduces the analyzer's dynamic range.

Linear ion trap

Linear, or 2D, ion trap mass analyzers use a set of quadrupole rods to radially confine ions and a static electric potential on the end electrodes to axially confine ions. Similar to quadrupole mass analyzers, linear ion traps can also be used as selective mass filters. Among the advantages of linear ion traps are increased ion storage capacity, rapid scan times, and versatile modes of operation. Compared with quadrupole ion trap mass analyzers, linear ion traps have a much greater trapping volume, which enables more ions to be trapped before space-charge effects become a matter of concern.

Ion cyclotron resonance

ICR-MS, or FTICR-MS, is based on the principle that ions in a magnetic field follow a circular motion (cyclotroning).

These mass analyzers measure *m/z* values by detecting the image current produced by ions that are accelerated outward from a common center along a spiral path in a magnetic field created by a high-field superconducting magnet (3−12 T). Ions are injected into a Penning trap (static electric/magnetic ion trap), where they form part of a circuit. Detectors at fixed positions measure the electrical signals from the ions passing by them in close proximity, producing cyclical signals that can be deconvoluted by performing a Fourier transform on the signal.

Among the main advantages of ICR-MS are its high sensitivity, high mass accuracy, and superior resolution (can exceed 1 million) [23]. As ICR mass analyzers are trapping-type analyzers, they are amenable to various modes of MS analysis, including MS^n. However, it should be noted that ion fragmentation is often not required for analyte detection due to the high mass accuracy of the mass analyzer. The disadvantages of ICR mass analyzers include high cost of instrument acquisition and operation, considerable space requirements due to the instrument's large footprint, requirement for a high-field superconducting magnet, relatively long signal acquisition time, safety concerns related to the high magnetic fields, and requirement of highly skilled operators. It is for these reasons that ICR mass analyzers are not amenable for use in routine clinical laboratory applications.

Orbitrap

The orbitrap mass analyzer was commercialized in 2006 [24,25], and it is similar to the ICR mass analyzer, but it does not utilize a magnetic field for trapping. It can readily achieve resolutions up to 100,000 and up to subparts per million mass accuracy, and its dynamic range is up to four orders of magnitude.

The operational principle of this trapping-type mass analyzer is trapping within electrostatic fields. The analyzer itself is a spindle-like central electrode surrounded by a barrel-like outer electrode. The central electrode confines ions, so that they orbit around the electrode and oscillate back and forth along the long axis of the central electrode. This oscillation generates an image current, and the frequency of which depends on the *m/z* value of the individual ions. Mass spectra are obtained in a manner similar to that of FTICR mass analyzers.

Orbitrap mass analyzers are commonly used in proteomic biomarker discovery applications in research laboratory settings [26], and they have great potential for use in clinical toxicology applications based on their high resolution and mass accuracy, which are beneficial to definitive analyte identification [27]. Orbitrap mass analyzers can be readily interfaced with LC systems, thus enabling the incorporation of the use of retention time along with accurate mass to aid compound identification.

Ion mobility

Although ion mobility mass spectrometers (IMSs) are not technically mass analyzers, they are worth mentioning in this section. IMS requires analyte ionization prior to detection, but instead of separating ions based on their *m/z*, ions are separated based on their mobility in an electric field. An IMS can operate at atmospheric pressure or reduced pressure, and in mass spectrometer configurations, an IMS can be situated upstream of the first mass analyzer or after one stage of mass analysis. In the clinical laboratory, IMS has been used for lipoprotein subfraction categorization [28].

Tandem mass spectrometers

In addition to being configured with only one mass analyzer, mass spectrometers can be configured with two or more mass analyzers arranged sequentially, with a collision cell located in between them to enable tandem MS, or MS/MS, analysis. Tandem MS has great utility for several applications including compound identification, the characterization of complex structures, and quantitative analysis.

MS/MS can be achieved using many different analyzer configurations. For beam-type mass analyzers, MS/MS analysis is accomplished via "tandem in space" wherein the analyzers are arranged in a linear sequence. This is in comparison with trapping-type mass analyzers wherein MS/MS analysis is accomplished via "tandem in time"—ions are retained in one region of space, while the precursor ion is selected and dissociated and the fragment ion(s) are analyzed sequentially in time.

In the most widely used configuration of trapping mass analyzers for MS/MS analysis, the first mass analyzer is used to select a precursor ion of a specific *m/z* value, which is an unfragmented ion. The precursor ion then passes into a collision cell where it collides with inert background gas molecules (often argon, helium, or nitrogen) to induce fragmentation, resulting in the formation of product or fragment ions. Mass analysis of the fragment ions is conducted in the second mass analyzer. When coupled with chromatographic separation, MS/MS applications have great selectivity owing to the ability to characterize compounds based on their chromatographic retention time, precursor ion mass, and product ion mass.

Although collision-induced dissociation (CID) is perhaps the most commonly used method to fragment gas-phase ions in MS, several other methods of fragmentation exist including electron transfer dissociation (ETD), electron capture dissociation (ECD), infrared multiphoton dissociation (IRMPD), and higher-energy C-trap (or collisional) dissociation (HCD). The fundamentally similar aspect of these methods of fragmentation is the dissociation of energetically unstable molecular ions, resulting

in unique mass spectral patterns that can often be compared with the spectra in well-curated spectral libraries for the identification of the analyte(s) of interest.

CID refers to the process whereby an ion and a neutral gas (helium, nitrogen, or argon) collide, resulting in fragmentation. CID is useful in applications requiring structural determination. HCD is a variation of CID specific to orbitrap mass spectrometers wherein a higher RF voltage is used to retain ions in a C-trap. The HCD cell is used to fragment the ions, after which they are accelerated and stored inside of the C-trap. The ions are then injected into and separated inside of the orbitrap mass analyzer based on differences in their rotational frequency. HCD is not limited by the low mass cutoff of CID fragmentation and is therefore advantageous for applications entailing isobaric tag-based quantification.

ETD is primarily used for sequence analysis of peptides and proteins including the identification of labile posttranslational modifications. This method of fragmentation requires multiply charged ($z>2$) gas-phase cations, and it is commonly limited to use with an ESI source. After the cations are captured in an ion trap, they react with an anion such as the polycyclic aromatic hydrocarbon molecule, fluoranthene. The capture of an electron from the anion yields an unstable cation radical. The cation radial then breaks into two fragments, an N-terminal c-ion and a C-terminal z-ion. This cleavage occurs randomly between the N−Cα bonds of any two amino acids except proline on the peptide backbone. Similar to ETD, ECD induces fragmentation of higher charge state cationic molecules by transforming their electric potential energy to KE. Although ECD is used primarily with FTICR MS, it also has applications for quadrupole ion trap mass spectrometers.

IRMPD is another fragmentation method that is most often used with FTICR MS. It entails the introduction of a laser beam into an ICR cell. IRMPD fragmentation is based on the absorption by a given ion of multiple infrared photons from a tunable laser. Precursor ions become excited into more energetic vibrational states until a bond is broken, resulting in fragment ion spectra that can contain a wealth of molecular structure information.

Many different scan functions are possible with MS/MS, and they are summarized in Table 10.1. Product ion scanning entails the selection of a precursor ion of a given *m/z* in the first mass analyzer (termed MS1 or Q1) followed by a full scan of the complete spectrum of fragment or target ions. This mode of analysis is frequently used for peptide sequencing analysis. Precursor ion scanning is essentially the reverse of product ion scanning. In this mode of analysis, the second mass analyzer selects a product ion of a specific *m/z*, and the first mass analyzer scans the spectrum of precursor ions to enable the determination of the precursor ions that produce a specific product ion. In the neutral loss mode, both mass analyzers are scanned simultaneously for a constant difference between the transmitted *m/z* values. A signal is recorded only if an ion undergoes fragmentation, producing a neutral ion that is equivalent to the mass difference of interest. The most commonly used scan function in MS/MS applications is multiple (or selected) reaction monitoring (MRM), and it is performed using a triple quadrupole mass spectrometer in which two sets of quadrupoles are separated by an RF-only quadrupole, which functions as a collision cell and passes all ions regardless of *m/z* to the last quadrupole. In MRM acquisition, an ion corresponding to the intact molecular ion of the analyte of interest is selected in the first mass analyzer followed by

TABLE 10.1 Various scan modes entailing MS/MS fragmentation.

Scan mode	Description
Product ion scanning	• Q1 analyzer set to allow only the transmission of 1 *m/z* • Precursor ion collided with inert gas to form product ions • Product ions scanned in Q3 analyzer
Precursor ion scanning	• Q1 analyzer scanned • Precursor ion collided with inert gas to form product ions • Q3 analyzer set to allow only a single fragment ion of 1 *m/z* to pass
Neutral loss	• Q1 and Q3 scanned • Precursor ions collide with inert gas to form product ions • Q3 mass analyzer offset by neutral loss mass of interest • Only ions yielding product ions with the loss of interest are detected
MRM	• Q1 analyzer set to allow the transmission of precursor ion of interest • Fragmentation in collision cell produces product ions • Q3 analyzer set to allow transmission of product ion(s) of interest

MRM, Multiple reaction monitoring.

fragmentation in the collision cell to produce a range of product ions. One or more of these product ions can then be selected for quantitative analysis. MRM acquisition methods are particularly sensitive and specific.

Tandem mass spectrometer configurations are not limited to identical mass analyzers. Hybrid instruments exist, which combine two or more different types of analyzers. Among the most common configurations of hybrid instruments are quadrupole and TOF analyzers, as well as quadrupole and linear ion trap analyzers.

Detectors and processors

In mass spectrometers, after ions travel from the ion source to the mass analyzer(s), they reach the detector where a signal is emitted in response. Ions are converted to a current, and the current is amplified to increase the gain, which is a measure of the intensity of the ions that strike the detector.

Electron multipliers are the most commonly used detectors for mass spectrometers, with the exception of ICR, orbitrap, and some ICP mass spectrometers. The predominant types of electron multipliers are discrete dynode multipliers, continuous dynode electron multipliers, and microchannel plate electron multipliers. In discrete dynode electron multipliers, a series of dynodes are used to amplify the initial signal, thereby generating an electron cascade. After an ion strikes the first dynode, at least one electron is ejected from the dynode surface. This process is repeated for the remaining dynodes, resulting in a gain of 10^4-10^8 electrons.

Detection in ICR and orbitrap mass spectrometers is based on image current detection. Instead of ions being detected by striking a detector such as an electron multiplier, ions induce sinusoidal image current on detection electrodes, as they undergo cyclotron motion. Ions with different *m/z* values oscillate with different cyclotron frequencies. The signal collected by the electrodes is a sum of the various sine waves and is commonly referred to as a transient. Conversion of the transient in the time domain to the frequency domain occurs via Fourier transformation and results in the creation of a mass spectrum.

Following detection of the ions, the raw signal is processed either by the counting of individual pulses that correspond to individual ions, or the signal is converted to a digital representation. Regardless of the downstream data analysis method, when working with raw MS data, it is critical to differentiate between true signal, baseline, and noise. When tuning a mass spectrometer based only on the increase of the signal of a selected number of *m/z* values, an increase in noise often occurs concomitantly with an increase in signal. The relationship between increased noise and signal is not 1:1. Thus it is important to determine the signal-to-noise ratio, which is of fundamental importance when evaluating limits of detection and quantification.

Clinical mass spectrometry applications

As mentioned at the outset of this chapter, MS is a powerful analytical tool that is providing clinical laboratories with enhanced capabilities. This section will briefly highlight some of the ways in which MS-based applications are being used in the clinical laboratory, but the reader is encouraged to refer to Chapter 21, Applications of mass spectrometry in the clinical laboratory, for a more thorough discussion of this topic.

GC-MS based methods are routinely used by the US National Institute of Standards and Technology (NIST) for the development of definitive methods to quantify standard reference materials and assign accurate concentrations to reference materials. GC-MS is also used in clinical and forensic drug testing and screening for certain inborn errors of metabolism. LC-MS and LC-MS/MS assays are used for the measurement of several clinically relevant analytes including immunosuppressant drugs [29], vitamins [30], antiretroviral drugs [31], thyroid hormones [32], thyroglobulin [33], and steroids [34]. The majority of these assays incorporate the use of MRM due to its specificity, selectivity, and analytical sensitivity.

In the clinical microbiology laboratory, MALDI-TOF MS is now routinely used for rapid microbial identification. The implementation of MALDI-TOF MS in this setting has been shown to have cost savings of >50% compared with standard culture techniques [35]. MALDI-TOF MS is also routinely used in genomics applications for the identification of nucleic acid sequence changes (e.g., mutations, single-nucleotide polymorphisms, insertions/deletions, and alternative splicing), quantitative genomic changes (e.g., copy number variation, gene expression, and allele expression), and identification of modifications (e.g., genomic DNA methylation and post-transcriptional modification of tRNAs and rRNAs) [36,37].

Clinical applications of DESI MS-based methods include the surgical iKnife using REIMS [38] and the MasSpec Pen [17]. These devices were described earlier in the "Emerging ionization methods of interest" section.

Challenges and opportunities in the implementation of clinical mass spectrometry methods

The challenges in implementing clinical MS methods are well-known and include the lack of automation, manual nature of the assays, relatively low sample throughput, high capital expense ($200,000−$500,000 plus associated

construction/renovation costs), high level of required technical proficiency, limited assay standardization, and availability of commercial material/traceability [39]. Careful attention to the following parameters when developing MS assays will mitigate some of the drawbacks that lead to poor assay performance: test selection, matrix selection, analyte stability, establishment of reference intervals, and instrument downtimes.

The lack of optimization of some of the following essential features of MS can significantly compromise data quality and hence patient safety: sample preparation, prefractionation, ionization, ion manipulation, signal readout, and data processing. Accordingly, systemic quality management and sustained vigilance are required for MS-based methods that are applied in the clinical laboratory. The fundamental aspects of quality in MS methods applied in the clinical laboratory can be summarized as follows: (1) method design and optimization; (2) appropriate handling of the metadata associated with each run and each peak as postimplementation surveillance; (3) careful management of all steps of the analytical process to avoid gross handling errors; (4) adequate training of technicians including competency verification according to widely accepted quality management standards; (5) a proactive maintenance plan to limit the within- and between-instrument variations; and (6) continued quality verification based on the analysis of control samples and proficiency testing of samples with reliable assigned target concentrations [40].

The Clinical and Laboratory Standards Institute (CLSI) C50A [41] guidance document "Mass Spectrometry in the Clinical Laboratory: General Principles and Guidance" provides a general overview of MS and the principles that dictate its application in the clinical laboratory. The CLSI C62A [42] guidance document "Liquid Chromatography-Mass Spectrometry Methods" provides guidance to the clinical laboratorian for the reduction of interlaboratory variance and the evaluation of interferences, assay performance, and other relevant characteristics of clinical assays. Clinical laboratories performing LC-MS-based tests should be aware of the five directly applicable Clinical Laboratory Improvement Amendments requirements and the associated guidelines: facility administration, quality systems, proficiency testing, personnel, and inspection [43].

Indeed, MS is a highly sensitive and selective technique that can be used for the quantitative analysis of several clinically relevant analytes. Some of these highly specific assays can overcome the limitations of immunoassays, including cross-reactivity, low analytical specificity, and limited dynamic range [44]. Additional advantages of clinical MS methods include rapid assay development compared with immunoassays, potential cost savings on high volume send-out tests, the ability to multiplex multiple analytes in a single method, and the ability to analyze a wide variety of analytes including drugs, hormones, small molecules, carbohydrates, nucleic acids, and proteins. For many clinical applications, there is a clear benefit to the implementation of MS; however, there is considerable room for improvement of the application of this powerful technology in the clinical laboratory. Many of these desirable areas of improvement are related to enhanced automation, more FDA-approved MS-based platforms, and the commercial availability of NIST-traceable assay kits, calibrators, and QC materials. MS continues to be an ever-evolving technology due to the rapid pace of advances in instrumentation. Realization of the full potential of MS in the clinical laboratory requires a thorough understanding of not only the vast opportunities but also the limitations of the technology.

Self-assessment questions

1. Which of the following is the correct order of mass spectrometry analysis?
   a. MALDI → GC → TOF → processor
   b. LC → ESI → quadrupole ion trap → electron multiplier → processor
   c. ESI → MALDI → MS/MS → detector
   d. LC → DESI → ICR → APPI
   e. GC → TOF/TOF → APPI → processor → electron multiplier
2. Which of the following is not a type of mass analyzer?
   a. MALDI
   b. quadrupole ion trap
   c. linear ion trap
   d. ion cyclotron resonance
   e. TOF
3. Which of the following pairs is incorrectly matched?
   a. electron ionization: hard ionization
   b. quadrupole: corkscrew ion path
   c. chemical ionization: soft ionization
   d. MALDI: soft ionization
   e. APCI: pulsed laser beam
4. Beam type mass analyzers include which of the following?
   a. ICR
   b. TOF
   c. quadrupole ion trap
   d. APCI
   e. linear ion trap
5. What is the principle that governs time-of-flight analyzers?
   a. Heavy ions do not move (fly) as fast as light ions.
   b. Ion flight is measured one ion at a time.
   c. Ion flight time is independent of the ion *m/z*.
   d. Switching voltages allows only selected ions to reach the detector.
   e. Ions following an unstable trajectory will be eliminated.
6. Ion fragmentation can occur within which region(s) of a mass spectrometer?
   a. ion source
   b. vacuum
   c. detector
   d. collision cell
   e. b and c
   f. a and d
7. Which of the following is/are not an advantage of mass spectrometry analysis?
   a. increased selectivity
   b. fully automated instrument systems
   c. few interferences
   d. lack of matrix effects
   e. all of the above
   f. b and d
   g. a and c
8. Which of the following aspects of mass spectrometry is correct?
   a. Resolution can be determined from peak height.
   b. Mass accuracy is defined by the mass difference divided by the true mass.
   c. A mass spectrum is a plot of ion mass versus charge.
   d. Mass-to-charge ratio is defined as $m/\Delta m$.
   e. Ion formation occurs in the mass analyzer.
9. ESI is characterized by which of the following correctly ordered steps?
   a. Taylor cone formation → voltage applied → ions enter MS inlet → desolvation/evaporation
   b. Voltage applied → ions enter MS inlet → desolvation/evaporation → Taylor cone formation
   c. Voltage applied → Taylor cone formation → ions enter MS inlet → desolvation/evaporation
   d. Ions enter MS inlet → voltage applied → desolvation/evaporation → Taylor cone formation
   e. Voltage applied → Taylor cone formation → desolvation/evaporation → ions enter MS inlet
10. Which of the following statements is incorrect?
    a. Tandem mass spectrometry is highly selective because of the analysis of precursor and product ions.
    b. Quadrupole resolution is affected by applied voltages.
    c. ICR mass analyzers are commonly used with MALDI ionization sources.
    d. Only specimens capable of being volatilized to the gas phase are suitable for mass spectrometry analysis.
    e. MS^n is described as multiple, sequential rounds of ion fragmentation and analysis.

Chapter 11

Nuclear magnetic resonance technology and clinical applications

Deanna D.H. Franke[1] and Margery A. Connelly[2]

[1]*Technical Specialties, Atrium Health, Corporate Lab Services, NC, United States,* [2]*Laboratory Corporation of America Holdings (LabCorp), NC, United States*

Learning objectives

After completing this chapter, the reader will be able to:

1. Review theory and principles of NMR.
2. Summarize current applications of NMR technology for clinical analysis.
3. List three NMR-based tests that are currently available for reporting of patient results in the clinical laboratory.

Introduction

Nuclear magnetic resonance (NMR) has become a vital tool and transformative technology capable of producing molecular fingerprints for diagnostic use. This chapter will provide an overview of the theory, principles, and clinical applications of NMR spectroscopy. From bench to bedside, advancements in the NMR field have transformed how scientists, and clinical and laboratory professionals interrogate the human body—both physically and biochemically. The past couple of years have seen an expansion of use of NMR in the clinical laboratory, largely due to the high-throughput nature of NMR analyzers that have been designed specifically for this purpose. NMR provides the ability to quantify multiple analytes simultaneously by the acquisition of a single NMR spectrum. Furthermore, the development of powerful new software algorithms facilitates the quantitation of individual analytes while taking into account overlapping signals from the multitude of molecules in complex samples such as plasma and serum.

Theory of nuclear magnetic resonance

"NMR" is a property of the nucleus of an atom. Each positively charged nucleus spins on its own axis and creates a small nuclear magnetic field or magnetic moment (Fig. 11.1A). In the absence of an external magnetic force, nuclear magnetic fields are randomly oriented (Fig. 11.1B). However, when placed in a strong external magnetic field, the magnetic field of each nucleus aligns with the external magnetic field in either the same or the opposite direction, similar to a miniature bar magnet (Fig. 11.1C). When electromagnetic radiation in the radiofrequency range is applied to the sample, the nuclei that were originally aligned in the opposite direction to the external magnetic field flip, and the nuclei are then said to be "in resonance" with the strength of the external magnetic field (Fig. 11.1D). Different isotopes can have a variety of values for nuclear spin angular momentum or quantum number (I): no overall spin or zero spin (for nuclides with even numbers of protons and/or neutrons) or one spin (for nuclides with odd numbers of protons and/or neutrons). The most useful nuclei for NMR spectroscopy are nuclides with paired neutrons plus a proton of spin ½, where I = ½. Nuclei with ½ spin include hydrogen (^{1}H), carbon (^{13}C), fluorine (^{19}F), nitrogen (^{15}N), and phosphorus (^{31}P). These nuclei are "NMR active," as they produce the signals that comprise the NMR spectra and allow for the predictable determination of protons within their functional groups or neighboring substituents. These ½ spin, "NMR active" nuclei are the most common elements in biological specimens and, as such, can be readily analyzed by NMR spectroscopy. Because hydrogen (^{1}H) or proton NMR spectroscopy is the most widely used NMR technique in the clinical laboratory, the focus of this chapter will be on proton NMR spectroscopy.

Proton nuclear magnetic resonance spectroscopy

The underlying principle of proton (^{1}H) NMR spectroscopy is similar to that of magnetic resonance imaging

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00011-9

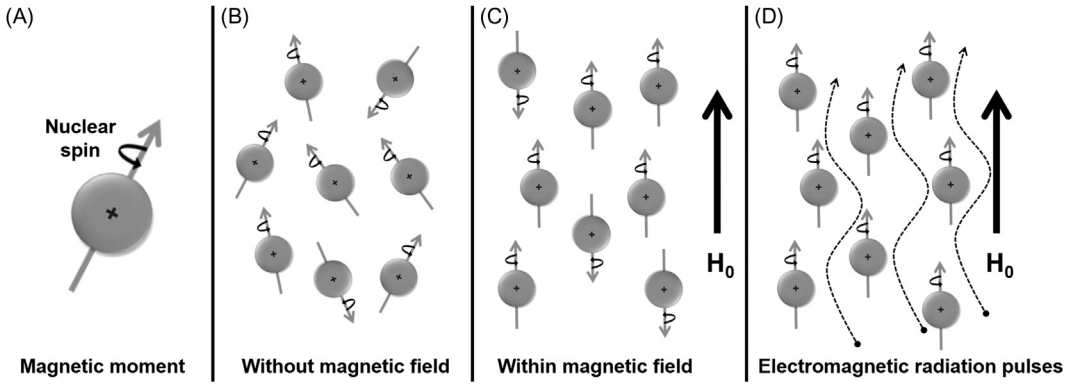

FIGURE 11.1 Nuclear magnetic resonance theory. (A) Nuclei with an unpaired proton have spin and a net magnetic moment. (B) When not in a magnetic field, the nuclear spins are randomly oriented. (C) In an external magnetic field, the nuclei align with the external magnetic field in either the same or the opposite direction. (D) The nuclei become aligned in the same direction and are said to be in resonance with the external magnetic field when subjected to pulses of electromagnetic radiation.

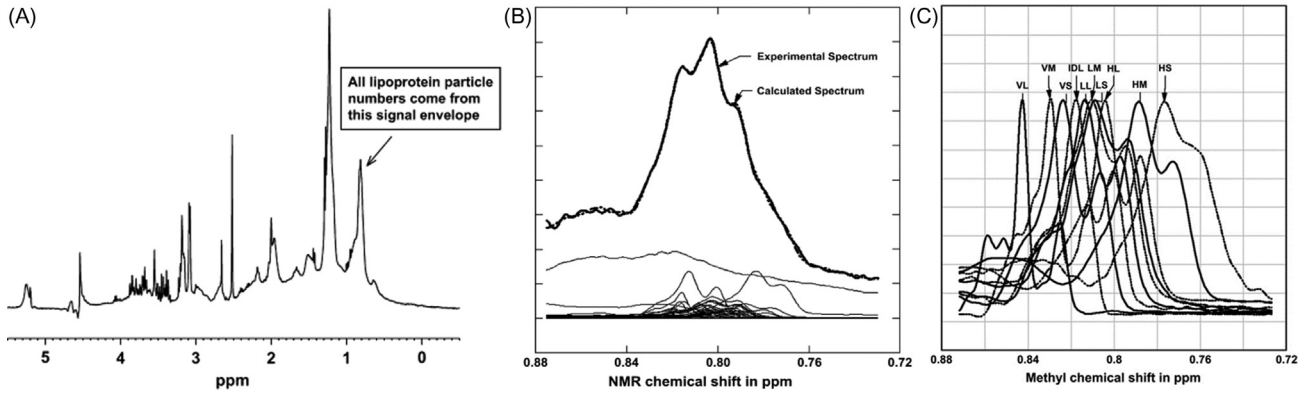

FIGURE 11.2 Proton nuclear magnetic resonance spectrum of plasma. (A) A typical proton nuclear magnetic resonance spectrum of human plasma recorded on a 400-MHz nuclear magnetic resonance clinical analyzer. The signal envelope centered at 0.8 ppm arises from the methyl proton signals of the lipoproteins. (B) A representative deconvolution of the methyl signal (0.7−0.9 ppm). The solid line represents the experimental spectrum, and the dotted line is the calculated sum of the individual lipoprotein subclass signals shown at the bottom. The broad peak in the middle accounts for the nonlipoprotein plasma protein signal. (C) Spectra of several lipoprotein subclasses. The lipoprotein subclasses were isolated by ultracentrifugation and agarose column chromatography and the spectrum for each subclass was acquired in order to illustrate their distinct nuclear magnetic resonance signals. *HL*, large HDL; *HM*, medium HDL; *HS*, small HDL; *IDL, intermediate-density lipoprotein*; *LL*, large LDL; *LM*, medium LDL; *LS*, small LDL; *VL*, Large VLDL; *VM*, medium VLDL; *VS*, small VLDL.

(MRI) [1]. Both involve placing an object or a specimen in a strong external magnetic field, irradiating the object or specimen with harmless radiofrequency pulses and recording the response of the nuclei. While MRI provides anatomic information, NMR spectroscopy generates an electromagnetic spectrum, providing molecular information (Fig. 11.2A). More specifically, ^{1}H NMR spectroscopy exploits the magnetic properties of protons in order to obtain information about both the identity and quantity of hydrogen containing molecules within a specimen. A description of the theoretical basis of ^{1}H NMR and a simplified depiction of an NMR spectrometer can be found in a recent review by Rankin et al. [2]. In brief, the test sample is placed in a strong external magnetic field and electromagnetic radiation, in the form of radiofrequency pulses, is used to excite the protons on the various molecules within the sample. As the protons relax back to equilibrium, the released energy is recorded as an oscillating electromagnetic signal, called the free induction decay (FID). Fourier transformation, a mathematical transformation of the FID signal from time domain to frequency domain, results in a spectrum with intensity plotted on the *y*-axis and chemical shift (δ), in parts per million (ppm), plotted on the *x*-axis (Fig. 11.2B, Fig. 11.2C).

The position in the NMR spectrum, also referred to as the chemical shift, of any given signal or peak depends on the structural environment surrounding the proton(s). The location of each peak is predictable, and the origins of the various signals or peaks within the spectrum have been fully characterized, facilitating the identification of the molecules within a specimen matrix. Fortuitously, the amplitudes of these signals are proportional to the number of molecules of the same kind that generated the signal. Using customized software, NMR signals can be

identified and signal amplitudes converted into concentrations, making NMR analysis of a specimen highly quantitative and reproducible. The strength of the magnetic field determines the resolution of the overlapping signals. For example, a 900-MHz magnet will provide the maximum resolution of the multitude of signals in a complex matrix. Even a 400-MHz proton NMR (^{1}H-NMR) spectrometer can quantify numerous, relevant analytes in common specimen matrices like serum, plasma, or urine with the highest accuracy and precision. Widely used in the clinical laboratory, 400- and 600-MHz ^{1}H-NMR instruments are relatively inexpensive. In contrast to other instrument systems commonly deployed throughout the laboratory, NMR spectrometers require minimal reagents and can simultaneously quantify many analytes with no preanalytical specimen manipulation. For these reasons, NMR spectroscopy has rapidly become a cost-effective means to measure analytes accurately and efficiently.

Nuclear magnetic resonance analyzers in clinical analysis

NMR analyzers are widely used in research and development, quality control, and quality assurance in food science, pharmaceutical, and chemical industries, as well as in academic, medical, and clinical arenas. They range in size, NMR type, resolution, and application, but have proven to be effective, powerful tools in their respective spectroscopic niches and disciplines.

Benchtop nuclear magnetic resonance spectrometers

A number of benchtop, low-field NMR analyzers exist on the market (Table 11.1). Distributed by different manufacturers, these analyzers have specific analytical chemistry applications for the identification of chemicals, compounds, and molecules in solid, semisolid, and liquid states. Routinely, these benchtop model NMR spectrometers are utilized in teaching laboratories and academic institutions for research purposes, performing a number of different types of experiments including, but not limited to, reaction monitoring and flow chemistry experiments. Similar to basic chemical reactions that are commonly monitored on large, automated chemistry platform in the laboratory today, these systems are capable of determining reaction end points and kinetics, as well as identification of intermediates or by-products. These benchtop systems also offer industrial applications for routine quality control and quality assurance of simple compounds to highly complex sample admixtures.

Of interest, and interrelated to pharmaceutical and clinical medicine, are applications for analysis and identification of prescribed and illicit drugs from seized samples as well as other biomarkers in biofluids [3,4]. For healthcare systems supporting large pain management populations, in partnership with law enforcement agencies and emergency room physicians, detection of active pharmaceutical ingredients (API) within seized drug samples is becoming increasingly important. Recent work using a high-throughput, benchtop NMR spectrometer and automated collection of ^{1}H-NMR spectra revealed that it is possible to easily screen for and detect novel psychoactive substances, herbal products mixed with synthetic cannabinoids, and illicit drugs. Spectral libraries from ^{1}H-NMR were compared with gas chromatography—mass spectrometry libraries as the currently accepted reference method, which demonstrated a 93% match of cases. NMR spectral analysis easily identified commonly abused drugs like cocaine, 3-4 methylenedioxymethamphetamine, heroin, mephedrone, ketamine, and diazepam in seized samples. This work confirms ^{1}H-NMR spectra generated via a high-throughput, benchtop NMR analytical platform that can rapidly ($\sim$5 minutes) identify API of drugs seized by law enforcement agencies [3]. Future work directed toward quantification methods to widen the applicability of qualitative identification may be of benefit to the clinical and forensic communities.

Other recent advancements in benchtop biofluid analysis have been made, specifically in urine and liquid biopsies [4]. Work in urinary biomarkers revealed that benchtop NMR systems successfully identified and quantified compounds like glucose and ketone bodies for diagnosis and monitoring of patients with type 2 diabetes (T2D). Benchtop 60-MHz ^{1}H-NMR quantitation of urinary glucose concentrations correlated well with chemical dipstick and glucose oxidase spectrophotometric methods. Interestingly, other biomarkers like alanine, citrate, and creatinine/creatine were found to be increased in this patient population, all consistent with previous reports of findings using high-field (400 or 600 MHz) ^{1}H-NMR instrument systems. Given the ease of specimen preparation, low cost, and increased investigations in biofluid applications, benchtop NMR systems are gaining appeal in near-patient, point-of-care fields [5]. Continued development and work using benchtop, low-field NMR systems may have future applications for spectroscopic analyses of a number of biomarkers in biological specimens, including blood, urine, saliva, and other body fluids.

Nuclear magnetic resonance expansion into the clinical laboratory

The first NMR analyzer to be cleared by the United States (US) Food and Drug Administration (FDA) for clinical diagnostic purposes was the 400 MHz Vantera Clinical Analyzer. The first clinical application for the

Vantera was the NMR LipoProfile test, or lipoprotein profile, which was cleared by the FDA as an in vitro diagnostic test. The lipoprotein profile reports a number of total low-density lipoprotein particles (LDL-P) for physician use in the management of LDL-related cardiovascular disease (CVD) risk [6]. Results for several laboratory-developed tests (LDTs) are also included in the lipoprotein profile report, including the following: lipoprotein insulin resistance (LP-IR) index, which produces a score that varies from 0 to 100, with higher scores indicating insulin resistance; total high-density lipoprotein particles (HDL-P); small LDL particles; and LDL size. These analytes, however, represent only a fraction of the lipoprotein parameters that can be quantified using the proprietary software algorithms that report data for the lipoprotein profile. Jeyarajah and colleagues [7] described how the first software algorithm developed was able to quantitate all of the lipoprotein parameters from the signal envelope at ~0.8 ppm in the NMR spectrum (Fig. 11.2B). The broad peak, which arises from the methyl group protons of lipids within the lipoprotein particles, is deconstructed to provide concentrations for all lipoproteins based on their size, largely due to the fact that each lipoprotein of a given diameter emits its own distinct NMR signal (Fig. 11.2C). This phenomenon has been described in detail along with illustrations of the unique signals emitted by the lipoprotein subclasses (Fig. 11.2C) [7]. Specially designed software measures these distinct

signals and provides quantitative information regarding the lipoprotein particle classes [very-low-density lipoprotein (VLDL), LDL, and HDL] and subclasses [small, medium, and large], as well as weighted-average VLDL, LDL, and HDL sizes. In order to measure the individual lipoprotein parameters, the shape of the broad methyl signal is modeled as the sum of the lipoprotein subspecies signals using nonnegative linear least squares deconvolution [7]. This approach provides the signal area contributed by each lipoprotein subspecies, which after multiplication by their respective signal to particle conversion factors gives the subspecies particle concentrations. Subsequently, the concentration of each of the three lipoprotein classes [VLDL, LDL, and HDL] is determined by the sum of the individual particle subspecies. For example, total HDL particles are calculated by adding the concentrations of small, medium, and large HDL subclasses.

Since its introduction, the initial procedure for acquiring the 400-MHz proton NMR spectrum from a patient's serum or plasma sample has remained the same. However, the computational process by which lipoprotein subclass concentrations are derived by deconstructing the broad methyl signal has been optimized over the past 20 years. Optimization of the assay, represented by versions LP1, LP2, and LP3 of the proprietary software algorithm, has primarily involved expanding the number of subspecies in the mathematical model to better account for the compositional diversity of human lipoproteins. The most recently developed software algorithm, called LP4 (the fourth-generation lipoprotein profile algorithm), uses a further-optimized deconvolution method to quantify lipoprotein subspecies. One of the incentives for developing the new algorithm was to enable a more detailed investigation of the disease relationships of different HDL particle subspecies, prompted by emerging evidence for the functional and proteomic diversity of HDL particles.

The LP4 algorithm quantifies seven different HDL subspecies with good precision and corrects a prior overestimation of the absolute concentrations of HDL particles. The granularity in the number of HDL subspecies may provide additional means to understand the biological and clinical relevance of HDL, which is thought to have both antiinflammatory and antioxidant properties [8]. Also corrected was an aspect of prior mathematical modeling that led to an underestimation of LDL-P concentrations. There was no clinical consequence to this change, as both the previous LP3- and the new LP4-generated LDL-P concentrations show close associations with CVD outcomes [9]. Notably, the concentration of LDL particles generated by the LP4 algorithm is more closely related to the number of apolipoprotein B (apoB) molecules they carry. Moreover, corrections to the NMR-generated total HDL and LDL particle concentrations bring the NMR technique a step closer to standardization with other methods used in the clinical laboratory to estimate apolipoprotein and lipoprotein (e.g., HDL fractionation using the calibrated ion-mobility mass spectrometry) concentrations [10]. In all, the LP4 algorithm reports data for quite a few new parameters including the modified lipoprotein profile and several clinically relevant metabolites. Over the past 20 years, lipoprotein profiles have been determined for millions of patient samples as well as for samples from over 1500 observational and interventional clinical studies. Lipoprotein data from these studies have been used to show efficacy and safety in clinical studies of potential new therapeutics as well as to evaluate the potential clinical applications for NMR-measured analytes.

Clinical utility of lipoprotein particle numbers

Multiple lipoprotein parameters from the NMR lipoprotein profile have been shown to have clinical utility. LDL-P values are used by physicians for management of LDL, which is known to be one of the major contributors to, and risk factors for, CVD [6]. Traditionally, the cholesterol content of LDL (LDL-C) has been used to estimate circulating LDL concentrations. However, the LDL-C content of particles varies widely among individuals and is often dependent on the metabolic state of the subject whose sample is being evaluated [6]. For example, patients with insulin resistance have a higher number of small LDL and HDL particles containing less cholesterol and cholesteryl esters and some LDL particles that contain higher triglyceride content as compared with individuals without insulin resistance. Therefore in patients with insulin resistance, metabolic syndrome, and T2D, NMR-measured LDL-P is a better measure of LDL quantity as it is unaffected by changes in cholesteryl ester content and particle size [6]. In fact, discordance between LDL-C and LDL-P has been noted in several large clinical studies [11–15]. Notably, CVD risk tracks more closely with LDL-P than LDL-C [6]. Discordance between LDL-C and LDL-P has also been noted in statin-treated individuals. Consequently, multiple medical society expert panels have recommended the use of LDL-P as a target of therapy to guide medical decision-making with respect to management of LDL-related CVD risk, especially in patients with underlying metabolic disease [11–15]. The medical decision limit for LDL-P is >1000 nmol/L, and measurements above this threshold are associated with higher risk of CVD (Table 11.2) [15].

Besides LDL-P, NMR-measured HDL-P may be useful for assessment of residual CVD risk in primary or secondary prevention settings. Results from key epidemiological and clinical trials, including the Multi-Ethnic Study of Atherosclerosis (MESA), Heart Protection Study (HPS),

ApoB, Apolipoprotein B; *HDL-C*, high-density lipoprotein cholesterol; *HDL-P*, high-density lipoprotein particles; *LDL-P*, low-density lipoprotein particles; *TC*, total cholesterol; *TG*, triglycerides; *TMAO*, trimethylamine-*N*-oxide.

and Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin (JUPITER), demonstrated that NMR-measured HDL-P was a stronger, more independent predictor of CVD risk than HDL cholesterol (HDL-C) content [8]. In JUPITER, investigators evaluated the relationship between HDL-C and HDL-P with CVD risk in more than 10,000 subjects randomized to receive rosuvastatin or placebo [16]. Similar to results from the HPS, JUPITER showed a strong, inverse association between the HDL-P concentrations and the CVD risk [16]. In contrast, HDL-C was not associated with CVD risk in statin-treated patients after adjustment for additional lipoprotein parameters [16]. Notably, with HDL-P measured by ion mobility, no association was observed with either incident CVD or CVD plus mortality in the JUPITER trial, suggesting that the HDL-P values obtained from NMR and ion mobility technologies are not equivalent. Therefore NMR-measured HDL-P has shown better promise as a marker of residual CVD risk than HDL-C and other measures of HDL-P [8]. The medical decision limit for HDL-P is <30 μmol/L, and values below this threshold are considered to be low and are associated with a higher risk of CVD (Table 11.2) [8].

Standard lipid panel and apolipoprotein B are measured by nuclear magnetic resonance

Recently, a traditional lipid panel assay, which reports results for total cholesterol (TC), triglycerides (TG), HDL-C and apoB, was added to the list of FDA-cleared tests on the Vantera Clinical Analyzer. This panel of traditional biomarkers has been used in patient care for many years, largely for the assessment of CVD risk. The NMR lipid panel results are substantially equivalent to the chemical measures for TC, TG, HDL-C, and apoB. While acquisition of the NMR spectra is the same as that used for the lipoprotein profile, the method for calculating the analyte concentrations is different. The software algorithm for determining results for the lipid panel and apoB uses a partial least squares (PLS) regression model that was trained on thousands of previously obtained NMR spectra, along with the chemistry results for TC, TG, HDL-C, and apoB. Using a PLS regression routine, the spectral information in the combined methylene and methyl region was trained against the chemical measurements. Cross-validation was performed to optimize the regression model. For any newly acquired NMR spectrum, the spectral information is then converted into TC, TG, HDL-C, or apoB concentrations. The use of PLS regression for the development of this assay differs from the traditional deconvolution technique used to quantify lipoprotein parameters. Precision for TC, TG, HDL-C, and apoB calculated from NMR spectra in this manner is similar to that reported by traditional chemical assays; % CV is for TC = 0.9%–1.6%, TG = 1.0%–1.4%, HDL-C = 1.3%–2.8%, and apoB = 1.2%–2.4%. Moreover, results from the NMR-measured lipid panel and apoB are comparable with the results from other assays vetted by the ReLABS Certification Program at the Northwest Lipid Research Laboratory at the University of Washington and the Lipid Standardization Program administered by the Center for Disease Control. This test increases the number of NMR assays that are available in the clinical laboratory for CVD risk assessment. Medical decision limits for the analytes of the standard lipid panel have been recommended by the The National Cholesterol

Education Program Adult Treatment Panel III Guidelines for the assessment and management of CVD risk (Table 11.2) [17–19]. Examples of reports and suggestions on how to interpret the results of these commonly reported laboratory tests can be found at the websites for various clinical laboratories.

LP-IR, a measure of insulin resistance that predicts future type 2 diabetes

As mentioned earlier, the LP-IR Index, which is currently an LDT, is useful for determination of a patient's insulin resistance status. Well-characterized changes in lipoprotein metabolism occur in subjects with insulin resistance, which may be observed in the NMR-measured lipoprotein parameters. Higher levels of large VLDL and small LDL particles and lower levels of large HDL particles have been observed [20]. In addition, mean VLDL particle size is generally greater, and mean LDL and HDL sizes are smaller, in insulin resistant subjects [20]. These six NMR-measured lipoprotein parameters have been combined into a single weighted LP-IR score (varying from 0 to 100); the higher the score, the more likely a patient is insulin-resistant [20]. Development of LP-IR was guided by data from the MESA cohort and verified by comparing LP-IR to glucose disposal rates measured during hyperinsulinemic-euglycemic clamps in insulin-sensitive, insulin-resistant, and untreated subjects with T2D [20]. The association of LP-IR with insulin resistance was validated in two independent cohorts of subjects studied at Duke University [21]. In both cohorts, there was a significant inverse correlation between LP-IR and the insulin sensitivity index measured during an intravenous glucose tolerance test, as well as a significant positive association with the homeostatic model assessment of insulin resistance (HOMA-IR) [21]. Taken together, these data suggest that LP-IR provides a simple, high-throughput means to identify individuals with insulin resistance from a single, fasting blood sample. Given that insulin resistance drives metabolic diseases such as T2D, knowing a patient's insulin resistance status is important for clinical decision-making and medical management.

Recently, it was shown in three varied study populations that LP-IR was able to predict future T2D [22–24]. In the MESA study, LP-IR was associated with future T2D with a hazard ratio (HR) of 1.59, even after adjusting for multiple diabetes risk factors including fasting blood glucose and TG to HDL-C ratio [23]. In the Women's Health Study (WHS), a study of nondiabetic women aged 45 or older, LP-IR was associated with incident T2D with a fully adjusted HR of 2.21 [22]. Similar to the MESA study, the WHS study showed that LP-IR was associated with T2D even in those subjects who would be considered to be of low risk. Hence, it was concluded that LP-IR detects insulin resistance and T2D risk years before clinically detectable dysglycemia. Moreover, in the WHS, LP-IR enhanced the performance of the Framingham Offspring Study diabetes risk score and gave improved performance when compared with 35 T2D risk factors, including a previously developed genetic risk score [22,25]. Furthermore, the JUPITER study showed that LP-IR was significantly associated with incident T2D in placebo and rosuvastatin-treated subjects after adjusting for traditional risk factors, body mass index (BMI), and lipids [24]. The authors concluded that the LP-IR score identifies individuals at risk for developing T2D including those taking statins, which have been shown in some studies to increase the risk of progressing to T2D.

In the Prevention of Renal and Vascular End Stage Disease (PREVEND) Study, a large cohort of men and women with a wide age range (28–75 years), LP-IR scores were strongly associated with incident T2D, even after adjustment for multiple T2D risk factors [26]. Moreover, LP-IR scores identified subjects with insulin resistance independently of BMI and glucose status. These results support the premise that LP-IR scores may be useful for identifying patients with insulin resistance who are at a risk of progressing to T2D, even when they do not show clinical signs of risk. While many of the multiparameter diabetes risk scores, such as those that are available for self-assessment on the American Diabetes Association website or based on the Framingham Offspring Study [25], include parameters that are not modifiable (e.g., age, gender, familial history of diabetes, and previous gestational diabetes), the LP-IR score takes into account lipoprotein changes that are fully modifiable with changes in diet and exercise [27–29]. Taken together, LP-IR may be a convenient way for physicians to assess insulin resistance and a patient's T2D risk, early in the progression of the disease, as well as monitor treatments aimed at reducing weight, improving insulin sensitivity, and preventing development of T2D. A medical decision limit or cut point for LP-IR and prediction of T2D was determined to be >68, above which a patient's risk of progressing to T2D would be high [26].

GlycA, a nuclear magnetic resonance-specific marker of systemic inflammation

GlycA, first described in 1987 and noted in several NMR metabolomics studies, is an example of the successful translation of an NMR-measured biomarker into a diagnostic tool for physician use [30]. The NMR resonance that is called GlycA was first noted by Bell et al. [31], who described a peak at approximately 2.04 ppm in the spectrum for human plasma was elevated in inflammation. The authors identified the signal as arising from the N-acetyl glucosamine residues located within the

carbohydrate side chains of acute phase proteins such as α1-acid glycoprotein, α1-antitrypsin, α1-antichymotrypsin, haptoglobin, and transferrin [30]. GlycA, quantified on the Vantera Clinical Analyzer as an LDT, has been demonstrated to be associated with common markers of inflammation such as high sensitivity C-reactive protein (hsCRP), fibrinogen, interleukin-6, and serum amyloid A [30–32]. Similar to what was found in the metabolomics studies, GlycA was shown to be higher in autoimmune diseases such as rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE) [31,33]. Moreover, GlycA was associated with disease activity and coronary artery atherosclerosis in patients with RA [31] as well as active inflammation at the vessel wall in patients with psoriasis [34]. Perhaps because it is a composite biomarker that measures both the increased protein levels and enhanced glycosylation states of the most abundant circulating acute phase proteins, GlycA has the advantage of having lower within-subject biological variation than hsCRP [30]. To illustrate this point, the homeostatic set points were determined for hsCRP and GlycA in a cohort of normal, healthy, adult volunteers collected for a previously published biological variability study [30]. This study calculated that 33 concurrent measurements of hsCRP would be required to estimate its true value for a single patient (similar to what was previously reported for hsCRP) compared with only one for GlycA, suggesting that GlycA is much less variable than hsCRP and, therefore, a more reliable measure of inflammation [30,35].

GlycA has been shown to be useful for predicting future CVD [36–38]. In the WHS, GlycA was associated with CVD events, independent of traditional risk factors [36]. In the PREVEND study, GlycA was associated with incident CVD, defined as the combined end point of CV morbidity and mortality, independent of clinical and lipid measures as well as renal function [37]. Baseline concentrations of GlycA in the JUPITER trial were significantly associated with incident CVD events, even when adjusting for established risk factors and a family history of premature coronary heart disease [38]. Remarkably, this association was only slightly attenuated by hsCRP [38]. GlycA was shown to be associated with future mortality [39,40]. GlycA was also found to be associated with CVD in patients undergoing angiography in the Intermountain Heart Collaborative Study [41]. In this large study, baseline levels of GlycA and hsCRP were the independent and additive markers of risk for future major adverse cardiac events, death, and hospitalization due to heart failure [41]. Given its usefulness for predicting future CVD and the fact that it is higher in RA, SLE, and psoriasis, GlycA may be useful for CVD risk assessment in patients with autoimmune diseases, where traditional CVD risk factors such as LDL-C and hsCRP are not predictive of CVD [42]. The medical decision limit for GlycA is ≥ 400 μmol/L, above which a patient would be considered to have high systemic inflammation, have higher CVD risk, and may warrant clinical management (Table 11.2) [30].

Clinical utility for nuclear magnetic resonance quantified metabolites

NMR has been used for 20 years for quantifying lipoprotein particles; however, only recently has significant attention been given to the wealth of additional analytes that can be quantified from the typical NMR spectrum. Metabolic phenotyping by NMR has become a widely used tool to identify analytes that have significant associations with various disease states [43,44]. Metabolomics, applied in the academic setting to many epidemiological studies, has uncovered NMR-measured analytes that are associated with metabolic disorders such as insulin resistance, metabolic syndrome, T2D, and diabetic complications [43]. These publications strengthen the already mounting evidence that suggests that there are predictable alterations in fatty acid, amino acid, and lipoprotein metabolism that occur in various metabolic diseases. Circulating fatty acids, TG, VLDL, and LDL particles, VLDL particle size, branched-chain and aromatic amino acids, and markers of inflammation are higher, whereas HDL particles, HDL and LDL particle size, adiponectin, glutamine, and β-hydroxybutyrate (β-HB) are lower in subjects with higher adiposity, metabolic syndrome, and T2D [45,46]. Branched-chain amino acids (BCAA) have been found to be altered in metabolomics studies of alcoholic liver disease and nonalcoholic fatty (NAFLD) liver disease, while NMR-measured N-acetyl glycoproteins, LDL, creatine, and albumin were decreased and citrate and VLDL were increased in subjects with chronic hepatitis C-induced liver fibrosis [47–49]. NMR metabolomics studies have also been applied in the area of CVD diagnostics in order to enhance CVD risk assessment [2,43,50,51]. Associations between NMR-measured analytes and mortality as well as Alzheimer's disease have also been uncovered [39,52]. Finally, metabolomics studies have been employed for the purpose of discovering novel biomarkers that might be useful for diagnosis, prognosis, or monitoring of disease activity for autoimmune diseases such as RA, SLE, and inflammatory bowel disease [53,54].

While metabolomics studies are useful for uncovering disease associations, in order to apply the metabolomics information for clinical diagnostic purposes, software algorithms should be developed that measure the analyte of interest in an absolute sense. These algorithms should, therefore, take into account the many overlapping signals that may occur in the same region as the desired analyte. For example, the NMR spectrum from a patient with severe hypertriglyceridemia will look very different from

that of a patient with a normal lipid profile. The NMR signals from the TG molecules overlap several key analytes and will have profound effects on their quantitation if not considered during the deconvolution process. This indicates that NMR, like other general chemistry and immunoassay platforms, is not free from common interferences and requires development and validation of appropriate deconvolutions for accurate analyte quantitation. Once complete, the assays may then be used to interrogate a patient's sample with confidence that the absolute concentration of the desired analyte has been determined despite the potential for interfering peaks that may be unique to their profile.

Branched-chain amino acids (BCAA) for prediction of T2D risk

The BCAA (valine, leucine, and isoleucine) are essential amino acids that are not only required for protein synthesis but also have been shown to regulate protein production, protein degradation, and glucose metabolism. Decreased circulating concentrations of BCAA are associated with several pathological states including liver disease, early chronic kidney disease, and all-cause mortality [55]. Increased BCAA, on the other hand, are associated with insulin resistance, T2D, coronary artery disease, and an altered microbiome [55]. While it has been hypothesized that increased circulation of BCAA may be a causal factor in the development of insulin resistance and T2D, recent genetic evidence supports the concept that insulin resistance may in fact drive higher circulating fasting BCAA concentrations [55]. BCAA can be measured from the same NMR spectra acquired for the lipoprotein profile by taking into account the overlapping signals from the proteins and lipoproteins in each sample, thereby allowing quantification from spectra collected for multiple clinical purposes [6,30]. Similar to the NMR LipoProfile and GlycA tests, the BCAA assay is high throughput with an analytical time of 90 seconds and there is no requirement for sample preparation before placing it on the clinical instrument for analysis. Furthermore, the analytical performance data revealed that the BCAA assay is robust and suitable for clinical testing [55].

BCAA are predictive of T2D development and are responsive to therapeutic interventions that enhance insulin sensitivity [55]. In fact, fasting concentrations of BCAA were found to be elevated before the onset of T2D [56]. Consistent with recent literature, analysis from two independent cohorts showed that NMR-measured BCAA are elevated in subjects with T2D compared with nondiabetic subjects [55]. Furthermore, BCAA demonstrated independent and positive association with T2D and metabolic syndrome in each cohort, and in subjects with varying degrees of glucose tolerance, NMR-determined BCAA concentrations have been shown to closely relate to insulin resistance, as assessed by HOMA-IR [57]. Observed in a small number of participants, this study also suggested that BCAA concentrations may be directly related to carotid intima-media thickness, a proxy of subclinical atherosclerosis, and independent of the presence of T2D and metabolic syndrome [58–61]. Though preliminary, this cross-sectional association added to recent observations showing that BCAA concentrations may predict incident CVD [62]. BCAA measurements may be useful for determining early metabolic dysfunction, well in advance of the development of chronic disease, thereby enabling preventative measures to reduce potentially disease progression. Medical decision limits for BCAA have not yet been established.

Ketone bodies for diagnosis of diabetic or alcoholic ketoacidosis

Ketone bodies (acetone, acetoacetic acid, beta-hydroxybutyric acid) are products of fat catabolism that are used as alternative sources of energy to glucose when carbohydrate intake is low and there is a surplus of circulating free fatty acids [63]. Elevations in ketone bodies occur when there is insufficient insulin to utilize glucose as an energy source (ketoacidosis), during times of prolonged fasting (mild ketonemia) or when consuming a carbohydrate-restricted diet (ketogenic diet). The predominant ketones are β-HB, acetoacetate, and acetone. Under normal physiological conditions, total plasma ketone concentrations fluctuate between 100 and 600 μM, but can rise to $\sim$1 mM after prolonged exercise or 24 hours of fasting [63]. For example, β-HB concentrations $>$2.8 mg/dL ($>$1.0–1.5 mM) are indicative of ketoacidosis and will alert a physician to the need for immediate treatment and follow-up testing. Concentrations of the three ketone bodies combined can rise as high as 6–20 mM in patients with diabetic or alcoholic ketoacidosis [64,65]. Therefore ketone bodies are key for diagnosis of diabetic and alcoholic ketoacidosis, both of which can be fatal if not recognized before symptoms become life threatening [66,67]. Like the BCAA, the three main ketone bodies can be concurrently quantified from lipoprotein profile spectra [66,67].

While measurement of ketone body concentrations is critical to diagnosis of ketoacidosis, it may also be useful for quantifying circulating ketones when there is only a mild elevation. For example, diets that are rich in proteins and fats but very low in carbohydrates (e.g., Atkins diet; also known as a ketogenic diet) have been shown to induce mild elevations of ketone bodies. Elevations in ketones produced while consuming a ketogenic diet are much lower than those observed in ketoacidosis and are not associated with a change in blood pH [68]. However,

since very high ketone levels may have nonbeneficial effects, physicians or patients may want to monitor ketone bodies to ensure the diet is managed correctly and is beneficial [69]. In addition, sodium-glucose transporter-2 (SGLT2) inhibitor treatment for T2D may elicit mild ketonemia that is reminiscent of the mild elevations induced by ketogenic diets and may be related to their ability to reduce plasma glucose via renal elimination, stimulate lipolysis, elicit weight loss, and enhance insulin sensitivity [70,71]. Physicians may, therefore, wish to monitor their patients to ensure that underlying pathologies do not contribute to higher than usual increases in ketone bodies while consuming a ketogenic diet or on SGLT2 inhibitor therapy.

Trimethylamine-N-oxide for assessment of gut dysfunction and cardiovascular disease risk

Trimethylamine-N-Oxide (TMAO) is a metabolite that is increasingly recognized as clinically important in the assessment of CVD [72]. TMAO is produced by a pathway whose initial rate-limiting step is gut microbe-dependent [72]. It has been observed that gut bacteria are responsible for metabolizing dietary choline and carnitine into trimethylamine, which is then transformed into TMAO in the liver. A study where oral broad-spectrum antibiotics were used to suppress the intestinal microbiota led to a reduction in circulating TMAO levels, providing direct evidence that dietary status and the gut microbiome affect TMAO concentrations [72]. While BCAA and ketone bodies are quantified from the same NMR spectrum as the lipoprotein profile, the TMAO LDT involves the acquisition of a proton Carr−Purcell−Meiboom−Gill (CPMG) NMR spectrum from a plasma or serum sample that has been adjusted to pH 5.3. The acquisition of the CPMG spectrum allows for suppression of signals from lipoproteins and proteins whose signals interfere with quantification of the signal peaks from small molecule metabolites. Moreover, the adjustment to pH 5.3 shifts the TMAO signal to a less crowded place in the spectrum (3.29−3.30 ppm), where it can be readily quantified without interfering signals from metabolites like betaine. The NMR signal is then modeled with a proprietary fitting algorithm.

Several clinical studies have shown an association of elevated plasma TMAO concentrations with increased risk of CVD, independent of established risk factors. A study of adults undergoing cardiac catheterization revealed that subjects with high TMAO had a 2.5-fold increased risk for a major adverse CVD event (myocardial infarction, stroke, or death) compared with subjects in the lowest quartile [73]. Subjects with underlying chronic kidney disease had higher fasting plasma TMAO levels and a higher risk of mortality than those with normal renal function [74]. TMAO levels showed a significant, graded association with CVD but not with measured carotid intima-media thickness [75]. In a cohort of patients with a history of heart failure, elevated plasma TMAO was associated with increased risk of mortality, independent of traditional risk factors and B-type natriuretic peptide levels. It has been shown that subjects with cardiometabolic diseases such as T2D and NAFLD exhibit altered gut microbiome and higher circulating levels of TMAO compared with healthy subjects or subjects on a vegan diet. In fact, a short-term, high-fat diet alone increased postprandial levels of circulating TMAO. Current thought in the field suggests that the bacterial changes and accompanying alterations in metabolic signaling that are observed in the gut microbiota of subjects with metabolic diseases elicit increases in TMAO, which then contributes to increased CVD risk in these patients. It has been hypothesized that changes in diet or dietary supplementation may reduce metabolic disease and its associated CVD risk, in part by reducing circulating levels of TMAO. Therefore monitoring TMAO levels before and after changes in diet and/or treatment with pre- or probiotics or dietary supplements may help physicians encourage patients to change their lifestyle and reduce long-term risk of CVD events. The medical decision limits for TMAO with respect to CVD risk are as follows: <6.2 low risk, 6.2−9.9 moderate or intermediate risk, and ≥ 10.0 for high risk (Table 11.2) [72].

Nuclear magnetic resonance instrument and diagnostic test manufacturers entering the US diagnostic market

Emerging into the US NMR-based diagnostic care market, Numares Health, based in Germany, is one of the new players in the NMR-based diagnostic business. The company has marketed the Axinon lipoFIT assay, which is deployed on the Axinon 600-MHz NMR system [76−78]. Similar to the NMR LipoProfile Test, the lipoFIT test reports data for the standard lipid panel (TC, TG, LDL-C, and HDL-C) as well as for key lipoprotein particle concentrations (LDL-P, HDL-P, large VLDL-P, small LDL-P, large HDL-P, VLDL, LDL, and HDL size). This test is currently a research use only (RUO) product in the United States but holds a CE Mark in the European Union market. Recently, Numares Health brought forward another RUO test called the Axinon renalTX-score. This test is a metabolomics-based urine test for detection of kidney allograft rejection. This test is based on the results of four metabolites (alanine, lactate, urea, and citrate) and provides a score (0−100); the higher the score, the higher the probability of acute allograft rejection.

Like Numares Health, Bruker, also based in Germany, has recently entered the US market with an RUO test for

lipoprotein subclass analysis. This test, which is run on an Avance 600-MHz NMR instrument, reports results for the standard lipid panel (TC, TG, LDL-C, and HDL-C) as well as for key apolipoprotein (apoA-I, apoA-II, and apoB) and lipoprotein particle concentrations. Finally, Biosfer Teslab, based in Spain, has developed the LipoScale test for lipoprotein analysis as well as a test to measure GlycA [79,80]. A review of the various software techniques used to quantify lipoprotein parameters by these companies was published by Mallol et al. [81]. The number of available NMR tests and platforms is growing and may lead to new NMR-based diagnostic tests in the coming years.

Conclusions

This chapter provided an overview of theory, principles, and clinical applications of NMR technology. From bench to bedside, advancements in the NMR field have transformed how scientists, and clinical and laboratory professionals interrogate the human body—both physically, as images, and biochemically. Research and spectroscopic interrogation of biological specimens from normal populations as well as from a number of disease states using low- and high-field NMR will continue to revolutionize clinical applications of NMR in laboratory medicine.

Self-assessment questions

1. Nuclei are "in resonance" with an external magnetic field when they are:
   - **a.** aligned in the opposite direction as the magnetic field.
   - **b.** aligned in the same direction as the magnetic field.
   - **c.** randomly flipping in the magnetic field.
2. Clinical applications of NMR include the quantitative determination of:
   - **a.** lipoproteins
   - **b.** GlycA
   - **c.** LP-IR
   - **d.** ketone bodies
   - **e.** all of the above
3. Which isotopes have "NMR active" nuclei?
   - **a.** carbon, fluorine, hydrogen, nitrogen, and phosphorus
   - **b.** calcium, iron, magnesium, and potassium
   - **c.** chloride, potassium, and sodium
4. A Vantera Clinical Analyzer with a _____ MHz magnet was the first NMR analyzer to be cleared by the FDA for use in the clinical laboratory.
   - **a.** 40
   - **b.** 400
   - **c.** 600
   - **d.** 900
5. Which NMR-measured metabolites have clinical utility?
   - **a.** BCAA
   - **b.** ketone bodies
   - **c.** TMAO
   - **d.** all of the above
6. LDL particle number of LDL-P can be used by physicians:
   - **a.** for the management of a patient's LDL-related CVD risk.
   - **b.** to diagnose RA.
   - **c.** to monitor the gut microbiome.

[1]Department of Pathology, The Johns Hopkins University School of Medicine, Baltimore, MD, United States, [2]Department of Pathology, Columbia University Medical Center, New York, NY, United States

Learning objectives

After reviewing this chapter, the reader will be able to:

- List factors that affect antibody–antigen binding
- Discuss the various immunoassay formats used in clinical laboratories
- Explain the advantages and disadvantages of using immunoassays for quantitative analyses
- Discuss potential interferences with clinical immunoassays
- Discuss the use of immunoassays in point-of-care testing

Introduction

Immunoassays are analytical methods based on the use of antibodies as reagents. Highly specific binding and large association constants (K_a) of antibodies make them useful for the detection and quantitation of analytes in complex biological matrices such as clinical specimens. Methods based on immunochemical reactions are some of the most sensitive and specific assays available in clinical chemistry. Most immunoassays have been automated and are widely used in the clinical laboratory [1,2].

Antibodies belong to a group of glycoproteins called immunoglobulins that demonstrate highly specific binding to analyte molecules, also called *antigens* [3]. The site where the antibody binds to the antigen is called an *epitope*; each antigen may have multiple epitopes depending on its size and molecular structure. Antibodies can be classified as either polyclonal or monoclonal. The term *polyclonal antibodies* refers to a heterogeneous group of antibodies from multiple B-cell clones that are all specific for the same antigen but bind to different epitopes with varying affinity. *Monoclonal antibodies* are derived from a single B-cell clone and are more specific in that they are directed toward not only a certain antigen but also a specific epitope on that antigen.

There are five different types of immunoglobulins characterized by their function and they are abbreviated as IgA, IgD, IgE, IgG, and IgM; IgG is primarily the type of immunoglobulin used as an immunoassay reagent. Immunoglobulin G is a glycoprotein composed of multiple subunits with a molecular weight of approximately 160 kD; it consists of two identical heavy chains and two identical light chains that are joined by disulfide bonds (see Fig. 12.1). The amino acid sequence at the carboxyl terminus is conserved regardless of the antibody specificity and is known as the constant region of the antibody. Conversely, the amino acid sequence at the amino terminus is highly variable, and this is the portion that confers antigenic specificity to the antibody. The classic "Y" shape of the antibody gives it a single constant region with two variable regions that allow one antibody to bind two antigens, barring steric interference.

The structure of an antibody can be further characterized by how it is cleaved with proteolytic enzymes. The enzyme papain cleaves IgG in the "hinge" region of the antibody and divides the antibody into the three sections labeled in Fig. 12.1. The constant region, or "stem" of the Y, is one fragment and is known as the Fc fragment—this has no antigen-binding properties. The remaining two fragments are the "arms" of the Y and are identical antigen–binding fragments known as Fab fragments—these have one binding site each. An alternative enzyme, pepsin, can be used to digest antibodies, which yields a different fragmentation pattern. No Fc fragment is produced in this digestion, because the constant region of IgG is digested completely. The fragment that remains after digestion consists of both binding sites and is known as an $F(ab)_2$ fragment, which is identified in Fig. 12.1.

Antibodies are produced by the immune system from B lymphocytes when a molecule called an *immunogen* is introduced into a foreign host. An immunogen can be a protein, or sometimes an analyte of interest or synthetic peptide coupled to a large carrier molecule. In order for a substance to be immunogenic, it must have three key attributes: (1) it must possess randomness of structure; (2) it must maintain some areas of structural stability; and (3)

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00012-0

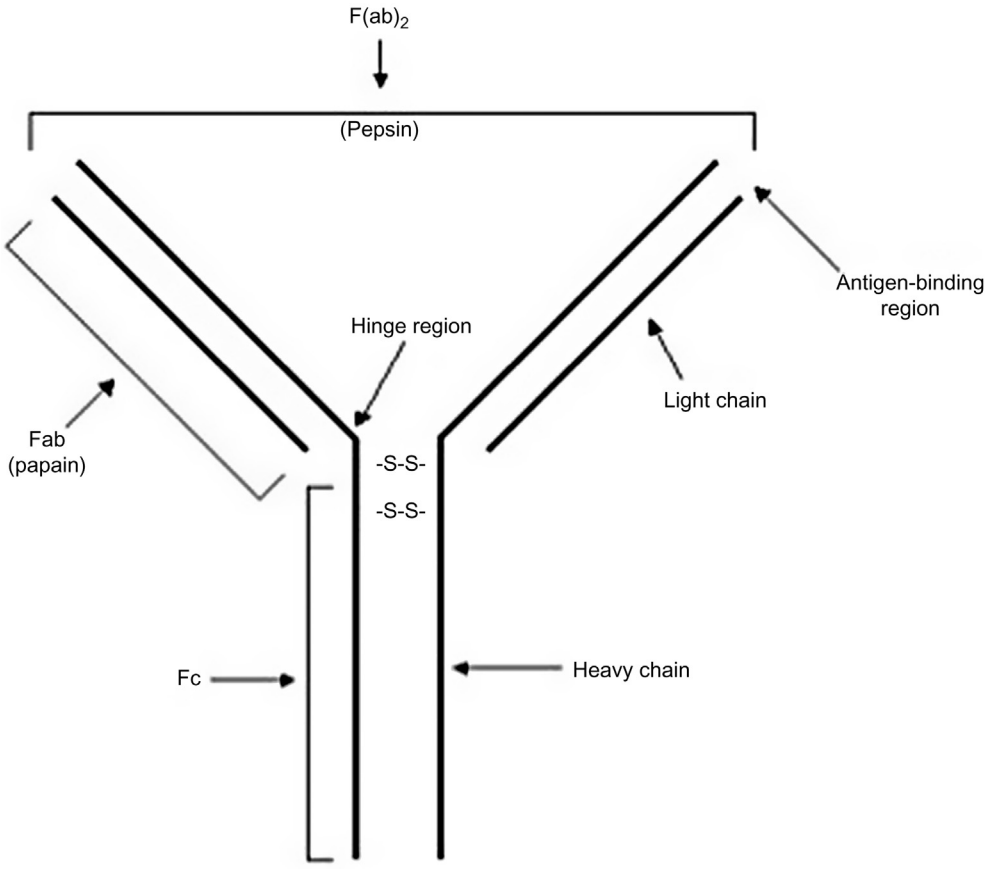

FIGURE 12.1 Basic antibody structure.

it must have a molecular weight of at least 4−5 kD and be recognized as foreign by the host species. An analyte/antigen that is unable to induce an immunogenic response on its own is called a *hapten* and must be coupled with a large carrier protein, such as keyhole limpet hemocyanin or bovine serum albumin, to stimulate a response.

Antiserum is the product of immunogenic stimulation that contains antibodies directed toward the antigen of interest. Polyclonal antiserum is derived by simple introduction of an immunogen to a normal animal host, typically rabbits or goats, which produces a heterogeneous mixture of antibodies from many cell clones directed against a wide variety of epitopes on the antigen of interest with varying affinities and isotypes. Nonspecific antibodies can also be produced. Antisera may be used directly or in a diluted form, or it may undergo purification to isolate only immunoglobulins. Antibodies can be isolated with techniques that yield total IgG or by immunoaffinity using a chromatographic support with immobilized antigen, or immobilized protein A or protein G. Use of immobilized antigen allows the isolation of only IgG that is specific for the analyte of interest.

Monoclonal antiserum is the product of a single clone or plasma cell line, so all the antibodies produced are identical and bind to the same epitope. Production of monoclonal antibodies begins by immunizing a host animal (usually a mouse) just as in polyclonal antibody production. Next, sensitized lymphocytes from the spleen of the immunized animal are fused with an isolated myeloma cell line, which consists of immortalized B-cells. The myeloma cell line is deficient in the enzyme hypoxanthine guanine phosphoribosyl transferase, meaning they cannot synthesize purine bases from thymidine and hypoxanthine in the presence of aminopterin (a synthetic enzyme that blocks tetrahydrofolate synthesis). The spleen cells, however, are not deficient in the enzyme, so when the fusion mixture is cultured in a selective medium containing hypoxanthine, aminopterin, and thymidine, only the fused cells survive. The surviving cell lines are screened for binding to the antigen of interest, with the end product being immortalized cell lines that produce antibodies of a single, known binding specificity.

Antibody−antigen binding is typically described in terms of binding affinity and avidity. *Affinity* refers to the

strength of binding for one site and can be described in terms of the energy of interaction for a single antibody-binding site and its corresponding epitope. *Avidity* refers to the overall binding of one antibody molecule to antigen, describing the sum of binding sites for the whole molecule (e.g., IgG has two binding sites, while an IgM pentamer has 10 binding sites). For example, when comparing an IgG molecule versus Fab fragments obtained from the same clonal population, they would have identical affinities for the antigen of interest, but the IgG would have a higher avidity, because it could bind two antigens and the Fab could only bind one. As a rule, affinity is characterized as a property of the antigen, while avidity is a property of the antibody.

Binding between antibody and antigen is best described as an equilibrium process:

$$\mathrm{Ag} + \mathrm{Ab} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{AgAb}$$

where $k_1 >> > k_{-1}$; depending on the time frame of reference, binding can often be considered irreversible. Antibody−antigen interactions are based on electrostatic (van der Waals) forces, hydrophobic forces, coulombic (ionic) forces, or a combination of the three. The interaction of antibodies and their corresponding antigens is pH- and temperature-dependent, and can be affected by electrolyte concentration as well, depending on which types of interactions are prominent in binding.

Based on an assay on antigen−antibody binding, factors affecting binding can be manipulated to optimize assay sensitivity. Increased temperature will increase the rate of reaction between antibody and antigen, but typically lowers the binding affinity constant—this means that often higher sensitivities can be achieved at lower incubation temperatures due to an increase in binding affinity and a decrease in proteolysis. For protein-bound analytes, a higher temperature may give a higher sensitivity, because it will encourage dissociation of the analyte from the binding protein, while affecting the antibody binding to a lesser degree. Incubation time is also an important parameter to optimize. Longer incubation times allow the reaction to come to equilibrium and let everything that is going to bind to the antibodies have a chance to do so. However, this can lead to long analysis times, as well as decreases in sensitivity when the labeled antigen is sensitive to degradation. To avoid these issues, assays can be performed under nonequilibrium conditions with shortened incubation times. Buffer conditions are also important for assay optimization. In some cases, the antibody−antigen binding is pH-dependent—design of the assay must include an examination of how various pH conditions affect the assay. In addition, pH effects may vary with temperature, so both factors must be examined together to arrive at the optimum assay design. Cationic salts inhibit antibody binding with cationic haptens corresponding to decreasing ionic radius and increasing radius of hydration:

$$\mathrm{Cs}^+ > \mathrm{Rb}^+ > \mathrm{NH}_4^+ > \mathrm{K}^+ > \mathrm{Na}^+ > \mathrm{Li}^+$$

The same effect is seen with anionic haptens and anionic salts:

$$\mathrm{CNS}^- > \mathrm{NO}_3^- > \mathrm{I}^- > \mathrm{Br}^- > \mathrm{Cl}^- > \mathrm{F}^-$$

Immunoassays

Using chemical labels coupled to antibodies or antigens, very sensitive immunoassays can be developed that detect much lower concentrations of a substance than other analytical techniques. These assays can be performed in many different formats with a wide variety of detection methods and can be used to detect both large and small analytes. Immunoassays can be characterized with regard to whether a separation step is necessary, whether the antigen or antibody is labeled, or by the type of label that is used for sample detection. Immunoassays are simply one type of ligand-binding assays, which may use receptors, carrier proteins, and others in addition to antibodies for binding the analyte of interest. For example, intrinsic factor and folate-binding protein are used in competitive protein-binding assays for serum vitamin B12 and folate, respectively.

Homogenous versus heterogeneous immunoassays

Heterogeneous immunoassays are assays that require physical separation of the labeled antibody−antigen complex from the unbound components (antibodies and/or free antigen) for analysis [4]. During the separation step, heterogeneous assays assume that antibody−antigen binding is essentially irreversible during the separation step, since k_1 is much greater than k_{-1} (the amount that dissociates is very small). One way this separation happens is through precipitation of the labeled antigen−antibody complex, either using a precipitating chemical or by cross-linking with other antibodies, and analyzing the precipitate to quantify the amount of bound label. In addition, adsorbents such as activated charcoal or silica particles can be added to solution to bind free antigen for subsequent removal by centrifugation. A common approach is to bind the antibodies to a solid support and then remove the unbound molecules through various wash steps. In an enzyme-linked immunosorbent assay (ELISA), the solid support is the wall of a microwell plate, while in automated immunoassay systems, the solid support is often a magnetic bead or particle. Separation

techniques such as size-exclusion or ion-exchange chromatography, as well as electrophoresis, can also be used for heterogeneous immunoassays.

Homogeneous immunoassays are able to distinguish between the free and bound label for detection without a physical separation step [4]. This is accomplished by selecting a label that is modified by antibody binding, whether it results in an increase or decrease of signal. For this type of assay to be useful, it is important that the change in signal due to antibody binding is proportional to the concentration of analyte in the specimen. This technique allows a combination of the label incubation and detection of analyte into one simple step. The homogenous approach is useful, because it eliminates the wash step and is very compatible with most automated chemistry analyzers.

Competitive immunoassays

Competitive immunoassays are based on immunochemical reactions in which the number of antigen-binding sites is limited. Both the antigen of interest and a labeled analog are incubated with a known amount of antibody, and the signal produced is based on the competition between the analyte and the corresponding label for the antibody-binding sites [5]. The amount of labeled antigen bound to the antibody is inversely proportional to the amount of analyte in the sample and can produce a calibration curve, as seen in Fig. 12.2A.

The most common approaches to competitive immunoassays are the simultaneous or sequential addition techniques. In *simultaneous addition*, both the label and sample (or calibrator) are added to the reaction mixture at the same time. After a fixed period of time, the amount of bound label is determined and used to construct a calibration curve or determine the concentration of the unknown. For optimum results using this technique, the differences in antibody-binding affinity due to matrix effects for both the sample antigen and the labeled antigen should be minimal. In addition, it is important that the probability of binding for both the labeled antigen and the sample antigen is similar. *Sequential addition* is a valuable technique when a lower limit of detection is needed. First, the sample is incubated with the antibody until equilibrium is reached; then, label is added and comes to equilibrium, followed by the detection of bound label. Importantly, the length of time needed for incubation will be determined by the type of interactions between the Ab−Ag and the relative amounts of each. The sequential approach to competitive immunoassays can lower the limit of detection up to fivefold and is also useful if there are slight differences in affinity for the analyte antigen and the labeled analog.

An alternative approach to a competitive immunoassay is the displacement immunoassay. In this technique, reagent antibody is saturated with labeled analog followed by addition of sample. The analyte in the sample displaces the label, and the displaced (free) labeled compound is measured rather than the bound label. This type of assay is dependent on local equilibria, so if $k_1 >> k_{-1}$, then less label is displaced in contrast to the situation where $k_1 \geq k_{-1}$. The signal for displacement immunoassays is directly proportional to the analyte concentration (Fig. 12.2B), in contrast to the inversely proportional signals seen in the simultaneous and sequential addition immunoassays.

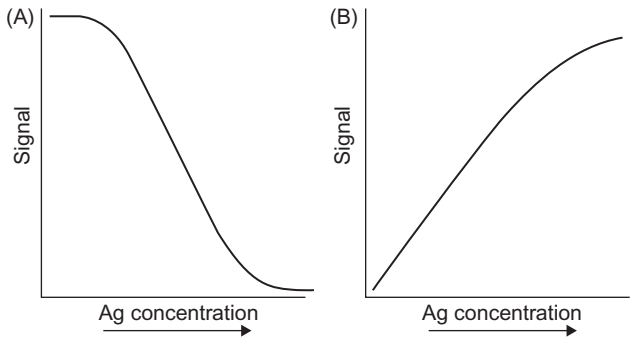

FIGURE 12.2 Immunoassay calibration curves: (A) competitive binding assay and (B) noncompetitive binding assay.

Noncompetitive (immunometric) immunoassays

Noncompetitive immunoassays, or immunometric assays, are based on immunochemical reactions, where there is reagent excess [5]. In noncompetitive immunoassays, the signal is directly proportional to the amount of analyte in the sample, producing a similar curve to that obtained with a displacement immunoassay (Fig. 12.2B). The most common noncompetitive immunoassay format is the *sandwich immunoassay*, where two antibodies are used for analyte detection. Both polyclonal and monoclonal antibodies are suitable for use in sandwich immunoassays. However, in order to use this format, the antigen of interest must be large enough to bind simultaneously two separate antibodies. The first antibody in the reaction is called the *capture antibody*, which is either adsorbed or covalently linked to a solid support and is used to extract the analyte from the sample matrix. A second labeled antibody, known as the *tracer* or *conjugate antibody*, reacts with the captured antigen at a separate and distinct epitope from the capture antibody and is used to detect the analyte when all other components have been washed away. This type of assay can be performed either in a sequential or simultaneous incubation format, although for simultaneous incubation two distinct monoclonal antibodies for different epitopes must be used to prevent competition.

Immunoassay detection methods

There are many different types of labels, for both antigen and antibodies, that can be used in immunoassays. Choice of label is dependent on the analytical sensitivity desired for the measurement, as well as the immunoassay format. A list of label types along with typical detection limits associated with them can be seen in Table 12.1. The earliest immunoassays used isotopic labels such as ^{125}I, ^{131}I, ^{3}H, ^{57}Co, and ^{32}P for antigens in competitive immunoassays and for antibodies in sandwich immunoassays—these were appropriately termed radioimmunoassay (RIA) and immunoradiometric assay. The appeal of radioactive labels is based on the low limits of detection achieved due to very low background interference. Radioactive labels were also used to develop an early homogeneous assay [6] based on the modulation of ^{3}H or ^{125}I labels by scintillant-laden microparticles. However, RIAs are now used infrequently in clinical laboratories due to concerns regarding safe handling and disposal of radioactive materials, as well as the inherent instability of radiolabels.

Currently, nonisotopic labels are more widely used in immunoassays because of the drawbacks that come with handling radioactive labels. As early as the 1970s, enzyme labels for immunoassays were developed, and since then, a wide variety of nonisotopic labels have been established. These types of labels include enzymes, fluorescent molecules, chemiluminescent labels, and even electrochemical labels as well as many other newly developed, unique labels. Some of these labels are able to achieve detection limits well below those possible with radiolabels, and none of them pose the problems of handling and disposal that occur when working with radioactive materials. Increased specificity can be gained in an immunoassay by coupling a biotin–avidin interaction with the antibody–antigen interaction by using biotin-conjugated antibody or antigen and then introducing labeled avidin to the reaction mixture. In some applications, multiple labels are utilized by taking advantage of the multiplicity of avidin–biotin binding. One avidin molecule can bind four biotin molecules, so this complex scheme would involve a biotin conjugate followed by addition of avidin, which could then bind three more labeled biotin molecules. It should be noted that in assays utilizing biotin–streptavidin interactions, biotin supplementation may cause falsely elevated or decreased results depending on assay design.

TABLE 12.1 Immunoassay label detection limits.

Label type	Detection limit (M)
Fluorescence	1×10^{-10}
Chemiluminescence	1×10^{-13}
Fluorescence polarization	1×10^{-14}
Radioactive	1×10^{-15}
Time-resolved fluorescence	1×10^{-17}
Electrochemiluminescence	2×10^{-20}
Enzyme-based	
Photometric	1×10^{-16}
Fluorescence	1×10^{-19}
Coupled enzyme reaction	1×10^{-20}
Chemiluminescence	1×10^{-21}

Fluorescence

Fluorescent labels are commonly used for competitive binding and sandwich immunoassays in much the same manner as radioisotopes. The most commonly used label is fluorescein isothiocyanate (FITC), but dyes such as Lucifer Yellow or Rhodamine B can also be employed as fluorescent labels. Detection limits using fluorescence range from 0.1 pM to 1 nM, which is sensitive enough to use for low concentration analytes, but avoids the handling and disposal issues that come with using radioactivity. However, a major challenge with fluorescence detection is that many substances found in patient samples (e.g., drugs and drug metabolites, proteins, and bilirubin) exhibit fluorescence and can cause a high background and interference. One way to avoid this interference is the use of *time-resolved fluorescence* with labels derived from lanthanide elements (i.e., europium, terbium, and samarium). The fluorescence lifetime for these lanthanide chelates is much longer than typical fluorescent molecules, so after excitation, a delay time (400–800 ms) is introduced to let background fluorescence decay, and then the signal may be measured [4].

Fluorescence detection can be used in homogenous immunoassays by employing a fluorescence polarization immunoassay (FPIA) format. This approach is based on competitive binding of antigen in the sample with a fluorescein-labeled antigen reagent [4]. An FPIA uses the changes in polarization of fluorescence due to molecular rotation in solution to determine the extent of label–antibody binding. When the labeled antigen is unbound, it rotates very rapidly and therefore has a low degree of polarization; but when the label is bound to an antibody molecule that rotates at a much lower rate, the degree of polarization is increased (see Fig. 12.3). The change in polarization is proportional to the concentration of antigen in the sample, and because the label behavior is modified by antibody binding, no separation step is needed. FPIA assays were once widely used for drug measurement, primarily in the Abbott TDx analyzer, but their use in

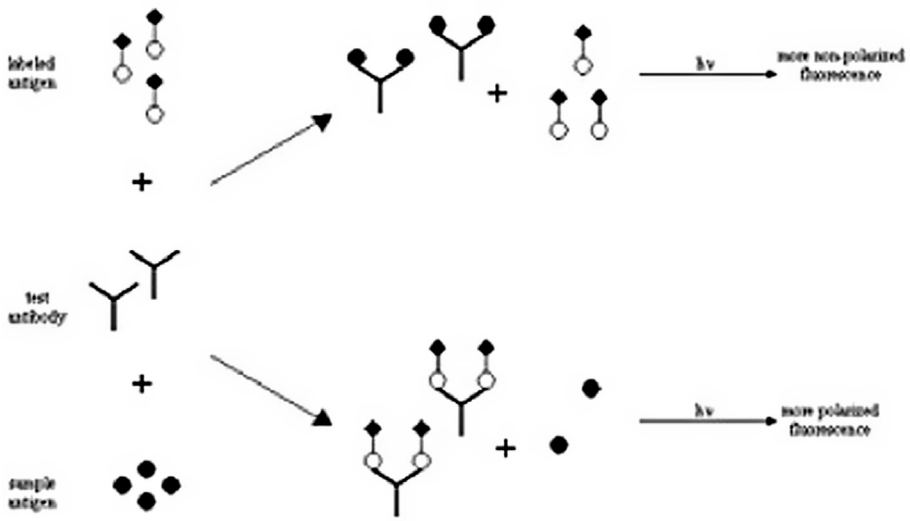

FIGURE 12.3 Fluorescence polarization immunoassay.

clinical chemistry has significantly decreased since that analyzer was removed from the market in 2011.

Enzymes

Enzyme-based labels such as alkaline phosphatase, horseradish peroxidase, glucose-6-phosphate dehydrogenase, and β-galactosidase are frequently used in quantitative immunoassays [4,7]. One significant advantage for enzyme labels is the amplification of signal; one enzyme label can produce many reporter molecules, up to 100-fold amplification (using a fluorescent substrate can produce amplification up to 100,000-fold). The substrate for enzyme detection systems can be chosen to produce a colored product for photometric monitoring, a fluorescent product such as umbelliferone, or even to produce an intermediate substrate for a second enzymatic reaction to produce further amplification. The most common heterogeneous enzyme immunoassay is the ELISA, which is an immunometric assay where the captured antibody is bound to a solid support and the tracer antibody is enzyme-labeled [4]. After the capture:antigen:tracer complex is formed, all other sample components are washed away and substrate is added; the amount of product formed is proportional to the concentration of antigen in the sample (Fig. 12.4). An ELISA can also be used to detect antibodies of a given specificity by using antigen linked to the support, adding sample and using labeled antibodies to IgG as the tracer (e.g., detection of anti-HCV antibodies).

There are two commonly used types of homogeneous enzyme immunoassays: the *enzyme-multiplied immunoassay technique* (EMIT) and the *cloned enzyme donor immunoassay* (CEDIA) [4,8]. In an EMIT assay, the patient specimen or calibrator is incubated with an enzyme-labeled antigen and a fixed amount of antibody specific for the antigen of interest as well as enzyme substrate (Fig. 12.5) [4,8]. Antigen in the sample and the labeled antigen compete for antibody-binding sites; when antibody is bound to the labeled antigen, the enzyme is inhibited, because it is blocked from interaction with the substrate. The change in enzymatic activity is proportional to the concentration of antigen in the patient sample or calibrator (e.g., as the concentration increases, so does the enzyme activity).

A CEDIA assay is also a competitive immunoassay [8,9], but it is more complex than the EMIT assay. Using genetic engineering techniques, two inactive fragments of β-galactosidase are produced by manipulating the Z gene of the *lac* operon of *Escherichia coli*. These two fragments are able to reassemble to form an active enzyme, even if one of the fragments is covalently linked to another molecule. The competitive antigen in the assay is labeled with one fragment of the enzyme and is incubated with patient sample, along with the second enzyme fragment, the enzyme substrate, and a fixed amount of antibody directed toward the antigen of interest (Fig. 12.6). Antibody that binds to labeled antigen prevents reassembly of the enzyme and no reporter molecule is produced; as the sample antigen concentration is increased, the enzyme activity is also increased. As in the EMIT assay, the change in enzymatic activity is directly proportional to the concentration of antigen in the sample.

Chemiluminescence

Chemiluminescent labels are based on the emission of light produced during a chemical reaction. These labels are very useful, because they provide very low limits of detection with little to no background interference; however, in these assay formats, the reaction conditions must be carefully controlled. Chemiluminescent labels exist as

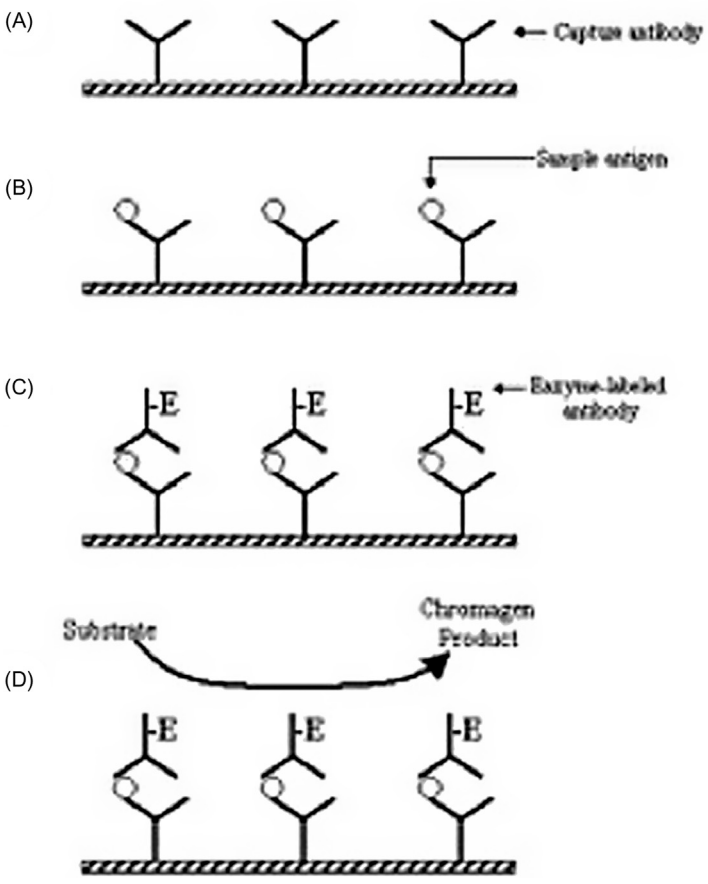

FIGURE 12.4 Enzyme-linked immunosorbent assay.

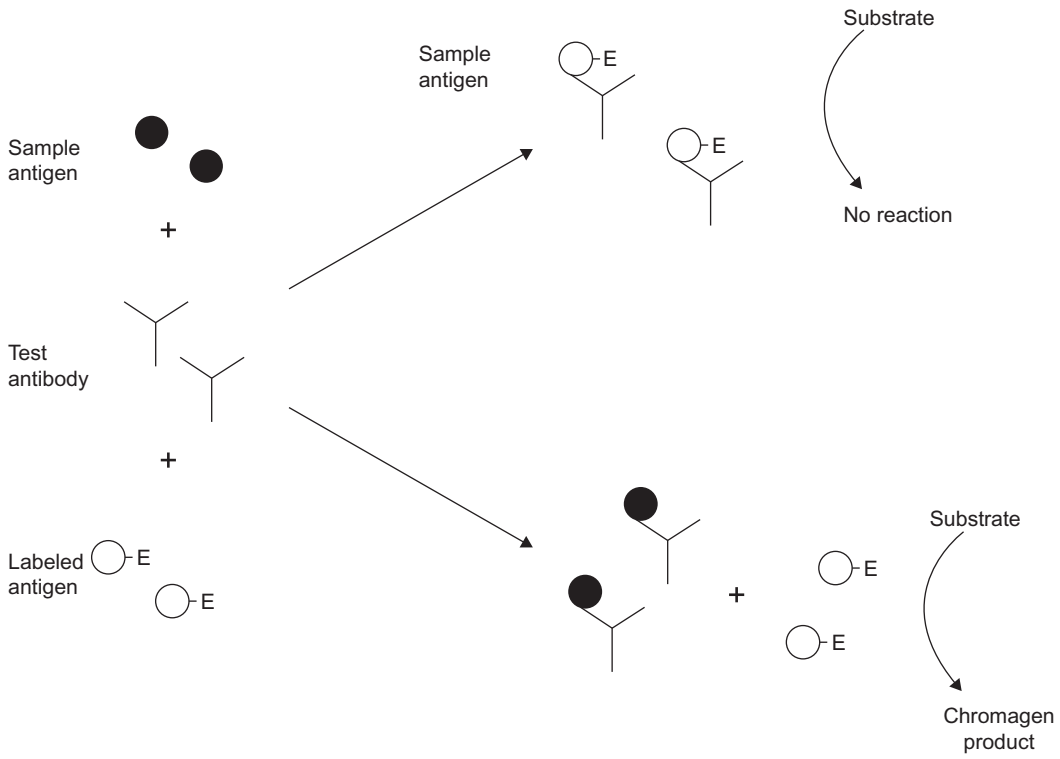

FIGURE 12.5 Enzyme-multiplied immunoassay technique.

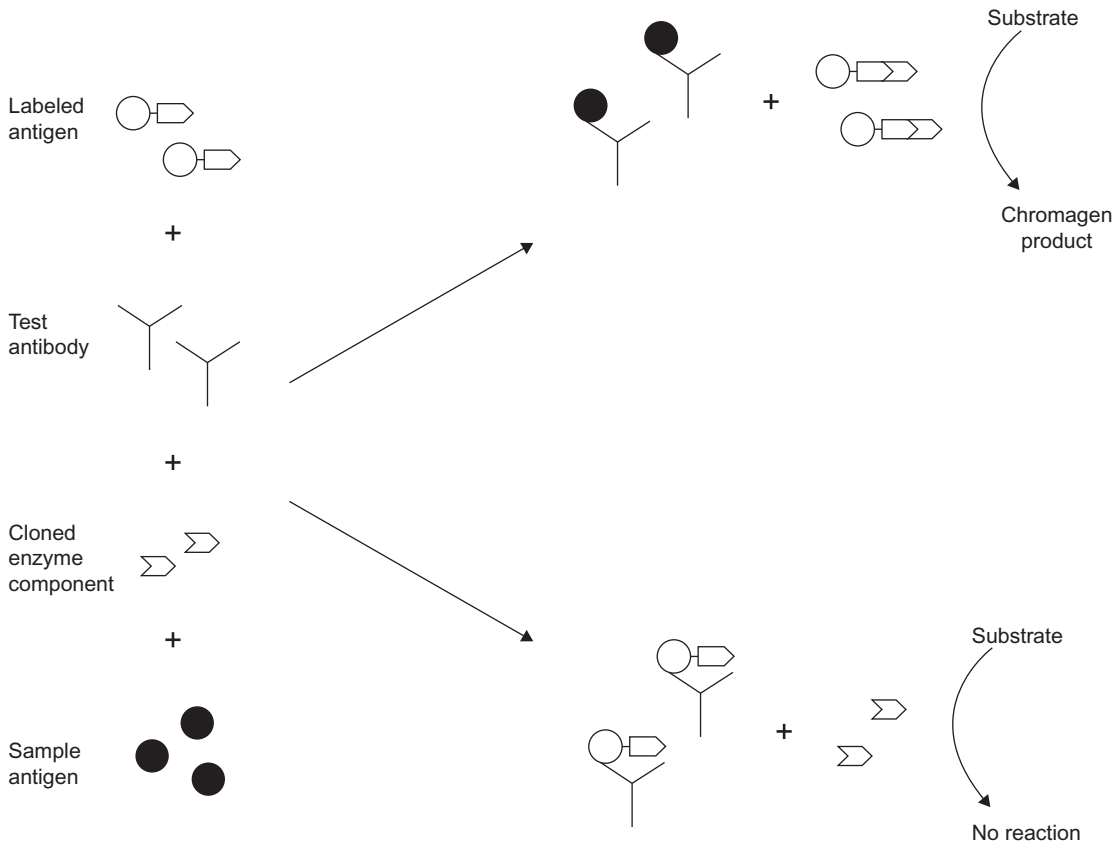

FIGURE 12.6 Cloned enzyme donor immunoassay.

both biologically derived and chemically manufactured compounds [10]. Biologically derived chemiluminescence labels include firefly luciferase and apoaequorin, a protein derived from the bioluminescent jellyfish *Aequorea victoria*. Firefly luciferase activates D-luciferin substrate by oxidation in the presence of ATP, molecular oxygen, and magnesium ions to emit light at 560 nm, while apoaequorin is activated by reaction with coelenterazin and calcium ions to emit light at 469 nm.

Nonbiologic compounds can also be used as chemiluminescent labels, including isoluminol and acridinium esters [11]. Isoluminol is oxidized in the presence of a catalyst such as microperoxidase, producing a relatively long emission at 425 nm. Acridinium esters are highly sensitive labels that are activated by oxidation using hydrogen peroxide in alkaline solution to give a brief flash of light at 429 nm. Chemiluminescence can be made even more sensitive when combined with other detection methods. For instance, electrochemiluminescence utilizes a molecule such as ruthenium (II) tris(bipyridyl) that undergoes chemiluminescence at a given redox potential, producing mass detection limits as low as 20×10^{-21} moles [10,12]. In addition, chemiluminescent substrates can be combined with enzymatic labels to take advantage of enzyme amplification effects and the inherent sensitivity of chemiluminescence by using a substrate known as disodium 3-(4-methylspiro-[1,2-dioxetane-3,2′-tricyclo-[3.3.1.1]decan]-4-yl) phenyl phosphate to obtain mass detection limits as low as 1×10^{-21} moles [13].

Particle-based immunoassays

Some automated immunoassays are based on antibodies or antigens linked to solid, spherical microparticles [14]. In some cases, such as the homogeneous particle-enhanced turbidimetric inhibition immunoassay, the microparticles are linked to the analyte of interest, and when antibodies are added to the reagent solution at an optimized ratio, the microparticles agglutinate and form insoluble complexes that scatter light. Competing analyte from a patient specimen (or control specimen) inhibits the formation of the insoluble complexes at a rate proportional to the concentration of the analyte. A similar mechanism is responsible for analyte quantitation in the kinetic interaction of microparticles in a solution immunoassay platform. An example of a microparticle-based light scattering immunoassay can be seen in Fig. 12.7. Measurement of light scattering immunoassays by turbidimetry and nephelometry is described in Chapter 7, Spectrophotometry.

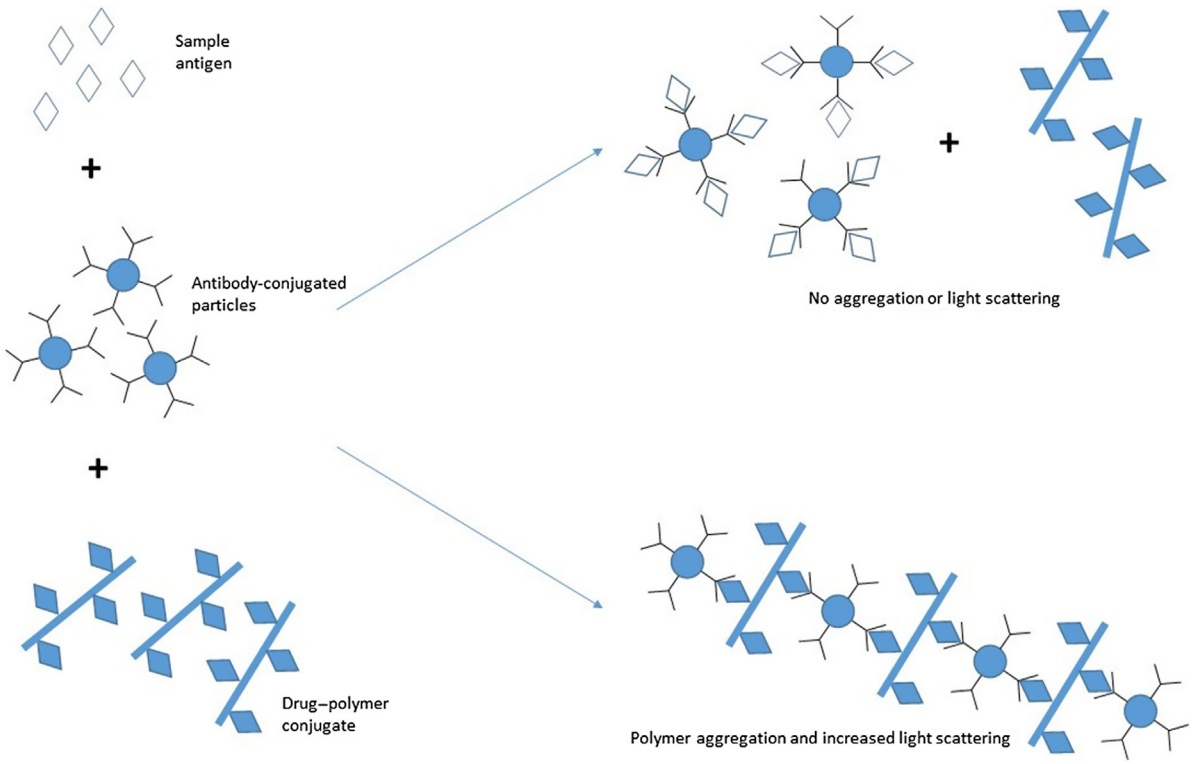

FIGURE 12.7 Particle-based light scattering immunoassay.

An alternative use of microparticles for heterogenous assays is microparticle enzyme immunoassay. In an immunometric format example, a sample is incubated with antibody- or antigen-coated microparticles and enzyme-labeled conjugate. An aliquot is filtered through a matrix such as a glass-fiber capture surface. Conjugate can alternatively be added at this step following a wash. The surface is washed and enzyme is added with the signal generated in proportion to the analyte concentration.

Alternative labels and technologies

Alternative detection techniques for nonisotopic immunoassays have been developed in response to demands for lower detection limits, an increase in label specificity, or increased flexibility in applications. One example is the *enzyme channeling immunoassay* that combines the simplicity of a homogeneous immunoassay with the specificity of a sandwich immunoassay [15]. In this approach, the antigen of interest binds two antibodies that are labeled with different enzymes; the enzyme reactions are coupled and signal is produced when the enzymes are in close proximity due to binding within the immune complex. A similar technique is the *fluorescence resonance transfer immunoassay* (FRET), which utilizes coupled fluorescence reactions [16,17]. In the reagent mixture of competitive assays, the labeled antigen contains a fluorophor donor, while the antibody is labeled with a fluorescent acceptor; when the labeled antigen is antibody-bound, a fluorescent signal occurs; as the analyte concentration increases, the signal decreases. Time-resolved FRET forms the basis for the time-resolved amplified cryptate emission methodology on the Kryptor instrument (Thermo Fisher Scientific) that is currently used for procalcitonin measurement. Another related homogeneous immunoassay technique is luminescent oxygen-channeling immunoassay, a sensitive methodology employed on the Siemens Dimension Vista. In this immunometric assay format, antibody-coated sensitizer and chemiluminescent beads form a sandwich with the antigen. When the photosensitizer containing bead is exposed to light, the singlet oxygen produced diffuses into the associated chemiluminescent compound-containing particle, which initiates a chemiluminescent reaction [18].

Many other methods have been developed, including those that incorporate polymerase chain reaction amplification with DNA or RNA labels, optical diffraction detection, and surface physiochemical detection techniques for biosensors as well as those with single molecule detection and ultrasensitive properties [19–22].

Immunoassay interferences

Although there are many advantages inherent to immunoassays, it is important to consider some of the factors

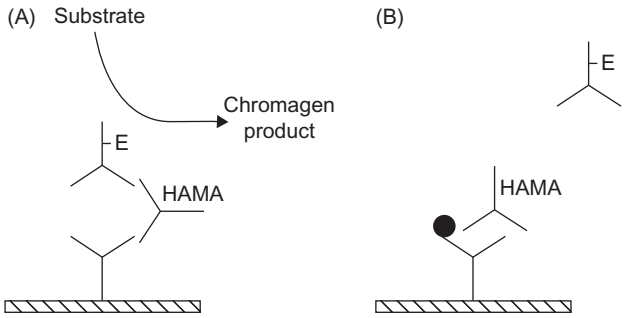

FIGURE 12.8 Heterophilic antibody interference: (A) positive interference and (B) negative interference.

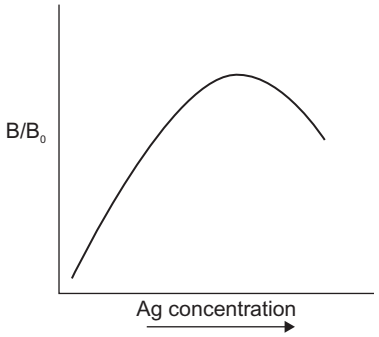

FIGURE 12.9 Calibration curve demonstrating the hook effect.

that may interfere with an immunoassay. These include heterophilic antibodies from the patient, assay artifacts caused by large analyte concentrations (hook effect), and a lack of standardization between immunoassays for the same analyte from different manufacturers. Each of these interferences can influence both immunoassay performance and utility.

In sandwich immunoassays, one particular problem is interference from circulating heterophilic human antibodies specific for animal immunoglobulins when they are used as reagents. The most common type of these is human antimouse antibodies (HAMA) that are often present in the blood of patients that have been given mouse monoclonal antibody imaging or therapeutic agents, or have been exposed to other mouse antigens [23]. Heterophilic antibodies can cause false-positive results by cross-linking the capture and label antibodies in a manner similar to the analyte of interest or they can cause false negative results by blocking analyte binding to the capture or label antibody (Fig. 12.8). The presence of HAMA or other heterophile antibodies can be confirmed through dilution experiments that do not give linearly proportional results, or retesting of a sample after incubation with animal serum (e.g., mouse antisera for HAMA) or other blocking agents. Nonimmune animal serum is often included in immunoassay kits using animal antibodies as reagents to minimize the effects of heterophilic antibodies. In addition, many antibody-based therapeutic agents are now derived from antibody fragments or chimeric antibodies (i.e., fusion proteins genetically engineered to make animal produced proteins mimic human proteins) in order to avoid heterophilic antibody reactions.

Another problem that can arise and give falsely low results for immunometric assays is known as the "hook effect" [24]. This phenomenon occurs when the concentration of analyte is so high that both the capture and label antibodies are saturated. As a result, the assay response will decrease at high antigen concentrations—the response will drop off after a maximum response giving the curve a characteristic "hook" shape (see Fig. 12.9). This effect leads to falsely low patient results when the concentration of an analyte is elevated far above the analytical range of the assay and can be discovered by dilution followed by sample retesting. This type of error can be avoided by using a large excess of capture and label antibodies with respect to the analytical range of the assay.

A different sort of problem arises when immunoassays are developed for the same analyte by different researchers or manufacturers. Each developer uses a different antibody directed to a unique epitope that may exhibit varying binding properties, leading to different responses for the same concentration of analyte. In an isolated environment, this is not a problem as long as the institution uses only one type of assay; however, the establishment of a standard reference interval for the analyte becomes much more difficult, because various institutions often use different assays for the same analyte. A good example of this is demonstrated in the development of a cardiac troponin I (cTnI) assay. cTnI is present in the circulation in three forms: free cTnI, a two-unit complex with cardiac troponin C (cTnI-cTnC), and a three-unit complex with cTnC and cardiac troponin T. Various assays fail to agree with each other, because the reagent antibodies for each assay recognize different epitopes.

Therefore common antibodies in addition to a primary reference material are needed for standardization of the method [25,26].

Advances in immunoassay testing

Although immunoassays are some of the most widely used tests in the clinical laboratory today, they do suffer from multiple drawbacks and are subject to interferences. In recent years, a number of advancements have led to progress in the development of new methods utilizing antibodies, which have been able to circumvent some of these limitations. Three such examples are described below.

HIV Ag/Ab combination assay

For HIV diagnosis, the seroconversion window corresponds to the period between HIV infection and the

presence of detectable antibodies to the virus. This period is 2−4 weeks after infection. During this initial phase, the virus is actively replicating, produces high titers in the blood, and can produce an acute HIV syndrome. This initial phase is a period of high transmission, and acutely infected individuals, who may be unaware of their status, are responsible for a substantial fraction of newly transmitted infections. Despite the multiplicity of changes taking place in this early phase, anti-HIV titers remain low in the blood during this period. Thus traditional tests that only detect HIV antibodies are simply not adequate to identify and diagnose these individuals.

The HIV Ag/Ab combination assay is a fourth-generation assay that allows for the simultaneous detection of p24 antigen and anti-HIV antibodies. Abbott was first to receive FDA approval for this test in the United States in 2010. Since then, other companies have also commercialized products, including Siemens, BioRad, and Alere. These fourth-generation assays are similar in that they can all detect both acute and long-term infection. The former is manifested through p24, a component of HIV that is detectable in the blood during the acute phase. Abbott's assay is a chemiluminescent microparticle immunoassay. The assay provides a signal/cutoff value, which reaches detectable levels in the presence of either p24 or anti-HIV antibodies. This assay will not allow for the discrimination in signal origin. Alere's Determine HIV-1/2 Antigen/Antibody Combo is a lateral flow, point-of-care immunoassay and, in contrast to the Abbott test, is not performed on an automated analyzer. It, however, contains distinct zones on the test strip, which allow for the distinction between the signal generated from p24 and that from the anti-HIV antibodies. Most recently, the BioRad Bioplex 2200 also has received FDA approval for an automated assay to detect HIV p24 antigen and anti-HIV antibodies and can not only detect these analytes but can also distinguish between them.

For additional details, see Chavez et al. [27] and references therein.

Mass spectrometry measurement of thyroglobulin

For patients with differentiated thyroid cancers, the use of serum thyroglobulin testing has been the mainstay of surveillance regimens to identify residual disease and to detect recurrence. Historically, immunoassays have been the method of choice for this analysis; however, there are some significant challenges encountered with current Tg immunoassays. For example, the presence of anti-Tg autoantibodies in 10%−30% of patients can result in falsely elevated or depressed levels of this marker in routine testing. One approach to circumvent such problems with this immunoassay is by adding a recovery step. The addition of a defined amount of Tg to the sample and then calculating its recovery after measurement enables the laboratory to determine whether anti-Tg antibodies are present in the sample. This additional step provides an opportunity to limit the reporting of inaccurate results. However, such recovery experiments are not recommended in the most recent guidelines of the American Thyroid Association [28].

Alternately, mass spectrometry can be used to circumvent some of the interference issues with Tg immunoassays. Hoofnagle et al. [29] and Hoofnagle and Roth [30] have developed such an approach. In this published method, the authors utilize a peptide immunoaffinity enrichment followed by liquid chromatography−tandem mass spectrometry (LC-MS/MS) analysis; using this approach, they have successfully demonstrated the analytically sensitive detection of single peptides of thyroglobulin in human serum samples. Their procedure includes a step whereby all proteins within the sample are digested into peptides. In contrast to the immunoassay approach that detects epitopes on the full length protein and is susceptible to being masked by an interfering antibody, their approach captures and detects peptides and is not subject to interferences at the protein level. Further developments in their assays and subsequent prospective evaluation will determine whether these technical advancements can directly translate into improved patient outcomes.

Multiplexed immunoassay testing

Relative to traditional single-marker assays, multianalyte panels offer the advantage of testing multiple analytes at once, allowing for the reduction in cost, time spent on testing, and specimen volume requirements. They have been developed for a number of applications including autoimmune testing via antinuclear antibody detection/characterization [31], autoantibody profiling for antiphospholipid syndrome [32], HIV testing, and other diseases. In each of these cases, the presence/absence or quantitation of multiple analytes is useful for clinical decision-making and patient management. Several successful FDA approved diagnostics have become available over the last few years, including those from manufacturers such as BioRad, Biomerieux, BioSite, Focus Diagnostics, and Randox.

The advantages conferred by these assays may translate into improved test performance characteristics such as higher sensitivity and/or specificity. In order to make this testing practical in a clinical laboratory setting, a multiplex testing system must be able to process samples in high throughput, support random access testing of specimens, and lend itself to automation. The BioRad Bioplex 2200 analyzer is one such platform—it is a fully

automated, random access, multiplexed immunoassay analyzer capable of providing both quantitative and qualitative assessments of antibody measurements. Its testing methodology is based on the Luminex X-MAP technology for multiplex analyte profiling. Briefly, it utilizes fluoromagnetic beads as the solid phase and these beads are coated with antibodies directed to various analytes. The different beads fluoresce as spectral variants and allow for the simultaneous measurement of many different antigens simultaneously in a single sample. It is one example that highlights the advantages of using multiplex assays on a single platform suitable for clinical testing and a powerful tool in the armamentarium of the clinical laboratory.

Point-of-care immunoassays

The most widely used point-of-care testing (POCT) immunoassay is used for the detection of human chorionic gonadotropin (hCG), more commonly known as a "home pregnancy test" or qualitative pregnancy kit. Many different manufacturers produce these tests, but all the tests operate on the same basic principle. A urine specimen is applied to a porous membrane that draws the liquid from the application point to immobilized anti-hCG positioned further up the membrane. If hCG is present in the sample, it will be bound to the immobilized antibodies, followed by a detection step. Detection steps can be varied, depending on the manufacturer. One approach is to add a second labeled antibody solution that will bind to the captured hCG, followed by a color development step [33]. Another approach is to use colored microparticles for detection (Abbott). In this approach, the initial capture antibody is immobilized to colored beads, which are located at the point of application. As the sample and microbeads migrate across the membrane, they encounter a second capture antibody that will serve as a "detection zone"; if there is hCG present in a sample, a sandwich complex will be formed and a visible positive signal will occur.

Other applications of point-of-care assays are found in the hospital emergency department (ED) and in locations where testing for drugs of abuse is necessary. In addition, point-of-care tests for troponin I are available for use in the triage of patients that present to the ED with acute coronary syndrome [34]. POCT devices based on immunoassays are also being developed to screen for drugs of abuse in oral fluids [35]. In order to be useful, each POCT device must not only produce a clear signal that makes it easy to distinguish between positive and negative but also contain a control mechanism to ensure that the device is working properly (e.g., the specimen moves up the membrane, all reagents are included in the reaction, detect the presence of interfering heterophilic antibodies, etc.).

Self-assessment questions

1. Antibody–antigen binding is based on _____ interactions.
   a. electrostatic (polar/nonpolar)
   b. hydrogen bonding
   c. ionic binding
   d. all of the above
2. How will increased temperature affect the reaction between antibodies and antigens?
   a. Increase rate, decrease binding affinity
   b. Decrease rate, increase binding affinity
   c. Increase rate, increase binding affinity
   d. Decrease rate, decrease binding affinity
3. An ELISA can be characterized as a:
   a. homogenous competitive binding immunoassay
   b. heterogenous competitive binding immunoassay
   c. heterogenous immunometric assay
   d. homogenous immunometric assay
4. Commonly used fluorescent labels include:
   a. Lucifer red
   b. FITC
   c. ethidium bromide
   d. all of the above
5. Immunoassays based on the EMIT detection technology usually utilize b-galactosidase as the enzyme label.
   a. True
   b. False
6. Heterophilic antibody interferences with immunoassays can occur when:
   a. patients have received antibody-based imaging reagents
   b. patients are exposed to mouse antigens by having mice in their living space
   c. patients have been given mouse monoclonal antibody-derived therapeutic agents
   d. all of the above
7. The hook effect in immunometric assays causes:
   a. falsely low patient results
   b. patient results to drop in a nonlinear fashion upon dilution
   c. reagent antibodies to bind irreversibly (i.e., "hook") to the antigen
   d. all of the above
8. Nonstandardized immunoassay kits are produced when:
   a. reagent antibodies from different manufacturers recognize different epitopes
   b. there is no primary reference material for the immunoassays

Learning objectives

After reading this chapter, the reader will be able to:

- Describe nucleic acid biochemistry and important features of deoxyribonucleic acid and ribonucleic acid.
- Understand the basis of Southern blotting and FISH.
- Explain the multiple uses of nucleic acid probes.
- List the steps involved in PCR.
- List the various chemistries used in qPCR.
- Describe the different platforms used in next-generation sequencing and their associated library preparation methods.

Introduction

The past decades have seen significant advances in the field of genomics. Major advances in sequence analysis and computing technology over the last three decades have led to the successful completion of the Human Genome Project [1], Human Microbiome Project [2], and countless other sequencing-based studies. This influx of information has significantly increased our understanding of human disease processes, leads to the development of new diagnostic testing algorithms, and is now pushing the boundaries of precision (or individualized) medicine. A multitude of laboratory tests now exists to study both deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). This chapter will focus on both the basic elements of how these tests work as well as how subsequent results are interpreted.

The biochemistry of deoxyribonucleic acid

DNA is a polymeric molecule composed of repeating nucleotide subunits. The order of nucleotide subunits contained in the linear sequence of this polymer represents all of the genetic information carried by a cell and defines the functional gene unit. The DNA structure is a double helix, composed of two polynucleotide strands that are coiled about one another in a spiral [3] (Fig. 13.1). There are four nucleotides that make up a DNA strand: adenine, guanine, cytosine, and thymine (Table 13.1). Adenine pairs with thymine and guanine pairs with cytosine. Each nucleotide is composed of (1) a phosphate group; (2) a pentose (five carbon atoms) sugar; and (3) a cyclic nitrogen-containing compound referred to as a base. The two-carbon nitrogen ring bases are purines (adenine and guanine), whereas the one-carbon nitrogen ring bases are referred to as pyrimidines (thymine and cytosine). Each polynucleotide strand is held together by phosphodiester bonds, linking adjacent deoxyribose moieties. The two polynucleotide strands are held together by a variety of noncovalent interactions including lipophilic interactions between the adjacent bases and the hydrogen bonding between the bases on opposite strands. The sugar-phosphate backbones of the two complementary strands are antiparallel and, thus, possess opposite chemical polarity. As one moves along the DNA double helix in one direction, the phosphodiester bonds in one strand will be oriented 5′-3′, while in the complementary strand, the phosphodiester bonds will be oriented 3′-5′. This configuration results in base pairs being stacked between the two chains perpendicular to the axis of the molecule.

Transcription is the first step of DNA-based gene expression, in which a specific portion of DNA is copied into RNA. RNA differs from DNA in that it is a single-stranded molecule and the nucleotide thymine is replaced with uracil. Another difference between RNA and DNA is that the nucleotides in RNA contain the sugar ribose instead of deoxyribose. There are multiple different types of RNA that play important roles in normal cellular

processes. The different types of RNA and the functions they perform are discussed in more detail in the next section.

The human genome

The genome of the typical human cell contains approximately 3×10^9 DNA base pairs that are subdivided into 46 discreet structural units, termed chromosomes. The human genome is diploid in nature, meaning the typical human cell contains 23 pairs of chromosomes. There are 22 pairs of autosomes and the sex chromosomes X and Y (females being XX and males being XY). The length and number of genes per chromosome vary greatly, but all together, the human genomes contain roughly 22,000 protein encoding genes. "Coding" DNA sequences give rise to all of the transcribed RNAs of the cell, including messenger RNA (mRNA), which encodes the amino acid sequence of a polypeptide. The majority of the human genome ($>98\%$) is made up of "noncoding" sequences, which have been suggested to function in DNA packaging, chromosome structure, chromatin organization within the nucleus, or in the regulation of gene expression. The majority of eukaryotic genes are comprised of coding regions, knowns as exons, which are broken up by specific noncoding sequences, called introns. During transcription, both exons and introns are copied into pre-mRNA; however, the process of RNA splicing removes introns. Exons are the portions of human genes that make up mature mRNA strands that are subsequently used for building proteins, a process known as translation. In addition to mRNA, many other types of RNAs exist in the cell and include ribosomal RNA (rRNA), transfer RNA (tRNA), and small nuclear RNA (snRNA). rRNAs form complexes with ribosomal proteins to make up ribosomes, which translate mRNA into amino acids. tRNAs are

responsible for transferring amino acids to ribosomes during translation. snRNAs are only found in eukaryotes and are involved in complexes that are important in RNA processing. In addition, many other types of RNAs exist that are integral for DNA replication, posttranscriptional modification, and protein synthesis.

Considerable variability in the human genome has been identified between individuals. There can be upward of 1.1−1.4 million single nucleotide polymorphisms (SNPs) distributed throughout the genome. Most SNPs have no direct consequences on the health of a person; however, some SNPs can result in major changes to the gene's function, causing developmental and health issues. Being able to detect and characterize SNPs has proven to be important in medicine. Genetic modifications can affect gene expression and can be stratified into different categories: (1) substitution (exchange of one nucleotide by another); (2) insertion (incorporation of extra nucleotides); (3) deletion (loss of a region of DNA); and (4) frameshifting (shift the way the sequence is read). While the majority of pathogenic SNPs occur within exons, intronic SNPS may also result in harmful effects, especially those that occur in the splice donor or acceptor sites, which can have negative functional effects on splicing.

Complementarity

In order to analyze the human or microbial genome, several techniques have been developed using the complementary base pairing property of DNA. Watson and Crick [4] described this homology, whereby the adenine on one strand of DNA binds to the thymine on the opposite strand, and likewise cytosine binds to guanine. This specificity results from the hydrogen bonding properties of the bases themselves. Adenine and thymine can form two hydrogen bonds, and guanine and cytosine can form three hydrogen bonds. The specificity of molecular interactions within the DNA molecule enables one to predict the sequence of nucleotides in one strand if the sequence of nucleotides in the complementary strand is known. This biochemical principle allows for the rapid design of synthetic primers and probes once the sequence of the target is known. A primer is a strand of short nucleic acid sequence (generally ranging from 10 to 30 bases) that is complementary to the target sequence and is used by the enzymatic DNA polymerase to initiate replication. A probe consists of a homologous single-stranded nucleic acid sequence that can hybridize to a target genomic sequence. Probes carry detection molecules that allow for the detection and visualization of the hybridized probe to its target. How probes and primers are designed and used in nucleic acid analysis will be described in the following sections of this chapter.

Southern blot

In molecular biology, hybridization probes are fragments of DNA or RNA, usually between 30 and 1000 bases, which hybridize to a specific target within the genome. Probes are designed and utilized in a number of techniques. Notably, one common characteristic of the utilization of probes is that, in all cases, the genomic sequence of the target must be known. Southern blotting is an early example demonstrating the use of molecular probes for DNA identification. Southern blotting, developed in the 1970s, was one of the first technologies utilized in clinical settings [5]. The overall methodology of a Southern blot is to target a specific sequence of DNA with a labeled probe so that it can be detected, usually by incorporating radioactivity or tagging the molecule with a fluorescent or chromogenic dye. The process begins by fragmenting genomic DNA into smaller pieces via the use of restriction enzymes. Restriction enzymes are bacterial nucleases that recognize specific sequential motifs and, subsequently, cleave DNA at these restriction sites. The small pieces of DNA are electrophoresed on an agarose gel for size discrimination [6]. Mutations, deletions, or rearrangements occurring within a gene may result in a disruption of the normal nucleotide sequence, possibly altering the number of restriction sites within the gene or altering the size of the restriction fragments produced. Such a change in the patterning of DNA fragments produced by enzymatic cleavage is referred to as a restriction fragment length polymorphism. Complete cleavage of the genomic sample is essential for Southern blotting, especially when single-copy genes are analyzed. Digestion of genomic DNA is confirmed by the presence of a continual ladder of fragmented DNA along with distinct bands, usually in the lower portion of the gel. The fragmented DNAs are subsequently denatured in an alkaline solution (typically with sodium hydroxide), transferred to a nylon solid support membrane via capillary action or vacuum transfer, and are bound permanently to the membrane by brief ultraviolet (UV) crosslinking or by incubation at 80°C. Once DNA has been immobilized to a membrane, specific sequences of interest can be detected by hybridization with a labeled, denatured, single-stranded probe that binds to its homologous or complementary sequence (Fig. 13.2A). Visualization of a radioactive or fluorescent labeled probe is accomplished by exposing the membrane to an X-ray film. If a chromogenic detection is used, then visualization will be accomplished by the development of color on the membrane itself.

The interpretation of a Southern blot can be relatively straightforward when one simply wants to identify the presence or absence of a gene sequence. Gene amplification, the presence of multiple copies of a gene sequence, can be viewed as a band that is more intense than the normal single-copy control gene sequence. Structural gene

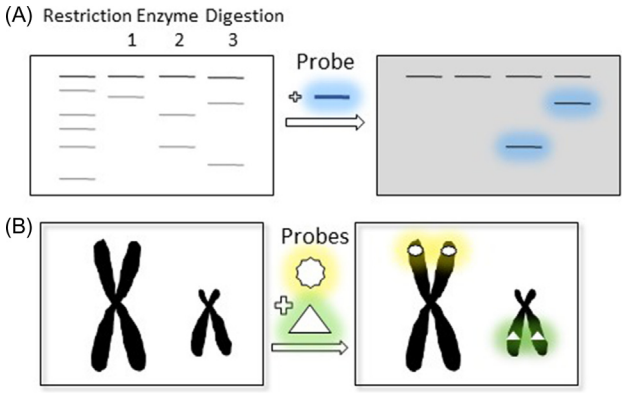

FIGURE 13.2 Schematic representation of nucleic acid probes in (A) Southern blotting and (B) fluorescence in situ hybridization.

alterations such as insertions, deletions, gene rearrangements, and point mutations in restriction enzyme recognition sites, can be detected by Southern blotting by observing banding patterns that are different from known control DNA samples.

Fluorescence in situ hybridization

Fluorescence in situ hybridization (FISH) is a molecular cytogenetic technique that has revolutionized the way chromosomes are examined [7]. Developed in the 1980s, FISH is used for examining the cellular reproduction cycle, specifically during interphase, to identify chromosomal abnormalities. It uses fluorescent probes that bind to specific targets on a chromosome with a high degree of sequence complementarity. Fluorescence microscopy is then used to identify where the fluorescent probe is bound to the chromosomes (Fig. 13.2B). The most significant development with FISH was the analysis of cells during interphase. Interphase analysis allows for cellular localization of target signals that can be associated with the morphologic phenotype. FISH is routinely used in the clinical laboratory to look for chromosomal abnormalities and gene mutations in individuals with certain diseases, such as Prader–Willi syndrome, Down syndrome, and cancer. However, the major limitation of FISH is that detection is limited to a specific abnormality for which probes are targeted.

FISH probes

A number of different kinds of probes have been developed for use in FISH. Whole chromosome probes (WCPs) are collections of small probes that bind to different sequences along the length of a chromosome. One can label all the WCPs specific to a single chromosome with one unique color, making it possible to identify when a piece of one chromosome is attached to the end of another chromosome (also known as a translocation). Locus-specific identifier (LSI) probes are used to determine if a certain gene is present in the genome and/or how many copies of that gene exist. Centromeric probes target the repetitive sequence regions of the chromosome centromeres. The common application of centromeric probes is to detect numerical chromosomal abnormalities and is referred to as chromosome enumeration probes (CEPs). Usually, a combination of an LSI probe and a centromeric probe that both target the same chromosome is used, with the CEP used as the internal control. In breast cancer, a polysomy 17-associated increase in *HER2* gene copy number is estimated using a combination of *HER2* LSI probe and a CEP 17 control probe. A multifold increase of the *HER2* gene on chromosome 17 over the chromosome copy number implies amplified expression of *HER2*, which has significant therapeutic implications. This is just one example of how FISH is used in the clinical laboratory.

The polymerase chain reaction

The polymerase chain reaction (PCR) was developed in the 1980s by Mullis and has had an unprecedented impact in the field of molecular diagnostics [8–10]. Mullis developed the PCR while working as a chemist at a biotechnology company called Cetus Corporation, first applying the technology to analyze mutations in sickle cell anemia. Mullis would go on to be awarded the Nobel Prize in Chemistry in 1993 for his work. Routinely used in clinical molecular diagnostic laboratories, PCR allows for the rapid amplification of target nucleic acid sequences to a level that can then be easily analyzed by other methods, such as chemiluminescence, fluorescence, and mass spectrometry. In doing so, PCR allows for both the qualitative and quantitative analyses of target sequences with high selectivity and sensitivity. PCR can be performed on virtually any sample type that contains enough biomass to extract DNA from. In the clinical laboratory setting, this includes blood, tissue, and formalin-fixed paraffin-embedded tissue, among others. This is advantageous if there is little starting material or in cases where the target is a pathogen derived from a patient as most of the extracted DNA will be of human origin and only a small portion obtained from an infectious organism. Numerous developments and improvements to the principles and applications of PCR have occurred since the 1980s, thus expanding how the technology may be used in both the research and clinical realms.

The process of polymerase chain reaction amplification

In a typical PCR, successive cycles are performed in which DNA polymerase copies a target DNA sequence

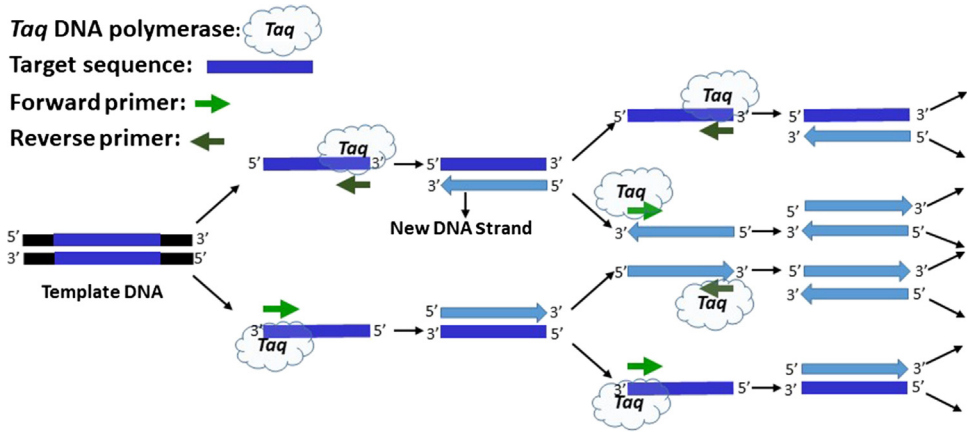

FIGURE 13.3 Schematic representation of the polymerase chain reaction.

from a template molecule in vitro (Fig. 13.3). The amplification products of each cycle provide new templates for the subsequent amplification. Thus the concentration of the target DNA sequence increases exponentially over the course of the PCR, increasing the analytical selectivity of the assay. The typical PCR mixture contains (1) a thermostable DNA polymerase (most commonly, Taq polymerase is used); (2) target-specific forward and reverse oligodeoxynucleotide primers; (3) deoxynucleotide triphosphates (dNTPs); (4) reaction buffer; and (5) a source of DNA template [genomic DNA or complementary DNA (cDNA)].

The active component of the PCR is a DNA polymerase enzyme that is required for DNA synthesis during the primer extension step. The contemporary PCR employs Taq DNA polymerase (isolated from *Thermus aquaticus*) [11]. Taq polymerase exhibits $5'\rightarrow3'$ polymerase activity, $5'\rightarrow3'$ exonuclease activity, thermostability, and optimum performance at 70°C–80°C. Temperature, pH, and ion concentrations (Mg^{2+}) can influence the activity of Taq polymerase. The half-life of Taq activity at 95°C is approximately 40–60 minutes, and extremely high denaturation temperatures (>97°C) will significantly reduce its active lifetime. Since time at temperature represents the critical parameter for maintenance of Taq activity, lowering of the denaturation temperature or reduction in the denaturation time can prolong the activity of the enzyme during a PCR. The typical PCR is carried out in a buffer (usually Tris-Cl) of pH 8.3. Taq polymerase requires divalent cations in the form of Mg^{2+}. Mg^{2+} binds to DNA, primers, and nucleotides contained in the amplification reaction. Lower divalent cation (Mg^{2+}) concentrations decrease the rate of dissociation of the enzyme from the template by stabilizing the enzyme–nucleic acid interaction. Most PCR mixtures contain at least 1.5 mM $MgCl_2$. However, a $MgCl_2$ titration is recommended for any new template–primer combination to determine the optional concentration. While Taq DNA polymerase is ideal for routine PCR, there are several other thermostable DNA polymerases with unique qualities, which make them useful for special PCR applications such as amplification of long pieces of DNA or high-fidelity amplification [12].

The target sequence is defined by the specificity of the oligodeoxynucleotide primers that anneal to complementary sequences on opposite template strands flanking the region of interest (ROI). During the PCR, these primers are extended in the $5'\rightarrow3'$ direction by the polymerase enzyme to yield overlapping copies of the original template. Each cycle of the PCR proceeds through three distinct phases: (1) denaturation; (2) primer annealing; and (3) primer elongation or extension. The denaturation step consists of destabilizing the double-stranded DNA (dsDNA) template by disrupting the hydrogen bonds between the complementary bases; this process allows access for the primer to hybridize. The denaturation is typically accomplished by incubating samples for up to 1 minute at >94°C. Primer annealing is accomplished at a temperature that is specific for the PCR primers and conditions employed; these conditions may be empirically determined during assay development. The optimal annealing temperature for a given oligonucleotide primer set is very important for PCR specificity. Generally, the annealing temperature used should be no more than 5°C below or higher than the lower primer melting temperature (Tm) and typically ranges from 55°C to 65°C. The Tm of an oligonucleotide primer can be calculated using a simplified formula that is generally valid for primers that are 18–24 bp in length. This formula is as follows: $Tm = 69.3 + 0.41(\%G + C) - (650/L)$, where L is the primer length in bases [13]. During the annealing step, primers hybridize to the complementary target sequence contained within the denatured single-stranded template. This step produces a starting point for the polymerase enzyme to catalyze the incorporation of dNTPs in a DNA-directed DNA synthesis reaction. However, due to the high concentration of the primers in the reaction, weak interactions can occur inducing nontarget amplification.

This phenomenon is known to have primer−dimer formation.

The primer extension/elongation step is accomplished at approximately 72°C. The actual times used for each cycle will vary from 15 seconds to 1−2 minutes depending on both the DNA polymerase used and on the length of the DNA region to be amplified (also known as the amplicon).

Amplification of target sequences is accomplished through repetition of these aforementioned steps (denaturation, annealing, and elongation) for 25−50 cycles. The exact number of cycles necessary to produce an amplicon that can be detected will depend on the starting concentration of the DNA template, size of amplicon, as well as downstream detection method. By the end of the third cycle of amplification, a new double-stranded molecule is formed in which both the 5′-end and 3′-end coincide exactly with the primers employed. Since the copy number theoretically doubles after each successive cycle, an exponential increase of 2^n (n being the total number of cycles) is accomplished during the complete reaction. Accumulation of amplicons corresponding to the target sequence eventually levels off and reaches a plateau, due to the exhaustion of PCR reagents and loss of activity of the polymerase. The initial number of target sequences contained within the template sample, the efficiency of primer extension, and the number of PCR cycles performed determine the upper limits of amplification.

There are many advantages and disadvantages to PCR. In addition to being sensitive and specific, starting material does not have to be genomic DNA but can be cDNA, which is discussed in the next section. The size of amplicons can also vary according to the result needed for clinical use. The size of the amplicons typically ranges from 50 to 1000 nucleotides; however, PCR with the appropriate polymerase can produce amplicons above 1000 bp. A drawback of PCR is the error rate. While Taq polymerase has a reported error rate of $1-20 \times 10^{-5}$, other high-fidelity polymerases are reported to have higher rates of accuracy [14]. Even so, if an incorrect base is incorporated into a newly synthesized strand in the early steps of PCR, that error is carried through the rest of the amplification process. This can lead to erroneous results, which can have negative consequences, especially in genotyping PCRs or when the PCR product is then used for sequencing. The chance of incurring errors increases in PCRs with long amplicons.

Reverse transcriptase polymerase chain reaction

In order to expand the power of PCR amplification to the transcriptome level, RNA is reverse-transcribed into cDNA in a reverse transcription reaction [15]. Reverse transcriptase (RT; retroviral RNA-directed DNA polymerase) is the enzyme used to catalyze cDNA synthesis. The RT reaction consists of five components: (1) a single cDNA synthesis primer; (2) an appropriate RT buffer; (3) dNTPs; (4) RNA template (total RNA or mRNA); and (5) RT enzyme. There are several commercially available RT enzyme preparations that can be used in standard reverse transcriptase polymerase chain reaction (RT-PCR) applications. These include RT from Moloney murine leukemia virus and avian myeloblastosis virus. More recently, recombinant derivatives of these RT enzymes have become available, offering advantages over the native enzymes. Advanced enzyme preparations like these produce the highest yields and confer high specificity when gene-specific primers are employed.

RT-PCR is a commonly employed method for analysis of RNA transcripts, especially for measuring low abundance species or working with limited amounts of starting material. Classic blotting and solution hybridization assays require much more RNA for analysis and lack the speed and ease of technique afforded by PCR-based applications. RT-PCR couples the tremendous DNA amplification capabilities of the PCR with the ability to reverse transcribe small quantities of RNA into cDNA. Other advantages of RT-PCR include versatility, sensitivity, and the ability to compare multiple samples simultaneously.

Analysis of polymerase chain reaction amplicons

There are numerous methods to analyze PCR products, and the method of choice depends on the type of information desired. In most cases, amplicons can be analyzed by standard agarose gel electrophoresis, which effectively separates DNA products over a wide range of sizes [from 100 bp to >25 kilobases (kb)]. Size markers can be electrophoresed on the gel to allow size determination. PCR products from 200 to 2000 bp can be separated quickly on a 1.2%−2.0% agarose gel. When greater resolution or separation power is required, such as in the analysis of very small amplicons (<100 bp), polyacrylamide gel electrophoresis (PAGE) is the method of choice. In both cases, a fluorescent dye that intercalates into the DNA can be added to the gel during preparation; alternatively, the dye can be added following electrophoretic separation for gel staining. Ethidium bromide (EtBr) is one such fluorescent dye that has been used for visualizing DNA on gels. Because EtBr is an intercalating agent, it can be potentially genotoxic. However, alternatives that are both safer and better performing have been developed and include Green-Glo and SYBR Safe. Regardless of the type of fluorescent dye used, DNA fragments are easily visualized as bands by UV-illumination.

If the clinical assay requires measuring the amplicon size with very high resolution (e.g., sequencing or fragment analysis), laboratories have turned to capillary electrophoresis (CE) systems [16]. Unlike standard SDS-PAGE separation, CE systems can provide molecule detection after separation through a light source and a detector. In addition, the system can utilize high voltages without overheating the samples. The CE was essential for the completion of the Human Genome Project. Although CE's role in de novo genome sequencing has decreased with the replacement of Sanger sequencing by the next-generation sequencing (NGS; discussed later in this chapter), CE is still used to improve quality control in the NGS by determining the amplicon size. CE is also widely used for DNA sizing in other methodologies, for example, in assigning short tandem repeat (STRs) and variable number tandem repeats for human identification or detecting pathogen biomarkers [17]. CE can also be used in multiplex ligation-dependent probe amplification assays, commonly used for the detection of unusual copy number changes (insertions or deletions) of human genes for the diagnosis of several genetic diseases whose pathogenesis is related to the copy number variation (CNV) of specific genes. A limit of CE is the requirement of expensive equipment but, once acquired, it has the advantages of low operating costs, small sample input, and high resolving power.

In some cases, the desired information resulting from a PCR analysis can be obtained through a simple analytical gel separation, as just discussed. However, in other instances, additional information is required. PCR products can be directly sequenced after purification. In addition, they can be cloned and used for the construction of molecular probes, in mutation analysis, in in vitro mutagenesis, or in gene expression studies.

Multiplex polymerase chain reaction

Another important milestone in the evolution of PCR involves the expansion of assay multiplexing capabilities [18]. Multiplex PCR is a powerful technique that enables the amplification of two or more products in parallel in a single reaction tube. It employs different primer pairs in the same reaction for simultaneous amplification of multiple targets. Multiplex PCR is used widely in genotyping applications and multiple areas of DNA testing in research, forensic, and diagnostic laboratories. Applications include gene expression and deletion analysis, SNP genotyping, forensic identity testing (e.g., STR typing), and pathogen detection. Quantification of multiple genes in a single reaction also reduces reagent costs, conserves precious sample material, and allows increased throughput.

Real-time polymerase chain reaction

A significant advance in the PCR methodology was the development of real-time PCR (qPCR) assays in the 1990s. This technology allows for simultaneous real-time detection of PCR products, as they are amplified with the use of fluorescent detection (Fig. 13.4) [19]. Various detection chemistries for qPCR were rapidly introduced and replaced many of the older detection methods (including gel electrophoresis, allele-specific oligonucleotide blots, and others). The fluorescent detection systems used in qPCR offer numerous advantages over most molecular technologies including closed-tube amplifications, decreased concern for contamination, the ability to perform qualitative or quantitative analysis, and the ability to perform variant screening with melt curve analysis.

The reason qPCR is so rapid is that it combines the amplification steps of traditional PCR with simultaneous detection steps that do not require post-PCR manipulation, because the PCR is monitored directly within the reaction vessel. In qPCR, the exponential phase of PCR is monitored, as it occurs using fluorescently labeled molecules [20,21]. During the exponential phase, the amount of PCR product present in the reaction vessel is directly proportional to the amount of emitted fluorescence and the amount of initial target sequence. The higher the copies of input DNA, the fewer the amplification cycles are needed to achieve a significant increase in fluorescence, allowing these reactions to be quantitative, resulting in the nomenclature of qPCR.

There are several types of detection chemistries for qPCR: those which use intercalating DNA binding dyes such as SYBR Green I and those that use various oligonucleotide probes with attached fluorophores [22]. Intercalating DNA binding dyes allow for the simple

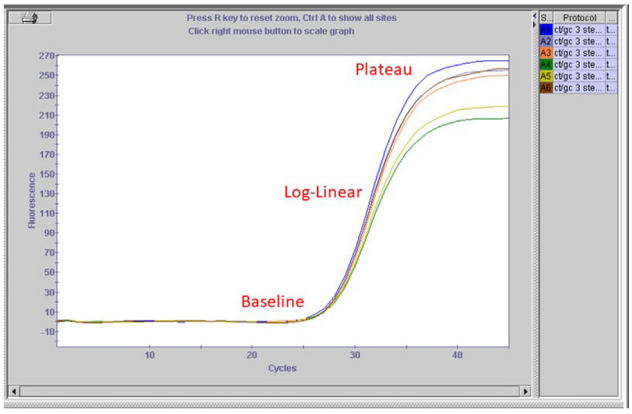

FIGURE 13.4 A real-time polymerase chain reaction amplification curve showing the baseline, log-linear, and plateau phases of the reaction. This set of curves was generated using the Smartcycler II (Cepheid, Sunnyvale, CA).

determination of the presence or absence of an amplicon. SYBR Green I, like EtBr, is a dye that emits fluorescence when it is bound to dsDNA. During the PCR, there is an increase in the copy number of the amplicon, as well as a simultaneous increase in the amount of intercalated SYBR Green I. This will then increase the level of emitted fluorescence in direct proportion to the copy number. One disadvantage to these types of dyes is that they are nonspecific and will bind to any dsDNA. To increase further detection specificity, primer-probes are used, and they are discussed in the next section.

Probes for real-time polymerase chain reaction

Probes for qPCR can be divided into two categories that are based on the fates of probes during PCR: a hydrolysis-type probe and a hybridization-type probe. The hydrolysis-type probes have a reporter fluorophore at one end of the probe and a corresponding quencher at the opposite end (Fig. 13.5). The reporter and the quencher are so close that excited energy from the reporter is transferred to the quencher by Förster resonance energy transfer (FRET); consequently, no fluorescence is emitted as the excitation energy is absorbed by the quencher molecule. When the probe hybridizes to its newly synthesized target sequences, the reporter fluorophore is released from the probe through the 5′→3′-exconuclease activity of the DNA polymerase during qPCR. The released fluorophores emit signals when they are excited by a specific wavelength of light, and the amount of the signal is proportional to the amount of PCR product generated. The most common example is the TaqMan probe (Fig. 13.5A).

There are several methodologies behind how hybridization-type probes work during qPCR [23]. The dual hybridization probe strategy utilizes two probes simultaneously, which are designed to hybridize adjacent to each other on the same target sequence. The first probe is labeled on the 3′ end with a donor fluorophore and the second probe is labeled on the 5′ end with an acceptor fluorophore. When these probes hybridize to the target sequence and are in close proximity, excitation of the donor fluorophore results in a transfer of energy to the acceptor fluorophore. This FRET process results in the emission of light at a wavelength specific to the acceptor fluorophore (Fig. 13.5B). By measuring the signals emitted at the wavelength of the donor and acceptor fluorophores, the amount of FRET can be determined by the qPCR instrument. An example is the HybProbes or FRET probes. One of the drawbacks to a hybridization probe-based approach is that two probes need to be designed instead of a single probe.

Another hybridization-type probe strategy takes advantage of the hairpin structure in which 5′ and 3′ ends of probes are close enough to allow fluorescence quenching in the absence of target sequences. Following the probe's hybridization to target sequences, the hairpin structure melts. This provides the reporter with enough distance from the quencher for fluorescence emission (Fig. 13.5C). This type of probe is known as the hairpin probe or the molecular beacon probe (HyBeacon). This probe is highly specific, because the hairpin and hybridized structures are interchangeable so that even an SNP in the target sequence results in the hairpin structure and not hybridization.

Alternatively, HyBeacon probes provide a method for fluorescence-based sequence detection, allele discrimination,

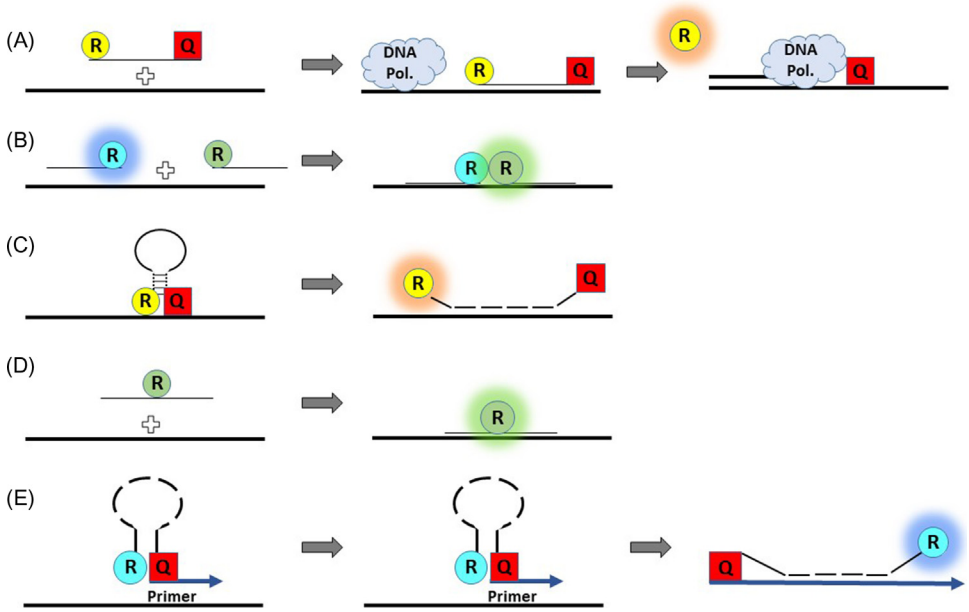

FIGURE 13.5 Schematic diagrams of probes used in real-time polymerase chain reaction. (A) TaqMan probes. (B) HybProbe or Förster resonance energy transfer probes. (C) Molecular beacon probe. (D) HyBeacons probe. (E) Primer-probe. The glowing images represent emitted fluorescence signals. *DNA Pol*, DNA polymerase; *Q*, quencher of fluorescence from fluorophore (R); *R*, reporter fluorophore.

and DNA quantification [24]. In the case of HyBeacon probes, a reporter fluorophore is used without any quencher (Fig. 13.5D). When the reporter is attached to the middle of a probe sequence instead of at the end of the probe (like the Taqman or FRET probes), fluorescence emission rates are considerably lower in a single-stranded state than a double-stranded state. This is because the probe alone emits weak fluorescence signals and the probe emits stronger fluorescence signals when it hybridizes to a target sequence. Design of the HyBeacon probe is simple, and it is inexpensive, because only one fluorophore is required.

Primer-probes are a group of probes used in qPCR and harbor both probe and primer capabilities in a single oligonucleotide molecule [21]. Primer-probes typically have an attached fluorophore molecule and a hairpin structure, which places the reporter fluorophore close to an attached quencher to reduce the background emission signal from the reporter (Fig. 13.5E). Primer-probes are the aforementioned molecular beacon probe combined with primer oligonucleotides. When the probe part of a primer-probe hybridizes to its adjacent, newly synthesized target sequence, the reporter emits fluorescence signals and the amount of signal is proportional to the amount of target sequence. The advantage of primer-probes is the identification of amplified product if there are shared probe-hybridization sequences in multiplex PCR assays. Other advantages are inhibition of primer−dimer formation and prevention of nonspecific PCR signal detection. Disadvantages include cost of the primer-probe and designing probes close to the primer sites. Examples include Scorpions and Amplifluour primer-probes.

Post real-time polymerase chain reaction analysis

There are two main post-qPCR analyses: one using the amplification curve and the other using a melting, or denaturation, curve. Amplification curve analysis allows for absolute and relative quantitation of the amplicon concentration, during each amplification cycle. The approach is to set a quantification threshold and to determine the quantification cycle Cq [the number of cycles required to attend this threshold, also known as cycle threshold (Ct)]. The threshold should be set in the exponential phase of the PCR reaction. The fluorescent baseline for the amplification plot is a crucial step in qPCR data analysis, and this is typically set at an early point in amplification. Quantification is either obtained by using several different samples of known concentration or a standard, in order to construct a standard curve or to quantify using a comparative Cq method. The comparative Cq method uses the formula $2^{-\Delta\Delta Ct}$ in order to calculate the relative gene expression (relative quantitation) fold change relative to reference samples (such as an untreated sample or endogenous control or housekeeping genes). The comparative Ct method demands that the PCR efficiency of the biological sample and amplification of the reference are approximately equal. Absolute quantitation of unknown samples can only be obtained by using a standard curve made of standard with known absolute quantities.

Melting curve analysis is based on the fundamental property of dsDNA denaturation with heat [25]. This separation can be monitored with the use of fluorescent dyes that specifically fluoresce when bound to dsDNA. As the temperature is raised, the double strand begins to dissociate, releasing the dye and leading to a decrease in the fluorescence intensity. Data generated are represented by a curve of fluorescence intensity versus temperature. The point at which 50% of the DNA is in the double-stranded state is called the melting temperature (Tm) and represents the peak of the derivative of the melting curve (Fig. 13.6). In the presence of saturating concentrations of the DNA binding dyes, a specific amplicon sequence will present with a specific melting profile containing a specific Tm and a melting curve shape. This distinctive melting curve can be used to detect DNA sequence variations in the amplicon without the need for any post-PCR processing. The development of both high-resolution qPCR instruments and new saturating DNA dyes allows for a more accurate assessment of sequence variations based on melting analysis. High-resolution melting analysis (HRMA) can discriminate DNA sequences based on their

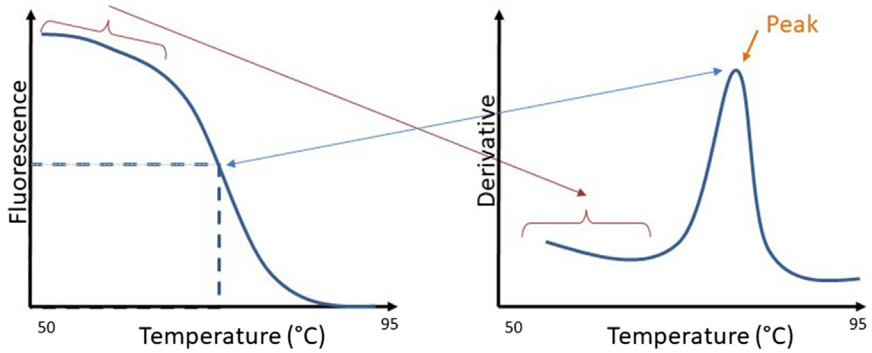

FIGURE 13.6 Melting curve output from real-time polymerase chain reaction.

composition, length, guanine-cytosine (GC) content, or strand complementarity. It can be used for mutation scanning experiments, methylation studies, and genotyping. The advantages of this method are its ease of use, high sensitivity, high specificity, and low cost. These characteristics make HRMA ideal for use in routine diagnostic settings [26]. However, the accuracy of the technique depends on appropriate instrumentation, saturation dyes, and software for analysis, which often introduces variability among clinical diagnostic laboratories.

Multiplexing with real-time polymerase chain reaction

The use of probes in qPCR allows for determination of more than one genotype in a single qPCR reaction. Modern qPCR instruments harbor up to five sets of excitation and emission filters for labeled fluorescence dyes [27]. When there are more than five known genotypes, the solution is to utilize independent, or separate, PCR assays. The introduction of multiplex technologies allowed for the detection of multiple variants in the same or separate genes simultaneously and in a single reaction tube.

Multiplexed genotyping often requires two probes per target molecule. One probe identifies the wild type or normal sequence, and the other detects the specific variant of interest. Typically, the various types of probes used are labeled with different fluorophores. Depending on the fluorescent signal detected, the genotype can be determined as either homozygous normal, heterozygous, or homozygous mutant.

The Idylla assays use a qPCR chemistry based on the PlexPrime and PlexZyme (also known as MNAzyme) technologies that allow multiplexed variant detection with high sensitivity and specificity [28]. With this technology, each primer is designed to have a 5′ target-recognition region, a short 3′ target-specific sequence complementary to the mutation of interest, and a distinct insert sequence that is mismatched (MM) to the target. This results in the production of allele-specific amplicons that are detected in real time by allele-specific PlexZyme enzymes and a universal fluorescent probe, allowing for the detection of a broad range of mutations in a single reaction. This system can be used for the rapid detection of somatic variants [29].

Multicolor melt curve analysis for high risk human papillomavirus (hrHPV) detection is a PCR-based DNA amplification method that enables simultaneous identification of amplified target DNA using melting temperatures of double-stranded targets from different hrHPV types.

Multicolor melting curve analysis is another way to use the potential of qPCR by combining the use of dual-labeled probes with high-resolution melting curve analysis. Such a system can be used for the rapid detection of human papilloma virus (HPV) [30]. In the assay developed by QuanDx, 14 different high-risk HPV genotypes are tested for within a single reaction because of high-resolution melting curve analysis (www.quandx.com).

Digital polymerase chain reaction

Digital PCR (dPCR) is a modification of conventional PCR methods that can be used to quantify directly and amplify clonally nucleic acids strands [31]. qPCR enables relative quantification of target sequences but not absolute quantification due to the issue of amplification bias and the requirement of standard references that can differ between the laboratories. dPCR offers significant benefits over other PCR methods by providing an absolute count of target DNA copies per input sample without the need for running standard curves. That makes this technique ideal for nucleic acid quantification, rare mutation detection, pathogen detection (viral load analysis and microbial quantification), CNV detection, microRNA expression analysis, NGS, single-cell gene expression analysis, and chromosome abnormality detection.

dPCR is derived from the digital readout, which utilizes numerical digits to identify “presence” or “absence” in single reactions. dPCR is performed by diluting target nucleic acid across a large number of reactions (termed partitions or fractions), which statistically results in one or zero molecules per reaction prior to amplification. A strong sample partitioning enables the reliable measurement of small fold differences in target DNA sequence copy numbers among samples. In addition, the creation of individual reaction compartments avoids the effects of cross-contamination and achieves absolute target quantification in each sample. However, there is always the possibility that more than one molecule will be present per reaction, thus requiring the need to use statistical methods, such as the Poisson distribution or negative binomial distributions.

There are four main ways to partition samples in dPCR: droplet-based sample dispersion (oil−water emulsions), microwell-based sample dispersion, channel-based sample dispersion, and printing-based sample dispersion [32]. The primary dPCR method is the droplet dPCR (ddPCR). After partitioning, the next step consists of thermal cycling amplification or isothermal amplification (Fig. 13.7). Then, each compartment is evaluated individually. This removes PCR efficiency bias from amplification and decreases error rates, thus enabling the detection of small fold differences. In addition, evaluation of an individual compartment in ddPCR reduces the background signal by increasing the signal-to-noise ratio, thus significantly improving the detection sensitivity. Fluorescent probes, such as the TaqMan hydrolysis probes or an intercalating dye, are generally used to detect the

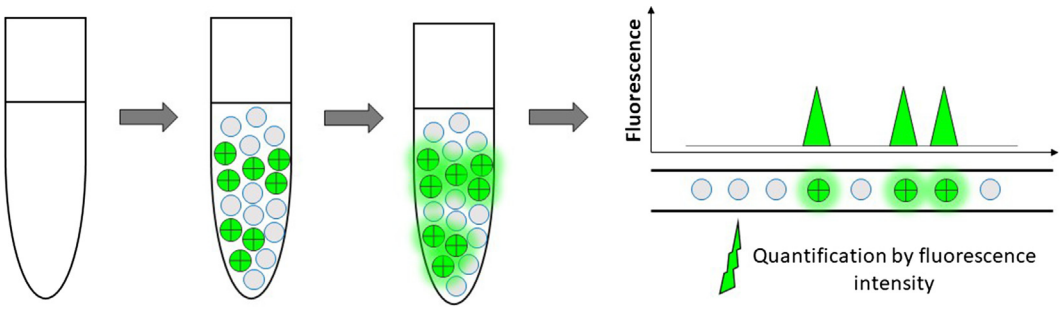

FIGURE 13.7 Overview of droplet digital polymerase chain reaction.

amplification products. A single template reaction yields a positive signal, which can be differentiated and eliminated from the fluorescence intensity generated by multiple target reactions. The ddPCR quantification process is droplet-based fluorescence signal counting, a method that determines the number of droplets that have different fluorescence intensities, similar to the principle of flow cytometry.

dPCR encounters the same challenges as PCR and qPCR in terms of experimental design and the need of internal controls. Though dPCR offers the potential to perform precise low abundance quantification, it is imperative to measure sources of false-positive signals due to low-level contamination and/or nontarget amplification (caused by mispriming and/or primer dimers) and may lead to overestimation. Conversely, PCR inhibition can lead to underestimation due to the fact that dPCR is only able to count positive partitions. This problem is also encountered when detecting RNA by RT dPCR. The use of an internal positive control, such as the housekeeping gene beta-actin, is highly recommended when measuring clinical samples, especially when reporting negative results. The optimal internal positive control gene will depend on the PCR conditions used for the genes targeted in the assay.

Digital polymerase chain reaction and multiplexing

Similar to the multiplexing applications with standard qPCR, it is also possible to duplex or multiplex with dPCR [33]. Competing duplex dPCR reactions can be utilized in which the same primer set is used but includes two probes, with each probe designed slightly differently in order to detect changes in a single targeted sequence. Each probe would have a unique reporter dye. Duplex or multiplex (if using more than two unique probes) reactions using this approach would be for used for detection SNPs, single nucleotide variants, and small insertions or deletions. In contrast, if using a noncompeting duplex or multiplex dPCR approach, each probe would have its own corresponding forward and reverse primer pair and each set of primers and probe would target a different nucleic acid sequence.

One of the current limitations in multiplex dPCR can be the number of available optic channels. Although newer instruments such as the Fluidigm BioMark and EP1 systems offer four optical channels for detections, many instruments only offer two channels for detection. Nevertheless, there are ways to apply higher order multiplexing to these two optic channel instruments by measuring the end-point fluorescence amplitude. This is possible with dPCR due to the advances in partitioning fluidics that enable a reaction to be subdivided into an increasing number of partitions. Each partition is a function of probe-dye conjugation and mixing, probe and primer concentrations, and the type and concentration of targets that are present. Thresholds must be determined for each partition, and appropriate software is required to analyze the data, which is often represented as a 2-D scatter plot. Clinical diagnostic assays such as genotyping and gene copy number can be determined using this approach.

Microarrays

A DNA microarray is another important clinical diagnostic method to measure the expression levels of large numbers of genes simultaneously or to genotype multiple regions of a genome (Fig. 13.8A) [34]. In contrast to the assays already discussed, microarrays can analyze large portions of an organism's genome due to the use of thousands or millions of different probes simultaneously. There are various approaches to perform microarrays but the basis of the microarray technology generally corresponds to a collection of microscopic features (DNA "spots") arranged on a chip in a grid-like format. These features can be probed with target molecules to produce either quantitative (gene expression) or qualitative (diagnostic) data. The spots correspond to the probe (e.g., DNA sequence) immobilized to a solid surface (i.e., membrane or beads). The nature of an array is such that it requires the location of every probe to be documented. This then allows for the identification of probes that have located complementary sequences/targets in the sample.

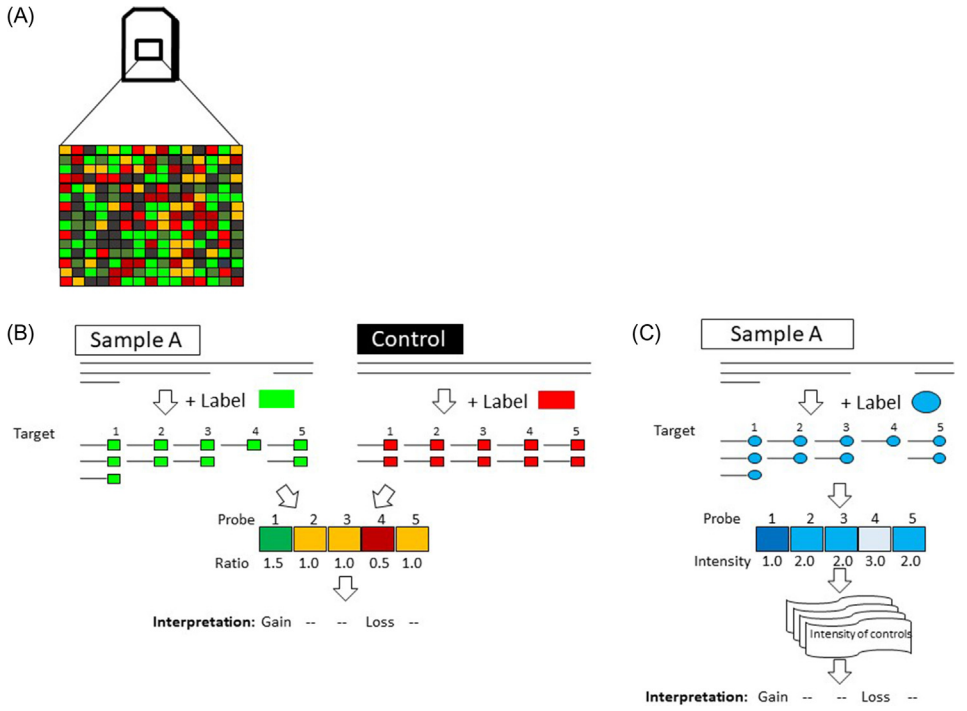

FIGURE 13.8 Microarray experiment design for copy number variants. (A) Overview of microarray. (B) Two-color microarray experiments. (C) One-color microarray experiments. In the two-color experiment (B), test sample and control are labeled with two different fluorescence dyes, displayed with white and black squares. Labeled targets are hybridized in a single microarray, and ratios of two fluorescence signals at each probe position are calculated to determine genome aberrations. In the one-color experiment (A), only testing sample is labeled and hybridized in a microarray. Signal intensities are compared with intensity data of a collection of controls to diagnose copy number variations.

The hybridization between the probe and the labeled target is detected and quantified using fluorophore, silver, or chemiluminescence methods. Due to technological advances and the variable experimental details (including probe length and synthesis, density of features, and the solid surface), the spectrum of microarrays is significant. Microarrays can be distinguished based on characteristics such as the nature of the probe (e.g., DNA) and the type of microarray.

Four major categories of microarray are available. The first category includes the printed arrays that use the process of "printing" or spotting of the probes onto the microarray surface, (glass microscope slide). The second category regroups the in situ-synthesized arrays that are high-density microarrays, such as GeneChips (ThermoFisher Scientific, Waltham, MA) and Sure Print (Agilent Technologies, Santa Clara, CA). The third category embodies high-density bead arrays (Infinium HD assay; Illumina, San Diego, CA), that uses silica beads as a support for the probes (i.e., specific oligonucleotides). The beads are randomly assembled and held in microwells on patterned substrates, allowing a uniform spacing. Each sample is fluorescently labeled and can be identified using distinctive indexes (IllumiCodes), which allows for multiplexing. The indexes are also used to map the location of the sample on the substrate. The fourth category pertains to suspension bead arrays, which are based on the use of spectrally distinctive beads as the solid support and the xTAG technology as the probe (Luminex Corporation, Madison, WI). The sample to be analyzed is mixed with unique oligonucleotide sequences (xTAG) specific to each target. To prevent cross-hybridization with any target sequence, the xTAG technology uses only three, instead of four, bases [thymine (T), adenine (A), and guanine (G)] in the antitag and tag sequences, hence the name of the xTAG technology. Binding with the TAG allows for allele-specific primer extension, during which biotin-labeled dCTPs are incorporated. The products are then mixed with color-coded beads. A specific antitag sequence is attached to a bead of specific color, and the tag sequences are hybridized to antitag sequences. The subsequent detection of a fluorescent reporter indicates that probe-target DNA hybridization has been accomplished using a special benchtop flow cytometer. An example of how this technology is used clinically is the laboratory developed test (LDT) Luminex cystic fibrosis genotyping assay, which can detect up to 71 mutations in the cystic fibrosis transmembrane ragulator gene in a single tube reaction (www.luminexcorp.com).

Microarray technologies also allow for CNV across the entire genome, which is far beyond the analysis capacity of qPCR or multiplex genotyping [35]. Microarrays for CNV identification, called array comparative genome hybridization (aCGH), utilize diverse types of probes [36]. In early aCGH approaches, BAC clones of approximately 100 kb were used as microarray probe and made it possible to cover the whole genome. However, the resolution was too low to detect small variations and to define break points. To improve resolution, cDNAs of 1−2 kb were developed for microarray probes. Limitations of cDNA probes, however, include lower

genome coverage and poor hybridization efficiencies when targets are genomic DNAs. To help resolve these technical issues, PCR products of about 1 kb were used as probes after being directly amplified from genomic DNA. Both PCR and cDNA probes, however, still have limitations with low resolution and technical difficulties of spotting these clones on limited space on a slide. To achieve higher resolution, oligonucleotides of up to 70 base pairs are used as microarray probes. Either ink-jet technology or photolithography generates over four times as many probes on arrays as older spotting technologies.

CNV microarrays are further divided based on experimental designs: two-color and one-color experiments. In the one-color experiment, biotin-labeled genomic DNA from a single patient hybridizes to probes (Fig. 13.8C), and then, streptavidin–phycoerythrin complexes convert the biotin label into a fluorescence signal. The signal intensities are measured as absolute values. Signal intensities at each probe are compared with a collection of controls to determine CNV. Absolute values from the one-color experiments can be directly compared with other experiments after intensity value normalization. In the two-color experiment, genomic DNA from a patient and a control are labeled with different fluorophores, such as Cy3 and Cy5 (Fig. 13.8B). These labeled targets hybridize to probes in a single array, and signals from Cy3 and Cy5 at each probe are converted into Cy5/Cy3 ratios. Statistically significant deviation in the signal ratio from expected distribution is interpreted as CNV. Ratio values from the two-color experiments can be compared only among experiments using the same control. Compared with one-color experiments, signal variation per probe is reduced in two-color experiments because of identical hybridization conditions. However, differences in labeling efficiency between Cy3 and Cy5 and in hybridization efficiencies between Cy3- and Cy5-labeled targets can influence fluorescence intensities and lead to inaccurate gene expression results [37]. To control for this, replicate microarrays can be performed in which the opposite dye orientations are used to control for gene-specific dye bias.

Microarrays are also widely used for identifying genome-wide single nucleotide polymorphisms (SNPs). There are two types of arrays for SNP genotyping: resequencing microarrays and genotyping microarrays. The biggest difference between the two approaches is in probe design (Fig. 13.9). In the resequencing microarrays, all four possible SNP variants (A, T, G, and C) are positioned at the center of the oligonucleotide probes with the remainder of the sequence being identical (Fig. 13.9A). Following hybridization, an SNP is detected by comparing the hybridization intensity among the four probes. Probes with the highest intensity identify the nucleotide in the middle of probe sequence. Resequencing microarrays can determine the identity of SNPs at any sequence variation position. However, there is no system for monitoring cross-hybridization, and therefore results may contain false positives in the cases where probes are binding to similar, but not identical sequences [38].

Genotyping microarrays have probes that hybridize to known allelic sequences (Fig. 13.9B). To increase the specificity of SNP calling, probes are designed to hybridize to target sequences at different levels, that is, a probe harbors an SNP in the middle of the oligonucleotide sequence, and other probes are shifted either upstream or downstream of the SNP position [39]. Accordingly, each probe is expected to hybridize to its target with a different intensity to determine the base in the middle of the target sequences. Besides perfect-matched (PM) probes, MM probes are incorporated to identify any nonspecific hybridization. These tiling probes determine homozygous or heterozygous genotypes at the SNP position. The amount of information can be limited compared with the resequencing microarrays, as genotyping arrays only detect specific allele sequences that the array was designed to detect. Therefore any alleles present in a given sample, which are not included in the microarray, will not be detected [40]. However, the genotyping microarrays with sliding probe sets provide greater specificity than the resequencing microarray. In addition, recently introduced genotyping microarrays are found to include only PM probes without the incorporation of mismatch probes or shifted probes (Fig. 13.9C). Thus the number of probes per SNP in genotyping microarrays is much less than that in the resequencing microarrays. This allows for a more cost-effective addition of more SNP probes to a single genotyping microarray at the cost of reduced specificity.

Both aCGH and SNP microarrays have advantages and disadvantages. SNP microarrays were originally designed to determine simultaneously a number of genotypes but have also been utilized to provide CNV information. The signal intensity differences at each SNP probe are compared between microarrays or within a microarray, and the differences are interpreted as CNV. Thus SNP probes provide allele frequencies along with CNV, which are widely used for cancer diagnosis. One misconception is that SNP probes are good enough for whole genome variant analyses. However, locations of SNP probes are restricted to a certain genomic region, resulting in coverage issues. In contrast, copy number probes can be designed to any genomic region but generate only CNV information without allele frequencies. Therefore SNP probes and copy number probes are incorporated into a single microarray to provide much higher resolution for DNA variants. The Affymetrix CytoScan HD microarray has 1,953,246 nonpolymorphic copy number probes and 743,304 SNP probes [41].

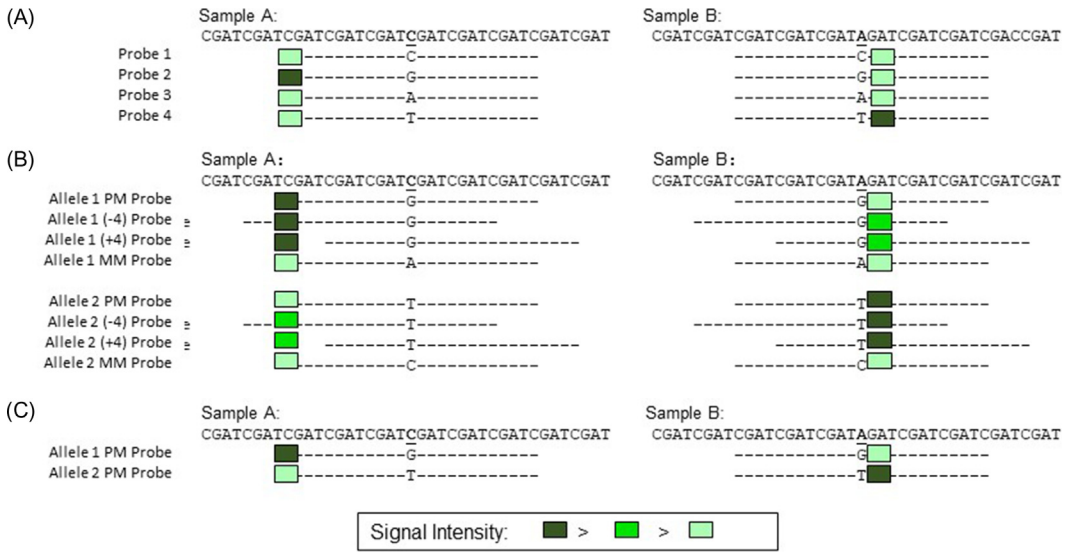

FIGURE 13.9 Microarray probe design for single nucleotide polymorphisms genotyping. (A) Resequencing microarray. (B, C) Genotyping microarray. In resequencing microarrays (A), four probes per single nucleotide polymorphisms are incorporated in the microarray. Probe sequences completely complementary to target sequences emit fluorescence signals, which are depicted by filled boxes. In old version genotyping microarrays (B), probe sequences are designed only from known allelic sequences. In the simplified depiction of the genotyping microarray (B), perfect-match and mismatch probes are incorporated. In addition, four base-shifted probes, either upstream (-4) or downstream (+4) from the middle position, are included. Complementary probes hybridize to their target sequences except for the mismatch probe (*upper left and lower right panels in B*). Polymorphic perfect-match and mismatch probes did not hybridize (*upper right and lower left panels*). But shifted probes at least hybridize to the target sequences with greater intensity than perfect-match and mismatch probes that are shown with gray boxes. That is because the shifted polymorphic site from the middle of the probe allows weaker hybridization. In recently introduced high-density genotyping microarrays as in (C), only perfect-match probes are incorporated.

Sequencing

While qPCR and dPCR assays are highly sensitive and specific, they require a prior knowledge of the target sequence. In contrast, sequencing methods are an unbiased approach to nucleic acid detection. Sequencing is widely used in clinical diagnostic laboratories to allow for identification of nucleic acid changes in genes, determine associations with diseases and phenotypes, and also identify appropriate drug targets. There are a number of different approaches to sequencing and analysis, and the next section will provide a detailed overview of the methodologies currently used in the clinical lab.

Sanger sequencing

Sanger sequencing was first developed in the 1970s and was the primary method of sequencing up until the advent of NGS in the early 2000s. The Sanger method utilizes the natural properties of DNA polymerase as well as terminator dideoxynucleotides (ddNTP) tagged with specific fluorescent dyes to generate sequence data using capillary-array electrophoresis [42]. The Sanger method makes use of the 2′,3′-dideoxy and arabinonucleoside analogs of the normal deoxynucleoside triphosphates, which act as specific chain-terminating inhibitors of DNA polymerase by preventing phosphodiester bond creation due to the absence of the 3′-hydroxyl group.

Sanger sequencing starts with amplification and purification of the target DNA. A primer is then annealed adjacent to the sequence of interest and extended by DNA polymerase. During the extension reaction, the nascent chain is terminated by the random incorporation of fluorescently labeled ddNTP, which are complementary to the base on the opposite strand. The different sized products are then resolved by capillary-array electrophoresis, and the resultant pattern of fluorescent peaks determines the DNA sequence. The technique is rapid, robust, accurate, and can typically achieve read lengths of up to 1 kb with relatively low cost. The entire Human Genome Project was completed using Sanger sequencing, and it remains the "gold standard" of DNA sequence analysis [1].

Next-generation sequencing

The complexity and duration (~10 years) of the Human Genome Project demonstrated the need for higher throughput sequencing technologies that were capable of sequencing more than one target at a time in a single run. NGS was being made available just as the Human Genome Project was wrapping up. This technology, also known as the second-generation sequencing, allowed scientists to

sequence an entire genome in one run through the use of massively parallel sequencing of millions of DNA templates. NGS rapidly produces an enormous volume of data at a lower cost than Sanger sequencing.

The commercially available NGS platforms differ from traditional Sanger sequencing technology in a number of ways. First, the DNA sequencing libraries are clonally amplified in vitro, eliminating the need to clone the DNA library into bacteria [43]. Second, the DNA is sequenced by synthesis (addition of complementary nucleotides), rather than through chain termination chemistry. Finally, the use of molecular barcodes allows the DNA templates to be sequenced simultaneously in a parallel fashion.

The workflow for NGS consists of four main steps: library preparation, template amplification, sequencing, and data analysis (Fig. 13.10). Extensive reviews have been published on the various NGS platforms [44–46]. Due to the rapidly evolving technologies, we encourage readers to visit the website of the commercially available platforms for the latest information (Ion Torrent, Illumina, Nanopore, and PacBio), and we will focus on the basic principles used for sequencing.

Library preparation

DNA library preparation usually involves fragmentation of isolated DNA into smaller, random, overlapping fragments followed by end repair and adapter ligation. Depending on the platform used, DNA is fragmented usually by physical/mechanical (i.e., ultrasonication) or enzymatic methods down to the range of 150–800 bp. While direct sequencing of RNA molecules is possible, many transcriptome-based NGS protocols will use reverse transcription to convert RNA into cDNA for sequencing [47]. cDNA libraries are prepared by removing rRNA, synthesizing cDNA, end polishing cDNA fragments (blunt-end conversion), and attaching platform-specific adapter sequences. Since the average size of RNA is smaller than DNA, no fragmentation is usually required. The cDNA library preparation method varies depending on the RNA species under investigation, which can differ in size, sequence, structural features, and abundance. Custom gene panels can be performed using libraries that are enriched with targeted gene sequences.

Amplification-based enrichment methods

Amplicon-based NGS methods use PCR to generate the sequencing libraries and are ideal for sequencing only specific ROIs (Fig. 13.11A). They are ideal when analyzing archived tissues that have limited material and rely on carefully designed sets of primers to avoid or minimize the amplification of pseudogenes (or genomic regions with high sequence homology to the ROI). At least four amplicon-based library preparation approaches are currently being used for preparation and enrichment of target sequences of interest: multiplex PCR, single-plex PCR, targeted capture followed by multiplex PCR, and anchored multiplex PCR [46,48]. Amplicon-based enrichment strategies can achieve 100% coverage of a region with little off-target sequence as the start and stop coordinates of each amplicon are predetermined. However, one limitation of amplification-based target enrichment is its susceptibility to allele dropout, which can result in false-negative calls. Allele dropout occurs when the variant is located in the primer-binding site, leading to failed amplification and allele bias [49].

Hybrid capture enrichment methods

Specific nucleotide probes are designed to pull out or capture specific ROIs by hybridization (Fig. 13.11B). These probes are much longer than typical PCR primers and, therefore, are not as affected by variants in the probe-binding site, avoiding dropout issues. The disadvantage is that probes can tolerate mismatches; thus there is less specificity, increasing off-target reads. Hybrid capture enrichment also requires more starting material than amplification-based enrichment, which could pose a problem if the amount of clinical sample is limited.

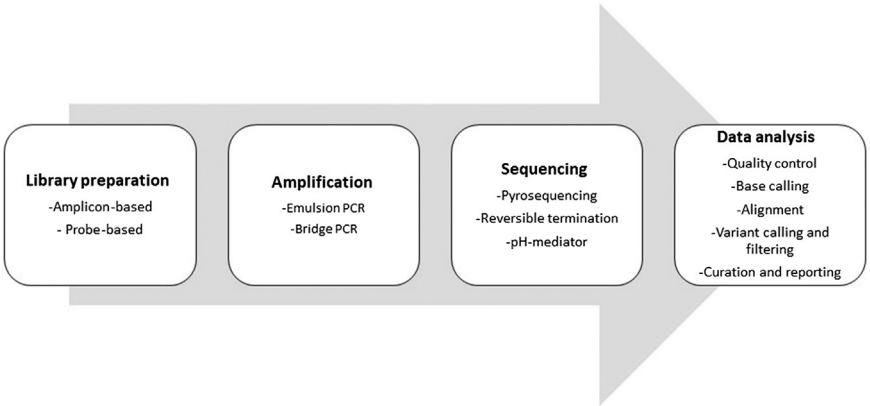

FIGURE 13.10 Overview of next-generation sequencing.

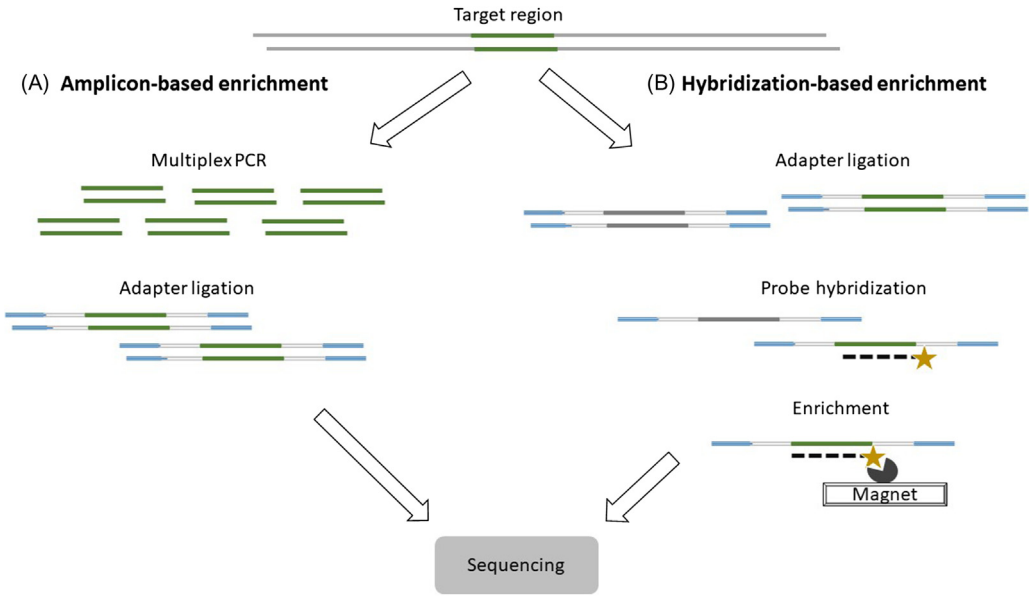

FIGURE 13.11 Schematic representation of the differences between (A) amplicon-based library preparation and (B) hybridization-based library preparation.

Template amplification

Template amplification allows for a significant increase in the available molecules for sequencing. DNA fragments selected after library preparation or specific amplification are subjected to clonal amplification. Clonal amplification involves solid phase amplification of the template and allows a strong detectable signal during sequencing. Single DNA fragments to be sequenced are either bound to beads or flow cells. Depending on the sequencing platform, emulsion PCR (emPCR) or bridge PCR is used to amplify the anchored DNA fragments into millions of spatially separated template fragments.

Emulsion polymerase chain reaction

emPCR is an alternative method that some NGS technologies utilize to replicate targeted DNA sequences. The adapter sequences ligated onto the ends of the DNA template hybridize to capture oligonucleotides covalently linked to beads. The template molecules and beads are then mixed to achieve an average of one template molecule per bead in an individual compartment created by the emulsion in an oil and water mixture. During emPCR, the surface of the bead becomes coated with clonal copies of the DNA template.

Isothermal bridge amplification (bridge polymerase chain reaction)

In isothermal bridge amplification, a method utilized by Illumina, the DNA template is first denatured, and then, during sequencing, the adapter sequences hybridize to complementary capture oligonucleotides covalently linked to the surface of the flow cell. These captured oligonucleotides are used as primers for the PCR amplification. After a second denaturation, the newly synthesized strand can then bend to hybridize with an adjacent capture oligonucleotide primer, and the cycle can be repeated to generate a cluster of identical template molecules [45]. Bridge PCR allows paired-end sequencing (sequence the DNA fragment from both ends) resulting in high coverage, a high number of reads, and more data as compared with single-end sequencing systems. This approach allows for the detection of genomic rearrangements (insertions, deletions, and inversions), repetitive sequence elements, gene fusions, and novel transcripts [50]. The majority of the sequencing chemistries use sequencing by synthesis.

Sequencing by reversible termination or sequencing by synthesis

This technique uses reversible, fluorescently labeled terminator nucleotides that are modified at the 3′ end with a cleavable terminator moiety to ensure that only a single nucleotide incorporation event can occur with each sequencing cycle [50]. Sequencing by reversible termination starts with the annealing of sequencing primer to the template molecule. Following this annealing event, each cycle consists of three steps: (1) incorporation of the complementary reversible terminator nucleotide by DNA polymerase into the DNA strand; (2) detection of the fluorescence signal for each cluster; and (3) the cleavage and removal of the fluorescent label and 3′ terminator moiety,

leading to the regeneration of the growing strand for a subsequent cycle. Repetition of these cycles leads to sequencing of the template. Natural competition between all four of the nucleotides present during each sequencing cycle reduces the inherent bias.

pH-mediated sequencing

This method is based on the detection of hydrogen ions liberated upon incorporation of each nucleotide and is not dependent on altered nucleotides, enzymes, or optical detection. Template DNA obtained after library preparation and clonal amplification is bound to ion sphere particles. Ideally, each bounded sphere is separated in a unique microwell of a chip. Then, a single type of dNTP is flowed on the chip at a time. If there is incorporation of the specific dNTP during DNA synthesis, the release of a hydrogen ion induces a change in pH, detected by ion-sensitive field-effect transistor sensors, which translates the chemical signal into digital signal, measured within seconds [51]. This technique is rapid as sequencing is done in real time with read length up to 400 nucleotides and operates at low cost, since it does not incorporate modified bases [52]. In this sequencing chemistry, homopolymer sequencing is error-prone, as repeats will be incorporated in one cycle, which leads to a proportionally higher electronic signal due to the corresponding number of released hydrogen ions. ThermoFisher has come up with the Hi-Q polymerase that has improved sequencing accuracy, decreased insertion–deletion (indel) error rates, and reduced GC-bias.

Data analysis

Data analysis consists of three steps: base calling and quality score computation; assembly and alignment; and variant calling and annotation [53]. Each NGS platform has a unique data processing pipeline, using their own proprietary analysis software to call base pairs and generate associated quality scores. The data output from an NGS instrument essentially consists of a text file of millions of raw sequence reads. The massive amount of sequence data generated by NGS creates new challenges for the laboratory, requiring significant investment in bioinformatics infrastructure and personnel. The accurate interpretation of the data generated by NGS is labor intensive, requiring expertise in genetics, pathology, clinical medicine, and informatics. The establishment of well-curated genomic databases with phenotypic information is a critical step for the widespread clinical implementation of NGS-based tests [54].

Third-generation sequencing

While NGS has revolutionized biomedical research and is now being used routinely in the clinical diagnostic space, the "third" generation of sequencing was introduced to the market in 2015 and is likely to have a role in the clinical lab in the near future. Developed by Oxford Nanopore Technologies Limited, the "MinION" is different from other sequencing technologies, because it utilizes nanopores for sequencing [55]. Able to fit in the palm of your hand and connected to a laptop computer with a USB connection, the MinION allows for direct, electronic analysis of single molecules in real time. It can be used for the analysis of DNA, RNA, proteins, and small molecules with a range of applications in personalized medicine, agriculture, and scientific research.

Implementation of molecular assays in the clinical laboratory

There is a wide variety of molecular assays that can be implemented in the clinical laboratory. In addition, the rapid evolution of sequencing and other molecule-based technologies is constantly changing the field. While the number of molecular diagnostic tests being performed for specific applications continues to increase, the number of FDA-approved or cleared tests represents only a small percent of those molecular tests conducted in laboratories. Most high volume tests that could financially justify submission to the FDA based on test volumes have been cleared and mainly affect infectious disease testing. The vast majority of molecular diagnostic tests fall into the LDT regulatory category and require significant analytical validation by the laboratory before they are used in patient care. There are numerous guidelines for validation of such LDTs; the College of American Pathologists has checklists specific for the different aspects of molecular testing. While there are current procedural terminology codes for various types of molecular tests based on technology and gene or variant tested, often payors use the "no FDA-approval" rationale to not reimburse laboratories for this test. This short-sightedness has a significant impact on patient care, as most of these tests have proven clinical utility and nonpayment limits access to these tests for which no FDA-approved options exist. For more common molecular diagnostic tests, reimbursement rates may cover the cost of performing the test, while for rare gene tests or more complex sequencing and array-based tests, reimbursement rates, if any are paid, are not even close to covering the costs.

Conclusion

Clinical molecular diagnostics is a rapidly growing and continuously changing field. The past 10 years in particular has seen significant improvements in the speed in which laboratory scientists can study the human genome. As discussed in this chapter, there are a wide variety of

nucleic-acid-based tests performed in the clinical lab, which are used to diagnose and monitor disease, detect risk, and decide which therapies will work best for individual patients. From PCR-based genotyping to the latest advances in whole genome sequencing, our knowledge of how specific biological markers play a role in disease has greatly contributed to precision medicine.

Self-assessment questions

1. A nucleotide is composed of all of the following except:
   a. phosphate group
   b. pentose sugar
   c. base
   d. fluorophore
2. The discreet structural units of the human genome are known as:
   a. nucleotides
   b. chromosomes
   c. bases
   d. Z DNA
3. Hybridization of probes to target sequences is possible due to:
   a. the presence of coding sequences
   b. the presence of noncoding sequences
   c. complementary base pairing
   d. all of the above
4. Electrophoresis of DNA for a Southern blot assay is accomplished by first:
   a. amplifying target sequences
   b. digesting DNA with restriction enzymes
   c. transferring the DNA to a membrane
   d. UV crosslinking
5. Primers used for the process of PCR are.
   a. single-stranded DNA oligonucleotides
   b. dsDNA oligonucleotides
   c. Single-stranded RNA oligonucleotides
   d. double-stranded RNA oligonucleotides
6. Detection systems used in real-time PCR are based on:
   a. radioactivity
   b. chemiluminescence
   c. fluorescence
   d. colorimetry
7. Which type of real-time PCR probe is dependent on exonuclease activity of the polymerase:
   a. Scorpion probes
   b. TaqMan probes
   c. FRET probes
   d. molecular beacons
8. Which of the following is NOT true about ddPCR?
   a. It quantifies the nucleic acid target of interest
   b. It is based on amplification of a single copy of DNA in an oil droplet
   c. DNA must first be digested with restriction enzymes
   d. It eliminates primer bias
9. Which two probes are incorporated in microarrays for genomic aberrations?
   a. copy number probes
   b. SNP probes
   c. exon probes
   d. gene probes
10. Next-generation sequencing set up requires:
    a. library preparation in the wet lab
    b. extensive understanding in bioinformatics
    c. multiple quality control steps during both library prep and bioinformatics
    d. all of the above

Answers

1. d
2. b
3. c
4. b
5. a
6. c
7. b
8. c
9. a and b
10. d

Chapter 14

Laboratory automation

Mark A. Marzinke

Departments of Pathology and Medicine, Johns Hopkins University School of Medicine, Baltimore, MD, United States

Learning objectives

After reviewing this chapter, the reader will be able to:

- Define preanalytical, analytical, and postanalytical tasks that may be automated.
- Distinguish between task-targeted, subtotal, and total laboratory automation.
- Identify the components of centralized laboratory automation systems.
- Explain the expectations and considerations associated with the implementation of integrated automation into the clinical laboratory.
- Discuss methods and approaches to monitor integrated automation performance and success postimplementation.

The global landscape of healthcare is in a perpetual state of transformation, and the clinical laboratory must adapt and evolve accordingly. Healthcare reforms, modifications to reimbursement plans, staffing shortages with increased demands, and fiscal constraints are just some of the factors that require clinical laboratories to subscribe to the "do more with less" ideology. One way in which laboratories have responded to such changes is via the adoption and incorporation of laboratory automation. While automation was once considered a luxury for larger clinical or reference laboratories, its use, in various iterations, has become pervasive in today's clinical environment. Currently, it would be rare to find a laboratory setting that did not rely on some form of automation, either during the analytical phase of testing or applied to pre- or postanalytical processes. Further, current estimates indicate that more than 30% of clinical laboratories in North America, Asia, and Europe have incorporated some degree of centralized automation into their laboratory workflows.

The transition from manual techniques to an automated platform is not new. For the clinical chemist, the beginnings of laboratory automation can be traced back to the mid-1950s with the introduction of AutoAnalyzer I, an analytical platform that utilized the discrete separation of a continuous stream of materials via air bubbles to perform sequential sample testing. AutoAnalyzer I exploited the principle of continuous flow analysis (CFA) for increased analytical throughput; thus the ability to automate the analytical phase of the testing process was readily adopted by clinical laboratorians for the measurement of routine chemistry analytes. While several iterations of automated analyzers followed in the coming decades, the field pivoted in the 1980s due to advances in centralized automation by Dr. Masahide Sasaki and colleagues. Using a combination of conveyor belts, basic circuitry, and robotics, specimens could be loaded and unloaded onto clinical analyzers. In addition, these activities were directed by process control software, also known as the laboratory automation software. Dr. Sasaki transitioned automation beyond the analytical testing phase; preanalytical automation and postanalytical automation were now possible and successful in a clinical laboratory setting. Three decades following the incorporation of "home-brewed" preanalytical automation and postanalytical automation within Dr. Sasaki's laboratory, all major vendors now offer fully integrated automation solutions for clinical laboratory testing.

The complementarity of work performed between the analytical phase and the pre- and postanalytical phases of the testing process led to the advent of total laboratory automation (TLA), an all-inclusive, assembly line-like approach toward laboratory activities. Currently, most automated analyzers are configured to perform random-access sample analysis, in which each specimen is independently analyzed for various test combinations. Automated analyzers can accommodate multiple analyte-specific reagents to facilitate the multiplexed testing of more than one analyte within a specimen. This is in contrast to batch-type analysis, in which specimens are grouped for testing; batch analysis can affect throughput and prolong result turnaround time (TAT).

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00014-4

Goals of automation

In many ways, laboratory automation is the ideal demonstration of the Lean Six Sigma philosophy, where efficiency is maximized and waste and errors are minimized. This is achieved through the integration of robotics, circuitry, and informatics to perform routine laboratory tasks in a standardized manner, thus circumventing the intra- and interindividual variabilities associated with manual processes. There are numerous pre- and postanalytical processes that are ripe for automation; these are summarized in Table 14.1.

Automation may be presented to the clinical laboratory in several ways; however, the utilization and incorporation of integrated instrumentation must be in line with the goals and activities of the laboratory. Globally, automation can be stratified as task-targeted, subtotal, or total in nature, depending on the activities and processes supported by the platform. Task-targeted automation, as the name implies, encompasses the automation of specific laboratory activities, for example, a task-targeted instrument may focus solely on the sorting of specimens for downstream laboratory processes. Subtotal or stand-alone platforms involve the automation of a number of tasks in order to streamline the overall laboratory workflow. Subtotal automation is not physically connected to the laboratory analyzer by a track system; thus the entire testing process is not automated, as specimens must still be transported manually to the testing area. TLA platforms offer all of the activities contained within subtotal automation, with the additional feature of physical connectivity with the laboratory analyzer via a track system. Centralized automation systems may be dichotomized as either open or closed systems. Open systems offer software and hardware flexibilities, so instruments from other vendors may be incorporated into the automated track system, or "line." Closed systems do not offer this flexibility, and all of the process control software and preanalytical, analytical, and postanalytical instrumentation are controlled by a single vendor. As of 2018, all major laboratory vendors, including Abbott Diagnostics, Beckman Coulter, Roche Diagnostics, and Siemens Healthineers, offer centralized automation solutions to optimize laboratory workflows. Further, many vendors also demonstrate open access and flexibility to facilitate the integration of third-party systems onto their automated lines [1]. This provides a notable advantage in the consolidation of testing across laboratory disciplines and subdisciplines.

Although the specific requirements for centralized laboratory automation may differ based on the specific clinical laboratory environment, many of the evaluable criteria are universal. Common considerations include the electronic identification and recognition of specimens and orders, specimen container flexibility, prioritization of sample management, and both physical and software-mediated integrations with analytical instrumentation, among others. These considerations will be discussed later in this chapter. Several reports, including those from Melanson and colleagues, describe processes for the evaluation and selection of central automation platforms [2]. While the capacity and functionality of each system differ among vendors, this chapter will discuss the general aspects of laboratory automation, as well as considerations and limitations with regard to introducing automation into a clinical laboratory setting.

Components of laboratory automation

There are a number of physical considerations and components that are associated with TLA systems. One prerequisite for centralized automation is the integrated capability for TLA systems to identify specimen-specific

TABLE 14.1 Preanalytical, analytical, and postanalytical laboratory activities that may be automated.

Preanalytical phase	Analytical phase	Postanalytical
Specimen receipt	Analyzer loading	Result reporting
Specimen accessioning	Specimen integrity checks	Recapping
Labeling	Testing	Specimen archiving
Sorting	Dilutional analysis	
Centrifugation	Result transmission	
Decapping	Specimen unloading	
Specimen quality inspection		
Aliquoting		
Specimen distribution		
Specimen retrieval		

characteristics from a barcoded sample. This is achieved through an interface between the process control software within the integrated automation platform and the laboratory information system (LIS). As barcode readers scan specimens placed on an automated platform, characteristics from the LIS, including order-specific information such as specimen container type, tests requested, required testing volumes, and the number of aliquots required by the analyzing instrument, will be used by the automated platform to direct follow-up activities. Of note, the process control software must be flexible enough to mask a module or portion of the automated platform while continuing other laboratory tasks. This flexibility facilitates minimally interrupted workflow if a specific portion of the centralized system requires maintenance, service, or other troubleshooting.

Because specimen barcodes direct the downstream activities of centralized laboratory automation, nonbarcoded specimens are suboptimal candidates for automation. Specimens received in this manner require additional manual processing, including the accessioning of pertinent information into the LIS as well as labeling of accessioned specimens by laboratory staff. A general schematic of the various stations or modules that are typically included in centralized laboratory automation solutions is illustrated in Fig. 14.1. However, it is noted that each vendor has its own specific performance footprint, characteristics, and workflows. An overview of commonly included stations will be discussed in more detail in this section:

1. ***Specimen loading area:*** Upon receipt in the laboratory, barcoded specimens must be placed in a transport carrier to facilitate subsequent processing steps. Nonbarcoded specimens may be accessioned into the LIS for the generation of an order (or specimen) label for instrument recognition. Centralized automation transport carriers vary by vendor and can range from single specimen carriers, which accommodate one specimen at a time, to racks that may accommodate 5−10 specimens. Every TLA platform requires (manual or automated) specimen loading into a carrier to facilitate subsequent activities on the system and movement within the track system. To stratify and triage testing priority between routine and stat, or emergent, samples, most automation platforms also offer two input areas to prioritize the processing of stat samples.
2. ***Barcode readers:*** Barcode readers are associated with the specimen loading area so that the aforementioned specimen-specific information may be directed from the LIS to the process control software of the automation platform. Barcode scanning by the TLA instrumentation also serves as an electronic receipt within the laboratory and can be used in the determination of laboratory receipt to result TAT or may be helpful in workflow-driven investigations. Platforms may have multiple barcode readers to track and direct downstream processes or a single barcode reader, in which the sample is scanned once in the specimen loading module. In the latter case, specimen-specific information may become associated with its location within the transport container; alternatively, the information may be linked via a radiofrequency ID chip. The standard and preferred barcode symbology used in integrated automation systems is Code 128, which is a high-density symbology with the capacity to encode all 128 characters

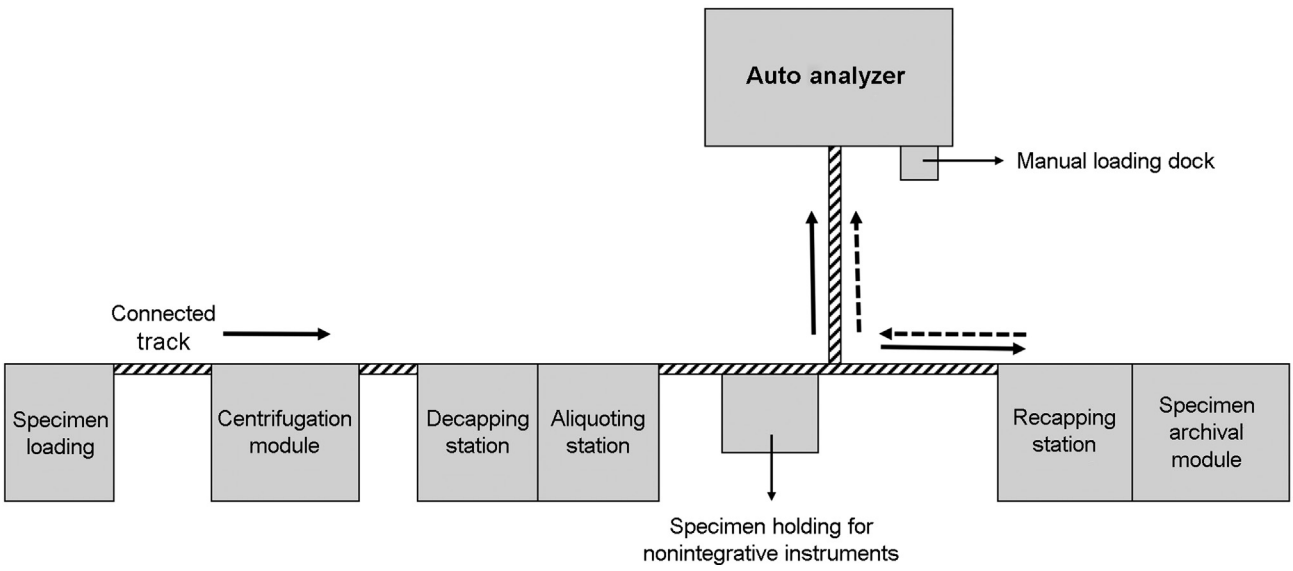

FIGURE 14.1 Representative layout of a centralized automation platform. Specific modules and functionality are vendor-specific.

from the American Standard Code for Information Interchange [3]. Several TLA platforms and LIS systems now recognize 2D barcodes, which include higher density-encoded information; however, specific barcode scanners are required for the reading of either linear (1D) or 2D barcoded samples.

3. ***Transport and sorting tracks:*** Using a conveyor-based track system, specimens are directed to other areas of instrumentation. Many TLA platforms are flexible, so that several destinations may be possible. Follow-up activities are driven by the process control software and the electronic information associated with the specimen or transport carrier. Some vendors use prebarcoded carriers or racks that will direct specimens toward specific modules within the platform. This flexibility in specimen routing facilitates the management and handling of multiple specimen types on a TLA system. For example, both specimens requiring centrifugation as well as those that do not may be processed on a TLA system. The track system must be able to accommodate both specimen types and appropriately direct the sample to a centrifuge or alternatively bypass that component of the system. Currently, TLA solutions from all major vendors have incorporated track bidirectionality into their centralized platforms, allowing for enhanced capability in automating routine laboratory workflows. Bidirectional tracks can assist in automating laboratory activities such as the fulfillment of add on requests or selecting a sample from a storage unit for retesting. The latter will be discussed later in this chapter.
4. ***Centrifugation:*** For samples that require centrifugation, specimens can be routed from the track system to the centrifuge module. Specimens in transport carriers are loaded into self-balancing centrifuges. Centrifuge throughput is platform-specific, and capacity is influenced by centrifugation speed and duration. However, the theoretical throughput of various preanalytical platforms ranges from 300 to 600 specimens per hour. A rate limiting step in preanalytical sample throughput is the volume of specimens requiring centrifugation as well as the potential test-dependent variability in centrifuge conditions. Some vendors offer TLA solutions that are modular in nature and can accommodate multiple centrifuges within a single system, thereby increasing and optimizing laboratory efficiency. However, one consideration in determining the number of centrifuge modules is the additional physical footprint and the impact additional capacity may have on space in the clinical laboratory setting. Depending on the platform, centrifugation may occur under refrigerated or room temperature conditions; most automated systems utilize the former for sample preparation. Following centrifugation, specimens are returned to the track for further preanalytical activities.
5. ***Decapping station:*** TLA decapping stations utilize robotic arms for the removal of the cap from the primary container introduced onto the platform. The cap is then disposed of in a waste repository, most commonly located within the system.
6. ***Aliquoting station:*** Following the removal of caps, specimens may be routed via the conveyor-like track system into an aliquoting station. Using robotic arms, specimen volumes are aspirated and aliquots are transferred to secondary containers. Depending on the specific layout and specifications of the system, barcode printers may be associated with this module, as secondary specimen containers may be labeled for downstream testing. Alternatively, for aliquoted samples that are tested in an integrated system and are transferred to sample cups, all of the electronic information associated with the specimen may be located within the transport carrier barcode. The process control software of the automation platform utilizes the requested test and order information to determine transfer volumes into the secondary container. Disposable tips are commonly used to prevent cross-contamination, and, postdispensing, tips are disposed of into a waste repository.

   Aliquoting apparatuses used in most current preanalytical automation platforms have the ability to detect clots; this is achieved through the sensing of increased resistance by the aliquoting probe upon aspiration. When the resistance threshold is exceeded or triggered, specimens may be defaulted from the system for investigation. When compared with manual workflows, automated aliquoting is a critical function and plays a significant role in reducing specimen-associated pour-over errors.

   All AutoAnalyzers can be sampled directly from the primary collection container, and the laboratory can opt to bypass sample aliquoting for direct downstream sampling and analysis. In the current landscape, in order to optimize efficiency and streamline intralaboratory workflows, many laboratories will directly sample from the primary container. However, if testing is performed on an automated analyzer that uses a probe-based system for sampling, carryover and contamination studies should be conducted to minimize the risk of contaminating a primary container during testing, particularly if the sample is being used for analysis in other testing areas. If aliquoting is required for offline or send out testing, this activity may be performed after integrated testing is performed on a primary container. The specific needs within the laboratory will often

drive the physical footprint and configuration of a centralized automation system, including how an aliquoting module may fit into an operational workflow.

7. ***Recapping station:*** Centralized platforms may also include a recapping module, where aliquots or primary tubes may be sealed prior to analysis. The functionality and workflow for sample recapping is dependent on the downstream activities of the specimen. For instance, if the destination of an aliquoted sample involves direct routing to an analyzer via the track system, recapping may not be necessary. However, if a primary tube is being routed to a longer-term specimen holding area or a specimen archival system, then airtight recapping is desirable. For samples that remain uncapped, stability due to exposure to ambient temperature or air must also be assessed; analytes such as CO_2 are sensitive to exposure to ambient air and may result in falsely low results. Vendors approach recapping differently, and recapping systems vary from foil-based resealing to the use of pop-top or screw-top caps; some vendors have the capacity to facilitate more than one workflow.
8. ***Specimen removal module:*** Upon the completion of specimen processing, which may involve any combination of sorting, centrifugation, decapping, or aliquoting steps along the automated track system, samples may need to be removed from the integrated platform for analysis on nontracked analyzers or for other follow-up activities, such as completing esoteric test requests. Consequently, specimens (primary tubes or aliquots) may require routing to a holding area for removal.

While the aforementioned components all encompass preanalytical laboratory processes (however, barcode reading and specimen loading areas are universal processes in all areas of the laboratory), the analytical and postanalytical areas are also included in TLA solution platforms. Common components include:

9. ***Specimen integrity checks:*** Most analytical instruments use spectrophotometric techniques to assess the quality of a specimen prior to analysis. Many chemistry and immunochemistry tests can be affected by common endogenous interfering substances, such as hemoglobin, lipids, and bilirubin. Currently, automated analytical instruments for clinical chemistry testing assess the impact of hemolysis, lipemia, or icterus on analytical assays via spectrophotometric measurements at relevant, potentially interfering, wavelengths.

In newer iterations of TLA platforms, several vendors have incorporated specimen integrity checks during the preanalytical phase of centralized automation, allowing for the identification of samples that may be hemolyzed or compromised prior to reaching an analyzer. However, the methodologies used in these check modules are commonly based on specimen opacity as opposed to measurements at specific spectral wavelengths, and therefore should be optimized based on the types of specimens handled by the laboratory. One benefit of specimen integrity evaluation in the preanalytical phase of TLA is that problem specimens can be more acutely identified and acted upon by laboratory staff.

10. ***Dilutional analysis:*** For laboratory values above the primary linearity or measuring range of an assay, dilutional analysis may be indicated as a follow-up action. Automation of this process involves the instrument or middleware-controlled dilution of a specimen with a known diluent for reanalysis, and back calculation of the analyte activity or concentration. Further, performing dilutions online can significantly reduce analytical errors and improve workflow, as samples do not have to be retrieved and further manually manipulated by staff.
11. ***Computer interfacing:*** While all systems include computer controls to execute the physical functions associated with an integrated automation system, it is imperative that there is cross-talk between the TLA platform and the LIS. Centralized laboratory automation software must be able to interface with the instrument operator as well as mainframe computers and the LIS. Standard information that is typically communicated between the instrumentation and the LIS, either directly or through middleware software programs, includes status information of each preanalytical or analytical analyzer, specimen type, patient demographics, and data related to specimen orders, tests, results, as well as any rules to control follow-up activities, including sample reruns or dilutions.

Within the last three years, the major TLA vendors have marketed and implemented more dynamic and adaptive interfaces to allow for greater control of automation systems. Notably, these interfaces can be used to extract important laboratory performance parameters, including TAT, productivity reports, and shifts in test performance through patient result monitoring (i.e., moving averages). Enhanced access to these data can help streamline and optimize laboratory workflows.

12. ***Specimen archival module:*** In fully realized centralized automated workflows, the automation of specimen storage is critical to the complete integration of laboratory processes. Specimens can be directed to long-term storage via the track system in a manner similar to the track-driven routing to instrument

analyzers. Unlike the specimen removal module, which is typically nonrefrigerated and has limited capacity in terms of sample storing capacity, specimen archival systems (or stockyards) are refrigerated and can accommodate anywhere from 3000 to 30,000 specimens, depending on the vendor and system. Via the laboratory automation software or middleware-mediated interfacing with the LIS, the location and removal of specimens is performed using robotic arms. As previously mentioned, more recent configurations of centralized laboratory automation have incorporated a bidirectional track into their workflow. Bidirectional tracks allow for the robotics-driven identification and removal of a specimen from the stockyard, followed by the placement of the sample into a transport carrier and subsequent routing to the analyzing instrument for testing. Although associated with a larger footprint, bidirectional tracks further automate the overall laboratory workflow.

Expectations of automation

If thoughtfully approached, there are a number of benefits that may be achieved through the incorporation of automation into the clinical laboratory. A study from Holman and colleagues demonstrated that following the automation of numerous preanalytical processes, including sample sorting, centrifugation, decapping, labeling, and aliquoting, there was an 80% reduction in errors involving sample sorting, aliquoting, and labeling [4]. In a 2014 report published in *Clinical Laboratory News*, it was conveyed that postinstallation of laboratory automation reduced error rates by more than 70% [5]. Further, TLA systems may offer additional benefits, including the ability to manage larger workloads, accommodate staff shortages, and reduce overall operational costs, topics to be discussed later in this chapter.

Additional expectations of integrated laboratory automation include increased throughput and improved TAT. The consolidation and centralization of several manual preanalytical steps can maximize the efficiency of the overall testing system. However, it should be noted that the throughput and TAT of automated analyzers is dependent on a number of criteria, including specimen container type, instrument type, configuration complexity, and total testing volumes. Based on these variables, which are laboratory-specific, theoretical automation throughput may not reflect real-world operations. Therefore familiarity with current ordering and testing practices, including the number of samples tested during a period of time, the average number of tests associated with each specimen, and the physical location and number of analyzers utilized in the laboratory are all important factors in tempering unrealistic expectations with regard to centralized laboratory automation performance. A list of attributes to be considered for complete centralized laboratory automation is described in Table 14.2.

The move to subtotal or total automation is typically associated with a major shift in laboratory workflow and management. Further, the selection and subsequent success of automation is dependent on setting achievable and realistic expectations of the instrumentation for one's specific laboratory environment. As indicated by Boyd and Hawker, many laboratorians use an 80% benchmark to direct automation decisions; this means that if 80% of specimen containers and handling activities can be standardized, improvements will be achieved with regard to overall labor and costs associated with specimen handling and processing [6]. However, a comprehensive knowledge of both the current processes as well as laboratory needs is critical for automation success. Failures in implementation may occur for a number of reasons, including noncompatibility and suboptimal workarounds between the manual and automated processes, the lack of familiarity with the proposed automation system, and the overall loss of flexibility with other systems or open channels. Further, vendor contributions such as inadequate technical support and unforeseen maintenance and supply costs can impact automation success [7].

The selection and decision to incorporate and implement laboratory automation into the clinical laboratory is largely based on the needs of the laboratory. As described by Hawker and colleagues [8,9], a comprehensive workflow analysis of all laboratory activities, including staffing required for all laboratory functions, can identify areas for efficiency as well as predict the impact of centralized automation in the clinical environment. A simplified, representative workflow analysis is depicted in Fig. 14.2. Not surprisingly, common expectations and goals following an assessment of existing workflows are to improve laboratory efficiency. Preanalytical goals include the following: a reduction in sorting steps required prior to testing; a reduction in the number of times each sample is handled by laboratory staff, as well as the number of staff handling each specimen; streamlining the flowpath of a specimen with regard to specimen processing and delivery; decreasing laboratory staff traffic in the management and dissemination of samples. Analytical goals include centralization of laboratory testing and reduction in the number of shared specimens across instruments, specimen integrity checks, and automated dilutional analysis. Postanalytical automation goals include integration of laboratory results to the hospital information system and storage capacity and retrieval capabilities for remnant specimens.

While many steps have been successfully automated in integrated laboratory systems, there is still variability

TABLE 14.2 Metrics to be considered for automation.

Questions to consider
Space considerations
What is the footprint of the automation platform?
Will the laboratory space accommodate the automation platform's heat and electrical requirements?
Throughput and performance considerations
Is the throughput of the system amenable to the laboratory's needs?
What is the predicted impact on reducing laboratory errors?
What is the predicted impact on laboratory TAT?
What additional workload can the system accommodate above the laboratory's current operational needs?
What is the flexibility of the automated platform with regard to specimen containers?
Will the system be easily incorporated into existing LISs?
Analytical considerations
Will the automation system accommodate the test menu?
What is analyzer and component flexibility in terms of sample loading?
Can AutoAnalyzers perform on-board dilutions?
Does the platform have the capability to perform specimen integrity checks?
Maintenance and training considerations
What is the maintenance time of the entire system, and each component?
Is there service support to accommodate all facets of the automated platform on a 24/7 basis?
What degree of training is required for each component of the automated system?
Cost considerations
What is the initial investment in the automated platform?
What is the predicted cost-savings associated with the transition to automation?
How many full-time employees (FTEs) will be needed to operate the instrumentation?

TAT, Turnaround time.

as to how specimens are delivered to the clinical laboratory. Depending on the patient population that is served, laboratories may receive samples from a variety of locations. Common delivery mechanisms include pneumatic tube systems or courier services, which typically accommodate inpatient and outpatient or off-site locations, respectively, although not exclusively. However, there are nonintegrated automated alternatives to specimen delivery, including electric track vehicles and mobile robots [6]. Electric track vehicles have a larger carrying capacity than standard carriers used in a pneumatic tube system layout. Mobile robots may be used in delivering specimens to or within the laboratory; however, for optimal efficiency, samples should be delivered in batch. Thus, while mobile carriers may alleviate potential staff shortages, depending on the layout and needs of the laboratory, they may not increase overall efficiency.

Automation beyond the chemistry analyzer

In the current landscape, centralized laboratory automation has mainly involved the integrated connectivity of the pre- and postanalytical phases of the testing process to chemistry and immunochemistry analyzers. However, integrated automation for hematology, coagulation, urinalysis, and molecular and microbiological testing is also available. For example, Sysmex Corporation and Beckman Coulter offer track-based automation for hematology and urinalysis testing, respectively. Several centralized laboratory platforms now have the capability of automated specimen handling and transport to a variety of downstream instruments. As previously discussed, open access instrumentation can facilitate more integrated laboratory automation via track extension to nonchemistry and immunochemistry analyzers manufactured by other vendors.

Many of the benefits of centralized laboratory automation expand beyond the core laboratory setting. Automation has permeated labor-intensive and manually driven laboratory settings, including bacteriology and clinical microbiology. Automated tasks in clinical bacteriology include appropriate Petri dish selection, sample inoculation, spreading of inoculum on appropriate plates, as well as the labeling and sorting of media and plates. The automation of many of these tasks also provides a way to standardize assays across laboratories; for example, variability in the streaking of liquid or nonliquid specimens on plates is reduced by spreading inoculum via magnetic beads, an approach used by the automated specimen processing analyzer offered by BD Kiestra. Other

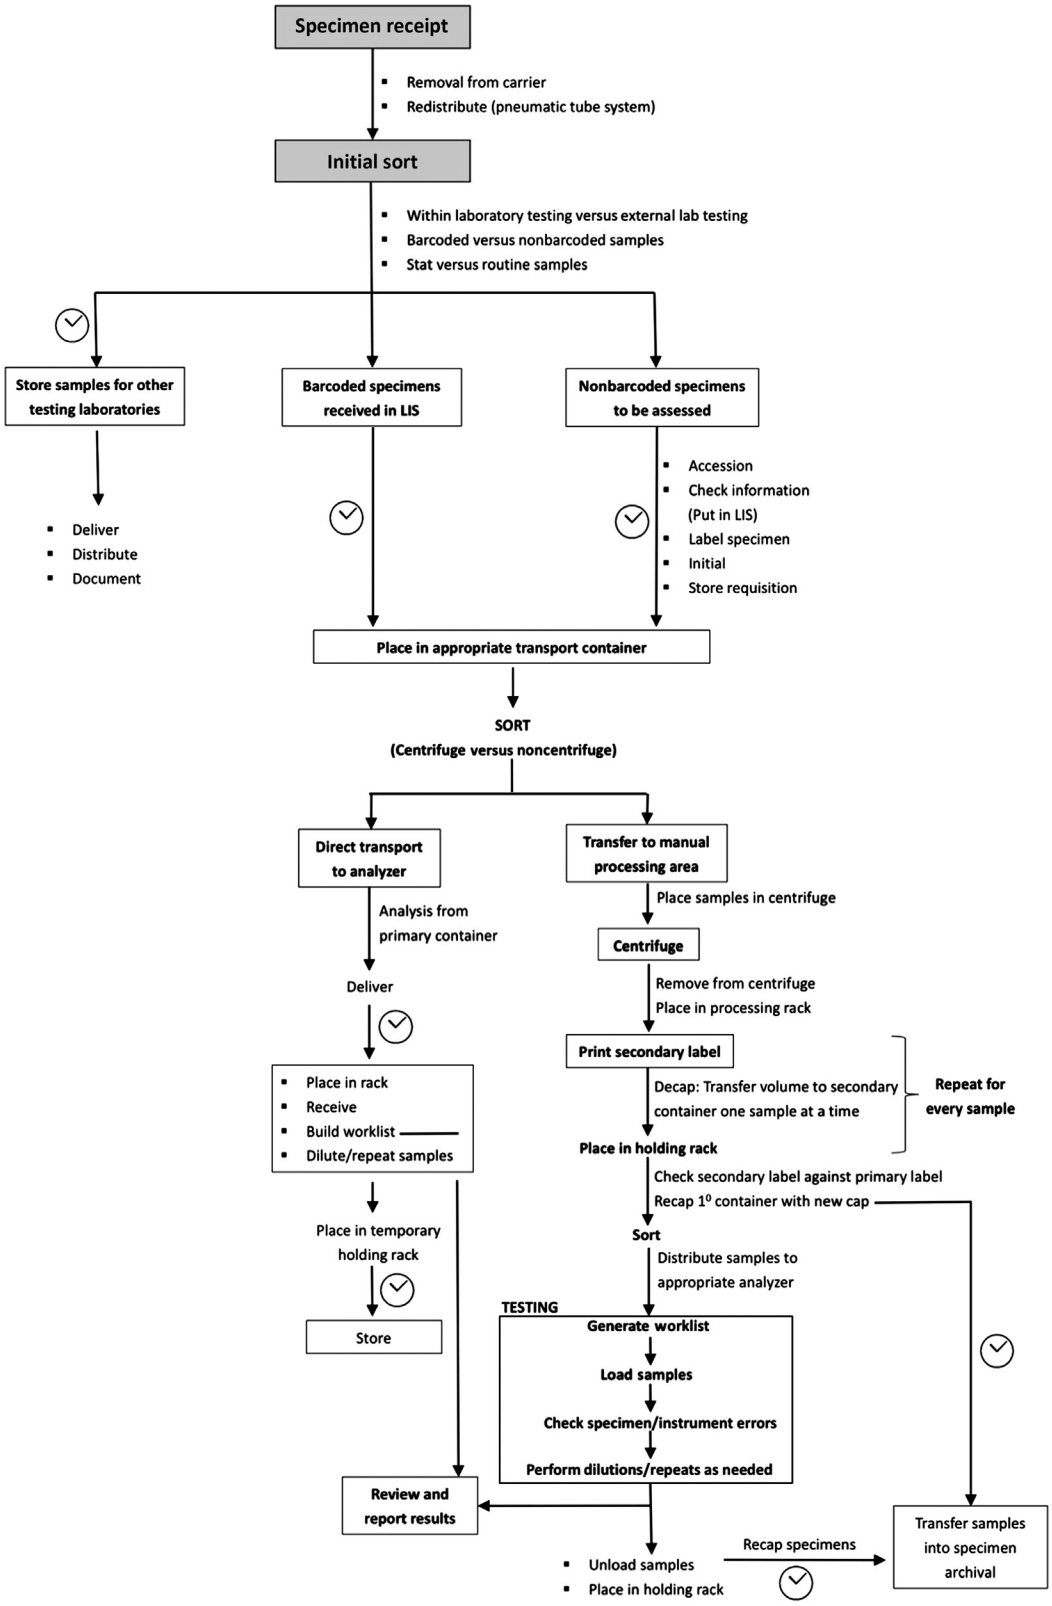

FIGURE 14.2 Simplified representative workflow integrating preanalytical, analytical, and postanalytical activities. Schematic clocks denote where workflow bottlenecks may occur.

vendors offering such automated solutions include bioMérieux Inc., Becton-Dickinson Diagnostics, and Copan Diagnostics. In addition, over the last decade, TLA systems targeting the clinical microbiology environment have been brought to market. Beyond exploiting automated barcode reading and a track-driven platform, incubators and digital equipment can be interfaced with the aforementioned microbiology and bacteriology specimen processing modules. BioMérieux Inc., BD Kiestra, and Copan Diagnostics all offer centralized automated clinical microbiology platforms. Further, a recent Q&A published in *Clinical Chemistry* reinforced the growing need and rationale for automation in clinical microbiology settings [10].

Fully integrated laboratory automation has also been met with success in clinical molecular laboratories, complementing work conducted in clinical microbiology. Various automation platforms offer barcode recognition of specimens, as well as automated nucleic acid extraction and polymerase chain reaction (PCR) amplification of DNA regions of interest. Laboratory automation focused on preanalytical DNA extraction, or PCR amplification and detection techniques are available through a number of vendors, including Abbott Laboratories, BD Diagnostics, bioMérieux Inc., Qiagen, Roche Diagnostics, and Thermo Fisher Scientific. However, much like automated chemistry and immunochemistry analyzers and TLA systems, specimen handling capabilities, tube-type flexibility, barcode detection, and laboratory automation software components are vendor-specific and should be considered when selecting an integrated platform.

Although many laboratories continue to look toward integrated automation solutions to reduce errors, improve efficiencies, and combat staff shortages, there are still areas that require automated preanalytical and centralized solutions. While mass spectrometry has successfully transitioned from a basic and translational tool to a clinical platform used for identification and/or quantification of small molecules and, more recently, proteins, specimen handling and management are still largely manual. Given the success of immunosuppressant and pain management testing by liquid chromatographic-mass spectrometric (LC-MS) techniques, centralized automated solutions may further integrate these methodologies into the clinical testing environment [11]. While vendors are pursuing automation-driven solutions with regard to mass spectrometry, including the automated review of mass spectra and chromatograms and interfacing of these data with the LIS, fully integrated automation for LC-MS platforms is still in its infancy.

Measurements of success

There are a number of ways through which the success and sustainability of subtotal or centralized laboratory automation can be evaluated postimplementation. Objective measures include comparison of specimen receipt with result TAT pre- and postimplementation, as well as the impact of automation on laboratory-derived errors. A number of reports have demonstrated improvements in TAT and reduction in laboratory errors postautomation. For many laboratories, TAT is defined as the time interval in which a specimen is received in the laboratory to the time a result is released or available to the provider. However, other TAT metrics may include the interval between order and result reporting, or collection and result reporting [7]. For the purpose of assessing the impact of automation of laboratory activities on overall performance, the interval from receipt in the laboratory to the releasing of results will be used and will be referred to as laboratory TAT. Laboratory TAT can be further stratified and defined based on test, priority, or patient population.

The positive impact of laboratory automation has been best demonstrated through the relationship between TAT reduction and improved patient outcomes in critical and emergent settings. Laboratory TAT is commonly used as a key performance indicator of laboratory performance, and delays in specimen resulting and unsatisfactory TAT events may not only result in complaints from providers, but also identify key areas for improvement. While recommendations and expectations regarding TAT may vary across institutions, a review by Hawkins has suggested a 90% successful laboratory TAT (specimen registration or receipt to result reporting) of $<$60 minutes for common laboratory tests as an initial TAT goal. In addition, physician and laboratory societies have provided recommendations regarding target TATs for stat samples collected in emergent settings. For example, both the American College of Cardiology/American Heart Association and the National Academy of Clinical Biochemistry (currently known as the American Association for Clinical Chemistry Academy) have recommended a laboratory TAT of $<$60 minutes for cardiac markers such as cardiac troponin (cTn) [12,13].

The thoughtful assessment of laboratory workflow and introduction of automation can assist in reaching quality metrics such as TAT. A case report from a large international hospital demonstrated an improvement in laboratory TAT postimplementation of a centralized laboratory automation system. A comparison of laboratory TAT both pre- and postautomation implementations was performed and a mean improvement of 27.7 $\pm$ 2.5 minutes in laboratory TAT for cTn samples, with TAT reductions also observed for nonemergent specimens [14]. Additional case reports have demonstrated improvements in laboratory TAT ranging from 30% to 50% following the incorporation of centralized automation systems [9]. However, as previously described, the benefits of automation in

improving TAT benchmarks are dependent on a clear understanding of the workflow and need of the laboratory.

In addition to reductions in the aforementioned preanalytical errors, labor and production costs and overall workload are additional metrics of automation success. Case reports from a number of institutions have demonstrated 50%−75% increases in sample volumes and workloads postimplementation of automation. These benchmarks were achieved without additional full-time employee (FTE) support. Laboratories have also observed 3−7 year payback on investment after implementation of integrated automation systems [9].

Oversight

With the growing incorporation and integration of complex and encompassing automation systems into the clinical laboratory environment, there is a growing need for standards and recommendations to ensure proper operation of the centralized platform. These concerns were raised in the 1990s by the Clinical Testing Automation Standards Steering Committee, who engaged the National Committee on Clinical Laboratory Standards [NCCLS; now known as the Clinical and Laboratory Standards Institute (CLSI)]. The NCCLS established a committee with an emphasis on automation to develop standards for laboratory automation. As a result, the CLSI has released a number of standard documents focused on both laboratory automation as well as LISs. Currently, approved standards are available for specimen containers (CLSI document AUTO01-A), barcode identification (AUTO02-A2), and communication with automated systems, instruments, devices, and information systems (AUTO03-A2), as well as nine other approved documents regarding laboratory automation. These documents can provide clarity to laboratories and vendors with regard to essential elements and components to be evaluated in the transition from manual to automated processes.

Limitations of automation

While centralized automation solutions can facilitate the standardization and streamlining of laboratory workflows, there are limitations in terms of the extent to which all steps in a process can become automated. Most centralized systems are currently unable to accommodate pediatric tubes (microtainers), resulting in the need for alternative and manual workflows to handle these specimens. Certain sample containers, including urine cups, may require upfront aliquoting before further handling on an automated line. Many laboratories also implement alternative workflows for the handling of rare and precious samples, such as body fluids. These may be processed offline prior to the analytical phase of testing. Thus all of these specimen types may require parallel infrastructure and processes to facilitate preparation and testing postspecimen receipt.

For centralized automation platforms, configurations typically involve a single preanalytical line that is connected to multiple analytical instruments. While most laboratories build in redundancy with regard to analyzers, the same is not the case for the preanalytical portion of a TLA system. Thus if there are track malfunctions or issues within the preanalytical modules of a centralized system, manual workflows would be required to continue routine operations. Further, centralized systems require at least some degree of downtime to replace reagents, reconcile software issues, or dispose of waste, among others. Depending on the degree of downtime for a preanalytical system, manual processes may be required to facilitate the continue management of emergent or stat samples. It is noted that, similar to analytical instruments, all of the components within a centralized system need to be properly maintained for optimal efficiency. This is further elaborated on in the following section.

Ongoing monitoring

An important consideration in the incorporation of centralized laboratory automation systems is the ongoing evaluation of its integrated functionality. While aforementioned metrics such as TAT and instrument downtime are important indicators of performance, other measures may also identify latent issues and improve overall workflow efficiency. Preanalytical processes can be evaluated for aliquot errors as well as transport efficiency of specimens throughout the preanalytical areas of the laboratory. Further, technical laboratory staff are well versed in the evaluation and assessment of analytical instrumentation, both via reviewing quality control material and performing proficiency testing challenges. In addition, automated analyzers produce alarms to indicate instrument-related issues; these may include temperature sensors, identification of a clog in an analyzer probe, or flagging an expired reagent. Postanalytical processes may be evaluated in several ways, including the review of autoverification rules and results reported to the hospital information system. As laboratories continue to introduce centralized automation into the workplace, understanding the pre- and postanalytical components is equally as important.

Maintenance performance on centrifuge and aliquot modules, monitoring the causes of defaulted samples that require manual follow-up, and identification of trends in preanalytical instrumentation performance can all serve as ways of proactively assessing centralized systems. As the preanalytical, analytical, and postanalytical phases of testing are consolidated in a centralized laboratory

automation system, expertise in the operation and ongoing evaluation of these components is critical to ensuring the benefits of integrated laboratory automation.

From a staff perspective, a survey of laboratory technologists, clinical laboratory scientists, and senior medical technologists highlighted frustrations centered around inadequate training for integration of laboratory automation system operation and troubleshooting [15]. Feedback from staff illustrated the need to ensure sufficient initial and ongoing training for all components of the centralized automation platform. Other concerns included issues with instrument downtime and perceptions regarding capacity, further supporting the need to utilize workflow analysis and establish realistic expectations for automation performance.

Future perspective

As TLA systems become more commonplace in clinical laboratory environments, the resulting question is then, "Where do we go from here?" Technology will continue to advance, offering more functionality and capacity to accommodate the growing responsibilities and diminishing resources given to the clinical laboratory. In a 2014 *Clinical Laboratory News* article, Dr. Robin Felder has postulated the future growth of automation, predicting further advances and expansions into the areas of specimen transportation, biobanking, cell-based assays, and home-based monitoring [5]. As processes continue to be streamlined and standardized via automation, the clinical laboratory will continue to play a central role in healthcare.

Conclusion

Over the last several decades, laboratory automation has progressed from CFA to centralized and total automation platforms, integrating many functions executed by the clinical laboratory. Automation platforms have become more prominent in laboratory settings and have become well accepted approaches of improving laboratory service, ensuring patient safety and accommodating cost reductions and staff shortages. As laboratories continue to "do more with less," automation will continue to be implemented and introduced into the laboratory environment. However, as demonstrated, the success of automation is dependent on understanding both existing workflows and expectant needs.

Self-assessment questions

1. The AutoAnalyzer I utilized the following analytical principle:
   a. centrifugal analysis
   b. TLA
   c. whole blood analysis
   d. CFA
2. The major distinction between subtotal and total laboratory automation is _____.
   a. subtotal automation platforms lack centrifugation capabilities
   b. subtotal automation platforms only identify barcoded specimens
   c. subtotal automation platforms do not have a connected track system
   d. subtotal automation platforms refer exclusively to the analytical phase of the total testing process
3. The typical barcode format used in clinical laboratory environments is _____.
   a. Code 39
   b. Code 128
   c. Code 28
   d. Codabar
4. Laboratory automation may reduce laboratory-associated errors by as much as _____.
   a. 10%
   b. 20%
   c. 50%
   d. 80%
5. What criteria are considered when evaluating TAT of automated instrumentation?
   a. The total number of samples tested in the laboratory
   b. The number of test requests associated with each specimen
   c. Instrument type and complexity
   d. All of the above
6. Which analytical testing area does not have integrated automation capabilities?
   a. Mass spectrometry
   b. Urinalysis
   c. PCR analysis
   d. Bacteriology
7. Which of the following is not a metric of automation success?
   a. Improved laboratory TAT
   b. Increased requirement for FTEs
   c. Increased laboratory volumes
   d. None of the above

Answers

1. d
2. c
3. b
4. d
5. d
6. a

Chapter 15

Laboratory regulations and compliance

Stanley T. Leung[1] and Jason Y. Park[2]

[1]*Incyte Diagnostics, Seattle, WA, United States,* [2]*Department of Pathology, University of Texas Southwestern Medical Center, Dallas, TX, United States*

Learning objectives

After reviewing this chapter, the reader should be able to:

- Discuss certification and accreditation of clinical laboratories.
- Discuss the importance of CLIA in the operation of clinical laboratories.
- Describe HIPAA and how its standards are applied in management of clinical information.
- Discuss adherence to OSHA regulations in the clinical laboratory.
- Describe regulations of laboratory billing and reimbursements.

Introduction

Operating a clinical laboratory requires both scientific and management expertise. In the United States, specific laws at the federal and state levels guide the analytical testing as well as the business operations of laboratories. This chapter will outline and discuss the most important regulations for clinical laboratories. Regulations affecting clinical laboratories will be broadly reviewed in the categories of quality, privacy, worker safety, and business practices.

Regulatory responsibility in the laboratory

Under federal law, laboratory directors have the overall responsibility of administration, operation, and employee competence. Within some healthcare organizations, some oversight may be assigned to a compliance officer, who monitors adherence to applicable regulations. In 1997 the US Department of Health and Human Services (HHS) Office of the Inspector General (OIG) issued a model compliance plan that was intended to address how laboratories should conduct their business regarding marketing and billing practices [1]. This model compliance plan contained the description of responsibilities for an individual in monitoring marketing and billing practices involving payment arising from federal programs. In practice, these responsibilities have generally expanded to include all billing practices, as well as compliance with other regulations. Laboratory directors have responsibilities for not only ensuring the quality of testing but also complying with appropriate business practices. The importance of the laboratory director is emphasized when noting that directorship involves two of the top 10 serious *condition-level* deficiencies cited by the Centers for Medicare and Medicaid Services (CMS) in 2018 (Table 15.1) [2].

Federal regulations

Clinical Laboratory Improvement Amendments of 1988

The federal regulation most important to clinical laboratory operations is the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88 or CLIA). The original statute adopted by Congress can be found incorporated into the United States Code (USC) at 42 USC 263a [3]. Congress directed the development of "standards to assure consistent performance by laboratories [who have been] issued a certificate." It is these "standards" that have been developed into the regulations issued by CMS.

CLIA is described as "amendments" since the original Clinical Laboratory Improvement Act had been passed in 1967. The original statute only applied to laboratories performing tests across state borders (interstate commerce) and affected mostly hospital-based and independent laboratories. The 1967 law specifically exempted physician office laboratories (POL). However, during the 1980s, there were a series of media stories identifying errors in laboratory testing that led to misdiagnosis, delayed diagnosis, and/or patient injury. Although the stories in the media focused on cervical cytology screening, drug

TABLE 15.1 Top 10 condition-level[a] deficiencies from Centers for Medicare & Medicaid Services surveys (2018).

Regulatory cite	Deficiency	Labs deficient	Percent deficient (%)
493.1403	Laboratory must have a director who meets the qualification requirements of 403.1405 and provides overall management and direction in accordance with 493.1407	417	2.48
493.1441	Laboratory must have a director who meets the qualification requirements of 493.1443 and provides overall management and direction in accordance with 493.1445	266	1.58
493.1250	Laboratory that performs nonwaived testing must meet the applicable analytic systems requirements in 493.1251 through 493.1283	236	1.41
493.1421	Laboratory must have sufficient number of individuals meeting the qualification of 493.1423 to perform the functions specified in 493.1425 for the volume and complexity of tests performed	185	1.10
493.1409	Laboratory must have a technical consultant who meets the qualification requirements of 493.1411 and provides technical oversight in accordance with 493.1413	189	1.13
493.801	Each laboratory must enroll in a PT program that meets the criteria in subpart I and is approved by HHS. The laboratory must enroll for each specialty and subspecialty, and must test the samples in the same manner as patients' specimens	179	1.07
493.803	Each laboratory performing nonwaived testing must successfully participate in a PT program approved by CMS as described in subpart I of this part for each specialty, subspecialty, and analyte or test in which the laboratory is certified under CLIA	117	0.79
493.1487	Laboratory must have sufficient number of individuals who meet the qualification requirements concerning State licensure, if applicable, and the educational requirements for high-complexity personnel as defined in 493.1489	92	0.55
493.1215	If the laboratory provides services in the specialty of hematology, the laboratory must meet the requirements specified in 493.1230 through 493.1256; and 493.1269 and 493.1281 through 493.1299.	65	0.39
493.1447	Have a technical supervisor who meets the qualification requirements as defined in 493.1449 and provides technical supervision in accordance with 493.1451	59	0.35

CLIA, Clinical Laboratory Improvement Amendments; *CMS*, Centers for Medicare & Medicaid Services; *HHS*, Health and Human Services; *PT*, proficiency testing.
[a]*CMS laboratory deficiencies are categorized as standard-level and condition-level; condition-level deficiencies are a more serious category and require correction before CMS will issue a certificate.*

testing, and AIDS testing, Congressional debate began to evolve around broader quality issues requiring oversight throughout all aspects of the clinical laboratory. Importantly, CLIA '88 was enacted to apply to all clinical laboratories including POL and small private laboratories. In addition, CLIA '88 not only applies to clinical laboratories but also applies to any person (e.g., physician and medical assistant), performing testing on human specimens for the diagnosis, prevention, or treatment of health conditions. Although CLIA '88 is administered under CMS, it applies to all testing situations in the United States regardless of whether the patient is a Medicare beneficiary. CLIA '88 set minimal national standards for laboratory quality assurance, quality control (QC), and proficiency testing (PT). The final version of CLIA '88 was published and became effective in 1992.

Administrative provisions

The foundation of CLIA is that all tests performed on clinical specimens are subject to CLIA's provisions. CLIA also applies to testing sites ranging from limited POLs with a few types of tests to free standing commercial reference laboratories with thousands of types of tests. However, when the laboratory testing is not intended for diagnostic or therapeutic purposes, then the application of CLIA is less clear. Testing for research purposes is excluded, as is drug testing performed by employers and forensic testing. However, CLIA applies to all tests that are communicated to clinical care providers or entered in the patient's medical record. Under CLIA, analytical results from research laboratories cannot be communicated to patients or be used by physicians or other clinical care providers.

Administrative provisions of CLIA created a nongovernmental advisory committee, the Clinical Laboratory Improvement Advisory Committee (CLIAC), consisting of 20 members selected by the HHS plus members from the Centers for Disease Control and Prevention, CMS, and the Food and Drug Administration (FDA). CLIAC meets several times a year to consider issues referred to it by CMS and to develop recommendations in response to questions.

Certification process

The CLIA regulation recognizes that different tests require different levels of scrutiny depending on the level of complexity of the testing performed. The categories of tests are (1) waived tests; (2) tests performed by the physician or advanced practitioners using microscopy [provider-performed microscopy (PPM)]; (3) moderately complex tests; and (4) highly complex tests. This classification is critically significant, because it determines the level of oversight and regulatory compliance requirements including PT, QC, and personnel qualification. The FDA determines the test complexity category.

Waived tests

The original language of CLIA described waived tests as those "methodologies that are so simple and accurate as to render the likelihood of erroneous results negligible, or ... [those posing] no reasonable risk of harm to the patient if performed incorrectly." The waived tests have expanded over time and now include some molecular diagnostic tests (Table 15.2). In 2005 the FDA issued a draft recommendation to manufacturers who seek to have their in vitro devices (IVDs) classified as waived [4]. To be considered for waived classification, a testing device cannot require any preanalytical steps (i.e., no specimen processing). In addition, the manufacturer must analyze the effects of deliberately making errors in test performance. The test accuracy, including a description of a comparative method, must be provided, and no postanalytical calculations can be required. As a result, a person with no technical training should be able to produce the same results as those produced by a trained medical technologist.

A laboratory holding a Certificate of Waiver (meaning it is approved to perform waived tests only) needs to follow two basic rules: It must perform only the waived tests named in its application, and it must perform those tests

TABLE 15.2 Examples of Clinical Laboratory Improvement Amendments waived tests.

Test	Use	CPT code
Dipstick or tablet reagent urinalysis	Screening urine to monitor/diagnose various diseases	81002
Urine pregnancy tests by visual color comparison	Diagnosis of pregnancy	81025
Fecal occult blood	Detection of blood in feces from various causes	82270/ 82272
Blood glucose by glucose monitoring devices cleared by the FDA for home use	Monitoring of blood glucose levels	82962
Hemoglobin by copper sulfate—nonautomated	Monitors hemoglobin level in blood	83026
Ovulation tests by visual color comparison for human luteinizing hormone	Detection of ovulation	84830
Blood count; spun microhematocrit	Screen for anemia	85013
Erythrocyte sedimentation rate—nonautomated	Screening test for inflammatory activity	85651
Abbott i-STAT Chem8 + Cartridges	Measures multiple peripheral blood chemistry analytes	Multiple
Abaxis Piccolo Blood Chemistry Analyzer	Measures multiple peripheral blood chemistry analytes	Multiple
Alere I Influenza A&B Test	Detection of Influenza A and B viral nucleic acids using isothermal nucleic acid amplification technology	87502QW

Streptococcus group A antigen by immunoassay with direct optical observation	Rapid detection of the group A streptococcus antigen for the diagnosis of infection	87880QW

Notes: An updated list of all waived tests is available on the CMS website: https://www.cms.gov/Regulations-and-Guidance/Legislation/CLIA/Downloads/waivetbl.pdf. *CPT*, Current procedural terminology; *FDA*, Food and Drug Administration.

in compliance with the manufacturer's instructions. Given that more than half of US laboratories are in the category of waived-testing laboratories, there is a significant incentive for a manufacturer to have its test classified as waived.

Provider-performed microscopy

These nine-specific manual microscopic examinations are by definition not "kits" or specific methods (Table 15.3). These tests are used to identify certain microorganisms or features, using bright-field or phase-contrast microscopy. They can only be performed by physicians or midlevel practitioners (e.g., advanced practice nurses, physician assistants, and nurse midwives). No requirements in the form of traditional QC exist, and no PT is required. However, PPM requires written policies and procedures for the assessment of personnel competency. Training and demonstrated competency must be documented. The regulation of PPM is a looser type of regulation based on the premise that physicians and midlevel practitioners interact directly with the patient, and therefore can correlate their microscopic findings with their clinical assessment. When PPM tests are performed in a hospital setting, laboratory staff may assist with or coordinate compliance, but generally, entities holding a PPM Certificate have little to do with the traditional laboratory. Although traditional QC and PT is not required, CLIA considers PPM a special type of moderate-complexity testing, and as a result, all waived testing can also be performed under a PPM certificate.

Moderate- and high-complexity testing

The distinction between moderate- and high-complexity tests is based on the characteristics of the testing process (Table 15.4). Most automated testing is classified as moderate complexity, whereas tests that are largely manual (electrophoresis, chromatography, microbiological procedures, and molecular pathology) are all high complexity. Initially, the classification as moderate- or high-complexity tests determined the QC procedures that the regulations required and the extent of test validation expected. These differences were dropped in a revision of the CLIA regulation issued in 2004, and the principal difference between moderate- and high-complexity testings is now in personnel qualifications of laboratory staff (Table 15.5). In addition to laboratory certification, there is individual certification with specific board organizations that are recognized by HHS for certifying individuals with a PhD in chemical, physical, biological, or clinical laboratory science (Table 15.6). Understanding the personnel qualifications of laboratory staff is critical to avoiding regulatory action. As noted in the *condition-level* deficiencies cited by CMS, personnel issues are six of the top 10 most common deficiencies (Table 15.1).

To be certified to perform moderate- or high-complexity testings, a laboratory must possess a Certificate of Accreditation. Unlike the Certificate of Waiver, which imposes very limited requirements on the waived laboratory, the Certificate of Accreditation imposes significant requirements. Certification requires a biennial inspection by an organization authorized by CMS to inspect and approve laboratories as meeting standards complying with CLIA requirements. These standards include successful participation in PT; compliance with QC, maintenance, and record keeping requirements; demonstration that the laboratory staff meets CLIA educational and certification requirements; and payment of a fee for issuance of the certificate (Table 15.7).

TABLE 15.3 Provider-performed microscopy tests.

Test	CPT code
Wet mounts, including vaginal, cervical, or skin specimens	Q0111
Potassium hydroxide preparations	Q0112
Pinworm examinations	Q0113
Fern test	Q0114
Postcoital direct, vaginal, or cervical mucous examination	Q0115
Microscopic urinalysis	81015
Fecal leukocyte examination	89055

TABLE 15.4 Food and Drug Administration criteria for categorizing test complexity.

Category	Lowest complexity	Highest complexity
Technical and scientific knowledge	Minimal knowledge	Specialized knowledge is essential
Training and experience needed for all phases of testing process	Minimal training	Specialized training or substantial experience is essential
Reagent and material preparation	Reagents and materials are stable, reliable, and/or prepackaged	Reagents and materials require special handling or require manual steps such as gravimetric or volumetric measurements
Characteristics of operational steps	Automatically executed or easily controlled	Close monitoring or control are required (e.g., precise temperature control, accurate pipetting, and extensive calculations)
Calibration, quality control, and proficiency testing materials	Stable and readily available calibrators	Require special handling
Test system troubleshooting and equipment maintenance	Automatic or self-correcting; requires minimal judgement	Manual; requires decision-making to resolve most problems
Interpretation and judgement	Minimal interpretation or judgement	Extensive interpretation and/or judgement required

TABLE 15.6 US Department of Health and Human Services approved certification boards for PhD laboratory directors of high-complexity testing.

Abbreviation	Certification board
ABB	American Board of Bioanalysis
ABCC	American Board of Clinical Chemistry
ABFT	American Board of Forensic Toxicology
ABHI	American Board of Histocompatibility and Immunogenetics
ABMGG	American Board of Medical Genetics and Genomics
ABMLI	American Board of Medical Laboratory Immunology
ABMM	American Board of Medical Microbiology
NRCC	National Registry of Certified Chemists

Notes: A medical doctor, doctor of osteopathy, doctor of podiatric medicine, or PhD with the appropriate experience can be a high-complexity laboratory director. A PhD laboratory director must hold an earned doctoral degree in a chemical, physical, biological, or clinical laboratory science from an accredited institution and be certified and continue to be certified by a board approved by HHS. ABFT and NRCC also certify nondoctoral individuals.

TABLE 15.7 Clinical Laboratory Improvement Amendments certificate fees, as of 2017.

Type of lab	Number of specialties	Annual test volume	Biennial certificate fee
Waived	N/A	N/A	$180
PPM	N/A	N/A	$240
Low volume A	N/A	Less than 2000	$180
Schedule A	Three or fewer	2000–10,000	$180
Schedule B	Four or more	2000–10,000	$180
Schedule C	Three or fewer	10,001–25,000	$516
Schedule D	Four or more	10,001–25,000	$528
Schedule E	N/A	25,001–50,000	$780
Schedule F	N/A	50,001–75,000	$1,320
Schedule G	N/A	75,001–100,000	$1,860
Schedule H	N/A	100,001–500,000	$2,448
Schedule I	N/A	500,001–1,000,000	$7,464
Schedule J	N/A	>1,000,000	$9,528

TABLE 15.8 Accreditation organization with deeming authority under Clinical Laboratory Improvement Amendments.

AABB American Association for Laboratory Accreditation, American Osteopathic Association/Health Facilities Accreditation Program, American Society for Histocompatibility and Immunogenetics
COLA College of American Pathologists Joint Commission

Notes: Only American Association for Laboratory Accreditation, American Osteopathic Association/Health Facilities Accreditation Program, College of American Pathologists, and Joint Commission provide accreditation for all the major specialties of histocompatibility, microbiology, diagnostic immunology, chemistry, hematology, immunohematology, pathology, and cytogenetics. Only two states are exempt from Clinical Laboratory Improvement Amendments: Washington and New York. *AABB*, American Association of Blood Banks; *COLA*, Commission on Office Laboratory Accreditation.

Inspecting organizations

The laboratory inspection, which must be performed before initiation of laboratory operation and at 2-year intervals thereafter, may be performed by a state agency responsible for public health or by a private organization approved by CMS for conducting accreditation inspections. Approved entities are referred to as *deemed agencies*, because they have been deemed to represent CMS for the purpose of accreditation compliance. There are multiple organizations with deemed status (Table 15.8): American Association of Blood Banks (now called AABB), Commission on Office Laboratory Accreditation (now called COLA), American Association for Laboratory Accreditation (A2LA), American Osteopathic Association, American Society for Histocompatibility and Immunogenetics, College of American Pathologists (CAP), and the Joint Commission for Accreditation of Healthcare Organizations (Joint Commission). Each deemed organization has specific areas of the laboratory, which they can inspect. Only A2LA, American Osteopathic Association, CAP, and the Joint Commission cover all of the major laboratory areas recognized by CLIA.

Laboratory inspections have a fee (payable to the inspecting organization), which is separate from the certificate fee (payable to CMS). There are subtle differences in the perspective of the deemed organizations' inspections compared with inspections conducted by governmental agencies. The CLIA certificate fee depends on the

number of different specialty types of tests (chemistry, hematology, coagulation, microbiology, transfusion services, etc.) and the test volume for a given laboratory.

Proficiency testing

A CLIA certified laboratory must participate in PT using an approved external provider of proficiency test materials. PT, when it is conducted for the purposes of compliance with the provisions of CLIA, is evaluated according to criteria defined in the regulations. In general, the CLIA PT requirements are less stringent than PT evaluations conducted for quality assurance purposes. Not all tests have the same PT requirements; CLIA specifically lists the tests that require PT as well as the limits of acceptability. PT must be performed in a manner identical to the way patient samples are tested, and communication with other laboratories regarding proficiency test results is prohibited. PT must be performed by staff who routinely perform patient testing, and no extra calibration of instruments or duplicate testing of proficiency samples are allowed. Documentation should be maintained to support the proper manner of testing.

For tests requiring PT, there are two types of analytes: regulated and nonregulated. For regulated analytes, CLIA specifies that three sets of five proficiency challenges must be completed by accredited laboratories each year (Table 15.9). Although achieving acceptable results is not typically challenging, the consequences of repeated failures can be dire, and even more severe consequences may result from deliberate violation of the prohibition of "cheating" (e.g., having proficiency samples run at another laboratory or in collaboration with others regarding results of PT). When a set of five specimens is received, the laboratory must produce acceptable results on at least four of the five to receive a satisfactory grade for that challenge. In other words, an 80% level of acceptability is satisfactory. If an unsatisfactory result ($<$80% acceptable) is obtained, then the laboratory must achieve at least 80% acceptability on the next two subsequent challenges for the same analyte, or the laboratory's PT performance is considered unsuccessful. Unsuccessful PT results may eventually prompt an investigation of the laboratory, with the possibility of suspension of certification until correction and improvement is proven. During a suspension, a laboratory may be prohibited from operating or may be required to refrain from testing in the area that was unsuccessful. Suspensions are not automatic or instantaneous but depend on the outcome of an investigation.

Patient test management

CLIA contains many provisions regulating the pre- and postanalytical phases of testing. This section includes requirements such as documentation of physician orders for tests performed, the availability of an up-to-date procedure manual, records of instrument maintenance and repair, and reports of test results that include a reference range and any pertinent patient and/or specimen information, as well as standards for records retention.

Quality control

The first version of the CLIA regulations contained QC requirements that reflected the long-standing laboratory tradition of running two liquid controls with every run of patient samples. Over time, however, it became apparent that analytical inaccuracy was not the most common cause of laboratory error, and an updated version of QC regulations was published in 2005. One driving force behind this change was the increased use of single-use testing devices, in which the traditional statistical sampling approach for QC did not apply. In addition, test device manufacturers have developed electronic controls capable of monitoring various elements of the test instrumentation, providing assurance that test components are operating within defined specifications.

While retaining the two-controls-per-run practice as an acceptable QC practice, CMS has allowed laboratories to document the effectiveness of alternative approaches to QC such as electronic checks, use of patient means, and other nontraditional approaches to ensure the accuracy of testing. Overall, CMS is attempting to encourage the development and use of a systems approach to quality assurance in place of the traditional focus on the analytical phase of testing. An example of an innovative practice is *Individualized Quality Control Plan*, an alternative QC option under CLIA, which permits laboratories some customization in their QC practice.

Personnel standards

Compliance with CLIA further requires that the laboratory be directed by a qualified individual, with qualification being determined by academic degree and experience (Table 15.4). Some states have set additional requirements for laboratory staff qualifications, and state requirements must be met when they are more stringent than CLIA.

Enforcement

Ultimately, failure to comply with CLIA regulations is a criminal offense, carrying the possibility of conviction and punishment. In the laboratory profession, there have been cases in which laboratory owners and top managers have spent time in jail, but historically such cases have involved fraudulent billing, not QC or PT failures. The most serious penalty facing a laboratory charged with CLIA violations is a bar to participation in Medicare business.

[a]*This list of tests is current as of February 2019; there are proposals to add and delete tests from this list.*

Patient privacy

The *Health Insurance Portability and Accountability Act* (HIPAA) of 1996 was passed into law to ensure that an employee could not be denied health insurance (e.g., because of a preexisting condition) if he or she changed employers. At the same time, it created a single electronic standard; it was recognized that this electronic standard would increase the privacy risk of unauthorized persons gaining access to private health-related information.

Therefore strict privacy provisions were entered into the regulatory framework, which would cover all healthcare providers. Because laboratories are the largest single producer of data, the burden of protecting that data falls heavily on the staff who manage and operate laboratory information systems. HIPAA's protections fell into two categories: the privacy standard and the security standard.

Privacy standard

Healthcare providers are required to provide a statement explaining how they handle confidential patient information [protected health information (PHI)]. Eighteen specific identifiers including name, birth date, admission date, and discharge date are all described as PHI by HIPAA. This manner of handling the PHI must be in compliance with HIPAA, and the provider must provide this statement to each patient and obtain a signature acknowledging receipt. An organization with multiple providers such as hospitals can merge multiple HIPAA notices into a single statement with a single patient signature. Providers that do not have direct contact with patients (i.e., clinical laboratorians) are not required to obtain such a signature; however, they need to demonstrate a good faith effort to ensure that their HIPAA statement reaches the patients whom they serve. The HIPAA privacy standard further defines when PHI can be shared without the permission of the patient. The major categories of sharing PHI without permission are treatment, operations, and payment. The treatment category is what authorizes reporting of laboratory results to physicians, nurses, consultants, and any other provider treating the patient. Laboratories are expected to use reasonable judgment in balancing the benefit of communicating a result for the patient's treatment with the obligation to protect the patient's privacy. For example, if a telephone caller identifies himself or herself as a nurse or physician in need of laboratory data on a certain patient, the laboratory may provide that information without written documentation of the request or proof of the caller's identity. The operations category allows laboratory staff to review the test results or the clinical record of any patient for whom tests are done. Similarly, because QC and certification are operational requirements of a laboratory, access to patient results by an inspecting entity, such as CAP or Joint Commission, is allowed. Finally, the payment authorization allows passing PHI to an outside billing agency for the purpose of seeking payment for services rendered.

Any other release or PHI requires either the authorization of the patient or record keeping as an unauthorized release. Provision of records in response to a subpoena or in compliance with health department requirements (e.g., reporting of infectious disease cases) must be recorded, as well as any accidental or erroneous release of patient records. This might occur if a patient report is sent to the wrong physician, for example. The patient is entitled to request an accounting of all unauthorized releases of his or her data. The intent of this provision of HIPAA was so that patients could be informed of accidental or misdirected releases of their PHI. Compliance with the privacy standard is typically achieved with the following approaches:

- control of paper containing PHI (avoiding commingling with general trash);
- shredding of documents containing PHI;
- limiting the inclusion of PHI on reports and worksheets to the minimum necessary to achieve the purpose of such reports; and
- recording of all releases of information that is not specifically related to treatment, operations, and payment.

The security standard

The security aspects of HIPAA require creating and enforcing policies that provide physical security such as using passwords, maintaining computer firewalls, and investigating attempted unauthorized entry into an electronic database. This is generally the responsibility of information systems personnel and is very similar to the requirements commonly in force for the protection of finance- and accounting-related systems. Generally, once these provisions are put into place, they continue to operate to meet the security standard. Because the requirements of HIPAA cover all healthcare providers and not specifically laboratories, there is typically a unified effort to comply and to find strategies that work for all elements within a healthcare operation.

Health Information Technology for Economic and Clinical Health Act

Enacted in 2009, the Health Information Technology for Economic and Clinical Health (HITECH) Act provides additional civil and criminal enforcement of the HIPAA requirements for patient privacy and healthcare data security. HITECH specifies actions for reporting HIPAA violations; for example, when more than 500 patients are affected by a data breach (unauthorized disclosure of PHI), not only are patients notified, but HHS and the news media must also be notified. Under HITECH, the civil penalties can be as high as $1.5 million for repeat violations.

Genetic privacy

Genetic data are not one of the 18 specific PHI identifiers under HIPAA. Because genetic data are not considered PHI, genetic data are protected under Federal law only

when it is associated with one or more of the 18 specific PHI identifiers. Once genetic data are deidentified, it is no longer protected under Federal law. Although there is no current Federal requirement for protecting deidentified genetic data, clinical laboratories should consider the future risk to patient privacy if deidentified data are reidentified. Reidentification of genetic data has been demonstrated using publicly available resources such as social media, phone books, and genealogy records. An individual patient's genetic data provide insights into the genetic data of all biologic relatives. Thus risks to the genetic privacy of one individual are transferred to all biologic relatives.

Biobanking and providing specimens for research

Clinical laboratories may serve as resources for biologic materials in research. After patient samples are used for clinical testing, the remaining (residual) material is considered waste and may qualify for future research. Biobanks may also contain materials specifically collected for research. The main federal regulations to consider include institutional review board (IRB) oversight under the Department of HHS' Office for Human Research Protections, patient privacy, and determining whether the proposed use of the materials is considered human subjects research under the "Common Rule." The Federal "Common Rule" is the standard of ethics for human subjects research in the United States and defines the actions of IRB oversight. The establishment and ongoing activities of a residual human specimen biobank need to be reviewed and approved by a local IRB. In addition, any project that intends to use specimens from the biobank needs separate IRB oversight and approval.

Occupational Safety and Health Administration regulations

The federal Occupational Safety and Health Administration (OSHA) is responsible for workplace safety and health issues. OSHA focuses on workplaces in general and not on healthcare or clinical laboratories in particular. The underlying principle is protection of workers and not protection of patients or quality of the services provided. If a laboratory were operated without a single human worker, then OSHA would not apply to that laboratory. Two specific OSHA rules are pertinent to clinical laboratories: bloodborne pathogens and chemical hygiene regulations.

Bloodborne pathogens

There are federal laws that contain detailed protections that must be implemented to prevent transmission of infectious disease to workers through exposure to blood or blood-containing products. The regulations are referred to as "The Bloodborne Pathogen Regulation" and set standards in the following areas:

- personal protective equipment such as fluid-resistant lab coats, eye protection, and gloves;
- engineering controls such as needle-stick prevention devices, hand-washing sinks, and barriers used when opening tubes containing blood;
- housekeeping, including decontamination of workbenches and equipment, and disposal of infectious waste;
- employer-provided hepatitis B vaccination;
- communication and training; and
- record keeping of exposure incidents and review of causation and potential preventive measures.

The Bloodborne Pathogen Regulation underlies the protective measures that are part of every accreditation inspection. Although stool and urine can contain equally dangerous infectious organisms, they are not covered by this rule.

Chemical hygiene rule

The Chemical Hygiene Rule is a federal regulation intended to prevent exposure-related injury to employees. The focus is on toxic or harmful materials such as carcinogens; caustic, irritating, and combustible materials; explosive materials; and compressed gases. The regulation requires an organization to designate a chemical hygiene officer and, if appropriate, a chemical hygiene committee. This person or committee is responsible for the creation and maintenance of a chemical hygiene plan and development of a list of dangerous chemicals on hand, the amount used annually, and plans for protection of employees in the event of an accidental spill. However, when chemicals are commercially prepared and all of the reagents needed to conduct a test are contained in a kit, then OSHA considers them as having no potential for employee exposure, and they are thus outside the scope of the regulation.

Reimbursement regulations: fraud and abuse

When compared to compliance with CLIA and OSHA regulations, handling reimbursement under the Medicare and Medicaid programs is a more complex challenge. The issue of fraudulent billing arose in the mid-1990s in the context of rapidly escalating healthcare costs. Medicare is generally the government program, providing healthcare benefits for the elderly, and Medicaid is the government program providing healthcare benefits for the poor.

These were both created in 1966. Initially opposed by physicians, Medicare payments were divided into Part A (healthcare facility technical fees) and Part B (physician professional fees). Because reimbursement was initially based on what was actually billed, healthcare providers and facilities virtually controlled reimbursement rates. The programs were quickly recognized as an opportunity for significant income by all healthcare providers, including laboratories. As a result, government costs began to rise more rapidly than initially projected, so the Health Care Finance Administration (now called CMS) began implementing techniques to control Medicare spending.

For laboratory services, a major change occurred in 1984, when payment for laboratory testing performed on Medicare patients began reimbursement on the basis of a fee schedule amount instead of a "reasonable cost" basis. This initial fee schedule was based on prevailing charges submitted by laboratories during 1982−83 and then discounted to reflect the discounts commonly offered by laboratories. Despite the promise that this fee schedule would be increased for inflation, the increase was deferred or eliminated more than 50% of the time between 1985 and the present, while, at the same time, Congress mandated "National Limitation Amounts," which effectively decreased the payment to laboratories even further. More than 20 years after implementation of the fee schedule and despite many changes in testing technology, Medicare is still reimbursing for laboratory testing under its original fee schedule. As a result, reimbursement for a peripheral blood thyroid stimulating hormone (TSH) test is still approximately seven times the reimbursement for glucose. At the other end of the spectrum, newer immunoassay tests, if they do not have specific billing codes assigned, must be submitted as a nonspecific "Immunoassay, Other," which is reimbursed substantially below the cost of testing. As a result, CMS receives many complaints from the laboratory profession that Medicare underreimburses for certain tests. An investigation by the Institute of Medicine found that Medicare laboratory payment policy is badly flawed [5].

In 2014 Congress passed the Protecting Access to Medicare Act (PAMA), which significantly changes how CMS pays for clinical laboratory tests under the Clinical Laboratory Fee Schedule (CLFS). PAMA requires CMS to establish a new market-based payment system; these new payment rates apply to most clinical tests, including POLs. This market-based system requires certain laboratories, including physician office-based labs, independent labs, and hospital outreach labs, to collect and report private payor payment and test volume data to CMS. For each laboratory test that is reported for a data collection period, CMS calculates a weighted median payment for the test. As a result, in 2018, the payment amount for most tests is equal to the weighted median of the *surveyed* private payor rates. Payment rates under the private payor rate-based CLFS are updated every 3 years. If the Secretary of HHS determines that an applicable laboratory has failed to report or made a misrepresentation or omission in reporting information regarding a clinical diagnostic laboratory test under PAMA, a civil monetary penalty of up to $10,000 per day for each failure to report or each such misrepresentation or omission can be assessed.

The original intent of PAMA was to ensure that the new payment rates for clinical laboratory tests were based on market data from the "full spectrum of laboratories, including hospital, independent, and POLs." However, when CMS released its new proposed CLFS in 2017, more than 90% of the surveyed payment data used were derived from commercial laboratories, and only 1% were from hospital-based laboratories. This distribution of payment data is not representative of the laboratory testing market, where physician office and hospital laboratories account for approximately 43% of Medicare Part B spending for outpatient lab testing. It is likely that payment data disproportionately surveyed from independent labs (with higher volumes and lower cost margins) could skew prices downward and lead to deeper cuts to the CLFS than Congress had intended. While PAMA does place some limits on the reduction of the payment amount for an existing test as compared with the payment amount for the preceding year, the resulting data are projected to still lead to significant rate reductions in laboratory reimbursement, with Medicare annual cuts of 10% to most tests in the fee schedule each of the 3 initial years through 2020, and up to 15% annual cuts for the subsequent 3 years. After this 6-year phase-in period, there will be no limits to annual payment reductions.

Early examples of fraud and abuse

As CMS moved to a fixed fee schedule, laboratories, which had embraced automation and the technology for performing large numbers of tests at small incremental cost during the 1980s, saw that profits were limited by the fee schedule and began to reexamine business practices to increase their volume. In so doing, some laboratories created marketing tools to encourage physicians to order additional tests on their patients. These techniques were initially financially successful but were eventually deemed at least abusive, if not fraudulent.

It is instructive to examine the government's critical analysis of the practice of bundling tests together for ordering purposes and unbundling them for billing purposes. With reimbursement for tests limited by the fee schedule, some laboratories, especially for-profit laboratories, attempted to increase test volumes by assembling a package of tests directly to physicians at low costs. However, when the same packages of tests were offered

to Medicare beneficiaries, each test was individually charged to Medicare at higher prices. For example, a 20-test chemistry profile might be billed to the physician for $8.00, but the same test with an added TSH would be billed to the physician for $8.50. When the 20-test profile was billed to Medicare, Medicare paid $15.00. However, when a claim was submitted to Medicare for both the 20-test profile and a separate TSH, the reimbursement would have been $15.00 for the chemistry profile and an additional $23.00 for the TSH assay (total = $38.00). The position of the government was that the laboratory was deliberately misleading the physician to order tests that were unnecessary, or at least of minimal utility, but noting that the additional test (the TSH) was provided at only a very slight additional charge (the extra $0.50 above the charge for the chemistry profile), whereas Medicare was paying $23.00 more than the charge for the chemistry profile.

Government investigators viewed this tactic as a deliberate attempt to induce fraudulently the physician to order unnecessary tests. These charges were brought not under a theory of common law fraud that individuals and private corporations would utilize, but as a violation of federal statutes, most importantly the False Claims Act.

The False Claims Act

The False Claims Act, passed in 1863, was in response to war profiteers during the Civil War who sold inadequate or nonexistent war materials to the Union Army. The law provided for a high fine for each false claim that was submitted to the government for payment and a reward to the individual who informed the government of the fraudulent claim. Following the Civil War, the law fell into disuse, but it was revived in the 1980s in response to news stories of defense contractors selling items at inflated prices to the military during the Cold War, an era marked by reports of governmental waste such as the $435 hammer and the $640 toilet seat. Congress changed the False Claims Act by increasing the fine per false claim to as much as $10,000, providing the whistleblower who filed the charges against the defendant up to 30% of the total recovery, and requiring the defendant to pay the legal fees of the whistleblower. Because each Medicare claim was considered a separate false claim, it was possible for the total fine assessed against a large high-volume laboratory to reach into the hundreds of millions of dollars. In addition, any entity convicted of filing false claims could be barred from participating in Medicare, essentially ensuring the demise of that company. Laboratories who had engaged in these practices were willing to settle all charges for fines that ranged up to $325 million, provided they were not required to admit wrongdoing and, more importantly, provided they were not barred from participating in Medicare work in the future.

Inducements and kickbacks

The Social Security Act contains a provision that bars the payment of cash or the provision of any item of value when it is given for the purpose of inducing or having the effect of inducing healthcare providers or Medicare beneficiaries to order or use a Medicare benefit. This law applies to laboratories that induce a physician to use a specific laboratory's services. Examples include cash bribes as well as providing computers or fax machines. While computers may be permissible if they are for the exclusive purpose of delivery of test results, these same items can be considered an impermissible inducement if used by the physician for purposes unrelated to the lab test. More creative, but equally illegal, kickbacks include rental of office space for the storage of phlebotomy supplies and payment of consulting fees to client physicians. Under the antikickback law, it is equally criminal to offer, provide, request, or receive goods, services, or anything of value to induce the use of Medicare services; parties on both sides of such a transaction can be charged and punished. The government does not need to prove that there was specific intent to provide the inducement, only that the provider should have known that the item or service of value is likely to influence the beneficiary. This standard is met when a provider acts with deliberate ignorance or reckless disregard to the possibility of inducing a referral.

Less clear-cut is the billing practice when a physician refers both Medicare and non-Medicare testing to a laboratory. The laboratory may legally discount the non-Medicare testing but, to stay clearly within the law, the discount must be reasonable from a business point of view. Discounts may not vary in any way relating to the volume of Medicare tests sent and may never be below the actual cost of testing. To help guide providers faced with such decisions, both laboratories and physician practices may request an advisory opinion from the HHS OIG. The OIG's advisory opinions are published on its website (http://www.oig.hhs.gov), and although they have legal force only for the parties submitting the question, they are a valuable source of guidance and insight into the OIG's legal logic in evaluating potentially illegal activities.

Office of the Inspector General's Compliance Guidelines

The OIG has published compliance guidelines for many healthcare entities, and they have all followed the same organizational pattern. As such, the guidelines are general in nature and only occasionally give detailed guidance. In

addition to clinical laboratories, there are multiple other healthcare entities that have received OIG compliance program guidance (Table 15.10).

The guidelines that the OIG have published do not carry the force of law, but if they are carefully put into practice in a healthcare organization, such compliance can be offered as evidence of lack of criminal intent in the event of a prosecution for fraud. Committing Medicare fraud is intentionally submitting false information to the government or government contractor to receive money or a benefit. Submitting bills for tests not performed or on fictitious patients is an example of fraudulent activities. A common defense in the face of fraud charges is that the provider did not see anything wrong with their coding or billing practices, or their marketing or business relationships. In other words, whatever the fraudulent act, the provider will assert that they did not deliberately set out to defraud the government. An accused healthcare entity that can produce evidence that it did not knowingly seek to defraud the government has a potential defense against the government's case. Following the OIG's guidelines can be helpful in that effort to demonstrate a lack of fraudulent intent.

The OIG's guidelines for laboratories contain the following recommendations. (1) The laboratory should have written compliance procedures and policies. These should give direction to employees and there should be written notices to physician clients regarding Medicare policy and reimbursement. Standards of conduct should be defined, and billing practices should be clearly described. Adherence to the written standards of conduct should be an element of performance evaluations for staff and managers. (2) The laboratory should designate a compliance officer and, depending on its size and complexity, a compliance committee. The compliance officer should have sufficient independence to investigate any area of the laboratory and should report directly to senior management. The committee or individual should be involved in developing the standards of conduct described earlier. (3) Training and education should be conducted regularly. The laboratory should ensure that all employees, new as well as existing, are educated regarding its compliance policy and practices. (4) There must be effective lines of communication between the employees and the compliance officer. This includes a requirement to keep records of complaints, investigations, and corrective actions. (5) Compliance standards must be enforced through disciplinary practices that are publicized and understood by employees. This includes, specifically, holding corporate officers and managers accountable for enforcing the compliance policies. (6) There must be a process for auditing and monitoring the laboratory's practices. This includes coding and billing practices as well as sales and marketing programs. The auditing process must be conducted in sufficient detail that any significant increase in the billing for individual current procedural terminology (CPT) codes will come to the attention of the compliance officer, so they can consider whether this is the result of improper marketing efforts. (7) Corrective action must be undertaken if violations are detected. Misconduct must be reported to the government, and improper payments must be returned.

The largest settlements (amount of money including fines and reimbursement) paid by laboratories occurred during the mid and late 1990s, just before the issuance of the OIG's compliance guidelines. A review of these settlements makes it clear that upward of 80% of total settlement amounts were payments involving for-profit laboratories. This may be an expected consequence of a for-profit business using creative and sometimes illegal means to enhance revenue.

Not surprisingly, the OIG has focused its guidance on the wrongdoing of these laboratories. However, not-for-profit laboratories, such as those based in not-for-profit hospitals, have entirely different organizational goals and correspondingly different paths to achieve those goals. As a result, in the past, nonprofit entities have enjoyed less scrutiny. However, the need to sustain and grow healthy profit margins in any organization can incentivize even a nonprofit to run into compliance issues. Therefore while the OIG's compliance guidelines may be less applicable for a laboratory operating in a not-for-profit environment, the guidelines should remain a reference point. The benefit of these guidelines and of the OIG's advisory opinions is that they help laboratory managers understand the arms-length relationship that the OIG expects laboratories to maintain with their clients. Regardless of profit incentive, organization winning business through improved service and price is perfectly acceptable, but through any other kind of benefit is strictly forbidden.

Direct billing

The Social Security Act, where it states requirements for reimbursement for services under Medicare, contains a provision that limits reimbursement to only the healthcare provider who actually provided the service. This provision, referred to as the "direct billing" requirement, was considered necessary to prevent a healthcare provider (e.g., a physician practice) from shopping around different laboratories to obtain the lowest priced services, below the fee schedule amount, and then profiting from the difference between what Medicare reimbursed the provider for the tests and what the physician practice actually paid to the laboratory for the tests that were performed. Quality and abuse concern arise from such arrangements. Laboratories and physician offices may compromise appropriate handling and testing protocols to make up for

TABLE 15.10 Office of the Inspector General compliance program guidance for healthcare entities.

Year	Healthcare segment	Reference
1998	Clinical laboratories	63 Fed. Reg. 45076

2005	Recipients of public health service research awards	70 Fed. Reg. 71312

the lost margin for the laboratory. It also creates an incentive for the provider to order as many tests as possible, because the physician practice would enjoy a profit from each test ordered and performed. The direct billing requirement, which mandates that the laboratory be reimbursed directly by Medicare, eliminates the incentive to the physician practice of ordering excess tests. Unfortunately, novel creative business practices have emerged to circumvent the direct billing requirement.

Stark amendments

The direct billing rule resulted in the creation of business entities that could be paid for performing tests. Ordering physicians became owners or investors in contrived laboratories so they could profit from the tests that they ordered. In these "shell" or "sham" laboratories (owned by physicians or physician groups), all the actual testing would be referred to an outside laboratory; usually, it was the outside lab that would set up the shell laboratory entity. The shell laboratory would bill and be reimbursed by Medicare, and profits would be distributed back to the owning physicians or physician practices, sometimes in direct proportion to the number of tests referred. In some cases, the shell laboratory was little more than a location used to redirect all specimens to the laboratory that set up the shell arrangement and performed the actual testing. A well-publicized lawsuit involving a California shell laboratory (*Hanlester Network v. Shalala*) resulted in a victory for the defendant laboratory and physicians involved, unfortunately based mostly on legal technicalities.

To eliminate this practice, laws were introduced by Congressman Pete Stark, eventually becoming known as the Stark Amendments, which strictly prohibited a physician from sending laboratory tests to a laboratory in which s/he or a family member had a financial interest. The law was later expanded to include other entities, such as radiology or physical therapy facilities, and this expansion became known as Stark II. Both can be considered two parts of the same concept—prohibition of physicians referring a Medicare patient to a laboratory or other designated health services if the physician or an immediate family member of the physician has a direct or indirect financial interest in the entity providing such services. A financial interest includes an ownership interest or a compensation arrangement. There are also reporting requirements under the Stark Amendments. Entities furnishing items or services for which payment may be made under the Medicare or Medicaid programs must submit information to CMS concerning their financial relationships.

Key financial compliance considerations

The bottom-line is that inducing a physician or a patient to order or receive laboratory tests, or any other healthcare service, for reasons not related to medical necessity is strictly prohibited. The OIG issued an alert in 1994 that specifically forbade the following practices:

- Advertisements that state, "Medicare accepted as payment in full," "insurance accepted as payment in full," or "no out-of-pocket expense."

- Advertisements that promise that "discounts" will be given to Medicare beneficiaries.
- Routine use of "financial hardship" forms that state that the beneficiary is unable to pay the coinsurance/deductible.
- Collection of copayments and deductibles only where the beneficiary has Medicare supplemental insurance coverage.
- Charges to Medicare beneficiaries that are higher than those made to other persons for similar services and items.
- Failure to collect copayments or deductibles for a specific group of Medicare patients for reasons unrelated to inability to pay.
- Programs that cover copayments or deductibles only for items or services provided by the entity offering the insurance.

It is important for laboratorians to develop an appreciation for the guidelines expressed by the OIG and others involved in regulation of government reimbursement for healthcare services. Practices that seem, on the surface, to be acceptable may be strictly prohibited, and developing sensitivity to suspect practices is the best way to remain compliant.

Food and Drug Administration oversight of laboratory developed tests

Over the past two decades, there has been a debate within US healthcare regarding federal regulation of laboratory developed tests (LDTs) [6]. An LDT is defined by the FDA as "an IVD that is intended for clinical use and design, manufactured and used within a single laboratory." These tests are currently regulated under CLIA '88 as high-complexity tests. CMS estimates that approximately 11,000–12,000 laboratories have the needed certification to perform this level of testing. Therefore only about 5% of the more than 250,000 laboratories in the United States can perform LDTs—most often in academic medical centers, large commercial laboratories, and hospitals.

The FDA asserts that it has statutory authority to regulate LDTs under the Medical Device Act of 1976, but previously deferred to CMS under its "enforcement discretion." However, the growing complexity of LDTs has forced the agency to reevaluate its position. The FDA released two draft guidance documents outlining how it proposes to regulate LDTs. Many laboratories argue that complying with the proposed new requirements would result in the cessation of performing LDTs. The FDA proposal to expand its oversight to LDTs has divided the broader healthcare community in two separate camps. One side argues that enhanced LDT oversight should be carried out under the current CLIA regulatory structure. The other side argues that the FDA should expand its oversight. Legislators have focused more on the larger issues of process and what, if any, role the FDA should play in LDT oversight. The FDA's role in LDT oversight is not yet determined.

State regulations

State law traditionally revolves around issues such as interpretation of contracts, general health and welfare, and public safety. Insurance law is another area specific to state law that affects healthcare organizations, particularly regarding scope of coverage and policy determinations, and occasionally, that may affect, for example, whether a patient's out of state reference lab testing is covered under a policy. However, state law usually does not have a direct impact on laboratory oversight. Many states, however, have laws and regulations that affect all businesses such as employee protections and insurance regulations that apply to healthcare businesses just as any other business. One way to become familiar with general business regulations unique to a state is to obtain business-oriented publications from a chamber of commerce or similar organizations that serve the business needs of the state. Unique laboratory regulations can be obtained from state laboratory or hospital organizations, from the state public health department, libraries, and of course, Internet sites.

Negligence

The last area of regulation, tort law, is not a regulation at all in the sense that it requires compliance to a set of rules outlined by a governmental agency, but its presence and effect is as important as any law. It is how private individuals can seek a civil remedy for an injury outside of specific laws and regulations. Medical negligence is also a form of tort law. Under common law, a person can bring a lawsuit seeking compensation for injury—this is the basis of medical malpractice cases. The essential elements to prove compensable damages are establishing duty or obligation among the parties of the suit, a breach of that duty, and a resulting injury directly related to the breach. In the case of a laboratory, a laboratory performing testing has a duty to perform the test in a reasonably careful manner. If, because of a violation of that duty, it results in some error and if a patient suffers from some injury as a result of the error, the patient can claim damages. While the laboratory as an independent entity or part of a larger organization can be liable for patient injury under tort theory, the laboratory medical director can be held

professionally responsible for a breach of duty by abrogating the responsibilities outlined in the CLIA regulations for the laboratory director. However, in terms of professional liability, laboratories and their medical directors enjoy relatively low rates of negligence or malpractice actions. Nonetheless, because a laboratory error has the potential to cause injury, those responsible for testing need to be aware of the risks and to minimize them whenever possible.

Self-assessment questions

1. The federal regulation that most directly affects clinical laboratories is:
   - **a.** OSHA regulations
   - **b.** CLIA
   - **c.** HIPAA
   - **d.** Stark amendments
2. Compliance with the HIPAA privacy standard includes the following:
   - **a.** control of paper containing PHI
   - **b.** limiting inclusion of PHI on reports and worksheets
   - **c.** recording of all every instance of release of PHI that is not specifically related to treatment, operations, and payment
   - **d.** shredding of documents containing PHI
   - **e.** all of the above
3. What is the legislation that prohibits a physician from sending laboratory tests to an entity in which they have a financial interest?
   - **a.** Stark amendments
   - **b.** CLIA '88
   - **c.** HIPAA
   - **d.** The False Claims Act
4. What role can a certified clinical chemist or clinical pathologist fill in a clinical laboratory providing moderate- or high-complexity testing?
   - **a.** Director
   - **b.** Clinical consultant
   - **c.** Testing personnel
   - **d.** a and b
   - **e.** All of the above
5. Which of the following tests are "waived" under CLIA?
   - **a.** Urine dipsticks
   - **b.** Erythrocyte sedimentation rate
   - **c.** Rapid strep test
   - **d.** a and b
   - **e.** All of the above
6. Which Federal agencies are tasked with administration of CLIA?
   - **a.** CLIAC
   - **b.** CMS
   - **c.** FDA
   - **d.** CAP
   - **e.** All of the above
7. Which of the following organizations is not considered "deemed" by CMS for the purposes of clinical laboratory accreditation?
   - **a.** Joint Commission
   - **b.** American Osteopathic Association
   - **c.** American College of Medical Genetics and Genomics
   - **d.** College of American Pathologists

Learning objectives

After reading this chapter the participant will be able to:

- Explain each of the basic evidence-based laboratory elements of asking the clinical question, acquiring the evidence, appraising and analyzing the evidence, applying the findings to the clinical problem, and how to assess or audit the process.
- Define the PICOTS strategy for formulating a clinical question. Provide two examples of clinical questions developed in the PICOTS format.
- List five different types of investigative studies listing a strength or a limitation for each type of study.
- Sketch or write expressions for the ROC curve, likelihood ratios, odds ratios, and diagnostic sensitivity, and specificity.
- List and describe five resources and/or tools that are useful in the application of EBLM for the purpose of translating the evidence into changes in the practice of laboratory medicine.

Introduction

In 2001 the Institute of Medicine (IOM) reported that there was a massive chasm between what is known to be good health care in the United States and the health care that patients actually receive. To help address this mismatch, the IOM stated that health care should strive to be safe, timely, efficient, effective, equitable, and personalized. Evidence-based medicine consists of tools that can help meet these goals and assist in bridging the healthcare gap.

Evidence-based medicine (EBM) was initially described as the "use of the best data available to generate unbiased informed decisions and treatment of patients." Although by this definition, EBM practice may appear to focus on the science of medicine, "best data" must also include the clinical wisdom accumulated over years of experience combined with clinical intuition and understanding of healing. Further, once available alternatives and recommendations have been discussed, patient preferences and expectations must be considered a most important component in decisions regarding treatment and management. A more evolved definition of clinical EBM is "the integration of the best research evidence with clinical expertise and patient values." Evidence-based laboratory medicine (EBLM) differs in that it has components both before and after the clinician–patient discussion on how to manage disease. Before this discussion, EBLM involves the use of the best research evidence and laboratory medicine expertise to aid in disease diagnosis and stratifying risk. After patient management decisions, laboratory evidence and expertise are used to monitor the effects and outcomes of such decisions.

Traditionally, basic science, pathophysiology, and pharmacology were the foundation of medical and laboratory training used to decide if an action makes sense. During training, learning at the bench and bedside was largely from the experience of master laboratory professionals and clinicians. Once in practice, individuals learned and remained updated through continuing education lectures and seminars from thought leaders. Moreover, clinical experience, which stressed the successes, outcomes, and adverse events in our own experience, guided future behavior. This traditional approach has been problematic, however, because professional judgment improves over time, up-to-date knowledge of the best, most current evidence may become obsolete. There have been numerous studies that demonstrate suboptimal adoption of proven therapies and management strategies, because the best evidence must frequently be revised, updated, disseminated, adopted, and adhered to. Information from expert advice and textbooks necessarily lags behind the current medical and scientific literature. On the other hand, because the pace of scientific discovery and production of peer and nonpeer-reviewed literature is increasingly rapid, determining which information

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00016-8

represents valid and relevant scientific evidence is complicated and time-consuming. EBLM can facilitate the task of laboratory professionals, clinicians, managers, and policymakers faced with complex decision-making when the information is required in a real-time environment. In addition, EBLM can aid in the task of utilization review both at the Laboratory Medicine and Institutional levels by providing evidence-based guidance for translating, tailoring, and implementing effective testing systems and strategies. Use of EBLM can enhance the value of laboratory medicine by optimizing health outcomes and efficient resource deployment in the preanalytical, analytical, and postanalytical phases of testing.

Elements of evidence-based laboratory medicine

The clinical question

Fig. 16.1 outlines an example of a cyclic process utilized for practicing EBLM. This example was specifically developed for the Center for Disease Control's (CDC's) Laboratory Medicine Best Practices program. It is known as the CDC-LMBP A-6 Systematic Steps or the A-6 Cycle [1,2]. Additional information on projects and activities conducted under the auspices of the CDC-LMBP can be found at https://www.cdc.gov/labbestpractices/index.html. As illustrated in Fig. 16.1, the first step of the EBLM cycle is to frame focused question(s) that are to be answered by the evidence review. Once a focused clinical question has been identified, the evidence is acquired, appraised, analyzed, and applied, and the application(s) are audited and assessed. Following these six steps then provides the option to cycle back to a need for framing a new focused question to be answered. In this way, the process evolves into another A6 cycle addressing a new, further refined or related evidence review.

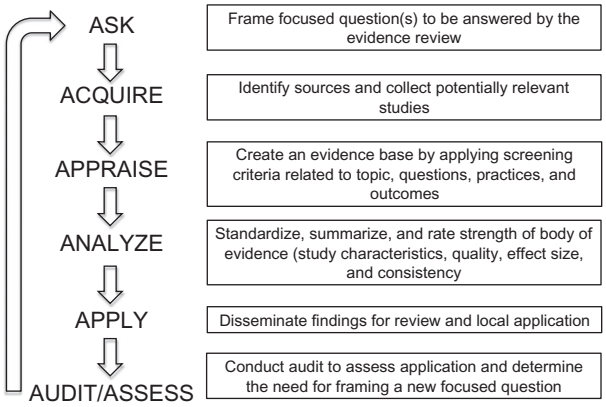

FIGURE 16.1 The A6 cycle is shown as an example of the elements of the evidence-based laboratory medicine process. Use of the A6 cycle to review systematically the literature is one aspect of the Centers for Disease Control Laboratory Medicine Best Practices program.

Formulation of a clearly stated and clinically relevant question is an important first step necessary for effective practice of EBLM. Key reasons why physicians and other caregivers order laboratory medicine tests on individual patients are to screen for a variety of conditions, rule in or rule out a diagnosis, monitor a response to therapy, assess prognosis for long-term outcomes, and guide therapy or interventions. A widespread and convenient method for initially formulating focused, clearly stated, and clinically relevant questions uses a strategy represented by the acronym "PICOTS" to explicitly state the framework for the question being asked and to initiate the review of the evidence. As shown in Table 16.1, PICOTS stands for *p*atient (clinical situation), *i*ntervention (or assay), *c*omparison (reference or control population), *o*utcome(s), *t*iming, and *s*etting(s). The example provided in Table 16.1 for a key question focuses on the use of procalcitonin (PCT) measurement in addition to clinical criteria for infection compared with clinical criteria for infection alone for the purposes of guiding antibiotic therapy and affecting outcomes in patients. This question became the basis for a comparative effectiveness review (CER) conducted by the Agency for Healthcare Research and Quality [3]. The elements of PICOTS for this question are provided in Table 16.1.

As the landscape of healthcare delivery continues to transform rapidly across the world, the need to conduct EBLM studies focusing on clinical questions considerably more complex than the diagnostic accuracy of laboratory tests has become the norm. The clinical question posed for the PICOTS elements in Table 16.1 is a real example. The utility of PCT to guide antibiotic therapy in selected patient populations extends beyond the analytical quality and diagnostic accuracy of PCT tests. The clinical question was structured to compare whether patients managed with a diagnostic intervention (use of PCT testing) coupled with other clinical criteria fared better than patients who were managed with clinical criteria alone. As this evidence-based review reported, the analytic framework ultimately focused on the value of the intervention in affecting intermediate outcomes as well as health outcomes.

Finding the evidence

The PICOTS strategy is useful not only for focusing question formulation but also for finding evidence that addresses the question. Keywords derived from the PICOTS structure can be used to search the literature directly in the context of the clinical question. Perhaps, the most useful resource for finding evidence is PubMed, a service provided at no charge by the United States

TABLE 16.1 Components and example of structured PICOTS[a] relating to the key question[b].

PICOTS	Questions to consider	Specific of each element of PICOTS
P: Patients or patient population(s)	What are patients' characteristics, symptoms, and demographics? Consider the condition(s) that may be present	Adult and pediatric patients with known or suspected local or systemic infection, including critically ill patients with sepsis syndromes or ventilator-associated pneumonia, adults with respiratory tract infections, neonates with sepsis, children with fever of unknown source, and postoperative patients at risk of infection
I: Intervention	What laboratory medicine test is being considered? Are other criteria being considered?	Initiation, discontinuation, or intensification of antibiotic therapy guided by procalcitonin plus clinical criteria for infection
C: Comparator (or control)	What is the reference or "Gold standard" for the intervention?	Initiation, discontinuation, or intensification of antibiotic therapy guided with procalcitonin compared to clinical criteria alone.
O: Outcome	What is (or what are) the endpoint(s) of interest?	Antibiotic use (duration of antibiotic therapy, prescription rate, and total antibiotic exposure), mortality, morbidity (length of stay and severity of illness score), total cost, and adverse events of antibiotic therapy (persistent or recurrent infection, and antibiotic resistance)
T: Timing	What is the target time frame for studies to have been conducted?	3 months
S: Settings	What are the clinical settings for studies to have been conducted?	ICUs (medical and surgical), inpatient acute care hospitals, emergency departments, and outpatient clinics

- Intermediate outcomes, such as initiation, discontinuation, or change of antibiotic therapy; antibiotic use; and length of stay?
- Health outcomes, such as morbidity, mortality, function, quality of life, and adverse events of antibiotic therapy (persistent or recurrent infection, and antibiotic resistance)?

[a]PICOTS, *Patient, intervention or test, comparator or control, outcome, timing, and settings*
[a]*In selected populations of patients with suspected local or systemic infection, what are the effects of using procalcitonin measurement plus clinical criteria for infection to guide initiation, discontinuation, or a change in antibiotic therapy when compared with clinical criteria for infection alone on:*

government. The Internet address for PubMed is http://www.ncbi.nlm.nih.gov/pubmed/. The Boolean logic terms AND, OR, and NOT are used to combine keywords, authors, and terms either to limit or broaden the search strategy. For example, to search the PICOTS question stated above, one could begin by entering the following terms: PCT, infection, and antibiotic therapy.

Resources for searches on diagnostic tests

Although there are numerous databases available electronically, it is important to recognize that the Internet is a dynamic tool. Information can go out of date, links may change, new databases may appear, and so on. Table 16.2 summarizes resources that provide useful information when conducting searches for relevant evidence. Some databases listed here are free and some are provided at a cost; also, some databases are from a single source, whereas others are combined resources. Consulting experts in library science as well as the particular field of interest can assist in finding potentially useful information. Further, unpublished studies may be located by examining bibliographies of identified articles and literature from governmental institutions.

Approaches to evidence-based laboratory medicine—types of analyses

As mentioned earlier, EBLM has components before and after the clinician–patient interaction and is a separate branch of EBM pertaining to the use of laboratory tests to improve patient outcomes. Diagnostic tests are frequently released for clinical use without adequate assessment of clinical effectiveness. Furthermore, the rising costs of health care and the ease of quantifying laboratory processes make it even more imperative to ensure that resources are used most efficiently with the best clinical evidence. Given the importance of health outcomes, the availability of tools and resources devoted to evidence-based practice and EBLM has steadily evolved from opinion-based narrative reviews to objective, structured systematic reviews (SRs). Before searching for evidence, it should be noted that there is a hierarchy of evidence that needs to be considered (Table 16.3). Randomized controlled trial (RCT) SRs and meta-analyses are at the top, while expert opinions (narrative reviews) and case reports are at the bottom [5].

SRs are structured, usually more resource-intensive, and use defined methods and strategies to locate, evaluate,

and compile scientific evidence that addresses focused questions about healthcare issues of diagnosis, screening, treatment, monitoring, and preventive services. SRs are frequently prepared by investigators who are not necessarily experts in the field, using a systematic approach incorporating all the elements listed in Table 16.4 as recommended by the IOM to not only minimize bias and random error, so a "minimum level of objectivity, transparency, and scientific rigor is met" [6]. Indeed, the importance of standards are readily apparent when SRs focus on especially high impact questions that affect a broad population while using public resources. This ensures that the quality of SRs is maintained while being scientifically valid, transparent, and reproducible. Proper SR addresses the key questions by limiting the effects of bias, integrating relevant information from available evidence, distilling data to manageable levels, and identifying limitations in methodology. The ultimate goal of SR is to present information that clarifies what is known from what is speculated, identifies sources of

TABLE 16.3 Types of studies and their respective key domains.

Study	Key domains covered	Strengths	Weaknesses	Strength of evidence
Systematic reviews • Meta-analysis	Study question, search strategy, inclusion and exclusion criteria, data extraction, funding or sponsorship	• Strongest form of evidence • Comprehensive summary of multiple studies to answer a research question • Meta-analyses use statistics to evaluate the effectiveness particularly when there are inconsistencies between studies and different sample sizes • Standardization of methodology	• Publication bias (negative results are usually not published) • Low-powered studies may affect the meta-analysis in a negative manner • Potential heterogeneity between studies may lead to inappropriate conclusions	
Randomized controlled trial	Study population, randomization, blinding, interventions, outcomes, statistical analysis, funding, or sponsorship	• Most reliable form of scientific evidence for clinical research • Avoids bias and uses concurrent control group • Premature discontinuation of the study due to significant findings or perceived disadvantages in control subjects, but this will lead to incomplete data collection	• Results may not be reproducible between settings such as patient characteristics, study procedures, outcome measures, and incomplete reporting adverse events • Very expensive and time-consuming • Conflict of interest from commercial sponsors	

Observational studies
• Cohort
• Case-control
• Cross sectional
• Case report
	Comparability of subjects, exposure or intervention, outcome measurement, statistical analysis, funding, or sponsorship	• Cohort studies:
		  • Can help determine risk factors for disease
		  • Longitudinal study to track incidence of disease over time
		• Case-control:
		  • Relatively inexpensive
		  • Shorter than cohort studies
		• Cross sectional:
		  • Very inexpensive
		  • Can provide valuable epidemiological data on whole populations
		• Case reports:
		  • Provide resolutions to rare diseases or conditions and unusual presentation to common diseases
			• All observational studies indicate causal associations, but not true causality
			• Cohort studies:
			  • Expensive to conduct
			  • Prone to loss of active participation
			  • Long timeline delays the collection of data and conclusions	

Diagnostic test studies	Study population, adequate description of test, appropriate reference standard, blinded comparison of test and reference, and avoidance of verification bias	• Specifically focuses on a diagnostic test or testing strategies	• Reference method or true Gold standard may not exist or is not practical to be used as a comparator • Usually only focus on accuracy and cannot link to outcomes

TABLE 16.4 Institute of Medicine Standards for systematic reviews.

Standards for initiating a systematic review

1. Establish a team with appropriate expertise and experience to conduct the systematic review
2. Manage bias and COI of the team conducting the systematic review
3. Ensure user and stakeholder input as the review is designed and conducted
4. Manage bias and COI for individuals providing input into the systematic review
5. Formulate the topic for the systematic review
6. Develop a systematic review protocol
7. Submit the protocol for peer review
8. Make the final protocol publicly available, and add any amendments to the protocol in a timely fashion

Standards for finding and assessing individual studies

1. Conduct a comprehensive systematic search for evidence
2. Take action to address potentially biased reporting of research results
3. Screen and select studies
4. Document the search
5. Manage data collection
6. Critically appraise each study

Standards for synthesizing the body of evidence

1. Use a prespecified method to evaluate the body of evidence
2. Conduct a qualitative synthesis
3. Decide if, in addition to a qualitative analysis, the systematic review will include a quantitative analysis (meta-analysis)
4. If conducting a meta-analysis, then do the following:
   a. Use expert methodologists to develop, execute, and peer review the meta-analyses
   b. Address the heterogeneity among study effects
   c. Accompany all estimates with measures of statistical uncertainty
   d. Assess the sensitivity of conclusions to changes in the protocol, assumptions, and study selection (sensitivity analysis)

Standards for reporting systematic reviews

1. Prepare final report using a structured format
2. Peer review the draft report
3. Publish the final report in a manner that ensures free public access

COI, Conflict of interest.

TABLE 16.5 Types of biases to consider when reviewing the evidence.

Time-lag bias	Often long time required for a study to appear in print
Publication bias	Publication of the same data multiple times
Outcome reporting bias	Some important outcomes are frequently left unreported in publications
Language bias	Virtually all studies are published in the English language, and thus are more likely to be cited and used in systematic reviews
Indexing bias	Higher probability that positive results, published in leading journals, are cited and indexed more frequently in easily accessible search tools (e.g., Medline) compared with negative studies
Population bias	All participants are not equally balanced or objectively represented
Verification bias	Results are not evaluated with the reference or gold standard

inconsistency, aids in development of future research questions, and instills confidence that the review outcome represents thoughtful interpretation of the best evidence. Nevertheless, SRs can be subject to bias, whereby negative findings are less likely to be reported in the literature or inclusion of nonpeer reviewed unpublished studies may lead to overly optimistic conclusions. As a generally accepted practice, it is recommended that the effects of unpublished studies and data on the overall conclusion be evaluated by performing separate meta-analyses with and without the unpublished studies to evaluate consistency. Other biases are summarized in Table 16.5.

SRs incorporate summaries of data whenever possible. Perhaps, the most important of these summaries is termed a meta-analysis, which entails statistical analysis of results from similar but independent primary studies, meeting specific and clearly stated aims and criteria to produce a single overall estimate and uncertainty. The distinction between the SRs and the meta-analysis is important, although both involve the summarization of data. In principle, systematically reviewing a body of data is always appropriate and desirable; however, employment of statistical methods to summarize these results with a meta-analysis can produce a stronger and more objective conclusion. Sometimes, the statistical meta-analysis of pooled data from separate primary studies is not appropriate in all cases, because there is always some measure of heterogeneity with regard to subject inclusion, assay use, and other variables that can yield inappropriate or misleading results. Nevertheless, meta-analysis is performed to summarize the results of multiple studies, and expresses the most accurate reflection of the true effect or risk of a treatment or a test's true performance, addressing a well-defined research question in a homogeneous population of patients. Meta-analysis is considered by many experts to be a scientific endeavor and is used whenever appropriate as a method of summarizing and analyzing data during the performance of an SR. Therapeutic and device trials frequently use meta-analysis to evaluate and better define the effects of interventions. This technique is particularly powerful when there are conflicting results among a set of studies, some of which have large sample sizes. In such cases, analysis of a set of studies that investigates differences in research design may lead to explanations of the conflicting results. Meta-analysis is also helpful when there are inconsistently positive findings in a set of studies, none of which has large sample sizes. In this case, combining the results of several studies may give sufficient sample size and power to help answer a specified question.

Similarly, meta-analyses of test accuracy studies involve the computation of a weighted average of individual study results, which can improve the precision of estimates of test accuracy and reveal differences between the studies that affect test performance. The results are frequently summarized by "Forest plots." An example Forest plot is displayed in Fig. 16.2 for providing data to address the question: Are barcoding practices effective at reducing patient specimen and laboratory testing identification errors? [7]. This example allows the reader to examine the heterogeneity of data from nine studies examining this question. The overall summary effect in the lower portion of Fig. 16.2 provides a better notion of the actual odds ratio and uncertainty to be expected. However, it should be noted that individual biases associated with each study may be compounded and lead to inappropriate conclusions [8].

RCTs are studies in which at least one "test" treatment, intervention, or diagnostic strategy is compared with a control group that receives placebo, a different, or no intervention, or a different diagnostic strategy. RCTs typically enroll patients fitting prespecified criteria; subjects are assigned to receive either the test or control arms of the study by a random process. Patients assigned to

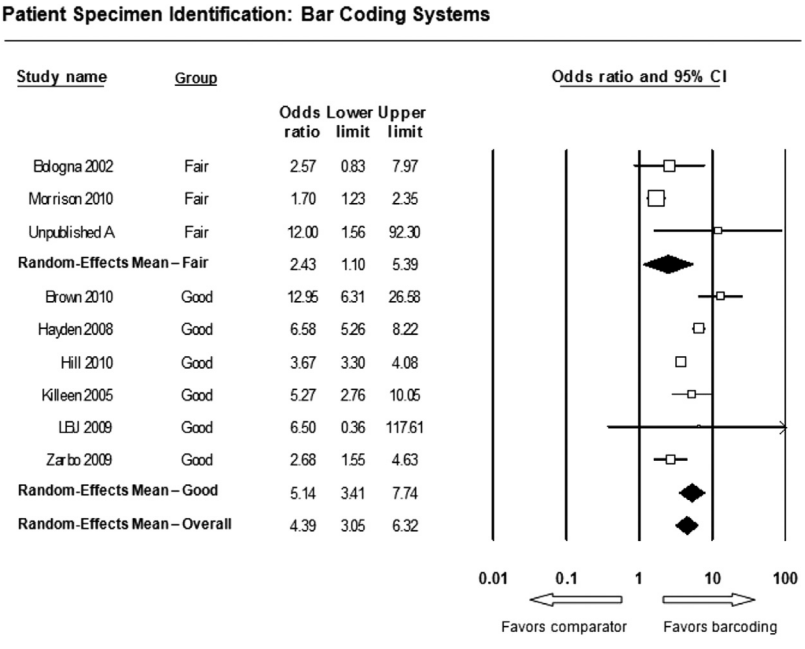

FIGURE 16.2 Forest plot showing the meta-analysis effect size results for barcoding systems practice over the nonbarcoding practice for improving identification error rates indicating a consistent and statistically significant effect. The mean odds ratio for an individual study is indicated to the far left, with the box size is proportional to the study sample size. The endpoints of the lines on the left and right sides of the box represent the lower and upper limits, respectively, of the study odds ratio's 95% confidence interval, with the numerical values provided to the left. The bottom line represents the overall summary effect (or grand mean) for all the studies in the body of evidence along with its confidence interval. In addition, meta-analysis results were tabulated separately for two subgroups using the two study quality ratings "Fair" and "Good." *Source: Reprinted with permission from Clinical Biochemistry and from Elsevier Inc. Copyright 2012 [7].*

either the test or control arms are concurrently enrolled, and there is complete follow-up of both. RCTs are a reliable method for determining whether a treatment, intervention, or diagnostic strategy is different from that in controls. The RCT design is superior for comparing interventions, because it avoids many biases and uses a concurrent comparison group (controls) to compensate for any trends over time. Characteristics of a well-designed RCT include: (1) an appropriate randomization procedure for unbiased allocation of patients to the test or control arm; (2) an appropriately sized sample to provide the statistical power to allow meaningful comparison; (3) an intention-to-treat analysis (results are based on initial treatment assignment and not on the treatment eventually received) that includes all individuals randomized to the test group; and (4) statistical results that include a specific *P*-value with confidence interval. Provided the patient enrollment criteria and aims are similar, data from RCTs may be pooled for meta-analyses to generate a more accurate and precise estimate of the effect of the treatment, intervention, or diagnostic strategy. Indeed, eligibility criteria for patient enrollment such as sex and race of each RCT should be considered when conducting an SR and meta-analysis as they can affect the interpretation.

Observational studies are not designed to alter or influence patient or practitioner behavior. Subjects are monitored either prospectively or retrospectively during their episode of care and no effort is made to change treatment, intervention, or testing strategy. Observational studies provide useful information about care patterns and patient preferences. They are also useful for generating hypotheses for future studies. However, these studies are frequently susceptible to patient-selection bias and may lead to inaccurate conclusions about the comparative benefit of various treatments, interventions, or testing strategies. This is because observational studies may be comparing patient groups with different prognoses due to temporal trends in disease characteristics, diagnostic methods, or supportive care. Observational studies can be described as a cohort, case-control, cross-sectional, or in the most simple form, a case report.

Cohort studies are longitudinal and follow a group (cohort) of people who share a common characteristic such as a disease state, treatment of a drug, or exposure to an environmental agent, and are compared with a group taken from the cohort general population. Cohort studies can be conducted retrospectively or prospectively by studying the group before or after the intervention of interest (e.g., disease state, treatment, and exposure), respectively. Ideally, the cohort is identified before the disease in question in order to determine risk factors (prospective cohort study). Conclusions from cohort studies cannot refer to cause and effect, but can only draw associations from the results. The advantage of cohort studies is that longitudinal observation allows collection of data at regular intervals and can help determine associations and risk factors over the natural history of the disease. By the same token, the disadvantages of cohort studies are due to their long-term framework and associated costs to conduct the research. Case control studies are conducted where the disease condition is already present and the differences between the case group with disease in comparison with a control group without the disease that is similar in all other ways possible (e.g., age, sex, comorbidities, community setting, etc.) are studied to help identify risk factors. In comparison with cohort studies, case control studies are relatively less expensive and shorter in duration and are mainly for explorative analysis. Cross-sectional studies focus on the analysis of data at one specific point in time. While case-control studies are concerned with a particular subpopulation, cross-sectional studies can include descriptive epidemiological data on an entire population at little expense. Case reports are detailed reports on individual cases including clinical presentation, diagnosis, treatment, and follow-up of the patient. Compared with the other studies described above, the case report is considered to be more anecdotal in nature and have significant limitations to objective evidence as it pertains to methodology and statistics. Nevertheless, case reports have useful roles by describing and documenting rare diseases or conditions, and unusual presentations of common diseases.

Diagnostic studies can be either RCTs or observational studies that are designed to establish the performance characteristics of a test or testing strategies. Alternatively, diagnostic studies may also aim at comparing two or more tests or testing strategies. To establish or compare performance, it is necessary to designate a reference method comparator as part of the study design. Performance of a new diagnostic test is ideally evaluated by comparison with a true reference method or "gold standard." In many cases, however, a true reference method does not exist and an imperfect standard must be used. Although statistical methods are well defined for assessing the accuracy of a new diagnostic test compared with a reference method, similar methods are sparse in a setting where a gold standard is unavailable. The challenge is to find a comparator as close as possible to the theoretical reference method, because accurate assessment of a new test may be compromised when an inappropriate reference strategy with its own uncertainty of estimations (e.g., the test is subjective, is histological, or contains findings of no clinical significance, etc.) is used. Further, the use of a reference standard may be limited if the new test is more advanced than the reference, or if the reference test is expensive, invasive, or unethical; while ensuring that the same reference standard is applied to all subjects to avoid bias.

Although diagnostic studies have traditionally focused on accuracy with a reference method, they do not address clinical outcomes. Indeed, RCTs would be ideal by randomizing patients and assessing whether or not the diagnostic test prior to treatment affects patient outcomes. Given that such studies are lacking or inadequate, analytical frameworks have been proposed and devised to include a "linked evidence approach" [9,10]. This analytical framework involves transferring or linking accuracy-based studies to RCTs on treatment effectiveness. Therefore a diagnostic test that is deemed accurate to a reference standard may be considered to be clinically effective if the population receiving the new test would be the same population that receives treatment for the condition. This transferability of the diagnostic study can be especially powerful if the RCT has shown good evidence for positive outcomes. Table 16.3 summarizes key domains that should be covered by SRs, RCTs, observational studies, and diagnostic test studies as well as their strengths and weaknesses.

Although EBLM has now evolved and placed more emphasis on SRs, narrative reviews still have a place in helping practitioners interpret evidence-based information as well as in instances where resources are lacking to perform a proper SR. Narrative reviews are usually written by experts in the field who have a keen interest in the review topic. This keen interest is frequently accompanied by a particular view (or bias) developed over years of study and often through direct involvement in the reviewed topic. On the one hand, narrative reviews can provide detailed insight into a field by an expert investigator and practitioner. On the other hand, narrative reviews are often developed using idiosyncratic methods and data presentation. For this reason, these reviews usually represent a subjective appraisal and qualitative summary of data that support the view of the expert author. Conflicting data are frequently discounted or not included at all. As a result, such reviews typically present a broad "10,000-foot" view about etiology, pathogenesis, diagnosis, clinical management, and the prognosis rather than addressing specific and focused clinical questions. Recognizing that narrative reviews are almost exclusively produced by proponents for test use is important. As such, narrative reviews tend to be subjective and are prone to bias and error, but are still useful for gaining background knowledge about a subject and may help with the dissemination of EBLM.

Indeed, utilization of clinical practice guidelines (CPGs) depends on the four As: physicians must be aware of them, agree with them, adopt them, and adhere to them [11]. Studies have shown that production and dissemination of evidence is not enough to ensure CPGs are put into practice. It has been suggested that there are leaks or barriers in the pipeline encompassing the four As, thus leading to diminished adherence and that proper investigation into each stage of CPG utilization is needed [12]. For proper success of guideline implementation, it is important to assess awareness, agreement, adoption, and adherence by clinicians through questionnaires and actual clinical practice audits, while further studying the causes of diminished adherence or increased barriers.

Critical appraisal of evidence

Critical appraisal is the systematic evaluation of clinical research papers to determine: (1) if the study addresses the question of interest in a focused way; (2) if valid methods were used to address the question; (3) if valid, are the study's results important to answering the question?; and (4) are the results applicable to the relevant patient or population? Fortunately, there are tools available for use in the Critical Appraisal process; a good example of these tools can be accessed at the Centre for Evidence-Based Medicine portal at http://www.cebm.net/critical-appraisal/. Here "Worksheets" in a checklist format have been developed that are specific for evaluating the type and design of study being assessed, that is, separate tools for diagnostic studies, SRs, prognostic studies, and therapeutic/RCTs. The worksheets guide the appraiser through the process with a series of steps. For example, for studies dealing with diagnostic questions, Step 1 assesses a series of items that address: are the results of the study valid?; Step 2 has items regarding: What were the results?; and Step 3 evaluates the applicability of the results (full listing of the diagnosis study tool is available at http://www.cebm.net/wp-content/uploads/2014/04/diagnostic-study-appraisal-worksheet.pdf).

Critical appraisal is frequently accomplished by a single individual whose goal is evaluation of evidence, addressing a question relevant to a local case or issue. However, when conducting SRs, typically two or more appraisers independently examine each source of evidence using a common assessment tool and scoring system. Table 16.6 displays such a scoring system that is used for assessment of evidence in the CDC's Laboratory Medicine Best Practice program [2]. Training of the appraisers is necessary to assure harmony in the criteria and reviewing methodology. Moreover, criteria must be established that defines when appraisers' scores are "discrepant" and explicitly states how discrepancies are resolved.

Critical assessment is also a task undertaken when deciding if a developed guideline should be championed or adopted/adapted by an institution, group, or professional organization. While a number of guideline appraisal tools are available, the second edition of the Appraisal of Guidelines for Research and Evaluation (AGREE) instrument [13] has been widely utilized by many clinical

TABLE 16.6 Summary table format for rating the body of evidence table.

and laboratory societies. The AGREE system addresses 23 key points that should be included in guidelines and the quality score of each. An analysis of using the AGREE II instrument has recently been published [14]. Whether the scope of a clinical question is on the individual, institutional, national, or international level, thoughtful and methodical critical assessment of the body of evidence is essential for ensuring the validity, significance, and relevance in the EBLM process.

Another tool intended to guide investigators in reporting studies of the diagnostic accuracy of laboratory tests and critically evaluate studies to detect bias is a checklist developed from the Standards for Reporting of Diagnostic Accuracy (STARD) initiative and STARD statement [14–16]. In this initiative, several editors of leading scientific and clinical journals reached a consensus statement on what elements regarding the performance of a laboratory test should be reported in studies of diagnostic accuracy. Since publication of the initial STARD statement, this initiative has led to significantly greater standardization in how laboratory test diagnostic accuracy studies are reported. An updated STARD checklist of essential items for reporting diagnostic accuracy studies was recently published [15]. This 2015 STARD checklist includes nearly 35 elements for reporting studies on the diagnostic accuracy of laboratory tests in the sections of title, abstract, introduction, methods, results, and discussion and for other information (Table 16.7). It is recommended that all studies on diagnostic accuracy should use the STARD checklist. One noteworthy point with the 2015 STARD document is that it mainly focuses on the validity of analysis. Appraisers must also evaluate the preanalytical and postanalytical aspects of the study, because these phases are most susceptible to error and are not included fully in the STARD checklist. In addition, readers may use the STARD checklist to assess the potential for bias and validity of the study conclusions.

Using the evidence to develop clinical practice guidelines

Clinical practice guidelines

Development of CPGs is a critical activity in using evidence to affect the practice of laboratory medicine and enhance the quality of patient care. CPGs provide statements that inform healthcare providers on how best to use evidence to make appropriate clinical decisions in specific patient care situations with a goal of optimizing the impact of guideline recommendations on patient outcomes in a way that is intended to improve patient care. Additional important goals for developing and using CPGs include the aim to disseminate best practice based on scientific evidence; decrease practice variation and the potential or frequency of professional misconduct; improve patient safety; improve the quality and effectiveness of care; improve cost-effectiveness of care; facilitate training, education, and continuous professional development; and increase explicitness, transparency, patient information, and autonomy of choice [17]. In laboratory medicine, guidelines also aim to improve the appropriateness of test utilization [18], an issue of growing significance for healthcare providers including clinical laboratory professionals.

While the developers of CPGs generally intend to achieve all or most of the above goals, experience has proven that there is a significant amount of variability from one CPG development group to another and even among a single CPG development group over time working on different CPGs. Fortunately, as more issues, variations and inconsistencies have been identified, numerous resources and tools have been created, developed, and refined toward standardizing CPG development processes and ensuring a higher likelihood that CPGs are developed in accordance with the best practices in guideline development. In recent years, these issues have been addressed

TABLE 16.7 Standards for reporting diagnostic accuracy studies: questions that should be addressed by a good diagnostic study.

Section and topic	#	Item	On page #
Title or abstract			
	1	Identification as a study of diagnostic accuracy using at least one measure of accuracy (such as sensitivity, specificity, predictive values, or AUC)	
Abstract			
	2	Structured summary of study design, methods, results, and conclusions (for specific guidance, see STARD for Abstracts)	
Introduction			
	3	Scientific and clinical background, including the intended use and clinical role of the index test	
	4	Study objectives and hypotheses	
Methods			
Study design	5	Whether data collection was planned before the index test and reference standard were performed (prospective study) or after (retrospective study)	
Participants	6	Eligibility criteria	
	7	On what basis potentially eligible participants were identified (such as symptoms, results from previous tests, and inclusion in registry)	
	8	Where and when potentially eligible participants were identified (setting, location and dates)	
	9	Whether participants formed a consecutive, random, or convenience series	
Test methods	10a	Index test, in sufficient detail to allow replication	
	10b	Reference standard, in sufficient detail to allow replication	
	11	Rationale for choosing the reference standard (if alternatives exist)	
	12a	Definition of and rationale for test positivity cutoffs or result categories of the index test, distinguishing prespecified from exploratory	
	12b	Definition of and rationale for test positivity cutoffs or result categories of the reference standard, distinguishing prespecified from exploratory	
	13a	Whether clinical information and reference standard results were available to the performers/readers of the index test	
	13b	Whether clinical information and index test results were available to the assessors of the reference standard	
Analysis	14	Methods for estimating or comparing measures of diagnostic accuracy	
	15	How indeterminate index test or reference standard results were handled	
	16	How missing data on the index test and reference standard were handled	
	17	Any analyses of variability in diagnostic accuracy, distinguishing prespecified from exploratory	
	18	Intended sample size and how it was determined	
Results			
Participants	19	Flow of participants, using a diagram	
	20	Baseline demographic and clinical characteristics of participants	
	21a	Distribution of severity of disease in those with the target condition	
	21b	Distribution of alternative diagnoses in those without the target condition	
	22	Time interval and any clinical interventions between index test and reference standard	
Test results	23	Cross tabulation of the index test results (or their distribution) by the results of the reference standard	
	24	Estimates of diagnostic accuracy and their precision (such as 95% confidence intervals)	
	25	Any adverse events from performing the index test or the reference standard	
Discussion			
	26	Study limitations, including sources of potential bias, statistical uncertainty, and generalizability	
	27	Implications for practice, including the intended use and clinical role of the index test	
Other information			
	28	Registration number and name of registry	
	29	Where the full study protocol can be accessed	
	30	Sources of funding and other support; role of funders

as a top priority in the United States. Through the 2008 *Medicare Improvements for Patients and Providers Act*, Congress requested that steps be taken to implement recommendations from an IOM report on *Knowing What works in Health Care*. This, in turn, led to Congress commissioning the Secretary of the Health and Human Services to authorize the IOM to develop two evidence-based methodological standards—one on the development of CPGs and the other on standards for conducting SRs.

Best practices in guideline development

The IOM published *Clinical Practice Guidelines We Can Trust* in 2011 [19]. This report may be the single most comprehensive and authoritative resource presently available to those who intend to develop CPGs using the best practices that are presently recognized. Despite the variations in guideline development, which have long been recognized, particularly as numerous clinical organizations have developed their own procedures and processes for guideline development, the IOM report is built on a framework of standards for developing trustworthy CPGs. The eight critically important standards are listed in Table 16.8.

It may not always be possible to address every IOM standard in the development of a CPG. But the body of evidence regarding best practices in guideline development underscores that CPG developers should work toward significant adherence to these standards to the greatest extent possible. In fact, there is presently an abundance of resources and information available to developers of CPGs. Many professional organizations and societies have established guideline development policies and processes based, in large part, on the IOM report and standards with the end product being a standard operating procedure (SOP) for developing guidelines. Another group providing a wealth of resource information on guideline development is the Guidelines-International-Network (G-I-N). The G-I-N library contains many resources and materials that can be accessed at http://www.g-i-n.net/library.

Steps in guideline development

The first step in the development of any CPG is to select the topic of focus as well as how the subject area will be identified and refined. CPGs in the field of laboratory medicine can address diseases or conditions, symptoms, signs, or procedures (either therapeutic or diagnostic interventions), including the utility of tests for screening and monitoring. After identification of the exact area to be addressed, refining the scope of the guidelines should

TABLE 16.8 Institute of Medicine standards for developing trustworthy clinical practice guidelines.[a,b]

IOM Standard	Explanation
1. Establishing transparency	The process for guideline development including any sources of funding must be transparent, public, and fully disclosed
2. Management of COI	COI must be declared prior to CPG developing groups being formed. Leaders of these groups should not have any real or perceived COI. Sources of CPG funding must not influence the content of CPGs
3. Guideline development group composition	CPG group composition should be multidisciplinary including all stakeholders as well as patients and, if applicable, consumers
4. CPG—systematic review intersection	To the greatest extent possible, CPGs should be based on systematic reviews s that have been developed in accordance with recognized best practices
5. Establishing evidence foundations for and rating strength of recommendations	Recommendations should have clear descriptions of potential harms and benefits with a summary of evidence for each. Strength of evidence and strength of recommendations must be graded with differences of opinion explicitly stated
6. Articulation of recommendations	Recommendations must be clear and unambiguous in such a way as to allow full evaluation of compliance
7. External review	Draft CPGs should be provided to all relevant key stakeholders including the public for external review. CPG developers should record and address all comments regarding whether the issues raised were incorporated or not in the final CPG recommendations
8. Updating	Dates for the systematic review, CPG final publication, and future updates of the CPG should be documented in the initial final CPG. CPG developers should have a process identified for regular review of new evidence that could modify or alter future recommendations

COI, Conflict of interest; *CPG*, clinical practice guidelines; *IOM*, Institute of Medicine.

follow. What are the critical issues to be addressed and which ones can be omitted? Which issues are important clinically? Where do laboratory professionals or clinicians using the laboratory need guidance? Does the group developing the guidelines have enough expertise or should others be brought on board?

The initial step in the formation of the guideline development group is to select a chair and usually a co-chair or vice-chair. The composition of the group overall should include experts on the procedures and conditions from areas of laboratory medicine and clinical practice relevant to the focus of the CPG subject matter. Additional experts may be included to bring supplementary expertise in special areas such as statistics, appraising of evidence, and implementation of guidelines. Staff members from involved clinical organizations may be available to the group to assist in retrieving evidence, organizing meetings of the group, and coordinating publication of guidelines. When more than one organization or society collaborates on the development of a CPG, it is imperative that every organization involved have at least one member of the guideline development group. As noted in the IOM standards, a representative from the public or, if applicable, the consumer base is also desirable. All members of the guideline development group should fully disclose any potential conflict of interest (COI) in the earliest stages of the group's efforts. Chairs and vice-chairs of groups developing CPGs must not have any COI.

CPGs should be based on an SR of the literature with the provision of criteria for identifying the quality of the evidence and the strength of each recommendation. An established, clear, explicit, and transparent system for grading the recommendations and weighting the evidence must be preestablished. Recommendations established by consensus are acceptable as long as this approach is explicitly described and those recommendations of relevance clearly identified. However, before any SR is initiated, the CPG development group must define the CPG topic and focus including potential approval by an oversight leadership group in one or more professional societies.

Fundamentals for conducting a solid, evidence-based SR are described in several resources including the IOM report on conducting SRs [6]. The CPG group must identify the background for the search, the key question(s) based on PICOTS criteria, and the analytic framework for how the literature search process will address the PICOTS elements including the specification of outcomes to be evaluated. Other issues the CPG development group will likely need to address include defined conditions and target populations and identification of the primary target audience for which the CPG is intended. Many other issues must be addressed. But some of the most significant issues to consider are the impact of the evidence report on technology assessment and associated costs to the healthcare system, how the impact of the CPG recommendations will be monitored, and, typically, what the budget and timelines are for CPG development.

It is recommended that guidelines be reviewed by experts in the clinical content area, experts on systematic reviewing and guideline development, and potential users of the guidelines. Because guidelines become outdated in time, determining a date when the guidelines will be reviewed and updated is important. Alternatively, "living guidelines" where systematically developed and evidence-based recommendations are updated as evidence becomes available can be considered. The establishment of guidelines also provides a thorough review of data on the utility of a test, the way in which the test may be used clinically, and the benefit derived from its use. The holistic nature of a guideline also helps to identify the way in which practice may need to change when implementing a novel test or intervention. A guideline also provides an overview of the quality of the evidence, which indicates the robustness of the data on effectiveness of a test and how wide the applicability of the test might be in different clinical settings. Much of the material for a guideline will have been generated from the SR of the peer-reviewed literature. However, guidelines must allow for potential applications that are unsupported by evidence, because primary studies are not always available to answer every clinical question

Additional resources for developing clinical practice guidelines

The 2011 IOM report is presently one of the most comprehensive resources available to those developing CPGs. The largest source of laboratory medicine practice guidelines (LMPGs) is also available on the website of the Academy of the American Association for Clinical Chemistry (AACC), formerly named the National Academy of Clinical Biochemistry (http://www.nacb.org). While most of the Academy's earlier efforts are now archived, guidelines are available at this website such as those focusing on the use of tumor markers in selected cancers, and laboratory analysis and application of pharmacogenetics in clinical practice, pain management, biomarkers of cardiac disease, and diagnosis and management of diabetes mellitus.

Another resource found on the AACC's Academy website is a recently revised SOP for preparing, publishing, and revising LMPGs or CPGs. It also includes procedures for review and approval of external society/organization guidelines for endorsement and support by AACC and its Academy. Additional selected useful

resources for developing CPGs including the AACC Academy SOP are listed in Table 16.9. While this list is not intended to identify all resources available, tools such as GRADE, Guideline Implementability Appraisal, AACC's Academy SOP, STARD, Preferred Reporting Items for Systematic Reviews and Meta-Analyses, and AGREE II are well-recognized tools in the field of CPG development, particularly for guidelines relating in some manner to the use of clinical laboratory tests. The strengths and limitations of AGREE II are specifically discussed in the 2011 IOM report. Several CPG developers, including the AACC Academy, presently use the AGREE II resource to improve their guidelines while in development with a goal of striving for best practices.

Implementation of clinical practice guidelines

As stated previously, there are leaks or barriers in the CPG pipeline and for proper success of guideline implementation, and it is important to assess awareness, agreement, adoption, and adherence by healthcare practitioners. Indeed, production of good quality CPGs does not guarantee the implementation of best practices. Thus more focus must be put on guideline use instead of solely on guideline development. Guideline adaptation can be done in four possible ways: (1) adopting the recommendations without modification; (2) adapt recommendations to a new context; (3) develop recommendations de novo based on existing reviews of evidence; or (4) develop recommendations de novo based on new evidence [21]. It is often that the recommendations from guidelines that pertain to public health are more difficult to implement since this includes the use of entire health-care systems and many stakeholders [21]. Thus it is important to account for the local context for successful guideline implementation.

Given the barriers to implementation, current movements now recognize that guideline adaptation is more defined as a systematic approach to considering the use and/or modification of CPGs produced in one cultural and organizational setting to be applied in another different context [22,23]. In other words, adaptation is an extension of guideline development, whereby the existing CPG is customized to ensure the recommendations are suited to the local needs, priorities, legislation, policies, and available resources. Adaptation of guidelines can occur either formally or informally. Informal adaptation occurs without an established framework and may include at an institutional level where guidelines are adapted according to the AGREE instrument [21]. Informal adaptation can also occur on an individual basis where the healthcare provider adapts practice guidelines according to individual patient needs and resources such as the availability of certain laboratory tests or therapy [21]. The disadvantage of informal adaptation is that it can veer significantly outside the scope of the original recommendation. On the other hand, informal adaptation is performed according to an established framework to address the complexity, increase the rigor of review, and enhance the quality of the adapted guideline. To address these needs, the ADAPTE collaboration was born of two independent groups focusing on guideline adaptation: the ADAPTE group and the Practice Guideline Evaluation and Adaptation Cycle. The ADAPTE collaboration convened as an international collaboration of researchers, guideline developers, and guideline implementers to promote the development and use of CPGs through the adaptation of existing guidelines.

The main objective of this group was to develop and validate a generic user-friendly adaptation process that maintains the validity and high quality of the adapted CPGs as well as promote the users' sense of ownership of the adapted CPG. The ADAPTE manual includes a stepwise approach to guideline adaptation (Table 16.10), and there is an active focus on the barriers to guideline implementation and facilitating factors. Although the ADAPTE method employs a more formative, instead of prescriptive, approach, it should be realized that guideline implementation is a long process taking more than years in some cases and more complex than anticipated, particularly in the absence of guideline methodology and facilitation

TABLE 16.9 Additional resources for developing clinical practice guidelines.

Tool and link	Purpose
AACC Academy SOP (http://www.nacb.org)	Standard operating procedures for developing LMPGs
STARD 2015 (Ref. [15])	Updated checklist for studies on the diagnostic accuracy of laboratory tests
GRADE (http://www.gradeworkinggroup.org)	Grading the strength of evidence and recommendations
GLIA (http://nutmeg.med.yale.edu/glia)	Useful procedures and information for implementation of guidelines
AGREE II (www.agreetrust.org/) (also Refs. [13,14,20])	Useful tool for critical appraising guidelines in development and in their final stage addressing several IOM standards

support [21,24]. This is particularly important for groups that are newly formed and that are inexperienced in undertaking guideline adaptation and implementation planning. Nevertheless, a major benefit of guideline implementation is that this process engages front-line care workers and allows them to take ownership of the best practices and recommendations outlined in the CPGs [24]. Given the difficulties of guideline implementation, the CAN-IMPLEMENT framework has recommended that this process should address: (1) engagement and capacity building; (2) adaptation of a high-quality CPG; (3) the continuum of evidence-informed practice (as opposed to an episodic activity); and (4) a planned-action framework as a roadmap to embed properly and effectively guideline adaptation [24].

Implementation of evidence-based guidelines can lead to better patient outcomes by helping healthcare professionals to adopt best practices and assist policymakers in designing effective programs. It is estimated that 30%–40% of patients receive treatment that is not based on scientific evidence and that 20%–25% receive treatments that are not needed or potentially harmful [25]. Therefore the proper implementation of CPGs must be considered or else risk patient harm. Furthermore, proper implementation of CPGs according to established frameworks can prevent the waste of financial and human resources that are consumed in the development of guidelines. However, there remain several gaps in knowledge about guideline implementation. It is relatively unknown how adaptation of guidelines differs between countries with differences in economic development, since low-income countries may have limited resources. Formal frameworks have not been adequately evaluated in terms of their quality and have been mostly subject to subjective self-administered evaluations. Furthermore, formal evaluations have not been done to determine whether methodological experts could improve the adaptation framework. It is also unclear whether the expedited approach to adapt guidelines is worth the expense and whether this can affect the validity of the resultant recommendations of the original guideline. Finally, formal frameworks are in need of a process that advises guideline developers on how to implement the guideline.

Metrics for evaluating diagnostic laboratory tests

Measures of diagnostic accuracy

(Some concepts included in this section are also covered in Chapter 2: Statistical methods in laboratory medicine, and Chapter 4: Method validation, and the reader is directed to these sections for further reference.)

Diagnostic specificity and sensitivity are two common statistical indices that have been defined to aid in the evaluation of qualitative or quantitative tests. Sensitivity of a test is defined as its ability to make a positive diagnosis in patients who have the target disease. Specificity of the test is defined as its capability to make a negative diagnosis in patients who do not have the target disease. Both sensitivity and specificity are commonly expressed as percentages or decimals. As illustrated in Table 16.11, the sensitivity of the test is the number of true-positive results divided by the total number of cases with a confirmed presence of the disease. Specificity of a test is the number of true-negative cases divided by the total number of cases with confirmed absence of the disease. Frequently, sensitivity, and specificity are considered to be independent of the disease prevalence within a population. In reality, however, this supposed independence is not strictly true, because the definition of a clinical question often specifies the presence of clinical variables such as signs and symptoms. In even a slightly different population, for example, an urban versus a rural setting, sensitivity, and specificity may vary, because the proportion of false negatives and/or false positives may be different.

TABLE 16.11 2 × 2 contingency table for evaluating accuracy of diagnostic tests.

Result	Disease present	Disease absent	Total
Test positive	TP	FP	TP + FP
Test negative	FN	TN	FN + TN
Total	TP + FN	FP + TN	TP + FN + FP + TN

Notes: Sensitivity = TP/(TP + FN); specificity = TN/(TN + FP); positive predictive value = TP/(TP + FP); negative predictive value = TN/(TN + FN). *FP*, False-negative; *TP*, true-positive.

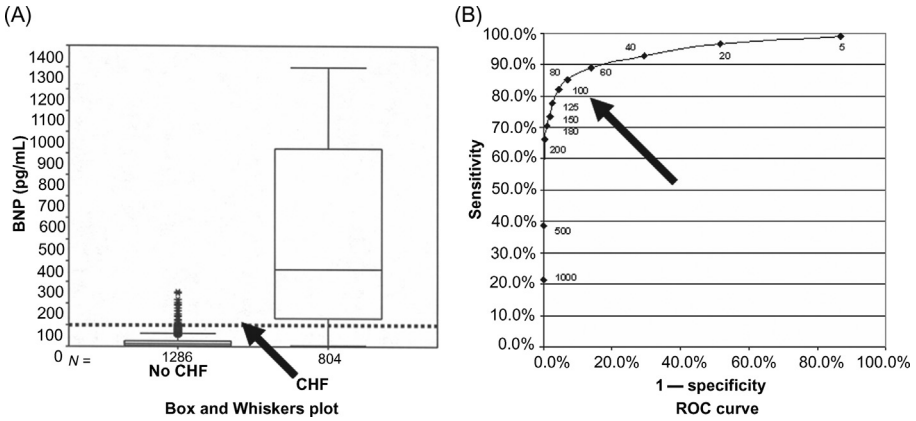

FIGURE 16.3 (A) Box and whiskers plot showing patients with target condition (congestive heart failure) and no disease (no congestive heart failure). The top of the box is the 75th percentile of data, and the bottom of the box is the 25th percentile. The line in the box is the median, and the error bars represent the range of data. (B) Receiver operating characteristic curve. Receiver operating characteristic curves are used to show the pattern of sensitivities and specificities when the performance of the test is evaluated at several diagnostic thresholds. The overall diagnostic performance of a test can be evaluated by examining the area under the curve. The *arrow* indicates the decision point that corresponds to the arrow at the cutoff point line in Panel A. This decision point yields the least number of false positives and false negatives.

Positive predictive value (PPV) and negative predictive value (NPVs) are also important performance characteristics. PPV expresses the probability that a patient has a target disease given that the test's result is positive [TP/(TP + FP)]. NPV expresses the probability that a patient does not have the target disease given that the test's result is negative [TN/(TN + FN)]. (See a more detailed discussion calculation in Chapter 2: Statistical methods in laboratory medicine.) PPV and NPV are parameters that are usually of interest to clinicians, because the following questions are frequently relevant: "What is the probability that the patient has the target condition when the test is positive (PPV)?" and/or "How often does a negative test result rule out the target condition (NPV)?" PPV and NPV depend on the prevalence of disease in the population examined. Although sensitivity and specificity of the test for the target condition may be high, the performance of the test for answering the clinician's question about the meaning of a positive test result may be poor if the disease prevalence is low. This is because a disproportionate number of positive results will be false-positives, and the positive result may not confer a high probability of the target condition. The dependence of predictive value on disease prevalence often confounds translation of clinical trial results and the test performance in clinical practice. Thus results of clinical trials should be considered the most optimistic performance of the test, because the disease prevalence and "all-comers" population specifics in "real-life" practice may not exactly match that in the trial.

Receiver operating characteristic curves

Receiver operating characteristic (ROC) curves are a plot of sensitivity on the *y*-axis versus (1 − specificity) on the *x*-axis, as shown in Fig. 16.3B. ROC curves always confer a binary outcome, for example, "yes" or "no" for a diagnosis, "yes" or "no" for an adverse event, "alive" or "dead" as an outcome, and so on. ROC curves reflect the performance of a test by evaluating the sensitivity and specificity of the binary outcome at a continuum of diagnostic thresholds or cutoffs from the actual plot of data (Fig. 16.3A). The overall performance of the test can be determined from the area under the ROC curve (Fig. 16.3B). Poor or useless tests have ROC curve areas close to 0.50, and the plot appears as a diagonal where sensitivity = 1 − specificity. For an excellent test, the

ROC curve rises steeply and passes close to the upper left-hand corner; the perfect test has an area of 1.0, where both the sensitivity and specificity are 100%. ROC curve areas should always be reported with a confidence interval around the area's value; commonly, the 95% confidence interval is utilized.

ROC curves are particularly useful for comparing the performance of two tests; this is done by running the tests on a single cohort of patients, and the test showing a significantly larger area is the better test. If there is no significant difference between the two, then diagnostic performances of the tests do not differ in their ability to predict the outcome. In SRs, summary ROC curves are used to display the results of a set of studies. In such plots, the sensitivity and specificity from each study are plotted as a separate point on the summary ROC curve.

Likelihood ratios

After formulating a clinical question—for example, "Does my patient have a target diagnosis?"—the clinician must estimate the pretest probability. Pretest probability and the pretest odds are both directly related to the prevalence of the target condition in patients showing similar signs and symptoms according to the following expression:

$$\text{Pretest probability} = \text{Prevalence of the target condition} \tag{16.1}$$

To convert into pretest odds,

$$\text{Pretest odds} = \frac{\text{Prevalence}}{1 - \text{Prevalence}} \tag{16.2}$$

Clinicians request laboratory medicine services after the pretest probability has been estimated, to assist in either raising or lowering the likelihood that the target condition is the diagnosis for their patients. This is done by determining the likelihood ratio, which is calculated to add insight into how likely it is that the patient has the target condition if the test is positive (positive-likelihood ratio) or how likely it is that the condition can be ruled out if the test is negative (negative-likelihood ratio). For practical purposes, the positive or negative likelihood ratios can be easily derived from diagnostic sensitivity and specificity according to the following.

$$\text{Positive} - \text{Likelihood ratio} = \frac{\text{Sensitivity}}{1 - \text{Specificity}} \tag{16.3}$$

$$\text{Negative} - \text{Likelihood ratio} = \frac{1 - \text{Sensitivity}}{\text{Specificity}} \tag{16.4}$$

The positive-likelihood ratio is interpreted as the likelihood that the patient has the target condition if the test is positive. The negative likelihood ratio is interpreted as the likelihood that the patient has the target condition if the test is negative.

The posttest odds of the patient having the target condition can be estimated once either a positive or negative test result is known, and the respective likelihood ratio calculated.

$$\text{Posttest odds} = \text{Pretest odds} \times (\text{Positive or negative}) \text{ likelihood ratio}$$

The posttest probability for the presence of the target condition if the test was positive or negative can be estimated from the following:

$$\text{Posttest probability} = \frac{\text{Posttest odds}}{1 + \text{Posttest odds}} \tag{16.6}$$

When positive, an excellent test will improve the pretest probability to a posttest probability value approaching 1.0 for target condition; when negative, the test will virtually rule out the condition. In practice, few laboratory medicine tests achieve excellent performance.

An excellent tool to facilitate determination of posttest probabilities is termed the Fagan nomogram [26] and is displayed in Fig. 16.4. This diagram allows simple conversion by simply connecting a line from the pretest probability (or prevalence) through the likelihood ratio (positive or negative, depending on the test result) to estimate the posttest probability.

Test as a probability modifier: example

A clinician asks "What is the probability that my patient with dyspnea in an emergency department (ED) setting has a diagnosis of congestive heart failure (CHF) if the B-type natriuretic peptide (BNP) test is negative?" Given that the prevalence in the ED population is 25%, the pretest odds = prevalence / (1 − prevalence) = 0.25/0.75 = 0.33. If the sensitivity of BNP for CHF in ED patients with dyspnea is 93% and the specificity is 85%, then the negative likelihood ratio = 0.07 / 0.85 = 0.08. Thus the posttest odds = pretest odds • negative likelihood ratio = 0.33 × 0.08 = 0.026. Converting posttest odds into posttest probability = posttest odds / (1 + posttest odds) = 0.026 / (1 + 0.026) = 0.025.

Thus only ∼2.5% of patients with dyspnea in the ED with a negative BNP test will have a diagnosis of CHF. Use the Fagan pretest/posttest probability nomogram in Fig. 16.4 to check this posttest estimation.

Is the test cost-effective?

There are three main approaches in health economic evaluations: cost−benefit analysis (CBA), cost-effectiveness analysis (CEA), and cost−utility analysis (CUA).

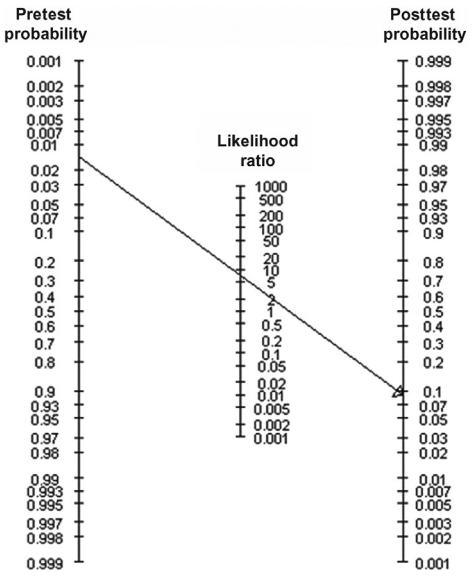

FIGURE 16.4 Fagan pretest/posttest probability nomogram [26]. To determine posttest probability, connect a line from the pretest probability value through the likelihood ratio for the diagnostic test and extending to the intersection with the right-hand axis to estimate the posttest probability. As an example, a line has been connected for a test with a pretest probability of 0.015 through a likelihood ratio of 7.5 to estimate the posttest probability of 0.1.

Although all three approaches require measurement of both cost and benefit, they differ in how effectiveness is measured and whether or not effectiveness is valued in terms of money.

Cost–benefit analysis

The goal of CBA is to determine whether the benefits of an intervention exceed its costs. CBA is suited to answering the question "Is the intervention worthwhile?" One challenge of CBA is that health outcomes must be valued by assigning a dollar amount to a year of life. Valuation of health benefits may be achieved by using the human capital approach, where the value of an intervention is based on the impact on a person's productivity and the value of earning based on wage rates. Alternatively, valuation of health benefit can be achieved through the willingness-to-pay (WTP) approach, in which respondents to surveys are asked to state the maximum amount they are willing to pay for an intervention, illustrated in the example below [27]:

> *Scenario*: Assume that your risk of cervical cancer death is the same as a woman living in Pennsylvania and screened regularly (1 in 37,000). By having the new Pap test, the risk of dying from cervical cancer is reduced to 1 in 50,000.
> *Question*: What is your WTP out-of-pocket for the new Pap smear test?
> *Choices*: \$0, \$200, \$300, \$400, \$500, \$600, \$700, \$800, \$900, \$1000.
> *Responses*: 175 females, average age 39 years, mean WTP \$237.00.

Cost-effectiveness analysis

CEA is aimed at answering the question "Given a fixed budget, what is the most efficient way (maximizing effectiveness) to spend it?" In CEA, effects are measured in one single metric that is a natural unit. Cost-effectiveness could be measured in the cases of disease averted or change in a physiologic measure. A preferred metric is the one that can be used to compare across diagnostic tests for different diseases. For example, life years or survival is a long-term, downstream measure of outcome that can be used to compare a new liquid-based cytology test for cervical cancer screening [28] and fecal occult blood testing for colorectal cancer screening [29]. The incremental cost per life year saved by using the new technology for cervical cancer screening was approximately \$147,000 with triennial screening [28]. Because the outcome measure metric is cost per life year saved, the cost-effectiveness of cervical cancer screening can be compared directly with the cost-effectiveness of colorectal cancer screening at \$92,000 per life year saved for annual fecal occult blood testing plus sigmoidoscopy [29].

Cost–utility analysis

In this approach, an attempt is made to consider the quality of the health outcome in addition to the quantity of the health outcome. Thus years of life in states less than full health are converted into healthy years based on health-state preference values. The result is usually expressed as quality-adjusted life years [30].

Economic evaluations provide the tools necessary to shift the way practitioners think about diagnostic tests and their value in the context of competing demands for healthcare dollars. An economic evaluation requires the identification, measurement, and valuation of the clinical benefits of a new intervention and the associated costs. There are well-accepted criteria for assessing economic evaluations that also apply to economic evaluations of diagnostic tests, and studies should be critically reviewed and planned using these criteria as a guideline [31].

Using clinical laboratory medicine data for decision-making

In the practice of laboratory medicine, a multitude of factors and considerations contribute to the value of laboratory test results. These well-known factors include the prevalence of disease in the population as well as the technical performance, diagnostic accuracy, and other considerations that largely focus on the laboratory test

itself. Furthermore, within the context of EBLM, this hierarchy of factors should always start with an appropriate clinical question that provides a focused framework for the assessed use of the laboratory test.

Consistent with the IOM's six aims for health care, a laboratory test result realizes its fullest potential and value when it truly affects patient-centered care, that is, there is a measurable impact on patient outcomes. Years ago, performing a laboratory test that was analytically robust with excellent diagnostic sensitivity and specificity would usually be sufficient for adequate reimbursement from most payers. But presently, while these factors are still requisite characteristics of a laboratory test, a growing awareness in providers and payers alike is that this same laboratory test result has considerably more value when it affects patient outcomes. As a result, the recently changing landscape of health care has defined a new paradigm for how the value of a laboratory test should be viewed. This paradigm can be illustrated in the laboratory test value-based pyramid depicted in Fig. 16.5.

As shown in Fig. 16.5, a laboratory test's technical performance, diagnostic accuracy, and appropriate clinical use remain fundamentally important. Furthermore, conducting various types of reviews of relevant laboratory medicine studies through appropriate practices is still required to produce significant EBLM recommendations. But these recommendations become even more significant when they can demonstrate or lead to showing how the laboratory test changes clinical practice and affects patient outcomes. The importance of patient outcomes was addressed in the Affordable Care Act through the creation of the Patient-Centered Outcomes Research Institute (PCORI). The purpose of PCORI was to help patients, clinicians, and policymakers make well-informed decisions about health care considering findings from comparative effectiveness research studies [32]. More information about PCORI can be found at www.pcori.org.

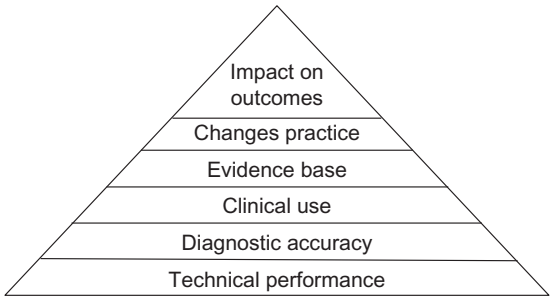

FIGURE 16.5 The laboratory test value-based pyramid. The value of a laboratory test still rests on the foundation of technical performance and diagnostic accuracy as well as appropriate clinical use. Ideally, these characteristics lead to the building of a robust evidence base. But in today's healthcare environment, the greatest value of a laboratory test is only fully realized if use of the test as supported by the evidence base changes practice and impacts patient outcomes.

But the critical importance of changing clinical practice and impacting patient outcomes sets a higher bar for even the most robust EBLM studies and activities. In the present healthcare environment, it is more important than ever to be able to translate the evidence into action. If successful in this effort, the final step is to understand and be able to use the presently available quality indicators and metrics that are applicable to the laboratory test value context being considered.

From evidence to action: changing clinical practice and improving outcomes

Translating evidence into action is highly valued although how best to address many challenges remains an area of discussion and further investigation. Evidence that affects clinical practice comes from health research that is adequately funded in order to translate knowledge into evidence-informed practices and policy [33]. For the effective practice of patient-centered laboratory medicine, key areas needing to be addressed include utilization of existing and new laboratory tests, wider development of standardized protocols for conducting sound, and robust biomarker studies as well as the benchmarking of existing and new tests in specified situations using commonly accepted measures of effectiveness [34]. As discussed earlier in this chapter, developing each new or revised LMPG by AACC's Academy requires systematic and standardized processes that remain current with the best practices in guideline development. How AACC's Academy and the EBLM Committee (EBLMC) use the SOP developed LMPGs and CPGs that can translate into improved evidence-based practice and patient care is illustrated in Fig. 16.6 [35].

As the paradigm for using resources such as laboratory testing shifts from volume to value, use of new tools and strategies for gathering, analyzing, and applying evidence has become prevalent. Evidence-based reviews focusing on good standards of laboratory practice using published literature as well as results of unpublished quality studies are the approach used in the CDC's LMBP initiative [1,2]. Published reports from the CDC's LMBP initiative also demonstrate how evidence from published as well as unpublished studies can be combined in a meta-analyses summary forest plot to illustrate when evidence-based recommendations might be worthy of strong consideration for translation into practice. Going back to Fig. 16.2, studies were rated as fair or good using the point system previously described in Table 16.6 earlier in this chapter, and go on to demonstrate that the random effects means of fair studies, good studies, and all studies; overall, favor the use of barcoding system to reduce patient specimen identification errors [7].

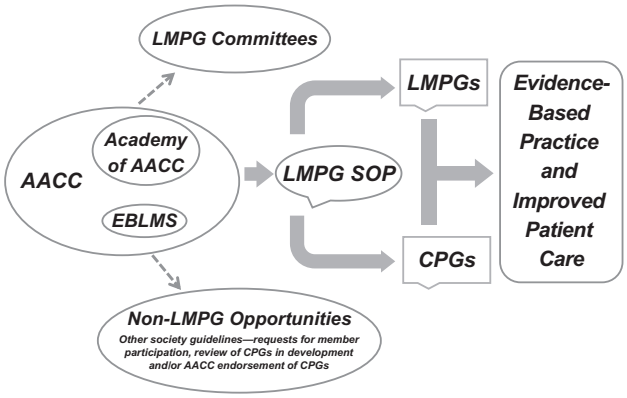

FIGURE 16.6 How the Academy and the Evidence-Based Laboratory Medicine Committee promotes evidence-based practice and improved patient care through use of Standard Operating Procedures for the development of laboratory medicine practice guidelines and clinical practice guidelines. *Source: Modified with permission for the e-Journal of the International Federation of Clinical Chemistry and Laboratory Medicine. The original article, Defining the path forward: guidance for laboratory medicine guidelines (http://www.ifcc.org/media/322288/eJIFCCVol26No3_pp158-167.pdf), was published in the e-Journal of the International Federation of Clinical Chemistry and Laboratory Medicine Volume 26 (3), p. 163, July 2015 [35].*

In addition to conducting SR or narrative review, other alternatives combine rigorous SR and meta-analyses with perspectives in a narrative format focusing on the best practices in the field by a consensus of experts. In a recent AACC Academy LMPG on laboratory analysis in the diagnosis and management of diabetes mellitus, roughly 25% of the final recommendations are "good practice points" (GPPs) [36]. GPPs are recommendations mostly driven by expert consensus and professional agreement and are based on specific items of information and/or professional experience, or widely accepted standards of best practice. In addition to [36], more information on the use of GPPs is available at https://www.aacc.org/science-and-research/practice-guidelines/diabetes-mellitus.

As laboratory professionals strive to apply the evidence from EBLM guidelines to their own practice settings, demonstrating value of laboratory test results for changing clinical practice and improving outcomes increasingly involves other medical disciplines and/or operating departments in many provider settings. A good example is the CER on the use of PCT to guide antibiotic therapy in selected patient populations [3]. This CER concluded that PCT-guided antibiotic therapy can lead to significant reductions in antibiotic use without adversely affecting patient outcomes in critically ill ICU patients. PCT-guided antibiotic therapy also reduced antibiotic prescription rates, and the duration of antibiotic therapy is selected patient groups such as those with respiratory tract infections without an increase in morbidity or mortality.

At present, one of the most intensively studied issues regarding the value of laboratory testing is that of laboratory test utilization. The accumulation and publication of evidence on this subject are accelerating, as numerous studies are being reported focusing on improving laboratory utilization. Excessive and inappropriate use of laboratory testing decreases its value. One recent meta-analysis conducted over a 15-year period reported that inappropriate testing takes many forms, may be as high as 30%–40% of all laboratory testing and involves overutilization as well as underutilization [37]. Taking effective action on recommendations from EBLM studies on laboratory utilization is a key priority for healthcare providers with many recognizing that "less is more for patients in laboratory testing" [38]. The American Board of Internal Medicine Foundation's website, www.choosingwisely.org, lists dozens of clinical society top recommendations to affect clinical practice and improve patient outcomes [39]. In the "Choosing Wisely" campaign, more than 40 (roughly 10%) of the evidence-based recommendations from all of the participating clinical societies pertain to improved use of laboratory tests. Table 16.12 lists a handful of key "Choosing Wisely" recommendations on laboratory tests and the societies that made them. As with all CPGs, laboratory professionals should apply the concepts of EBLM covered earlier in this chapter by using tools for critical appraisal and for adaptation and implementation of guidelines.

Quality indicators and metrics

It is said that quality improvement does not occur unless metrics associated with key aspects of the intervention are established and monitored on a regular basis. It is also said that quality improvement occurs more rapidly if monitoring is more frequent. In keeping with this notion, an important element of assuring that implemented practices and practice changes have the intended impact is establishing benchmark metrics for monitoring and auditing performance. Table 16.13 lists a number of organizations that have established quality indicators or metrics for improving healthcare venues and clinical care.

Summary

The processes and methods of EBLM are useful for determining what works for a continuum of healthcare stakeholders, from patients to practitioners to payers. The EBLM process consists of careful and proper question formulation, finding evidence, appraising the strength of the evidence, applying the knowledge to laboratory practice, and auditing the results. The use of medical evidence has significantly evolved from adoption of subjective narrative

TABLE 16.12 Selected recommendations from American Board of Internal Medicine's "Choosing Wisely" campaign related to the utilization of laboratory tests.[a]

Professional Society or Organization	Recommendation
American Association of Blood Banks	Do not perform serial blood counts on clinically stable patients.
American Association for the Study of Liver Diseases	Do not repeat hepatitis C viral load testing outside of antiviral therapy.
American College of Physicians	In patients with low pretest probability of venous thromboembolism, obtain a high-sensitive D-dimer measurement as the initial diagnostic test; do not obtain imaging studies as the initial diagnostic test.
American College of Preventive Medicine	Do not routinely perform PSA-based screening for prostate cancer.
AMDA—The Society for Post-Acute and Long-Term Care Medicine	Do not obtain a urine culture unless there are clear signs and symptoms that localize to the urinary tract.
American Society for Clinical Pathology	Do not perform population-based screening for 25—OH Vitamin D deficiency.
American Society for Clinical Pathology	Do not test for myoglobin or creatine kinase-MB in the diagnosis of acute myocardial infarction. Instead, use troponin I or T.
Critical Care Societies Collaborative—Critical Care	Do not order diagnostic tests at regular intervals (such as every day), but rather in response to specific clinical questions.
Society of Hospital Medicine—Adult Hospital Medicine	Do not perform repetitive complete blood count and chemistry testing in the face of clinical and lab stability.

opinion to objective SRs. This continuous growth of scientific literature has become more challenging and a number of helpful tools have been developed to evaluate the evidence. Further challenges to the delivery of high quality of laboratory services include increasing workload, continuous stream of new tests and new technology, uncontrollable demand, claims of excessive unnecessary testing, and slow transition of evidence to practice. In particular, more attention needs to be addressed to the impact of laboratory test utilization on health outcomes [40], while trying to cope with the problems of continuing education and the difficulties associated with changing practice [41]. All of these issues are compounded by the poor quality of evidence on the utility of new tests, the inability to demonstrate improved health outcomes, and the delays in bringing data into the peer-reviewed literature. EBLM should be used as the platform for decision-making for management of individual patients,

establishing guidelines, and guiding policy. In order to ensure that the best evidence is used, collaboration with clinical colleagues is essential for understanding how the laboratory information will be used to optimize care delivered to patients and improving health outcomes.

Self-assessment questions

1. The prevalence of pulmonary embolism in the ED population is determined by several studies as being 28%. The positive and negative likelihood ratios of D-dimer are 3.0 and 0.1, respectively. What is the posttest probability that patients with negative D-dimer test result will have a diagnosis of pulmonary embolism?
   a. 4%
   b. 50%
   c. 12%
   d. 7%
2. Which of the following can be used to estimate pre-test/posttest probability?
   a. ROC curve
   b. Fagan nomogram
   c. Forest plots
   d. likelihood ratio plot
3. Which of the following ROC curves indicates an overall excellent diagnostic performance of a test?
   a. A curve that is close to the diagonal
   b. A curve that passes close to the top left-hand corner
   c. A curve that passes close to the bottom right-hand corner
   d. A curve that has a slope of 1
4. Which of the following approaches of health economic evaluation aims to answer the question "given a fixed budget, what is the most efficient way to spend it"?
   a. CBA
   b. CEA
   c. CUA
   d. WTP
5. Which of the following is considered the best evidence for studying a diagnostic test?
   a. a double-blind randomized controlled trial
   b. a SR of observational study
   c. a SR of prospective cohort studies with blind comparison to a gold standard
   d. a prospective observational study
6. Which of the following is consistent with guideline development?
   a. Guidelines should be based on one or more SRs published on the topic.
   b. Because guidelines constantly become outdated, a date must be set to review the guidelines and determine whether an update is needed.
   c. The guideline development group must include members from the clinical and laboratory practice.
   d. All of the above are consistent with guideline development.
7. The diagnostic sensitivity and specificity of a test are 90% and 70%, respectively, at the optimum cutoff. What are the positive and negative likelihood ratios for the test?
   a. positive: 0.22 and negative: 8.0
   b. positive: 8.0 and negative: 0.22
   c. positive: 3.5 and negative: 0.12
   d. positive: 3.0 and negative: 0.14
8. Two tests, A and B, are compared for the screening of left ventricular dysfunction in a primary care clinic. Cutoffs selected show diagnostic sensitivities of 80% for A and 50% for B; diagnostic specificities are 20% for A and 40% for B. The area under the ROC curve is 0.75 for test A and 0.70 for test B. Which test is likely better as a screening test for left ventricular dysfunction?
   a. Test A is likely better.
   b. Test B is likely better.
   c. Test A and B are likely to be equivalent.
   d. There is insufficient information to determine which is likely better.
9. What are the four important factors to consider reducing barriers to clinical practice guidelines?
   a. Awareness, agreement, adoption, adherence
   b. Reduce, reuse, recycle, recover
   c. Ask, acquire, appraise, audit
   d. Accountability, accreditation, assessment, articulation
10. The PICOTS acronym is useful for specifying important aspects of formulating the clinical question and acquiring evidence. PICOTS for:
    a. Paradigm, Index, Comorbidities, Outcome, Timing, Setting
    b. Population, Indicator, Comparator, Outcome, Temperature, Sickness
    c. Paradigm, Indicator, Comparator, Outcome, Timing, Setting
    d. Population, Indicator, Comparator, Outcome, Timing, Setting

Chapter 17

Harmonization of results among laboratories

W. Greg Miller
Department of Pathology, Virginia Commonwealth University, Richmond, VA, United States

Learning objectives

After reviewing this chapter, the reader should be able to:

- Explain why harmonized results are important for applying clinical practice guidelines.
- Identify or establish the metrological traceability for calibration of measurement procedures.
- Identify reference materials and reference measurement procedures that are suitable for use to establish or verify metrological traceability.
- Explain why some measurement procedures are not harmonized and advise clinical care providers accordingly.

Why harmonized results are important?

Definition

Harmonization is achieving equivalent results, within clinically meaningful limits, among different measurement procedures for the same laboratory test. Standardization is a closely related term that means equivalent results are achieved by having calibration of measurement procedures traceable to a recognized reference measurement procedure (RMP) or certified reference material (CRM).

Impact of harmonization

Many clinical decisions are based on values from laboratory tests. In many cases, clinical practice guidelines exist that recommend specific medical decisions and actions depending on the value of a laboratory test result. Clinical practice guidelines, whether based on international consensus from outcome data or on recommendations in a textbook, assume the laboratory results are harmonized irrespective of the measurement procedure used or when a measurement is made. Some laboratory tests, such as hemoglobin A1c, cholesterol, glucose, and others, have been successfully harmonized by applying metrological traceability strategies for calibration described in a subsequent section, and are used very effectively in clinical practice guidelines. If laboratory results are not harmonized, then patients may get incorrect treatment based on different results from nonharmonized measurement procedures. Unfortunately, a substantial number of laboratory measurement procedures do not produce harmonized results, and clinical providers have difficulty using such results appropriately.

For example, a recent report showed lack of harmonization for parathyroid hormone (PTH) [1]. Individual patient samples measured by five commercially available PTH measurement procedures had an approximately fourfold difference in results. The impact of these differences was examined using guidelines from the UK Renal Association for treating hypophosphatemia in kidney disease. In this application, the number of patients who were identified as needing treatment varied from one-half of the group to almost all of them based only on which laboratory measurement was used. Clearly, the PTH assays were not adequately harmonized to support this clinical decision. Because of the differences among laboratory test results, the UK Renal Association guidelines recommend making treatment decisions when PTH results are two to nine times the reference interval for an individual measurement procedure [2]. However, the measurement procedures had very similar reference intervals despite differences in the values produced [1,3]. In principle, a reference interval could compensate for lack of harmonization. However, in practice, the difficulty to identify an appropriate reference population and to relate its reference interval to different disease conditions limits the effectiveness of reference interval-based treatment guidelines [3]. Given the limitations for use of PTH results for clinical decisions, a harmonization activity for this analyte

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00017-X

is being pursued by an International Federation for Clinical Chemistry and Laboratory Medicine (IFCC) working group.

Infrastructure to support harmonization

Metrology is the science of measurement. Metrology organizations are typically established by a country or a political unit, such as the European Union. For example, the National Institute for Standards and Technology in the United States and the Joint Research Center in the European Union provide metrology services. Metrology organizations produce CRMs and RMPs. The term metrological traceability refers to a series of calibrations and value transfers from CRMs and/or RMPs to the calibrators used in the clinical laboratory that enables the results from clinical samples to have their calibration traceable to the CRM or RMP that defines the reference system for a particular measurand. The components of a reference system are called "higher order," because they are expected to have lower uncertainty and be an accuracy reference for a clinical laboratory measurement procedure. Prior to 2003, many countries had organizations that approved reference system components as suitable for use in the calibration hierarchies of clinical laboratory measurement procedures.

The European Commission passed a directive that by 2003 all in-vitro diagnostic (IVD) devices sold in the European Union were required to have calibration traceable to a higher order reference material or RMP [4]. The directive was replaced by a regulation in 2017, effective 2022, with essentially the same requirements [5]. In response to the European Commission directive, the International Organization for Standardization (ISO) developed standards for higher order reference system components, and the Joint Committee for Traceability in Laboratory Medicine (JCTLM) was formed to approve reference system components for use by IVD medical device manufacturers. Because most IVD manufacturers sell on a global basis, the ISO standards and JCTLM largely replaced national organizations for the same functions, although some countries still retain calibration standard-setting bodies. In addition, many countries have regulations and a regulatory approval agency such as the Food and Drug Administration in the United States that approve all medical devices including clinical laboratory measurement procedures as safe and effective before they can be sold.

International Organization for Standardization

ISO Technical Committee 212, Clinical Laboratory Testing and In-Vitro Diagnostic Test Systems, has published standards for calibration traceability and the components of a reference system needed for traceability. The applicable standards are:

- 17511:2020, IVD medical devices—requirements for establishing metrological traceability of values assigned to calibrators, trueness control materials, and human samples;
- 21151:2020, IVD medical devices—measurement of quantities in samples of biological origin—requirements for international harmonization protocols establishing metrological traceability of values assigned to calibrators and human samples;
- 15193:2009, IVD medical devices—measurement of quantities in samples of biological origin—requirements for content and presentation of RMPs;
- 15194:2009, IVD medical devices—measurement of quantities in samples of biological origin—requirements for CRMs and the content of supporting documentation; and
- 15195:2018, Laboratory medicine—requirements for the competence of calibration laboratories using RMPs.

Joint Committee for Traceability in Laboratory Medicine

The JCTLM was created in 2002 through a Declaration of Cooperation between the International Committee of Weights and Measures, the IFCC, and the International Laboratory Accreditation Cooperation [6]. The JCTLM reviews and approves reference system components for conformance to the requirements in the ISO standards. Approved reference materials, RMPs, and reference measurement services are listed in the JCTLM database available on their website.

One caution regarding reference materials listed by the JCTLM is that information on commutability (explained in a subsequent section) is not provided. The individual certificate of analysis for a reference material should be reviewed to determine the intended use of a given reference material and if its commutability with clinical samples has been validated. Some pure substance reference materials are intended for use to calibrate higher order RMPs, such as isotope dilution−mass spectrometry, but may not be suitable for use to calibrate clinical laboratory measurement procedures.

How to achieve harmonized results

Two main requirements must be met to achieve harmonized results among a group of clinical laboratory measurement procedures. First, the calibration of all measurement procedures must be traceable to a common reference system. Second, all of the measurement

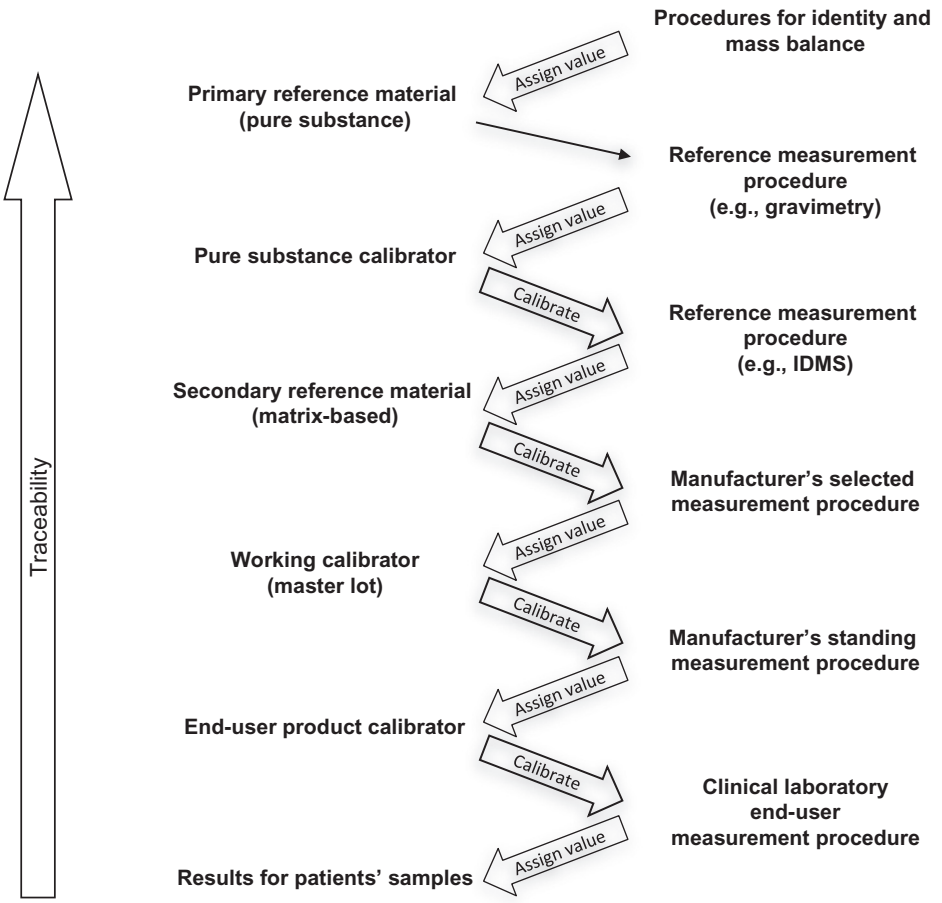

FIGURE 17.1 Calibration hierarchy for metrological traceability of values assigned to patients' samples based on ISO 17511 [8].

procedures must measure the same quantity. For example, if human chorionic gonadotropin (HCG) is to be measured by an immunoassay, then all measurement procedures must respond to the same molecular forms of HCG if harmonized results are to be achieved.

The International Vocabulary of Metrology defines a measurand as the substance intended to be measured that includes the matrix in which the substance is measured and units for reporting the result [7]. Laboratories use the term analyte to refer to the substance being measured. For harmonization of results, the substance actually measured including any molecular forms such as glycosylated, phosphorylated, complexed, or variants, present in disease conditions must be clearly understood. In addition, any other substances in the clinical sample that can influence the measurement must be considered. It is important to clarify a measurement procedure's selectivity for the measurand before attempting to establish its metrological traceability to a reference system. If nonselectivity for the measurand causes substantial differences in results for different patient samples, it may be necessary to improve the selectivity of affected measurement procedures before results can be successfully harmonized.

Metrological traceability of calibration to a reference system

A reference system ideally consists of a pure substance reference material and an RMP calibrated using that reference material. RMPs are generally not suitable for use in clinical laboratories, because they are capable of only making a few very precise and accurate measurements at a time and may require more than 1 day to complete. Measurement procedures used in a clinical laboratory have their calibration traceable to reference systems. Metrological traceability to a reference system can be reproduced over time and location to ensure that calibration of clinical laboratory measurement procedures remains consistent in different laboratories and for tests performed at different times.

Fig. 17.1 shows metrological traceability for the calibration hierarchy of results assigned to patients' samples according to ISO 17511 [8]. At the top of the hierarchy is a pure substance primary CRM that is characterized for identity and purity using appropriate RMPs. A primary reference material has a known mass fraction typically expressed as milligram per gram. For example, a glucose

reference material might be crystalline glucose of 993 mg/g. A CRM is typically provided by a national metrology institute (such as NIST in the United States) or another qualified producer, is well characterized, and is documented with a certificate of analysis. The next component in the hierarchy is a primary calibrator typically prepared by weighing a primary reference material with a calibrated balance (an RMP) to produce a solution of known concentration that is suitable for use as a calibrator for the next RMP in the hierarchy. The International System of Units (Système International, SI) is realized in the pure substance calibrator for example as mol/L. Techniques other than gravimetry are acceptable for preparing a calibrator from a pure substance reference material. Note that a pure substance dissolved in an aqueous solvent may be suitable for calibrating an RMP that is highly selective for the measurand and is not influenced by differences in matrix between the calibrator and other samples such as secondary reference materials or clinical samples that will be measured. However, a pure substance calibrator may not be suitable for use to calibrate some clinical laboratory measurement procedures that are more sensitive to the matrix of the sample being measured.

The next step in the calibration hierarchy is assigning values to a secondary CRM using a properly calibrated RMP. A commonly used measurement technology at this level is isotope dilution−mass spectrometry that is capable of very selectively measuring the measurand with little or no influence from matrix components. An RMP is typically operated with substantial isolation of the measurand from other matrix components, specialized calibration techniques such as calibrators that bracket the concentration in the sample, replication of measurements to reduce uncertainty in the result, and gravimetric preparation of all dilutions in the procedure. Using an isotope dilution−liquid chromatography−mass spectrometry procedure (ID/LC−MS) in a clinical laboratory is not sufficient qualification to be considered an RMP.

For measurands, such as enzymes, the reaction conditions for a measurement procedure determine the catalytic activity and thus define the measurand in SI units as microkatal per liter. In such cases, there is no pure substance reference material, and an RMP is the highest component in the traceability chain. The reaction conditions of the RMP define the SI unit for the measurand and are very completely specified including how to calibrate the equipment and to qualify the reagents used.

For measurands, such as HDL cholesterol or free thyroxine, the RMP defines the measurand, but there are primary reference materials available to calibrate the RMP used to measure the molecule(s) of interest. For example, in the case of HDL cholesterol, the ultracentrifugation conditions determine what fractions of lipoproteins are included in what is called HDL. The measurement of cholesterol is performed by an ID/LC−MS procedure using calibrators prepared from a cholesterol primary reference material. Similarly, for free thyroxine, the equilibrium dialysis conditions determine the amount of thyroxine that is included in the free fraction, but the measurement of thyroxine is by an ID/LC−MS procedure using calibrators prepared from a thyroxine primary reference material. The term international conventional RMP is used for such conditions, because part of the procedure is agreed by international consensus or convention.

A secondary reference material typically has a matrix the same as or similar to that of the clinical samples for which measurements are made. Certified secondary reference materials are produced by a metrology institute or similarly qualified producer and are supplied with certificates of analysis that describe the production of the material, how its measurand value was assigned and a statement regarding the commutability of the material with clinical samples for measurement procedures for which the secondary reference material is intended to be used as a calibrator (see the "Commutability" section). A panel of individual clinical samples may be used as a secondary reference material in the traceability hierarchy. A panel of clinical samples with values assigned by an RMP can be used as calibrators for the next step in the traceability chain. A panel of clinical samples is by definition commutable, because they are the samples intended to be measured and thus can overcome noncommutability limitations of secondary reference materials. However, an individual clinical sample may contain influence quantities (interfering substances) that alter the response of a clinical laboratory measurement procedure to a measurand, and thus make it not suitable for use as a secondary reference material. Experimental designs must take into consideration the possibility of sample-specific influences and include outlier identification as part of the metrological traceability step when individual clinical samples are used as secondary reference materials.

A secondary reference material is used to calibrate a manufacturer's selected measurement procedure. A selected measurement procedure is one that has acceptable performance characteristics for the purpose to assign values to a master lot of calibrator or to an end-user product calibrator intended for use to calibrate a measurement procedure used in a clinical laboratory. An end-user product calibrator is sold along with the instrument and reagents for use in a clinical laboratory for patient sample testing. A selected measurement procedure may be the same as the clinical laboratory measurement procedure but operated more stringently (e.g., with additional replication and/or more stringent calibration) to reduce the uncertainty in values assigned to a master lot of calibrator or to an end-user product calibrator. A master lot of calibrator, called a working calibrator, is

typically used by a manufacturer instead of a more expensive and limited availability secondary CRM to calibrate the selected measurement procedure used in a manufacturing process to value assign multiple lots of the end-user product calibrator over an extended manufacturing time interval. In the case of a laboratory developed test, a selected procedure may be the one that is used for measuring clinical samples. A secondary CRM may be used as a calibrator, or a laboratory may produce and assign values to a master lot of calibrator for daily use to calibrate the laboratory-developed measurement procedure.

The uncertainty of the value assigned to a sample measured at each step in the calibration hierarchy will increase with each measurement in the traceability chain. The uncertainty in the final clinical sample result will be the cumulative propagation of uncertainty at each step. It is acceptable to eliminate one or more steps in the calibration traceability hierarchy when possible, which has the benefit of reducing the uncertainty in the final result for a patient's sample.

Calibration traceability when reference system components are missing

It is desirable to develop pure substance reference materials and RMPs whenever possible, because these components enable a complete metrological traceability chain. Unfortunately, pure substance reference materials and RMPs are only available for a relatively small number of measurands in clinical laboratory testing. The ISO 17511 standard defines several categories of traceability that end at lower positions in the metrological traceability hierarchy.

Traceability to a secondary reference material

For a substantial number of measurands, the traceability hierarchy stops at a secondary reference material. In this situation, the commutability of the secondary reference material with authentic clinical samples is important to ensure the reference material will be suitable for use as a calibrator (see the "Commutability" section).

When there is no RMP, value assignment of the concentration in a secondary reference material can be done in several ways. One approach assigns an arbitrary number of units to the amount of measurand expressed as units per liter. Another approach bases the concentration on the amount of a purified substance added to a base material, for example, a recombinant protein hormone can be added to a base serum pool. The preceding approach allows a nominal concentration to be assigned, but the added substance may differ in reactive characteristics from a native measurand; for example, a recombinant protein will lack glycosylation or other posttranslational modifications and may not react in an immunoassay in the same manner as a native molecule in a clinical sample. An added substance may be of a different molecular form, such as a monomer, than that of the native molecule that may be part of a molecular complex. Another approach to value assignment isolates the measurand from the matrix of the reference material and quantitates it by an alternate analytical technique; for example, a protein can be isolated and measured by amino acid analysis. A common approach is to use a trimmed mean of measurements by a group of clinical laboratory measurement procedures that have been qualified to meet specified performance requirements [9–11].

Whatever approach is used for value assignment, a secondary reference material can be effectively used as a common calibrator even if the actual concentration is not known as long as the assigned value remains stable and the material is commutable with authentic clinical samples for the measurement procedures for which it will be used. In these conditions, harmonization of results can be achieved, and clinical decision values can be established that will be consistent and uniform irrespective of the measurement procedure used.

Traceability to a measurement procedure producer's working calibrator

JCTLM lists primary and/or secondary CRMs and RMPs for approximately 100 measurands. When there is no higher order reference system component available, calibration is traceable to whatever substance a manufacturer or laboratory selects as the best available calibration material. It is a common practice for IVD manufacturers to prepare a master lot of a working calibrator that is used to calibrate the internal (standing) measurement procedure used to assign values to sequential lots of the end-user product calibrator. Although metrological traceability can be described, there is no coordination among different producers of measurement procedures for a given measurand, and, consequently, no uniformity in what substance or matrix is used for calibrators. This category of traceability typically does not produce harmonized results for clinical samples among different measurement procedures.

Traceability to a harmonization protocol

An international conference in 2010 recognized that additional approaches to harmonization were needed to address both the limitation that some secondary reference materials were not commutable with clinical samples and the reality that RMPs and CRMs could not be developed for all of the analytes measured in clinical laboratories [12]. The IFCC Committee for Standardization of

Thyroid Function Tests has pursued an approach to harmonization of thyroid stimulating hormone based on a series of comparisons of results for panels of individual donor sera among clinical laboratory measurement procedures [13]. The manufacturers of the measurement procedures also included their internal master lots of working calibrators in the measurements. The results of each round of measurements were used to assess the status of harmonization, to identify method improvements that were needed, and to develop corrections to each manufacturer's calibration hierarchy to improve harmonization for clinical samples among the different measurement procedures [14,15].

The ISO Technical Committee 212 has developed a standard, ISO 21151:2020, that specifies requirements for calibration traceability to a harmonization protocol. Fig. 17.2 shows conceptually how a harmonization protocol could be designed. Suitable harmonization reference materials are value assigned for the concentration of a measurand. Potentially suitable materials include a panel of individual clinical samples, pools of clinical samples, supplemented clinical samples, or other materials that are commutable with clinical samples (see the next section). The value assignment process can be one of the approaches described earlier for a secondary reference material when no RMP is available or any scientifically acceptable approach. The value-assigned harmonization materials effectively become a type of reference materials that are measured along with working calibrators and end-user product calibrators by all measurement procedures for a given measurand. Based on the results, values are assigned by each manufacturer to their working or end-user product calibrators to achieve harmonization of reported results for clinical samples among all of the different end-user measurement procedures. Such an approach needs to consider how to sustain the harmonization process over time, as new lots of reagents, working calibrators (master lots), and end-user product calibrators are introduced, or new measurement procedures are developed. One approach to sustainability could be to prepare an additional set (or sets) of the harmonization reference materials for use at a future time. If the harmonization reference materials are not stable for storage, replacement panels will need to be prepared. In either case, the harmonization protocol needs to specify how to produce and qualify subsequent preparations of harmonization reference materials to ensure consistent metrological traceability to the protocol. Proficiency testing (PT) or external quality assessment (EQA) using commutable samples provides surveillance of the harmonization status and can identify when adjustments are needed. The harmonization protocol concept is sufficiently general that it can be applied to a range of technical approaches, such as chemical assays, immunoassays, nucleic acid-based testing, etc. The ISO 21151:2020 standard enables a harmonization protocol that conforms to the ISO requirements to be listed by the JCTLM as an acceptable approach for metrological traceability for clinical laboratory measurement procedures.

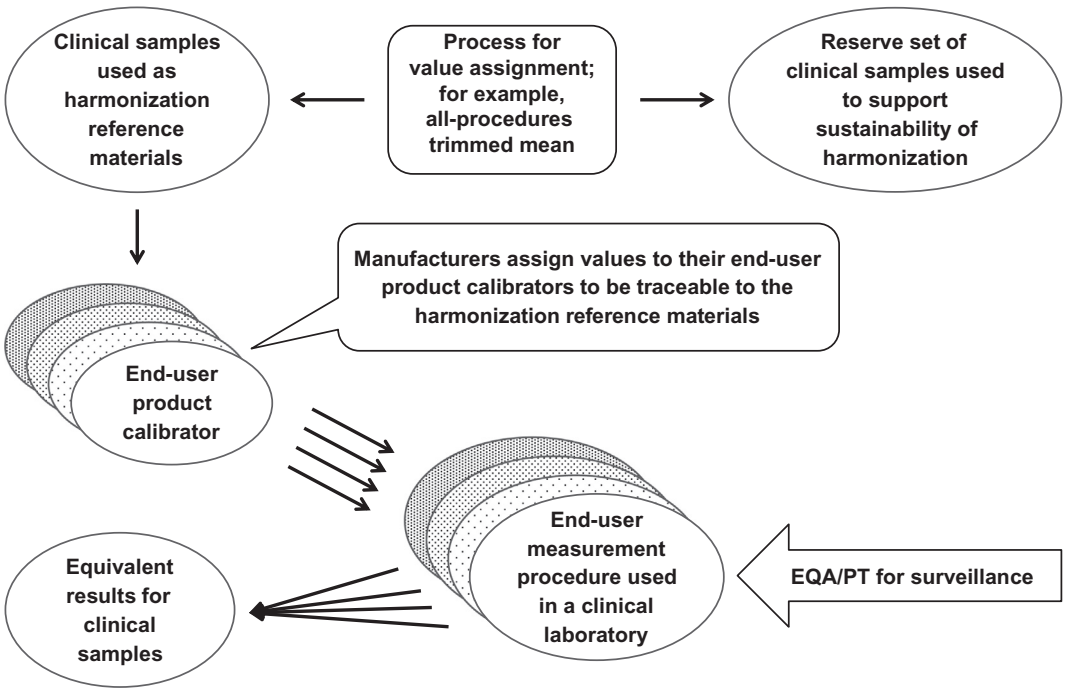

FIGURE 17.2 Example of a harmonization protocol for metrological traceability of calibration to a set of clinical samples used as harmonization reference materials based on ISO 21151.

Commutability

Commutability is defined by the International Vocabulary of Metrology as a property of a reference material, demonstrated by the closeness of agreement between the relation among the measurement results for a stated quantity in this material, obtained according to two given measurement procedures, and the relation obtained among the measurement results for other specified materials [7]. Other specified materials are clinical samples in the case of clinical laboratory testing. Stated differently, commutability is a property of a reference material in which values measured for the reference material and for representative clinical samples have the same relationship between two, or more, measurement procedures for the same measurand [16]. Fig. 17.3A shows the concept of commutability as the same relationship between two measurement procedures observed for reference materials and for clinical samples. Fig. 17.3B shows that noncommutable reference materials have a different relationship between two measurement procedures than observed for clinical samples.

The acceptability of a calibration traceability hierarchy requires that the materials used in each step are commutable with clinical samples among the involved measurement procedures. Because RMPs are designed to be highly selective for the measurand and not influenced by the matrix in which the measurand is found, commutability is generally not an issue for calibrators prepared from primary reference materials, or when measuring manufacturer's working calibrators or clinical samples. Commutability becomes a critical consideration when a secondary matrix-based reference material is used as a calibrator for a manufacturer's internal selected measurement procedure or for a clinical laboratory measurement procedure. Fig. 17.3C shows that using noncommutable reference materials to calibrate each of two measurement procedures causes a difference in agreement for results from clinical samples.

Commutability is a property of a reference material, and correct terminology is to state that a reference material is commutable with clinical samples among a group of measurement procedures. It is incorrect terminology to state that clinical sample results are commutable among a group of measurement procedures. The correct way to state the preceding is that clinical sample results are harmonized, or equivalent, among a group of measurement procedures. Using commutable secondary matrix-based reference materials in a calibration traceability hierarchy is a requirement to achieve harmonized results for clinical samples.

A limitation in laboratory medicine is that a number of secondary matrix-based reference materials intended for use as common calibrators for clinical laboratory

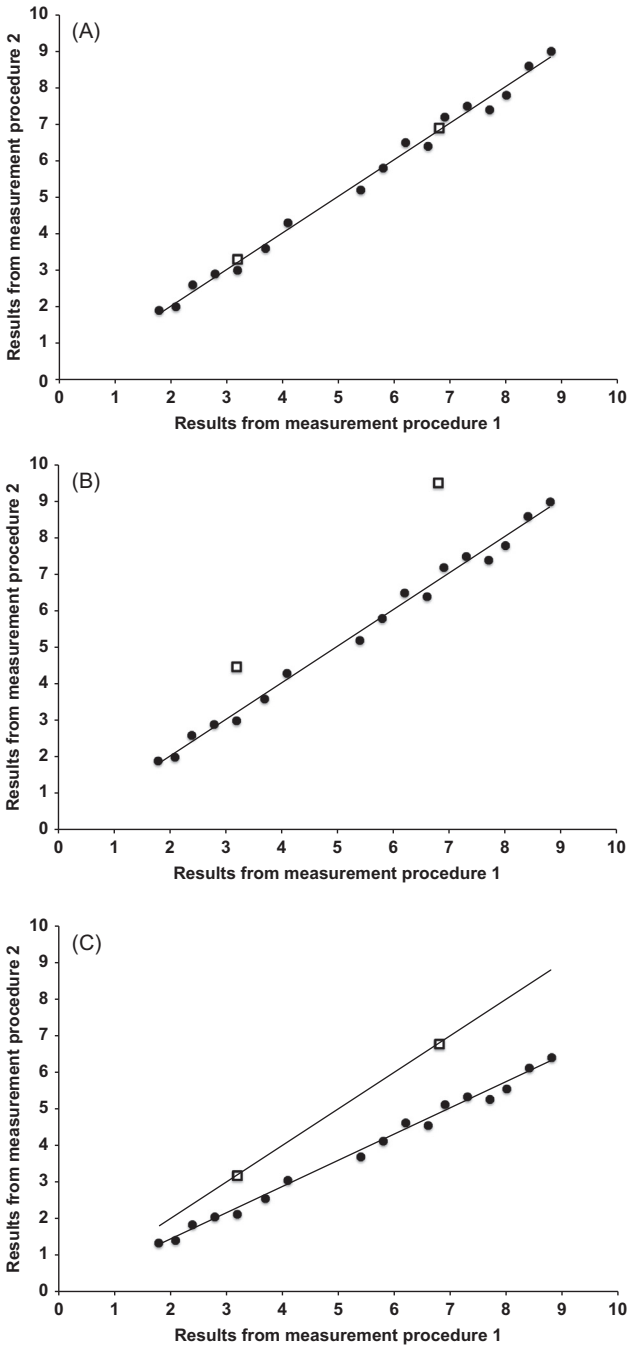

FIGURE 17.3 Plots showing the relationship of results for authentic clinical samples (closed circles) and for reference materials (open squares) measured by each of two measurement procedures. Panel (A) shows that commutable reference materials have a relationship between two measurement procedures that is the same as that observed for clinical samples. Panel (B) shows that noncommutable reference materials have a different relationship than observed for clinical samples. Panel (C) shows that, if the noncommutable reference materials were used as calibrators for each of the measurement procedures, the results for the reference materials appear to be equivalent, but the results for clinical samples are different between the measurement procedures.

measurement procedures have not been evaluated for commutability with clinical samples. A number of investigations have reported that differences among results for clinical samples can be attributed to calibration traceability to noncommutable secondary reference materials [16–18]. Even though the producer of a measurement procedure shows traceability, use of a noncommutable reference material breaks the calibration traceability chain, introduces noncommutability bias, and causes results for clinical samples to be different among different measurement procedures.

Note that most clinical laboratory measurement procedures are not designed to use calibrators prepared from pure substance reference materials in a nonphysiologic matrix, because the difference in matrix composition versus the usual clinical samples makes such calibrators noncommutable. A laboratory that intends to use a pure substance material to prepare a calibrator must validate that calibrator's commutability with clinical samples to ensure the calibrator is suitable for use with the measurement procedure.

Validating commutability of a reference material

Validating commutability of a reference material requires the following steps:

- Obtain representative clinical samples.
- Obtain candidate reference material(s).
- Measure clinical samples and reference materials with all measurement procedures for a measurand.
- Determine the relationships between the measurement procedures for the clinical samples.
- Determine if the relationships for a reference material are close enough to those for the clinical samples for the intended use of the reference material.

If an RMP is available, results from each clinical laboratory measurement procedure are compared with those from the RMP; otherwise, the results for all combinations of two clinical laboratory measurement procedures must be examined.

CLSI has two guidelines for assessing commutability that address many aspects of the experimental design [19,20]. Both guidelines include the common approach for determining the relationship between two measurement procedures by Deming linear regression and calculating the 95% prediction interval statistic. A prediction interval means if another measurement were made, its results would fall within the prediction interval with 95% confidence. A reference material is considered commutable if its result falls within the prediction interval derived from the clinical samples' results. A limitation of the prediction interval and similar approaches is that the prediction interval limits depend on the scatter in results between two measurement procedures. Consequently, each pair of measurement procedures has different acceptance criteria, and those criteria are not related to the intended medical use of results.

An IFCC working group on commutability published three papers in 2018 that provided updated approaches for commutability assessment. The first paper provided general guidance on experimental design [21]. Key design elements include that measurement procedures must meet performance requirements for selectivity for the measurand to be included in a commutability assessment; clinical samples must represent typical pathophysiology but not include unusual specimen specific influences; and the criterion for commutability is fixed for all combinations of measurement procedures and is based on medical requirements for using a test result. The second paper provides an approach for commutability assessment based on the closeness of agreement for the difference in bias between two measurement procedures observed for a reference material compared with the bias observed for clinical samples [22]. A reference material is considered commutable if the difference in bias plus its uncertainty are within a fixed criterion based on the medical requirements for using a laboratory result. The third paper provides an approach for commutability assessment based on substituting a candidate reference material for the current calibrators used in participating measurement procedures' calibration hierarchies, and determining if the improvement in intermeasurement procedure bias meets a fixed criterion based on the medical requirements for using a laboratory result [23]. This latter approach is only applicable to reference materials intended for use as matrix-based secondary calibrators.

How to verify traceability of a clinical laboratory measurement procedure

The manufacturer of a commercially available measurement procedure is responsible for establishing metrological traceability to the highest available level in the calibration hierarchy. The manufacturer is expected to inform the end user of the calibration traceability in the instructions for use provided with the measurement procedure. A clinical laboratory can accept the manufacturer's documentation regarding calibration traceability, and, in most cases, independent verification is not necessary.

When a laboratory wishes to verify calibration traceability, the following approaches can be considered:

- Splitting clinical samples with a laboratory that performs a JCTLM-listed RMP. Unfortunately, there are relatively few such laboratories, and the measurements are expensive. An alternative is to split clinical samples with another laboratory that performs a

measurement procedure similar to that listed by JCTLM with a robust calibration process. Another, less robust, approach is to split clinical samples with another laboratory that performs a measurement procedure that is known and verified to have its calibration traceable to a JCTLM-listed RMP. Results should be interpreted appropriately when using the latter approaches, because the measurement procedures may be less selective for the measurand and have the possibility for a bias in calibration. CLSI document EP09-A3 provides guidance on performing a comparison between measurement procedures using clinical samples [24].

- Measuring a CRM that is documented to be commutable with clinical samples from a metrology institute or other qualified provider. Caution is needed when using some reference materials, because many have not been validated for commutability, in which case they must be treated as noncommutable and so are not suitable for use to determine calibration traceability or bias for a clinical laboratory measurement procedure.
- Participating in a PT/EQA program that uses commutable samples. Some PT/EQA providers offer surveys that use commutable samples, and some also have RMP-assigned values. Results from such surveys can be used to verify the calibration status and bias of a clinical laboratory measurement procedure. Because PT/EQA programs, with some exceptions, typically make a single measurement, the statistical confidence in the results is limited and should not be the sole basis for an estimate of calibration bias. However, the PT/EQA results are a good indicator that calibration traceability is appropriate or may need correction. When commutable samples are used and an RMP value is not available, the results are useful to give a good indication of the harmonization among different measurement procedures. Mean or median values for participants using the same measurement procedures for commutable samples are useful to determine if different measurement procedures are calibrated to give equivalent results and to determine if a measurement procedure is calibrated to be traceable to a reference system when RMP values are assigned.

An important limitation with many PT/EQA programs is that noncommutable samples are used, in which case the results likely contain matrix-related bias and thus are not suitable to estimate calibration bias versus a traceability hierarchy [25]. The same limitation exists for quality control programs that include a comparison of results among different laboratories, because quality control samples are typically noncommutable with authentic clinical samples. These programs are useful to document that a measurement procedure produces results that agree with other laboratories using the same measurement procedure but cannot be used to compare the calibration status or agreement in results among different measurement procedures.

Calibration of laboratory developed tests

A clinical laboratory that develops a measurement procedure is responsible for establishing its calibration traceability. The principles described for IVD manufactures are also applicable to laboratories. Of particular importance is the choice of calibrator. Every effort should be made to use CRMs or international conventional reference materials when available. Attention must be paid to commutability with authentic clinical samples when using matrix-based secondary reference materials as calibrators or for traceability of calibrators prepared by the laboratory.

Self-assessment questions

1. What is harmonization?
   - **a.** having equivalent results among different measurement procedures
   - **b.** having a suitable reference interval for all measurement procedures
   - **c.** having calibration traceable to a secondary reference material
   - **d.** having calibration traceable to a reference measurement procedure
2. Metrological traceability means _____.
   - **a.** the calibrator value is assigned by a reference measurement procedure.
   - **b.** the accuracy of patient sample results is linked to a reference measurement procedure or a reference material.
   - **c.** the instructions for use describe how a measurement procedure is calibrated.
   - **d.** the lot-to-lot differences in calibrators are less than a specification.
3. What is JCTLM?
   - **a.** an international laboratory accreditation organization
   - **b.** an international group that publishes standards for calibration traceability
   - **c.** an international group that produces reference materials
   - **d.** an international group that approves reference materials that meet requirements specified by the ISO
4. A metrological traceability calibration hierarchy describes _____.
   - **a.** a sequence of steps that transfer values from certified reference materials to the calibrators used in clinical laboratory measurement procedures
   - **b.** a sequence of steps that should be followed when calibrating a clinical laboratory measurement procedure
   - **c.** calibration and quality control procedures for a clinical laboratory measurement procedure
   - **d.** how a manufacturer assigns values to each lot of calibrator for a clinical laboratory measurement procedure
5. What is an essential property for a matrix-based secondary reference material?
   - **a.** commutability with clinical samples
   - **b.** adequate volume to be used for several calibrations
   - **c.** sufficient quantity to be available for at least 3 years
   - **d.** commutability for at least one-half of the commonly used measurement procedures
6. What is a primary reference material?
   - **a.** the best available material to use for calibration
   - **b.** a pure chemical that meets American Chemical Society specifications
   - **c.** a pure substance that is characterized for identity and mass balance
   - **d.** a pure substance that can be added to a pool of clinical samples to prepare a calibrator
7. When there is no primary reference material or reference measurement procedure for a measurand, _____.
   - **a.** a laboratory should use a PT/EQA material for calibration traceability.
   - **b.** a laboratory should use any calibrator as long as a proper reference interval is established.
   - **c.** the calibrator from the manufacturer of a measurement procedure defines the calibration.
   - **d.** a secondary reference material should be the basis for calibration traceability when available.
8. Commutability means _____.
   - **a.** results for patient samples agree among different measurement procedures.
   - **b.** results for PT/EQA samples agree among different measurement procedures.
   - **c.** results for a reference material are the same as the results for clinical samples when measured by different measurement procedures.
   - **d.** the same reference interval can be used for all measurement procedures.
9. A clinical laboratory can verify the calibration traceability of its measurement procedures by _____.
   - **a.** splitting clinical samples with another laboratory performing the same method
   - **b.** measuring a commutable secondary reference material
   - **c.** participating in a PT/EQA survey
   - **d.** comparing its QC results to the interlaboratory mean values among all uses of the same QC material

Learning objectives

After reviewing this chapter, the reader will be able to:

- Describe the types of information commonly encountered in laboratory medicine.
- Discuss the benefits and limitations of different systems used for information management.
- Describe the basic architecture of LIS.
- Detail the flow of a test result from physician order to reporting.
- Define the nature and use of different messaging standards used in LIS.
- Explain the benefits and challenges of secondary data use.

Introduction

The primary role of a clinical laboratory is to provide information to healthcare providers on the biochemical status of patients; as a result, information management is a central focus of clinical laboratories. A laboratory must manage numerous and diverse forms of data to operate efficiently (Fig. 18.1). Data generated by a lab can take many forms including quantitative results from a chemistry analyzer or a DNA sequencer, image files from a microscope, and free text interpretation associated with a lab result. A large amount of data are collected to track the entire testing process from the sample and order receipt to reporting of final results. This information is often referred to as metadata and amounts to all of the information needed to understand the context of a laboratory result. A large part of the information generated by a laboratory is the metadata associated with a test result. These metadata include what procedures were in use at the time of testing, the time and date of sample collection, the analytical method used for sample analysis, quality control (QC) data, environmental data, and patient demographics.

Reporting a single quantitative clinical laboratory result requires integration of multiple streams of data (Fig. 18.2). Laboratory information systems (LIS) have evolved over time to make this process rapid, traceable, and reproducible. This chapter will describe the core functions of a modern LIS as well as provide supplementary information on management systems commonly found in clinical laboratory settings. The informatics needs of a clinical laboratory include sample tracking, relational database, appropriate QC modules, a document control system, an inventory control system, data exchange interfaces, and process automation. An ideal LIS is a modular software system that integrates all the informatics needs of the laboratory.

The LIS is an essential component of a modern clinical laboratory and fulfills three broad functions within the laboratory: it serves as a relational database, it acts as a data exchange interface, and it operates as a laboratory process automation system. These functions will be described in detail throughout this chapter. Briefly, the database function of the LIS links necessary metadata with a specimen to ensure that results are linked to the correct patient with the correct interpretive aids (e.g., comments, reference intervals, and units). However, this externally reported information represents only the tip of the iceberg when it comes to the data associated with a test result. The laboratory collects and records extensive information internally for quality assurance (QA) and accreditation needs. The LIS relational database organizes and stores all this information so that it can be accessed when needed. As the amount of information stored in a modern LIS increases, so does the value of the information; thus reuse of LIS data for clinical decision support, key performance indicators, and clinical research is common. The second broad role of the LIS is to serve as a hub for data exchange within the laboratory. The LIS is typically part of a larger collection of health information systems, and depending on the degree of information

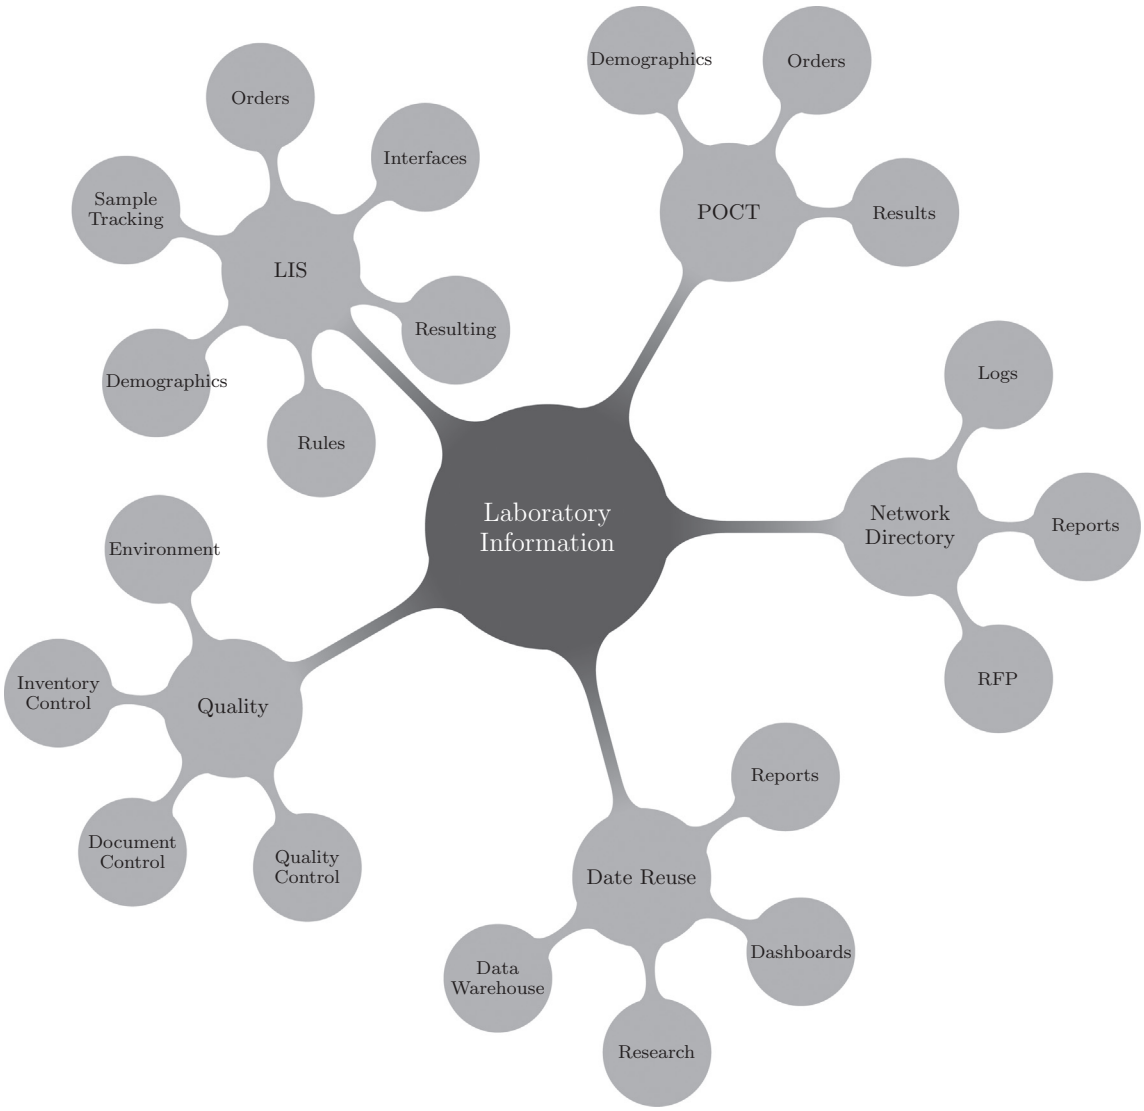

FIGURE 18.1 The informatics requirements of a clinical laboratory. Each secondary node represents a class of functionality required in a clinical laboratory setting. Tertiary nodes show specific examples of functionally.

technology integration that exists within a health system, the LIS can accept demographics and test orders, relay orders to instruments, and accept the verified results. Often, the LIS has interfaces for transmission of data to external systems such as electronic medical records or a data warehouse/repository. Finally, the LIS can automate many aspects within the total testing process; however, the extent of automation is dependent on the functionality of associated hardware (e.g., automation lines). The role of the LIS in process automation can include incorporation of QC rules for autoverification of results, the implementation of laboratory decision support rules such as delta flags, and the appending of prepared comments to results based on established laboratory triggers (or flags).

This chapter will focus primarily on the components of the LIS that are well established in clinical laboratory settings. A fully integrated LIS should allow a laboratorian reliable and timely access to the full breadth of information required to provide high-quality laboratory testing. However, it is important to recognize that laboratory information management is more than the LIS. As additional information relevant to the testing process is commonly not stored in a typical LIS, an overview of information stored outside the LIS will also be included in this chapter.

Management of digital laboratory information

Laboratory information systems

At the heart of clinical laboratory information management is the LIS. The LIS is required at each step of the

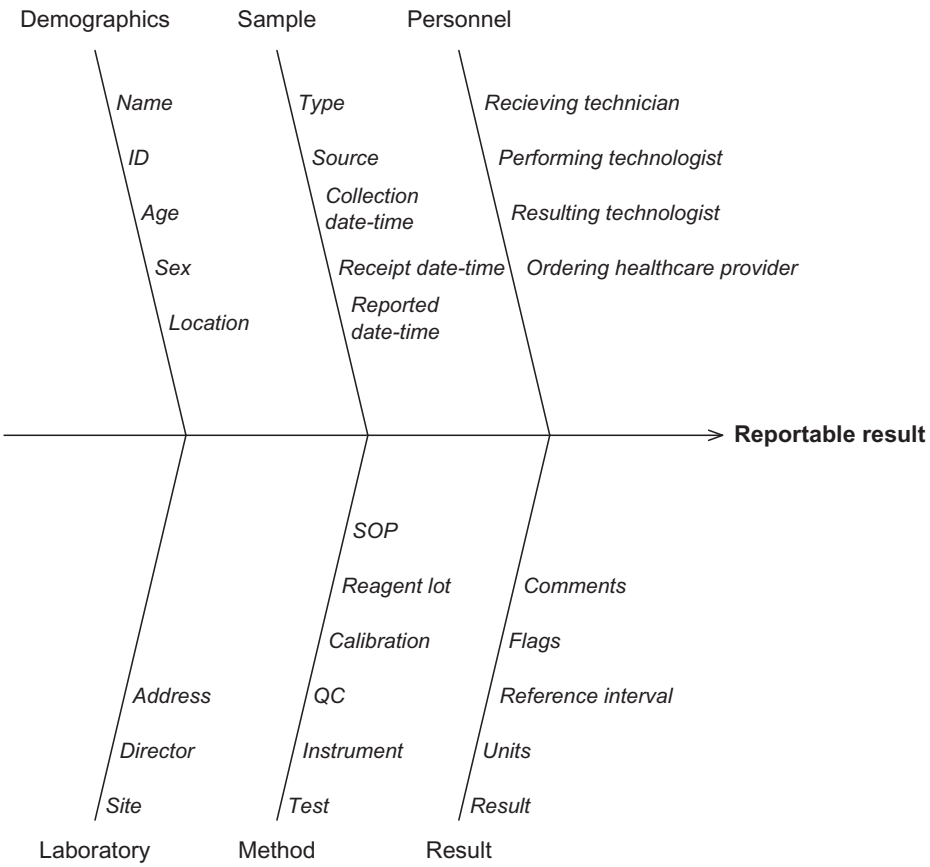

FIGURE 18.2 Streams of data that are linked to a reportable test result.

laboratory testing process, with information flowing to and from the LIS over the course of generating a result (Fig. 18.3). In this section, the testing process is broken down into the familiar preanalytical, analytical, and postanalytical phases for the purposes of illustrating the involvement of the LIS at each step. In the preanalytic phase, the LIS is involved in the processes of test ordering, specimen collection, and specimen processing. During the analytic phase, the LIS is necessary to route the specimen to the appropriate analyzers, to process data received back from the analyzer, and to generate a test result. In the postanalytic phase, the LIS is responsible for result transmission, report generation, and critical value identification and documentation

The LIS is a collection of software, operating systems, and hardware designed to serve the operational processes of the clinical laboratory. The configuration of the LIS is customizable and highly variable, depending on the needs of the individual laboratory. Most available LIS are modular, with separate software options for general laboratory (supporting chemistry, hematology, immunology, and other related laboratory sections), microbiology, and blood banking (also known as transfusion medicine); blood banking, in part due to the dissimilar nature of the information flow and enhanced regulatory requirements, may use a separate blood bank information system, as does Anatomical Pathology. Another key component, which may or may not be a part of a given LIS, is the Admission–Discharge–Transfer (ADT; Table 18.1) system (Fig. 18.3). ADT systems are the backbone of the patient encounter, providing demographic and patient status and location information status used to populate other systems [e.g., LIS, electronic medical record (EMR), and billing]. Underpinning all of these systems are interfaces, dictionaries, and worksheets.

Key concepts

Dictionaries and worksheets

The LIS provides the framework for the laboratory to exert control over the testing process. *The foundation of the LIS is a relational database containing a series of LIS dictionary tables* (Table 18.2). LIS dictionary tables (also known as maintenance tables) define the key elements necessary for the overall operation of the LIS. Examples of items defined in LIS dictionaries include tests, test worksheets, laboratory departments, available specimen and container types, ordering physicians, billing codes, and instruments. In essence, LIS dictionaries contain a dynamic list of all available people, places, and things.

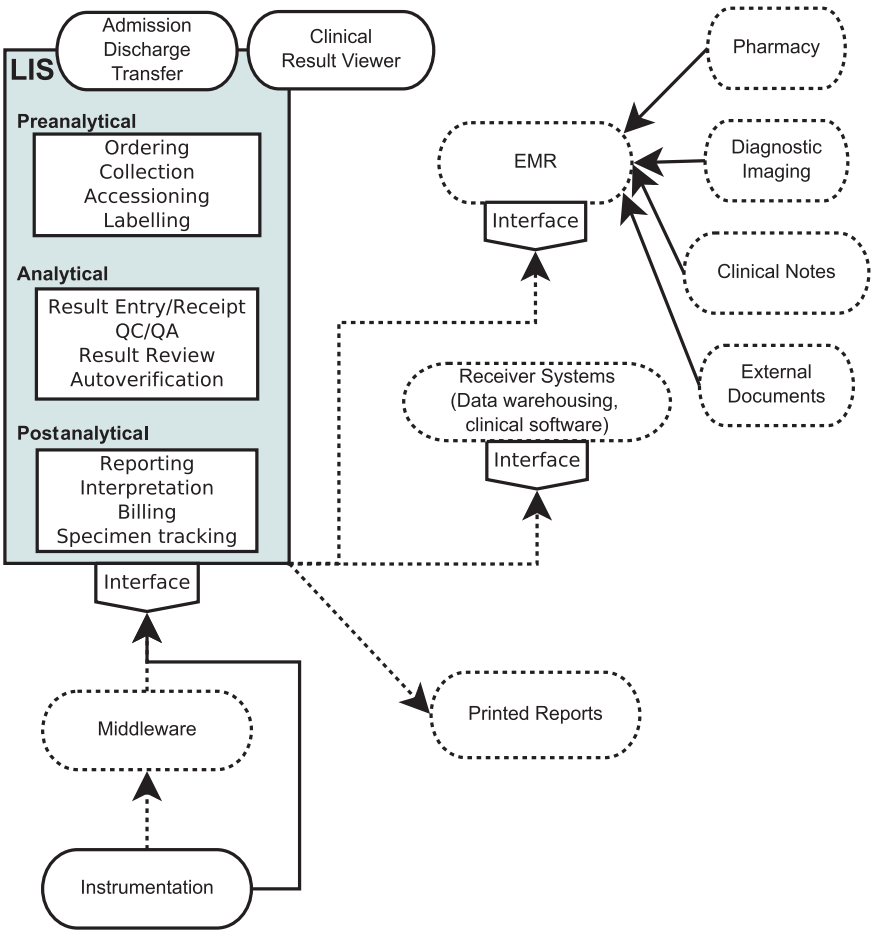

FIGURE 18.3 Overview of laboratory information systems structure and integration. The key components of laboratory information systems are the ability to order tests, collect and label specimens, and report results. Optional external components are surrounded by dotted lines, for example, where results may be transmitted to a data repository. Laboratory information systems have result viewers, though many systems transmit to an electronic medical record. Admission, discharge, and transfer systems also may be external to the laboratory information systems depending on whether the application is a single vendor suite or a composite of several different pieces solutions.

LIS dictionaries populate dropdown lists throughout the LIS application and limit choices in data entry fields to the items in the dictionary list. An example of the utility of this approach can be seen in the manual accessioning process, where the entry of the ordering physician from the ordering physician dictionary list promotes valid data entry; an attempt to order a test for a physician not in the system would be invalid. For each test in the LIS, several interrelated dictionaries define its key elements (Fig. 18.4). Careful attention to the content and maintenance of LIS dictionaries permits the processes of the laboratory to be standardized. LIS dictionaries may be prepopulated by the LIS vendor, but are highly customized to meet the specific needs and workflow of the individual laboratory (this can be both a blessing—in the form of site-specific workflow—and a curse in terms of lack of standardization and interoperability standpoints).

The LIS worksheet (or worklist) is a construct of the LIS that groups tests to be performed on a specific instrument or in a particular laboratory location. The worksheet is an important mechanism for standardizing laboratory workflow, since it links tests, instruments, and QC data. For manual testing, a printable version of the worksheet may be used to organize laboratory workflow and standardize processes. For automated instruments, worksheets are largely "virtual" and specify the elements needed for the correct transfer of data between the LIS and the instruments. Worksheets define the logical flow of a given test and are largely based on the instrument and location. A worksheet for a chemistry instrument, for example, would be linked to the test dictionary, QC and autoverification rules, as well as any associated calculation and available list of order sets.

Laboratory information systems: preanalytic phase

The preanalytical phase (Table 18.3) refers to the parts of the laboratory testing process that occur before a sample is analyzed. The preanalytical phase includes patient identification, sample collection and transportation, test ordering, specimen receipt, accessioning, and container identification (Fig. 18.5). The preanalytical phase accounts for an estimated 40%−70% of laboratory errors. These errors occur largely as a result of manual, highly

TABLE 18.1 Keyterms.

Term	Definition
Accession	Unique identifier for each specimen linked to orders and patient information.
ADT	Admission–discharge–transfer; patient registration system.
API	Application programming interface.
ASTM	American Society for Testing and Materials; defines standards for transmitting information from medical devices.
Big data	Databases that have one or more of the "three Vs": Volume, Variety (particularly of nonnumeric data such as free text), and Velocity (rate of data entering the database).
CID	Container identification; unique number for each tube; may be an extension of accession number.
CPOE	Computerized physician order entry; software allowing physicians to place orders digitally instead of using paper requisitions.
CPT	Current procedural terminology; codes defined by the American Medical Association used for billing; similar to ICD-10, but defines procedures rather than disease.
Discrete data	Quantitative whole number information; for example, counts.
EMPI	Enterprise master patient index; a database that spans a healthcare system, where a single patient identification number can be used across a multisite organization for an individual.
EMR	Electronic medical record; collection of patient health information stored in a digital format. Also called a clinical information system. Electronic health record is sometimes used as a synonym, though this may refer to a collection of EMRs.
Flat file	Plain unformatted text stored in a structure way (e.g., comma separate values).
HIPAA	Health Insurance Portability and Accountability Act; legislation regarding security and privacy of health information.
HIS	Hospital Information System; integrated clinical, financial, and operational information.
HL7	Health Level 7; standard messaging format for transmission of laboratory results.
ICD-10	International Classification of Diseases 10th edition; standard set of terms to catalog medical conditions.
Informatics	Use, storage, and acquisition of digital information to answer questions.
Interface	Computer system (driver) that translates and routes messages from one system to another.
LOINC	Logical observation identifier names and codes; standard naming system for laboratory tests.
Metadata	Information about a file or piece of information, e.g., file size, who created the file, date created.
Relational database	Information formally stored in tables, which use a set of rules and keys to connect to each other.
SNOMED	Systematized nomenclature of medicine; comprehensive set of medical concepts and terms used globally.

TABLE 18.2 Laboratory information systems dictionary fields.

Patient	Physician	Analyte	Sample
ID number	ID number	Name	Location
Date of birth	Name	Result	Encounter
Sex	Specialty	Flags	Reference interval
		Verification date-time	Ordered date-time
		Comments	Received date-time
			Priority

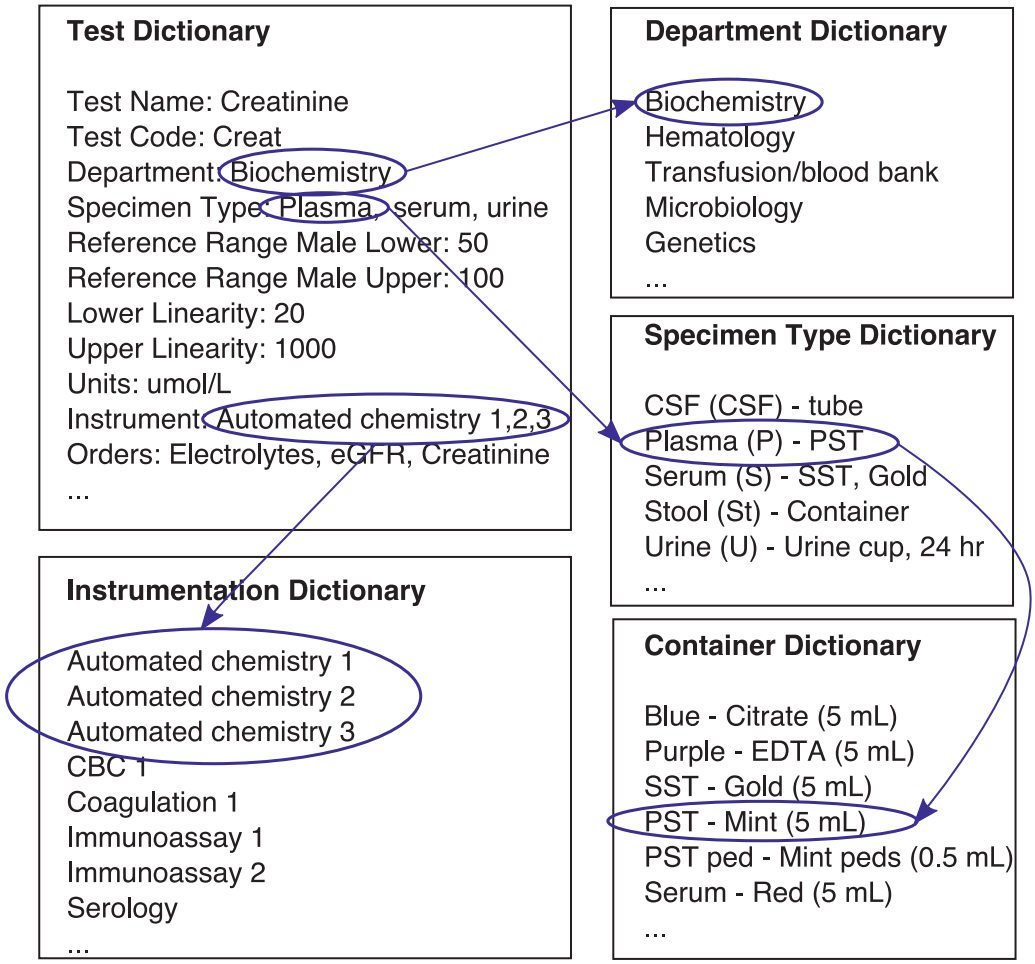

FIGURE 18.4 Laboratory information systems maintenance tables (dictionaries) define the key parameters of each laboratory test.

TABLE 18.3 Laboratory information system function in different testing phases.

Testing phase	LIS involvement in the testing process
Preanalytic	Patient demographics transmitted from registration system to LIS Tests requested by computerized physician order entry or manual test requisitions LIS converts test requests into orders and creates accession number for that order LIS provides collection lists of pending orders to phlebotomy service LIS creates barcoded specimen labels for tube labeling LIS electronically transmits orders to analyzer performing test LIS directs specimen for processing and analysis
Analytic	LIS creates instrument worklists LIS stores quality control data LIS verifies that results fall within reportable range and no flags requiring attention have been generated LIS autoverification finalizes result or a technologist reviews and releases the final result
Postanalytic	LIS sends electronic message with final result to clinical information system If test result is a critical value, the LIS alerts the laboratory staff to contact care unit emergently Clinical staff interpret results and act LIS sends test information to billing system

LIS, Laboratory information system.

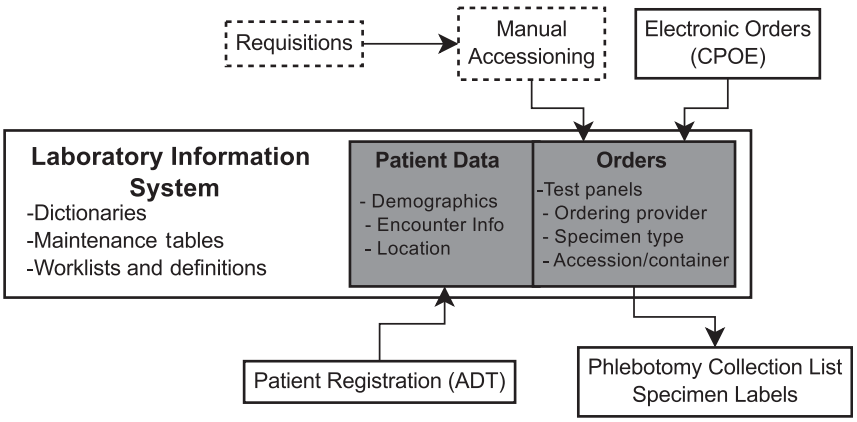

FIGURE 18.5 The role of the laboratory information system in the preanalytic phase of laboratory testing. The dashed boxes indicate error-prone processes.

variable processes, which are outside of the immediate control of the laboratory and include paper requisitions, manual registration, and manual LIS data entry. Preanalytical errors can be prevented with proper deployment of the LIS. The LIS can facilitate quality and safety by providing electronic interfaces for registration and ordering, phlebotomy collection lists, barcoded specimen identification, and process standardization.

Patient identification

Medical records rely on unique and permanent patient identifiers. Patient-specific information (e.g., a combination of name, date of birth, and health ID number) must be entered into the system before tests can be requested. In most health systems, the registration process involves acquiring patient demographic information. Patient demographics include patient name, date of birth, address, phone number, race (and sometimes religion), and sex. An important emerging LIS challenge is how to document nonbinary sex and gender. Briefly, demographic sex is defined as the biological assignment at birth based on external genitalia and chromosomes, whereas gender is a social/cultural construct and personal sense of being. While most LIS are designed to document binary sex only, an appropriate reference interval is required for result interpretation. Currently, there is a paucity of reference interval data on transgender patients, particularly those transitioning and on gender affirming hormone therapies. Consequently, laboratories should consider how to report patient results, either with cautionary notes or references to the albeit limited literature. Discussion with physicians is helpful in instances of hormonal therapy where the ability to provide appropriate reference intervals is limited. The situation is often complicated by the inclusion of biological sex in rules, calculations, and billing systems. Laboratories require procedures and practices to address these issues in the interest of patient care. In support of removing barriers to gender diverse patients, some hospital information systems (e.g., Epic) provide both preferred names and legal names and two- or three-step gender questions to document desired gender identity [i.e., female, male, transgender female (male to female), transgender male (female to male), other, or gender neutral]. Collectively, this is a complex topic with further guidance and software developments needed.

Using the aforementioned demographics, the registration system assigns the patient a unique medical record number (or retrieves it from a database) and electronically transmits patient demographic information to downstream systems, such as pharmacy information systems, clinical information systems, and the LIS. The registration system (ADT) transmits this information via a specially formatted message that is readily interpretable by the downstream systems; ADT messages conform to standards known as Health Level 7 (HL7). Where there are multiple institutions in a system, the entire health system may use an enterprise master patient index (EMPI) number. In such instances, the EMPI is used by all clinical systems at all institutions with a system, even if they also use a separate institutional patient identifier. The EMPI number allows the enterprise to maintain demographics centrally, simplifying the creation of a unified, enterprise-wide electronic patient record. Demographic information can also be manually entered into the LIS for patients that are unknown to the health system, as may occur with specimens sent from laboratory outreach clients. Irrespective of the scale and entry method, the LIS relies on patient identifiers and demographic information to report results.

Order generation

Orders are entered into the LIS either manually through staff who record paper requisitions or electronically in the form of computerized physician order entry (CPOE).

CPOE systems facilitate effective utilization practices by providing clinical order sets and care pathways based on the patient's clinical state. Since the physician is able to select only from available orderable tests, electronic order entry enables the removal of obsolete tests and the introduction of more appropriate options. CPOE applications have the additional potential for clinical decision support, such as test usage and reflex testing algorithms or suggestions for best practices. In CPOE systems, orders are transmitted electronically to the LIS at the time the provider requests the test. The LIS has order entry functionality where test requests, whether arriving via electronic messages or on paper requisitions, are converted into laboratory orders. In the case of paper requisitions, laboratory staff must manually enter the laboratory orders in the LIS upon receipt of the specimen and test requisition by the laboratory. The orders themselves come from physicians or other authorized ordering providers (nurse practitioners, midwives, and pharmacists depending on the state, province, and federal regulations). From workflow and error reduction perspectives, orders should come directly from the provider, whether electronic or paper-based, since misinterpretation and errors may occur when intermediates are involved in the order entry process.

Specimen collection

Specimen collection is driven either by batch collection lists from the LIS (e.g., morning collection rounds) or by *ad hoc* based on individual orders (e.g., outpatient collection or patient bedside). Typically, in a hospital system, collection lists drive the majority of inpatient collections with the goal of providing timely results for morning/evening rounding while taking advantage of the skills of phlebotomists. For collection lists, the LIS groups the orders by the desired collection time. Prior to the desired collection time, the LIS prints specimen labels in batches that contain at least two patient identifiers and specimen type (e.g., tube type) to collect. For *ad hoc* orders, specimen labels are produced on demand at the patient bedside with the use of specialized software and portable devices that permit scanning of a patient's wristband barcode and real-time printing of specimen labels. These are also known as "just-in-time" barcoding, where electronic orders are downloaded to portable devices, which print the appropriate labels and provide direction as to the type and number of containers needed to fulfill the order. Examples of devices used to scan wristbands and generate labels for blood tubes include Rover (Epic) and Bridge (Cerner; some versions). These systems close the loop on patient identification and eliminate many of the issues that arise by printing labels remote from the patient. For outpatient collections, labels and collection details (how many of each type of tube) are printed on demand based on the order. In all instances, samples are labeled with order, test, and demographic information and sent to the laboratory for analysis.

Specimen accessioning

The time at which a patient's orders are placed into the LIS, whether by electronic transmission from an order entry system or direct entry by laboratory staff, is known as the accessioning point. At the time of accessioning, the specimen receives a unique accession number (sometimes called a specimen number) used to track the specimen throughout the testing process. The accession number links the test orders and patient information to the specimen. In order to keep the accession number short, some LIS systems recycle accession numbers. Other LIS systems append the date to the accession number or utilize some other method to keep the accession numbers unique and permanent. In most LIS systems, each part of a given specimen (e.g., three different tubes that are drawn for one patient) is identified by a container ID (CID). The CID is a unique number that distinctly identifies every tube or container in a given specimen. If additional aliquots are obtained from the original tubes, those additional aliquot tubes are typically identified with unique CIDs. The CID is the key identifier that links order and result data in the analyzer and the LIS. The use of unique CIDs is a requirement for the use of robotic automation systems and is essential for specimen retrieval for adding on tests after the original order.

An example of the accessioning process is as follows: a provider fills out a paper requisition, requesting a basic metabolic panel (BMP) and a complete blood count (CBC). Two tubes (one lithium heparin tube for the BMP and one potassium EDTA tube for the CBC) are received by the laboratory along with a paper test requisition. At this point, the laboratory staff accessions the specimen and the LIS assigns an accession number to the entire order. The two individual tubes are assigned unique container identifiers, and the test orders are associated with those CIDs. The LIS generates tube labels that include the CID barcoded on the label.

Other information typically entered into the LIS at the time of test accessioning includes visit information for the patient-provider encounter that resulted in the laboratory testing. This visit information (often a unique "visit ID" or laboratory encounter ID) is stored in the LIS and is associated with the specimen. The visit information is important for patient billing, since the linkage of the laboratory testing to the clinical encounter may be needed to justify the medical necessity of the testing. Other data elements captured during the accessioning process that may be important for billing and reimbursement may include

the patient's diagnosis code [International Classification of Diseases, 10th Revision (ICD-10 code)] for that visit.

Specimen identification

Specimen identification is essential for the accurate reporting of results. Manual transcription, as may occur during manual laboratory accessioning, is likely to be the most important source of laboratory errors, with one in every 300 keystrokes estimated to be in error. Transpositions of digits or misplaced decimal places are especially difficult to detect as errors and can lead to result misreporting. In the preanalytic phase, CPOE and electronic transmission of orders to the LIS are important strategies for reducing manual transcription and its attendant errors. In addition, barcodes are heavily utilized in the laboratory to prevent transcription errors, as well as to identify and track specimens throughout the testing process. In most systems, each tube of a specimen is uniquely identified with a barcode. Barcode specimen labels allow simplified specimen tracking throughout the laboratory with the use of automated barcode scanners or manual scanning by laboratory staff. Most highly automated instruments will have barcode scanners incorporated into the instrument to permit automatic identification and tracking of barcoded specimens.

For tube identification, laboratories typically use linear or 1-dimensional barcodes (a series of black lines and spaces). The linear barcode on the LIS specimen label typically encodes the CID. Formats for the linear barcodes used in laboratories include Code 128 and Code 39. A limitation of linear barcodes is that they can be subject to reading error if the print quality is low or the label is poorly applied. Two-dimensional barcode formats, such as PDF417 and Data Matrix, store data using two dimensions of a surface. These formats enable more data to be represented in the barcode, with some 2-D formats holding hundreds of characters in a single square centimeter. The major disadvantage of the 2-D barcode formats is that they need a more sophisticated barcode reader (scanner) than the simple readers used for linear barcodes.

Radiofrequency identification (RFID) is a newer autoidentification technology that utilizes radio waves to identify objects. RFID systems utilize a small electronic tag that is read by an RFID scanner analogous to the way that a barcode scanner reads a printed barcode. The RFID tag consists of a small integrated circuit attached to an antenna. Data regarding the tagged object is stored in the memory of the integrated circuit. Information is sent wirelessly to or from the RFID tag via radiofrequency signals generated by the RFID scanner. RFID tags can hold large amounts of information, can be very rugged, and can be read through other materials, not requiring a line of sight between the reader and the tag. RFID tags may be well suited for numerous applications in the laboratory testing process including specimen tracking and patient wristband identification. Several automation vendors are currently using RFID technology as the basis of their automation specimen tracking systems. While they are used for carriers on automated lines, RFIDs are considered too expensive (in the current landscape) for widespread implementation and replacement of labels and barcodes.

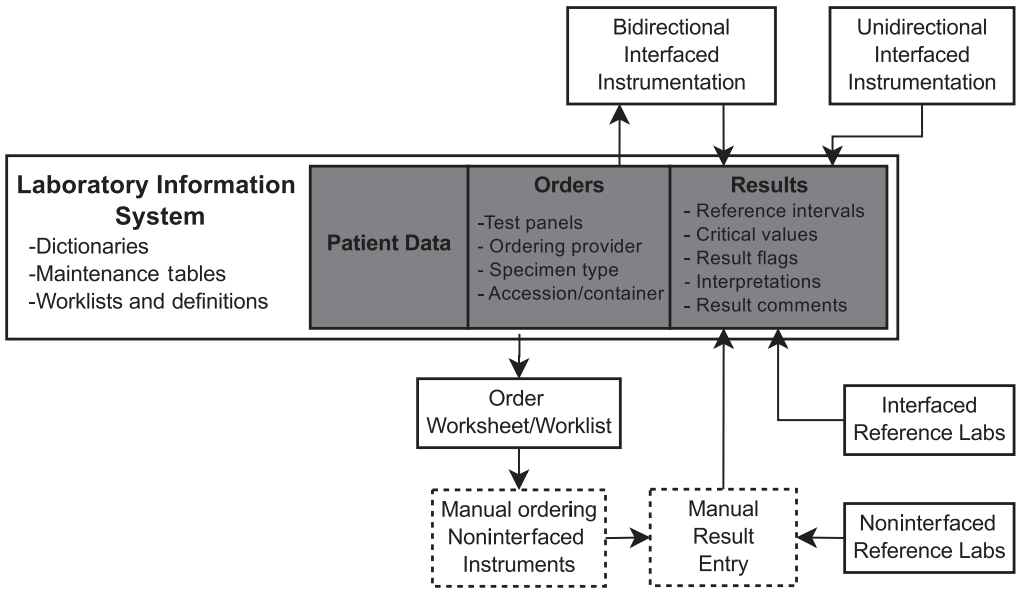

FIGURE 18.6 The role of the laboratory information system in the analytic phase of laboratory testing. The dashed boxes indicate error-prone processes.

Laboratory information systems: analytic phase

Manual results entry

Results are manually entered into the LIS when instruments are not interfaced (Fig. 18.6). These instruments may include osmometers, spectrophotometers, readers (e.g., pregnancy tests), and other technologies that are utilized too infrequently or are performed manually, making interfacing less advantageous from an economic perspective. For low-volume testing platforms, LIS interfaces can be costly in terms of both the capital and labor to install and validate the interface. For testing performed on noninterfaced instruments, the LIS typically provides a printed worksheet of pending orders organized with blank space to permit manual result transcription and to facilitate subsequent manual result entry in the LIS. Given the high rate of transcription errors due to keystroke mistakes, it is essential to have a QA plan in place to oversee manual resulting. One example of such error detection measures is the use of delta checks to identify mislabeling. Another option is for a secondary analyst check the transcription and result entry. In some jurisdictions, secondary checks of manually transcribed results are a regulatory requirement (Institute for Quality Management in Healthcare).

Instrument interfaces

Most laboratory tests are performed on analyzers that exchange data with the LIS through instrument interfaces. Interfacing high-volume automated instruments with the LIS greatly improves productivity and reduces errors. To interface an instrument, the LIS must be configured with software called a device driver or medical device interface (MDI) that allows the LIS to communicate with the instrument. Instrument manufacturers typically provide interface specifications to LIS vendors in advance of instrument introduction. Most instrument−LIS interfaces are based on standards and protocols defined by the American Society for Testing and Materials (ASTM), though newer standards that have been actively developed over the past 5 years are likely to supplant and improve current interoperability (e.g., Laboratory Analytical Workflow standards).

Instrument interfaces can be unidirectional or bidirectional. Unidirectional interfaces solely send results from the analyzer to the LIS. This type of data transfer may also be referred to as a data "upload," the direct transfer of results from the analyzer to the LIS. In a unidirectional interface, there are no data transmitted from the LIS to the instrument, so orders and patient/specimen-identifying information must be entered into the analyzer. The unique CID for each specimen container can serve as the identifying link in these scenarios, since the CID in the LIS is associated with the patient demographics. In addition, since the CID is typically barcoded on the specimen tube, having the analyzer scan the tube barcode can provide a simple way to provide specimen-identifying information to the analyzer. Laboratory blood gas instruments are often configured with unidirectional interfaces, since the full blood gas menu is performed on every sample, and thus the LIS to analyzer transfer of orders is not necessary.

A bidirectional interface permits the LIS and the analyzer to send data back and forth, eliminating the need for the direct entry of orders and patient/specimen identifiers in the analyzer. Bidirectional interfaces are typically required for random access analyzers (such as chemistry systems) where a wide variety of different assays may be performed on a given sample. With a bidirectional interface, the LIS sends patient/specimen identifiers and orders to the analyzer and the analyzer sends the results to the LIS. If the laboratory is already entering orders into the LIS, a bidirectional interface eliminates the need for reentering orders and patient/specimen identifiers in the analyzer. The transfer of patient/specimen identifiers and test orders from the LIS to the instrument is referred to as a "download" (the instrument downloads the information from the LIS). Depending on the sophistication of the interface and the instrument, bidirectional interfaces may send orders/demographics to the instruments in batches (batch download mode) or may dynamically send the information to instruments when requested (host−query interface mode).

Quality control and quality assurance

The LIS is essential to the laboratory for QA. The LIS provides the data elements necessary for the monitoring of assay turnaround time (TAT), since it timestamps the key events for a laboratory test: ordering time, collection time, in-laboratory receipt time, accessioning time (time orders are entered into the LIS), and result time. Specimens that have been received by the LIS but not yet resulted will appear on the technologist's pending test list, compelling them to investigate specimens that have remained on the pending test list for longer than the usual periods of time. In addition to TAT reports, a wide variety of other management reports are available from the LIS, including testing volumes, workload statistics, and billing. Further, the ability to create "*ad hoc*" reports from the LIS is supported in most LIS platforms. A sample *ad hoc* report would be to "select all calcium results from the last 12 hours that were below the reference interval"; further specific examples are shown later in this chapter. The LIS should provide views and reporting tools such that staff can easily create reports to ask important management and clinical questions. As

more data are available, an evolving role for laboratorians is to extract, analyze, and interpret information from the LIS to add value to the testing process.

Results review

The validation of results is an important function of the LIS. The preliminary result of an assay is flagged as "preliminary" or "performed" as it awaits technologist review. The LIS then provides an interface where technologists can review and release (e.g., finalize or verify) results. To ensure that only valid results are released, the LIS may apply rules to facilitate comparison of results against other laboratory metrics, including the reportable range for the analyte, the analyte reference range, or critical value limits. Critical value limits are defined in the LIS test dictionary. Critical values are defined as test values that would place the patient in immediate danger if not promptly treated. An example of a critical value would be a potassium result of 8.0 mEq/L. Such a patient with severe hyperkalemia would be at risk of potentially fatal abnormal heart rhythms. It is imperative that the LIS immediately alert a technologist to a critical value, since the patient's care team needs to be contacted immediately. Many LIS have modules that alert laboratory staff to the presence of a critical value result and permit documentation of the communication to the care team, both of which are necessary for patient care and regulatory requirements. In addition, the current results may be compared to the patient's prior results (a delta check) to alert the technologist to possible erroneous results. Delta checks may alert the technologist to a possible patient identification error or the change in test results may reflect a physiologic event in the patient.

Rules and calculations necessary for result reporting also typically reside in the LIS. Calculation of the international normalized ratio, the anion gap, and the estimated glomerular filtration rate are examples of calculations performed by the LIS. It is essential that the laboratory carefully tests calculations, especially in situations involving unknown patient age or sex, out of range results, and corrected results. Rules in the LIS also provide support for laboratory reflex algorithms. An example of a rules-based reflex algorithm would be to perform testing for free T4 on a specimen where the thyroid-stimulating hormone level was elevated. Reflex algorithms require the LIS to generate automatically orders for the additional testing based on the initial result.

Autoverification

Traditional technologist result verification, as described above, relies on "mental algorithms" that are applied to single results or groups of results. Reliance on individual judgment can lead to variability in process and error. Autoverification (automatic verification or autovalidation) refers to the process where computer-based algorithms perform actions on laboratory results without technologist review. The automated actions may include releasing results to the EMR, sample dilution, cancellation of associated orders, repeat analysis, reflexive testing, or adding comments to specific results. Most commonly, autoverification algorithms are utilized to release automatically results without the need for technologist review. To facilitate autoverification, most LIS have a parameter called the "release range," which can be defined for each test expressly for the purpose of autoverification. A carefully designed autoverification algorithm can lead to improved TATs, increased operational efficiency, and a more consistent process. In particular, it is not possible for humans to review thousands of results over a shift with the attention to detail required to identify potential errors or subtle patterns.

Autoverification rulesets may reside in the LIS or in middleware (Fig. 18.3). In order for autoverification to be implemented safely, the characteristics of the test must be thoroughly validated, and algorithms must be designed into the LIS. A typical autoverification rule would permit test values for a particular analyte to be autoreleased, provided the resulted value falls within a specified autoverification range (e.g., the release range), no QC failures are present, and no instrument flags are present. Delta checks are also commonly incorporated in autoverification algorithms. Autoverification algorithms should be thoroughly tested and periodically reevaluated to ensure that the rules are performing as expected. There are regulatory requirements (e.g., College of American Pathologists) for policies, audit trails, and autoverification retesting at least annually and each time there are system changes. Specific requirements vary with the regulatory body, but may include the need for procedures and testing of QC rules, dilutions, repeat testing, flags, and limits.

Middleware

In addition to test results, decisions during the analytic phase of laboratory testing may depend on clinical data such as the medication list, unreported test parameters, additional analyzer data, QA/QC data, the results of other tests, as well as historical test performance data. Many current LIS platforms do not have access to these data and alone have the capacity to generate an integrated display of such disparate information or to incorporate these data elements into rules and algorithms. To fill this need, laboratory "middleware" [software in the "middle" among the LIS, laboratory instruments, or point-of-care (POC) devices] has been developed to extend the capabilities of the traditional LIS. Middleware may be provided by the

instrument vendor or a third party and provides an environment for sophisticated rule-based processing.

The more advanced rule-based approaches, available through middleware and some advanced LIS vendors, allow rules to be authored that can provide control of retesting, alert when interfering conditions are present, permit reflex testing across multiple specimens and instruments, as well as support automated test add-ons and specimen tracking. In addition to its use for rules-based processing, middleware is often required for the high-resolution specimen tracking necessary for robotic automation lines and for centralized control of instrumentation.

Laboratory information systems: postanalytic phase

Reporting

The postanalytic phase of testing involves result access and interpretation by clinicians (Fig. 18.7). Optimal reporting relies not only on data availability but also on a presentation that makes result interpretation intuitive, efficient, and unambiguous. Further, laboratory reports may serve important medicolegal purposes. Well-designed electronic reporting applications can improve retrieval efficiency and clarity by highlighting recent results, grouping related tests, and enabling clinicians to filter results based on time intervals. Moreover, the availability of customizable, user-friendly charts and graphs allows identification of time-based patterns and intertest relationships. The laboratory does not typically control data displayed within the results viewer such as the hospital's EMR system or personal digital assistant-type results viewers. However, laboratory accreditation requirements require that the laboratory validates the display of laboratory results in downstream result-viewing applications. The laboratory review of result display should pay particular attention to the appearance of result flagging, reference intervals, test and specimen comments, and corrected results. In addition, the laboratory must ensure that the format of results printed out of the EMR and other applications (including the LIS itself) are unambiguous and meet all regulatory requirements for printed laboratory reports.

Result interpretation

With the increasing number of test options and complexity, many clinicians are unable to maintain sufficient knowledge to interpret complex laboratory test results in all clinical circumstances. Rules can be implemented in the LIS to attach coded comments (short interpretive paragraphs) to provide interpretive support for complex test results. For example, hepatitis B test panel results may be accompanied by an automatically generated coded comment that can differ based on the results of the hepatitis panel. In recent years, there has been interest in pathologist-provided interpretive reporting for complex laboratory evaluations such as coagulation and immunology workups. In this approach, a pathologist expert reviews the laboratory testing in the context of the patient's clinical condition and creates a patient-specific interpretive report that is transmitted to the medical record and is available alongside the test results. Interpretive laboratory reports may include a narrative describing the differential diagnosis, pertinent details about the assays that may affect their interpretation, and suggestions for additional testing. In several studies, narrative interpretations created by clinical pathology experts appear to provide positive benefits to the physician, the patient, and the hospital.

Billing

The LIS must report to financial systems an accurate accounting of all tests performed by the laboratory. For each transaction, the LIS typically reports to the billing system the test performed, patient demographics, ordering physician, visit information, and patient's diagnosis. Failure to collect and report this information accurately can lead to nonpayment or regulatory noncompliance. The LIS billing interface must be able to manage tests

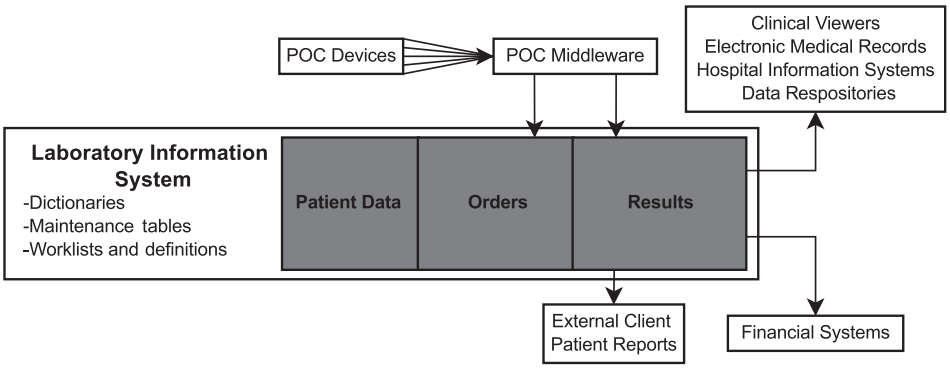

FIGURE 18.7 The role of the laboratory information system in the postanalytic phase of laboratory testing.

added onto the original order and ordered tests that were not performed. The interface with the billing system may dynamically transmit data for tests as they are resulted or the interface may operate in batch mode, sending a daily batch of qualifying tests.

Point-of-care results

With the rapid growth of POC testing, there is increasing interest in having POC results available in the EMR. In most settings, transmission of POC results to the LIS is a requisite step for POC result availability in the EMR. Transmission of results from the POC devices to the LIS occurs via an intermediate data management system (a "data manager" or middleware system) that is interfaced with the individual POC devices. The data manager then transmits data to the LIS. Some data management systems also provide functionality that allows users to result non-interfaced, manual testing (e.g., rapid flu antigen, stool occult blood) into the data manager, facilitating transmission of these results into the LIS and EMR.

POC interfaces differ from other result reporting interfaces, since for POC tests, the interface must simultaneously order and result in testing. Recent standardization of the interfaces among the POC devices, data managers, and LIS has improved the transmission of POC results to the LIS. In addition, this standardization has enabled the development of "vendor neutral" data managers capable of interacting with a wide array of POC devices from different manufacturers. This permits an organization to have a single interface between the data manager and the LIS transfer a wide array of POC test results.

Data exchange and standards

LIS were once largely standalone systems where laboratories managed data generated within the laboratory. This is no longer the case with the LIS being highly connected and involved in all phases of the diagnostic testing process, from test ordering to interpretation. The current generations of LIS are an integral part of the healthcare system and must interact with numerous other systems to function effectively (Fig. 18.3). The LIS must exchange data with practice management systems, hospital information systems, electronic medical record systems, and billing systems.

The connection of the laboratory to the rest of the hospital relies on standardized message formats and communications. Data exchange between these various information systems occurs via application interfaces. These interfaces include the software, protocols, and connections that enable electronic data exchange from one system to another. Common messaging formats and communication protocols serve to standardize data exchange between applications. The recent development of interface engines, which serve as "traffic cops" to route data between applications, has also improved communication in healthcare organizations.

Health Level 7 standards

HL7 is a standard messaging format for data exchange between information systems. HL7 is commonly used to send orders from an order entry system to the LIS and to send LIS results to a clinical information system. It also is used for ADT systems to transmit relevant demographic

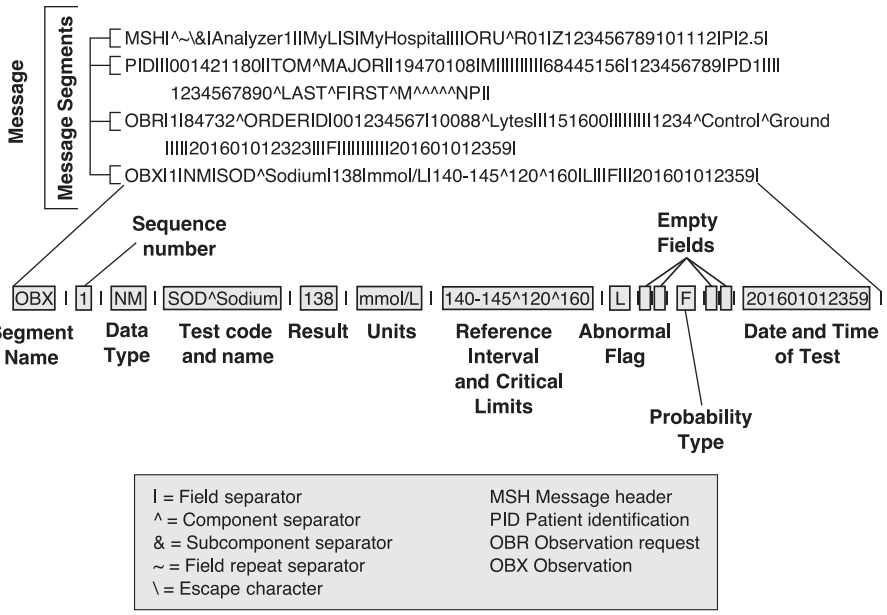

FIGURE 18.8 A sample Health Level 7 message. The message is a result message sent for a sodium result, with a value of 138, which is below the reference interval.

and patient status information (e.g., ADT-A01 is the code for admitting a patient). HL7 defines the types of messages that can be sent as well as the data that can be exchanged in each message. The use of extensible markup language (XML) for the encoding of data for storage, display, and transmission has become standard in many industries. Recently, healthcare has begun to utilize XML to supply the framework for clinical data, and XML-compatibility has been incorporated into newly developed HL7 standards.

HL7 message types include messages for test orders, test results, and ADT notifications. In addition, HL7 defines how the messages are to be exchanged and provides error communication guidelines. Each HL7 message is divided into segments [e.g., message header (MSH) segment and result/observation (OBX) segment] and the segments are further divided into fields (separated by the vertical bar character, "|") that contain the data to be exchanged (Fig. 18.8). For example, in the OBX (result) segment of the message, the OBX-3 field contains the test name and the OBX-5 field contains the test result value. In the example, the test name field in OBX-3 is divided by the caret character ("^") into two data elements, the test code, and the test name (e.g., 4498-2^Complement C4).

Logical observation identifier names and codes

Logical observation identifier names and codes (LOINC; see Table 18.4) is a standard for naming laboratory tests. LOINC attempts to provide a universal code to identify over 30,000 different laboratory-related items. LOINC specifies each test with a multipart name that includes the analyte name, property measured, timing (e.g., random time point or part of a timed collection), specimen type, and method (Table 18.3). LOINC was designed to enable disparate systems to more easily exchange and aggregate laboratory data. The utility of LOINC may include enhanced communication in integrated healthcare delivery networks and support for electronic health records, improved infectious disease surveillance, and improved laboratory test billing. The difficulty in utilizing LOINC is that there are many similar codes, and assignment of a specific code to a local laboratory test method can be challenging. LOINC is compatible with usage within HL7 messages and may be included in the result segment of an HL7 message.

Management of nonlaboratory information systems data

Unfortunately, no LIS capture all the data required to understand all aspects of the total testing process for a sample. Data that are typically not included and or maintained within the LIS include operational procedures, administrative data, environmental monitoring data, and spreadsheets. This section will discuss systems, requirements, and approaches for managing data that are not housed in the LIS. Non-LIS data can take many forms and are managed in a variety of ways; this section will focus on document control systems, quality and inventory control software, and networked file servers Topics are addressed in descending order of robustness, beginning with commercial off-the-shelf dedicated systems down to storage on shared network drives.

Standalone software systems

Inventory control, sample archiving, QC, and document control systems are all development tools that often have limited integration with the LIS. These systems are each complex independent software tools with many features and requirements. What follows is a discussion of the minimal requirements to link information housed in these systems back to patient test results.

Document control

Standard operating procedures are often housed in a standalone electronic document control system. One key requirement is that relevant standard operating procedures in use at the time of testing can be reliably retrieved and

TABLE 18.4 Logical observation identifier names and codes examples.

Code	Component (analyte) property measured	Timing	Specimen type	Scale
5802-4 Nitrite ACnc	ACnc	Pt	Urine	Ord
49563-0 Troponin I.cardiac	MCnc	Pt	Ser/Plas	Qn
2823-3 Potassium	SCnc	Pt	Ser/Plas	Qn

ACnc, Arbitrary concentration; *MCnc*, mass concentration; *Ord*, ordinal scale; *Pt*, random time point; *Qn*, quantitative; *SCnc*, serum concentration; *Ser/Plas*, serum or plasma.
http://s.details.loinc.org/LOINC/49563-0.html?sections = Simple.

reviewed. This is accomplished via a revision control system in which timestamped changes are linked to a user ID. Thus, at any time, a test result can be linked back to the appropriate version of a relevant procedure. The traceability between a result and the relevant procedures is vital for understanding the preanalytical, analytical, and reporting contexts of historical laboratory results.

Quality control

While some LIS programs have built-in QC modules, many laboratories opt to use a standalone QC system. Standalone systems typically have some advantages over a built-in program, including peer data availability, superior graphing capabilities, options, and customization, and associated modules for QC design, risk evaluation, QC rule selection, and uncertainty calculations. Built-in LIS QC programs are easier to interface and often have no added cost. However, they usually have limited graphing options and only basic functionality.

In general, QC systems record information about the QC material in use, such as name, catalog number, concentration, and lot number. The software allows for visualization of QC data over time. Equally important is automation of QC multirules and recording of timestamped metadata about the assay method such as maintenance, calibration, and reagent lot changes. This timestamped information is essential for assessing assay performance at the time of patient testing. These data may be retrospectively retrieved during laboratory investigations or audits. This traceability is required by regulatory bodies and legislation (e.g., Clinical Laboratory Improvement Amendments), which mandate that QC information for laboratory testing be directly linkable to the laboratory test result, and the LIS typically provides this functionality.

Inventory control

Commercial inventory control and sample archiving systems are not ubiquitous in clinical laboratory settings. Inventory control systems track information such as inventory location, lot, source, quantity, and expiration date. Inventory management systems ideally track expiry dates and flag inventory when quantities are below a set limit; however, many labs still use paper logs or spreadsheets to track inventory. Similarly, many labs have home brewed methods for archiving patient samples. Commercial sample archiving software tracks sample location, along with sample type, and patient identifiers.

Due to the maturity and sophistication of inventory control, sample archiving, QC, and document control systems, they appear amenable to integration with a modern LIS. In some cases, these systems may be included as a module within the LIS. However, a best of breed approach is possible through application interfaces between the LIS and the external systems; middleware programs are an example of this approach at work.

Servers, directories, and security

In the clinical laboratory, data that are not stored in the LIS or a commercial application are often stored on a networked drive with shared access. These networked drives reside on servers administered by the laboratory, department, or institution. Servers are computers that run an operating system configured for client/server networking. Client/server networking allows a program on a user's computer, called a client, to connect via a network to another computer called a server, through requests sent to the server's Internet protocol (IP) address. Servers are configured to provide access to shared resources, such as databases, and directories through open ports. These ports act as doors to access resources at the server's IP address. The server's operating system uses a network protocol to communicate with clients and fulfill requests. Server message block and network file system are two network protocols commonly used to allow clients to access files over a network. Storage of laboratory files on a shared network drive allows multiple users to access resources and facilitates scheduled backup of all stored data.

A networked file server allows user-controlled access to the servers file system. A file system controls how data are stored and retrieved by separating data into pieces and assigning each piece a name. Each named group of data is a file, and the structure and logic used to manage the groups of information are the file system. While not important for the file system, a consistent file naming convention is vital for users of the file system. Directory structures provide additional organization of files for the benefit of users and are also used to control user access to sensitive information as discussed in the next section.

Security and access control

Privacy of healthcare information is of utmost importance to the clinical laboratory. It is a good practice, regulatory requirement, and typically legislated requirement. In the United States, the Health Insurance Portability and Accountability Act (HIPAA) stipulates how personally identifiable information maintained by the healthcare and healthcare insurance industries should be protected from fraud and theft. The General Data Protection Regulation (GDPR) sets a similar direction in Europe. Modern file systems provide two levels of security to assist laboratories in complying with HIPAA and GDPR: access control and encryption.

File and directory access are managed via access control lists. An access control list is a table of entries that specify user or group rights to a specific file or directory.

Users are identified by logging on to the client system with a user name and password. User and group rights can include a combination of reading, writing, executing, and deleting a file.

Encryption is valuable in cases where the access control has been bypassed. Encryption encodes information so that only authorized parties can access the unencrypted content. Encryption does not prevent interference such as deletion of information, but denies the content to unauthorized users. There are two main forms of encryption for networked directories: file system-level encryption and full disk encryption. File system-level encryption is a form of disk encryption, where individual files or directories are encrypted by the file system. In file system-level encryption, metadata, such as directory structure, file names, sizes, and modification timestamps are not protected.

In contrast, full disk encryption encrypts the entire partition where the file system resides hiding the metadata. File system-level encryption allows files to be accessed and decrypted based on access-control lists. It should be noted that storage of laboratory data on a networked shared drive also provides physical security in the form of limited access to the secure server room.

File types

There are two generic types of computer files: text files and binary files. Text files are the most simple and flexible file type and are commonly used for long-term storage in flat files. Flat files are simple file types that have no internal structure or hierarchy. Typical examples used in the laboratory include comma separated values (CSV) files and plain text files. The characters in a text file are encoded either using American Standard Code for Information Interchange (ASCII) or the more modern Unicode (Universal Coded Character Set) Transformation Format-8-bit (UTF-8). Unicode is a computing industry standard for the consistent encoding, representation, and handling of text expressed in most of the world's writing systems. UTF-8 is an 8-bit character encoding system that is compatible with the older ASCII standard. Text files allow only plain text content with very little formatting (e.g., no bold or italic types) and can be viewed and edited in simple text editors. The advantages of text files for data storage include universal adoption, cross-platform compatibility, human readability, and resistance to file corruption. The CSV format is an example of a text file commonly used for data storage in clinical laboratories.

A binary file is a file type that contains more than plain text and is usually stored as a sequence of bytes intended to be interpreted as something other than plain text. A Microsoft excel spreadsheet file (XLS) is an example of a binary file. An XLS file contains formatting information, formulas, and graphics in addition to plain text. Converting an XLS file to CSV strips away all of the binary data resulting in a plain text file. Binary file types are essential for the day-to-day running of a clinical laboratory, but are not well suited to long-term data storage. One of the main vulnerabilities of binary files for long-term data storage is the need for proprietary software for interpretation. Consequently, the laboratory will have to keep copies of software on hand in order to access the contents of binary files. This can be problematic as vendor support for operating systems and software changes and expires.

Secondary data use

When considering the uses and management of electronic laboratory data, it is important to separate primary from secondary uses. Primary uses include preanalytic workflow of entering patient demographics and lab test orders, as well as postanalytic workflow of entering and verifying results and generating invoices. In other words, primary uses are transactions directly in support of the performance of individual tests. Most of the functions of LIS and other clinical information systems would be considered primary. Secondary uses, on the other hand, include a wide range of activities that occur after the generation of individual test results (see Table 18.5) to address clinical, operational, research, and business questions. Most

TABLE 18.5 Examples of secondary uses of laboratory data.

Clinical uses	Generation of antibiograms
	Detection of outbreaks
Operational uses	Calculation of laboratory throughput
	Analysis of quality control trends
Research uses	Biomarker association studies
	Analysis of historic disease trends
Business uses	Calculation of cost to serve different customers
	Analysis to support marketing efforts

secondary uses involve aggregation and analysis of data across multiple patients and/or tests.

Data warehousing

In order to support fully the secondary uses of data, healthcare organizations often build data warehouses that are separate from LIS and other transactional systems. Data warehouses that are broadly inclusive of data from the systems across the organization are referred to as enterprise data warehouses. Single-department warehouses are typically referred to as data marts. Although most transactional information systems (i.e., those in support of primary data use) allow longitudinal queries and in theory could support a number of secondary uses, there are a number of technical benefits to setting up independent data warehouses. One is performance. Within a busy laboratory, every second counts, and you do not want technologist workflow to be impeded by an LIS that is processing a massive longitudinal query. LIS database architectures are optimized for rapid individual transactions rather than large longitudinal queries. Another issue is that for many types of secondary uses, it is necessary to merge data across multiple sources. For example, a research query might involve data from both the laboratory and the radiology department, and a business query might involve data from both the laboratory and a customer relationship management system.

Creating a data warehouse involves much more than simply replicating data from multiple systems into a single large database. A number of issues must be considered in order to make the database useful and reliable for its intended purposes.

- Consistent data definitions: Users of the data warehouse need to know the precise definitions of the fields in the database. For example, a data warehouse might include a field named "Specimen collection time" to record the time of phlebotomy. This field could be useful for calculating TAT for different tests. Suppose, though, that the laboratory might not have a process for recording the time of nurse collections and that, for these specimens, the "Specimen collection time" field contains the time at which the specimen is received in the lab. Alternatively, the data from nurse collections might be entering the data warehouse from a separate nursing information system in which the collection times are defined differently from those in the LIS. A database analyst wishing to use this data warehouse field to produce TAT reports would need to know these details in order to avoid producing misleading results. A similar and very common issue is that the use of a field in an upstream transactional system can change over time due to changes in the associated work processes. Ideally, during the construction of the data warehouse, a different field is created for each different version of the collection time in order to retain integrity of data definition. But at a minimum, all these data definition details need to be documented in a central location.
- Use of clinical data standards (see also section on data standards for the laboratory): Established medical coding and terminology systems such as LOINC, ICD-10, and Systematized Nomenclature of Medicine can be used to increase both the quality and the usefulness of a clinical data warehouse. When disparate source systems map their data onto common standards, it facilitates the integration of these sources into the warehouse. Even more important, standards enable analytic and visualization tools to produce more useful output with far less end-user effort.
- Transformation and cleansing: Data warehouse loading processes are often referred to as extract, transform, and load (ETL). An extract from a transactional system might have missing and/or nonsensical data due to errors in the originating systems or the extraction process. A data warehouse ETL process should, therefore, check for these conditions. For example, the ETL software could check birthdate fields to ensure that all birthdates are in the past, but no more than 120 years in the past. Transformation also includes normalizing data, e.g., converting fields, such as dates, to a common format.
- Timeliness: Most data warehouses are not populated in real time, but rather rely on daily, weekly, or monthly extracts from the source systems. This is not a problem for most research applications, but it can limit the types of clinical, operational, and business functions that can be supported by the data warehouse. To the extent possible, it is helpful to identify requirements for near real-time data prior to the construction of the warehouse and ETL processes.

Decreasing storage costs, together with newer and more flexible database management system, have created opportunities to create and use much larger and more complex data sets than those in the past. The term "Big data" is often used to refer to databases that have one or more of the "three Vs": Volume, Variety (particularly of nonnumeric data such as free text), and Velocity (rate of data entering the database). A fourth V, Veracity, refers to data that are difficult to cleanse (also referred to as noisy). Examples of big data in a medical laboratory setting may include data generated from microbiome sequencing, whole exome sequencing, data from continuous biosensors, and collections of textual physician notes.

Data analysis

The last decade has seen a proliferation of tools that support analysis and visualization of data within warehouses. These are often referred to as business intelligence (BI) software. This has had a democratizing effect, opening up analysis of larger and larger data sets to end users who do not come from IT backgrounds. Just as with statistical software, though, BI software in inexperienced hands carries a risk of drawing inappropriate conclusions due to misapplication of analytic techniques. At the other end of the spectrum is a growing demand for expertise in analysis of larger and more complex data sets. Data science is a growing job category that combines statistics and software engineering.

Machine learning and artificial intelligence

An important subset of data science is machine learning (ML), also referred to as artificial intelligence (AI). While this field has existed for many decades, it has grown rapidly in recent years due to increased availability of big data. A detailed discussion of ML is beyond the scope of this chapter. Essentially, it represents a wide range of algorithms such as neural networks, association rules, and decision trees/random forests, all of which are designed to identify subtle patterns within large data sets. In contrast to more traditional statistical techniques such as regression, ML can tease out a much wider range of (especially nonlinear) patterns in data sets. On the other hand, this power comes at the cost of the ability to explain the roots of those patterns. Furthermore, ML algorithms may identify patterns that reflect artifacts in the data set that do not exist in the underlying real world. It is thus critical that ML algorithms intended for medical use are subjected to extensive clinical validation in real-world settings before they are used for patient care (see Box 18.1).

Data privacy

The growing volume, extent, and interconnectedness of online patient data have created new challenges for privacy and security (see section on "Servers, directories, and security"). HIPAA, the primary regulatory framework for these issues within the United States, was written in the 1990s, an era with much less computing capacity and online data. This limitation is illustrated by HIPAA's provisions for deidentified data sets, in which key identifying fields are removed. Such deidentified data sets are generally considered exempt from HIPAA and can be shared with other parties, used for research, and used for commercial purposes. A significant problem is that under some circumstances, it can be possible to reidentify data within such a data set using external sources. To illustrate, consider a whole genome sequence that identifies a rare serious illness such as Huntington Disease, information that the patient may want to keep confidential. Under current common practice, a laboratory might "deidentify" this record by removing fields such as the patient name and medical record number, and converting the birth data to a birth year. At this level of deidentification, a third party such as an insurance company might still be able to cross-reference the data against other sources, such as billing records, to discover the identity of the patient with the disease.

Opportunities

Research

Laboratory data can be a powerful research tool, but like all tools must be used properly to achieve useful results. In addition to privacy and security issues (see above) that require institutional review board oversight, there is a major issue of controlling for bias when using uncontrolled, real-world retrospective clinical data. Real-world data are not necessarily either better or worse than data

BOX 18.1 The problem with AI black boxes in healthcare

In the late 1990s a number of ML models were built at the University of Pittsburgh and Carnegie Mellon University as part of a project attempting to predict pneumonia mortality based on inpatient data. These models identified a surprising pattern: pneumonia patients with comorbid asthma were predicted to have a lower mortality than other patients. This contradicted previous research that showed that asthma in the setting of pneumonia is an independent risk factor for death. It turned out that the data set for the ML models had come from electronic patient records at the University of Pittsburgh Medical Center, where pneumonia patients with a history of asthma were routinely admitted directly to the intensive care unit. This practice, while certainly beneficial to those patients, created a bias in the data set. If this bias had not been identified, and if the algorithm had been used to identify patients who could be safely discharged to home, then asthmatic patients could have died as a result. Fortunately, for patient safety, the algorithm was subjected to considerable study and validation rather than simply being trusted at face value.

from randomized controlled experiments, but they has their own types of biases that must be respected. Most of these issues fall into the category of correlation that does not prove causation. In the pneumonia mortality example (Box 18.1), asthma was correlated with lower mortality within the data set, in spite of the fact that asthma actually increases pneumonia mortality in the real world. The causative driver in this case, namely different ICU admission criteria for asthmatic versus nonasthmatic patients, was not captured in the data set.

On the other hand, well-designed clinical research based on retrospective data sets has a number of practical and ethical advantages over randomized controlled trials (RCTs). It is simply not feasible to subject all clinical questions to large RCTs, nor would most patients want all of their care to take place within RCTs. The most practical way to generate new clinical knowledge out of real-world settings, then, is through careful retrospective analysis. RCTs can then be used in complementary roles, to confirm findings and tease out sources of bias.

Summary

An understanding of the laboratory information management is necessary for the effective practice of laboratory medicine. Information systems, such as the LIS, have a direct impact on nearly every employee in the laboratory and provide the framework for laboratory workflow. In effect, the LIS is the engine for providing information to clinical decision makers. Standardization of interfaces and terminologies has led to the integration of the LIS into the healthcare information network. Beyond the core use of laboratory information for direct patient care, there are secondary uses. These include operations, research, and quality. Maximizing these uses requires effective storage and retrieval capabilities while maintaining security and privacy.

Self-assessment questions

1. An LIS dictionary is used for which of the following? (more than one may be correct)
   a. Translate information from the instrument to the LIS
   b. Standardize the drivers between the LIS and the EMR
   c. For looking up patient results in the clinical viewer
   d. Populate worksheets
   e. Provide the source information for dropdown lists
2. The LIS may be used for QA purposed by which of the following mechanisms? (more than one may be correct)
   a. Implementing autoverification rules
   b. Storing QC procedures
   c. Ordering test panels
   d. Generating patient reports
   e. Recoding MDIs
3. Which of the following are true regarding LIS connectivity?
   a. LIS transmits results to the CIS
   b. ADT transmits results to the LIS
   c. EMR transmits demographics to the LIS
   d. Instrument transmits results to the EMR
   e. HL7 receives results from the electronic health record
4. Which of the following is the correct sequence of events in an LIS?
   a. Test order -> Sample receipt -> Result from instrument -> Transmission to EMR
   b. Result Order -> Sample collection -> Result transmission -> Reporting
   c. Sample collection -> Result from instrument -> Result label -> Transmission to EMR
   d. Test order -> RFID -> Result receipt -> Transmission to interface
   e. Sample collection -> Batch testing -> Sample receipt -> Result Label -> Transmission to EMR
5. The role of laboratorians in the age of integrated digital health information is which of the following? (more than one may be correct)
   a. Provide test results
   b. Provide information
   c. Analyze and interpret information
   d. Provide connectivity between instrumentation
   e. Order laboratory tests
6. The CID is used in all of the following processes EXCEPT _____.
   a. the CID distinctly identifies every tube or container in a given specimen
   b. the CID is the key identifier that links order and result data in the analyzer and the LIS
   c. the CID encodes sample type information
   d. the use of unique CIDs is a requirement for the use of robotic automation systems
   e. unique CIDs are required by robotic automation systems
7. Which segment of an HL7 message contains laboratory testing information.
   a. EVN: event type
   b. DRG: diagnosis-related group
   c. OBX: observation/result
   d. ROL: role
   e. MSH: message header
8. LIS data are amenable to what data manipulations techniques:
   a. filter, transfer, congregate, and sort
   b. sort, filter, aggregate, and transform
   c. collect, sort, file, and store
   d. sift, shuffle, pile, and dump
   e. ignore
9. Which of the following is NOT true of instrument interfaces?
   a. Most instrument−LIS interfaces are based on standards and protocols defined by the ASTM.
   b. To interface an instrument, the LIS must be configured with a device driver.
   c. Unidirectional interfaces solely send orders from the LIS to the analyzer.
   d. Bidirectional interfaces permit two-way exchange of data between the LIS and the analyzer
   e. Bidirectional interfaces may send orders/demographics to the instruments in batches or dynamically.
10. Which of the following is NOT a property of well-designed electronic result reports?
    a. Recent results are highlighted
    b. Related tests are grouped together
    c. Results can be filtered
    d. Interpretive comments are hidden from view
    e. Results can be trended graphically
11. Which of the following is not a function of a laboratory information system?
    a. Relational database
    b. Data exchange interface
    c. Laboratory process automation
    d. Data warehouse
12. Which of the following is not true for full disk encryption?
    a. Decrypts content based on access control lists.
    b. Encrypts file metadata.
    c. Encodes information so that only authorized parties can access the unencrypted content.
    d. Prevents deletion of encrypted information.

13. Which of the following best illustrates a secondary use of laboratory data?
- **a.** Research study using the past 4 years' worth of data to look for correlations among common biomarkers.
- **b.** Retrieval of a patient's lab results in response to a physician's query.
- **c.** Submission of lab results from an instrument to the laboratory information system via an interface.
- **d.** Review of results from a run of an immunoassay prior to verification.

14. Which of the following statements best represents an advantage of retrospective data analysis for clinical research versus prospective data collection?
- **a.** Retrospective data allow for greater control in selecting patients for a study.
- **b.** Retrospective data allow for greater blinding of participants with regard to therapy selection.
- **c.** Retrospective data are preferred by regulatory agencies such as the FDA.
- **d.** Retrospective data can be aggregated at less expense than conducting a prospective trial (correct answer).

Chapter 19

Point-of-care testing

James H. Nichols
Department of Pathology, Microbiology and Immunology, Vanderbilt University Medical Center, Nashville, TN, United States

Learning objectives

After reviewing this chapter, the reader should be able to:

- Define point-of-care testing (POCT).
- Identify the essentials of quality management for reliable POCT results.
- Describe POCT limitations.
- List the resources available to assist staff in managing their POCT program.

Introduction

Point-of-care testing (POCT) is laboratory testing conducted close to the site of patient care. There are a number of portable POCT devices on the market, and the available menu of analytes is extensive, including glucose, urinalysis, pregnancy, occult blood, electrolytes, blood gases, creatinine, urea, microalbumin, hemoglobin A1c, drugs of abuse, therapeutic drug monitoring (lithium), as well as testing for infectious diseases like streptococcus, mononucleosis, influenza, and HIV. Even coagulation testing [prothrombin/international normalized ratio (INR)], enzymes [alanine aminotransferase (ALT)/aspartate aminotransferase (AST)], and cardiac markers [B-type natriuretic peptide (BNP)] are available on the Clinical Laboratory Improvement Amendments of 1988 (CLIA) waived devices. CLIA waiver is granted to laboratory tests that the US Food and Drug Administration (FDA) and Centers for Disease Control and Prevention (CDC) have determined to be so simple that there is little risk of an erroneous result. CLIA waived tests have minimum regulatory requirements, so a majority of POCT is CLIA waived, allowing the test to be performed in a variety of settings by a diverse array of staff. However, as with any test, POCT, even CLIA waived testing, has limitations and poses risk of incorrect results and patient mismanagement if incorrectly performed or poorly managed. POCT is also sometimes referred to as near-patient testing, bedside testing, ancillary testing, and satellite testing, because the POCT devices can be used in many different patient-care settings: hospital acute and critical care units, operating rooms, emergency departments, physician's offices, visiting nurses, patient home self-testing, ambulances, and cruise ships. POCT devices have even traveled on the space shuttle.

POCT has a number of advantages (Table 19.1) compared with central laboratory testing. POCT devices use a small volume of sample, and the sample does not need to be processed. POCT is particularly useful in neonates, small babies, and those with increased risk of blood loss from phlebotomy. POCT devices can analyze whole blood, urine, and other body fluids. Test results are rapidly available while the clinician is examining the patient. There is no need to transport a specimen to a laboratory and wait for results to come back. POCT thus works with the clinical flow of patient care, because clinicians can order a test, receive results, and institute clinical action in the same visit. This provides the opportunity for faster therapeutic intervention and potential for improved patient outcomes.

However, POCT has some disadvantages (Table 19.1) as well. POCT is more expensive than traditional laboratory testing, because POCT reagents are single-use tests, while central laboratory reagents are packaged in bulk for high-volume analysis. POCT in hospital settings is often not performed by lab personnel, resulting in challenges in identifying deviations in preanalytic, analytic, or postanalytic components of testing. Documentation is an additional concern, because POCT may be performed and results not interfaced or documented in the patient's electronic health record. Clinical staff may be unfamiliar with the many laws and compliance requirements that apply to laboratory operations both within the United States and internationally.

Quality point-of-care testing

Quality POCT is the delivery of results that are safe, reliable, and trustworthy for patient care. Quality implies the appropriate use of technology to meet clinical needs. This

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00019-3

TABLE 19.1 Point-of-care testing advantages and disadvantages.

Advantages
• Immediate results—no lab transportation
• Small blood volume
• Wide menu of tests available
• Whole blood, urine, and other body fluids analyzed without processing
• Works within clinical patient flow
Disadvantages
• More expensive than traditional laboratory tests
• Quality is questionable as anyone can run the analysis
• Difficulties with regulatory compliance, billing, and documentation
• Patient-focused staff with little formal education/experience in laboratory testing

TABLE 19.2 Example point-of-care testing program for an academic medical center.

Method	Sites	Devices	Operators
Glucose meters	53	213	4500
Hemoglobin A1c	10	21	50

involves choosing the right method, POCT device or central laboratory analysis, to achieve the best outcome for a particular patient at a specific point in their pathway of care. This might involve selecting between a glucose meter, glucose on a blood gas analyzer, or glucose in a central laboratory, depending on the clinical situation. In addition, test results are legal documents and all of the quality control (QC), training, instrument validation, troubleshooting, and other quality assurance practices and documentation ultimately provide defensible evidence of regulatory compliance should a test result ever come into question. Above all, the reputation of the laboratory depends on the quality of its product, the test result.

Unfortunately, there are a number of quality concerns with POCT, which have been raised in the scientific literature. Complaints about glucose meters for patient self-testing, for instance, represent the largest number of complaints filed with the FDA for any medical device, with over 3200 incidents including 16 deaths [1]. POCT devices can be reservoirs for nosocomial and antibiotic-resistant organisms in the hospital, and infections have been transmitted by poorly cleaned urinometers and blood gas devices when carried between patient rooms [2]. Patients at nursing facilities in Mississippi, North Carolina, and California were diagnosed with hepatitis B infection transmitted in association with blood glucose monitoring from shared spring-loaded lancets, glucose meters, insulin vials, and poor hygiene between the patients [3]. In a two-state pilot study conducted by the Department of Health and Human Services (DHHS) on data from state laboratory inspectors, 77% of the 175,000 CLIA enrolled laboratories had no direct oversight by someone with laboratory training [4]. Most of these laboratories were physician office practices, and 50% of laboratories in Colorado and Ohio did not follow manufacturer's instructions nor did they have package inserts available to staff performing the testing. Other laboratories were cutting occult blood and urine dipsticks into segments to save costs and extend their use. In an expanded study conducted in eight states, 64% of laboratories (173/270) surveyed did not have manufacturer's instructions or failed to follow the instructions [5]. Twenty percent of laboratories ($n = 53$) were not performing QC as instructed, and 19% of laboratories ($n = 51$) did not provide training to staff or evaluate the staff's ability to perform testing adequately.

POCT is a complex system. In a central laboratory, there is one location and testing is limited to a few analyzers. Staff is also limited to a pool of medical technologists and medical laboratory scientists who have significant training and skills in laboratory analysis. Staff in a central laboratory has focused attention on testing. Their primary task is specimen analysis and producing quality test results, without the distraction of patient care responsibilities. POCT, on the other hand, is conducted at dozens of locations, with hundreds of devices and thousands of operators (Table 19.2). Getting all operators to

perform a test consistently, in the same way every time, is difficult. POCT is performed by clinical staff whose primary focus is patient care. Nurses and physicians are only secondarily focused on performing the necessary steps for QC, calibration, maintenance, cleaning, and quality assurance of POCT devices. There is the assumption that if a POCT device generates a result, then that result must be correct; otherwise, the device would not have generated a value. However, there are many factors that can affect the quality of the POCT results.

The DHHS studies from state inspectors uncovered quality concerns with the performance and staff training in a significant percentage of sites performing POCT, mostly physician offices [4,5]. Most physicians and facilities were eager to change once the issues were brought to their attention but had no resources or background to design the training and ongoing quality assurance program. Laboratory professional consultation was needed to improve the regulatory compliance of these sites and guarantee the quality of POCT results. For many hospitals and health systems, this consultation is available through a medical technologist who specializes in POCT quality assurance, called the "point-of-care coordinator." The point-of-care coordinator is the laboratory liaison to the nursing unit to assist with operator training, instrument validation, documentation, and quality improvement. For some health systems, the point-of-care coordinator is extended to physician office laboratories and home nursing networks under the health system umbrella, whereas other private physician offices hire pathologists, doctoral-level laboratory directors, or point-of-care coordinators as paid consultants to assist with their POCT regulatory compliance. The point-of-care coordinator is thus a specialized medical technologist who has the additional regulatory knowledge, communication, and management skills to help POCT sites improve the quality of their testing and meet regulatory guidelines.

Point-of-care testing regulations

The challenge of managing POCT is the complexity of ensuring regulatory compliance at dozens of sites, with hundreds of devices and thousands of operators. Each site must supervise equipment, personnel, and safety practices comparable with performing the testing at a single laboratory location; therefore POCT multiplies the many laboratory issues, like validation and monitoring of devices, reagent lots, expiration dates, and temperatures across dozens of sites. Inspectors use the phrase "site neutral" to describe the test requirements that are independent of where the test is conducted, and POCT sites are treated like independent laboratories regardless of location.

The quality of POCT, like other laboratory tests, is regulated by the federal CLIA law and inspected through centers for medicare and medicaid services (CMS) and the state departments of public health. CLIA sets the minimum requirements for laboratory testing based on the complexity of analysis, instrument maintenance, and result interpretation. Tests are categorized as waived, moderate, or high complexity with increasingly higher levels of requirements for operator education, training, method validation and quality documentation. The Joint Commission, the College of American Pathologists (CAP), and the Commission on Office Laboratory Accreditation are private accreditation agencies that are deemed under CLIA to inspect and accredit labs that meet the minimum CLIA standards in addition to their individual agency recommendations. Although each of the accreditation agencies varies in the details and stringency of their recommendations, all of the agencies require some level of equipment validation before use of the test on patients, written procedures, operator training and competency on the specific test, as well as ongoing management of patient results (with appropriate normal reference ranges or interpretive comments) and safe handling and disposal of biohazardous patient specimens. CLIA compliance is enforced by blocking Medicare and Medicaid payments for noncompliant laboratories and levying fines against the organization and laboratory director, while accreditation agencies can pull a laboratory's accreditation, institute fines, and publicize citations for laboratories with quality concerns. Despite the sale of many POCT devices in local grocery stores and pharmacies, a physician cannot simply walk into a store, purchase a device, and start testing patients without first ensuring licensure of the site performing testing and documentation of quality assurance for regulatory compliance.

POCT regulations cover laboratory testing conducted for patient care decisions and medical management. The portability and ease of use of POCT devices make them convenient for use in research protocols; however, research testing is exempt from the CLIA regulations, but only if no patient care decisions are made from the test results. Staff should be warned that the CLIA guidelines still apply to the use of a POCT device as part of a research protocol if a medical decision is made or patient care is changed based on the test result. For example, the use of a pregnancy test to determine whether a patient can enroll in a research study and potentially receive a study drug is a medical, patient care decision, so all of the CLIA and accreditation guidelines would apply to the pregnancy test. Alternatively, if the pregnancy test was performed as part of the study and none of the test results were communicated to anyone caring for the patient, no change in medical management could occur based on the test. This testing would be considered purely research. When results are recorded in a log to be reviewed after the study completion, the results cannot be utilized for

patient care and the test is classified as research; thus CLIA does not apply in this case. A good rule of thumb to determine if the regulations apply is to answer the question, "Will a change in treatment or management occur based on the result of this point-of-care test?" For the pregnancy test, a decision may be made to include the subject in the study if the test is negative and to exclude the subject if the test is positive. This constitutes medical management, in which a clinical decision (to enroll in the study) is made based on a test result. CLIA regulations therefore apply in this case, but do not apply when the test results are protected in such a way as to prevent the use of the result by any clinicians actively caring for the patient.

Documentation is fundamental to all of the accreditation requirements, and data records and logs are considered the supporting documentation for regulatory compliance. Some devices provide automated electronic capture of the necessary data (patient and operator identification, date, time, device serial number, reagent lot number, expiration dates, etc.) at the time of analysis. However, over 50% of POCT devices are manual, visually interpreted dipsticks and kits that require handwritten records or manual input into an electronic medical record. This has led to an increase in the utilization of automated readers for manual dipsticks and lateral flow tests that can automate the interpretation of results and be interfaced with the patient's electronic medical record. The amount of data requiring review from POCT can be overwhelming, and computerized POCT data management can assist personnel in regulatory compliance, billing, and review of data for quality improvement. Point-of-care coordinators can assist personnel with interpretation of the regulatory guidelines, development of a quality program, and preparation and review of the necessary documentation to meet the specific accreditation guidelines. Some laboratories may be accredited by multiple agencies and must prepare documentation to support inspection against multiple sets of recommendations. Federal agencies like CLIA may deem equivalence to another agency with stricter recommendations such as New York State, the Joint Commission, or CAP, for instance. Agencies are continuously updating their recommendations, so point-of-care coordinators and staff must keep current on the most recent changes that may affect their POCT operations.

Point-of-care testing connectivity and interfacing

Computerized data management automates the collection and review of the volumes of data acquired by POCT. Newer POCT devices have computerization that ensures regulatory compliance by collecting pertinent information at the time of testing and prompting the operator through the correct sequence of steps to perform the test consistently. Data stored within the device can be downloaded to a computer database or POCT data manager, by placing the device into a docking station that connects to the Internet, via modem, or wirelessly to a remote POCT data manager. The POCT data manager can also interface with a laboratory information system (LIS) and a clinical data repository (CDR), such as a hospital information system (HIS) or electronic patient medical record, and other clinical information system (CIS) for permanent storage of the test results.

The POCT data manager has multiple functions. The data manager communicates bidirectionally with devices. From the device, the data manager collects test information and associated date, time, patient identification (ID), operator ID, lot and serial number fields, as well as any associated result flags and comments. The data manager can also send current lists of competent operators and update any reagent and control lots, expiration dates, and other information to the device remotely. The data manager acquires control results to document successful performance of QC at the required frequency of testing, as well as any corrective actions for failed QC. POCT data managers use patient identification to search against active patients in the hospital or LIS to transfer patient results to those systems for permanent storage. Newer POCT devices have the capability of positive patient identification. These devices acquire admissions/discharge/transfer information on patients through the data manager and can display the patient's name on the POCT device before analysis. The operator then confirms the patient identification by entering a second patient identifier (like birth date) before the device will allow testing. Positive patient identification reduces the chance of ID entry errors that can prevent results from being transferred to the correct patient's medical record. The data manager thus acts as a central processor for information coming from POCT devices to the patient's medical record and for information required by a device for continued operation. POCT data managers automate the review of data and reduce the amount of labor required to manage POCT operations.

Historically, each manufacturer developed their data manager systems in isolation, meaning that different POCT devices required different physical cables to connect to the same data manager, and even language and communication protocols for data were not shared between different devices and manufacturers. This complicated and significantly increased the cost of implementing and changing devices because of the need to purchase additional computer systems and interfaces to accommodate the data transfer. The lack of common communication standards led to the development of the POCT1 standard for point-of-care connectivity by the

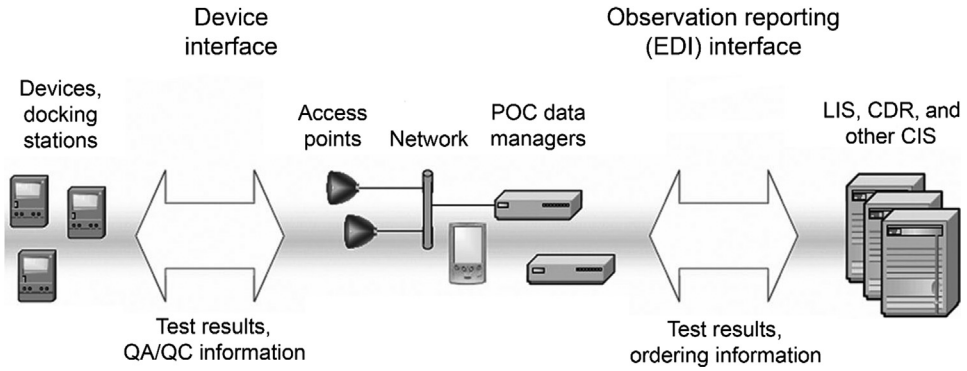

FIGURE 19.1 The POCT1 device connectivity standard describes two interfaces. The device interface allows bidirectional communication between the point-of-care testing devices and the point-of care data managers through docking station access points using the Internet, wireless, or serial communication. The observation reporting interface is an electronic data interface that transfers patient test results and order information between the point-of-care data managers and the laboratory information system, clinical data repository (an electronic medical record), or other clinical information system. *Reproduced with permission from Clinical Laboratory Standards Institute. Point-of-Care Connectivity: Approved Standard POCT1-A2. CLSI, Wayne, PA, 2006, p. 306.*

Clinical and Laboratory Standards Institute (CLSI) [6]. POCT1 was developed by a group of vendors, consumers, and government representatives to enable the seamless information exchange between POCT devices, electronic medical records, and LIS. This standard defines the physical connections as well as the communication protocols for data transfer between the POCT devices and the data managers (the device interface), as well as between data managers, and the LIS, CDR, or CIS through the electronic data interface (Fig. 19.1). The POCT1 standard is based on the Institute of Electrical and Electronics Engineers and Health Level Seven standards for medical information transfer, and representatives from these groups worked with CLSI in the development process. There are currently many devices that comply with the POCT1 standard, and several POCT data manager systems currently use this standard to connect to multiple POCT devices.

Point-of-care testing quality assurance programs

Compliance with regulatory guidelines requires an understanding of the regulations, good communication among all the staff involved in POCT, organization, and planning. The formation of a POCT committee, an interdisciplinary committee to oversee POCT approvals and quality concerns, can assist in the development of a quality assurance program and provide a discussion forum for issues as they arise. It is important to have representation from all groups involved in POCT. Administration, laboratory, nursing, and physicians are key individuals to have on the POCT committee, but representation from purchasing, distribution, pharmacy, and nutritional services may also be important when specific issues arise. POCT committees develop high-level policies that can cross departmental and institutional boundaries in hospitals and health systems with departmental or multihospital administration silos.

A key function of the POCT committee is to review and approve requests for new tests and to address compliance concerns with existing testing. Due to its interdisciplinary composition, the committee can balance opinions, depersonalize judgments, and deflect the political heat that may arise from decisions to remove testing or decline the implementation of new testing on specific nursing units or locations. The committee can take the blame for a decision rather than an individual like the POCT coordinator or laboratory director. Representation from purchasing and distribution can alert the committee to requests for tests outside of the committee approval process if staff try to go around the committee. Other ancillary staff, like nutritionists who may change diet based on glucose or electrolyte test results, may also be useful to have represented on the POCT committee.

Pharmacists are becoming more involved in POCT, not just because of drug dosing based on POCT results, but because pharmacies are now stocking POCT devices and pharmacists in some hospitals are starting to perform POCT as an alternative to nursing staff. Pharmacy-based clinics, in Britain and America, such as minute clinics and urgent care centers, are starting to offer POCT as part of a rapid care pathway designed to facilitate same day visits when patients cannot get a same-day appointment with their primary care physician. Patients are often seen by nurse practitioners, and POCT is offered to make a diagnosis (like rapid strep testing) and get treatment (such as an antibiotic prescription) in the same visit. POCT in these clinics is conducted at the request of the clinician or pharmacist, but in some locations, patients can even order their own tests and have them conducted by the

pharmacist (direct-access testing). Pharmacists, because of their training and experience with POCT, can provide a quality result that can be trusted more than patient self-testing at home, and pharmacy testing may be more convenient for patients than having to wait to schedule a physician visit, get a test order, travel to a phlebotomy station that will then transport a specimen to a central laboratory, and further wait for a test result to be communicated back to the physician where a call can be made to the patient to institute treatment. Think of the urine pregnancy test: if the patient performs the test at home, they must then go to a physician for repeat testing by a central laboratory to verify a positive result. Visiting a pharmacy creates a reliable test result that can be trusted for ongoing care, because the pharmacy must follow laboratory quality regulations when performing POCT compared with home self-testing, which has no quality requirements.

A POCT quality assurance program encompasses all of the device standardization, validation, training, competency, and operational aspects of performing POCT. POCT should be considered a part of patient care within the institution rather than an ancillary laboratory service, so POCT should be incorporated into the overall institutional quality improvement plan. Quantitative measures of POCT performance, such as compliance errors with monitoring temperatures, failure to recognize reagent expirations, or corrective actions after control failure, can be tracked and sorted by site to determine persistent problems and trends (Table 19.3). Nursing units and sites with recurrent quality issues should implement additional follow-up, closer supervision, or other actions to improve performance. Accreditation inspectors like to see trend graphs, demonstrating the identification of a problem, intervention, and improvement of performance over time. Accreditation agencies used to schedule periodic inspections with advance notification; however, the Joint Commission and CAP now utilize unannounced inspections. Staff must always be ready for an inspection and will no longer have time to prepare records and quality documentation in advance. Use of quantitative performance monitors and integration of the POCT program into the institution quality improvement plan are a good means of identifying and continuously improving on program weaknesses. Development of an individual quality control plan (IQCP) can identify risk of errors and define a quality assessment for tracking ongoing performance. Baseline performance assessment and monitoring trends of improvement over time also provide excellent documentation whenever a POCT result is questioned, regardless of who questions a result—a clinician, a patient, a staff member, or an outside inspector.

TABLE 19.3 List of possible quality improvement performance monitors for point-of-care testing.

Successful QC
• QC documentation • Number of errors where wrong QC analyzed (e.g., high control analyzed as low) • Percentage of QC that fail • QC outliers with comment • Failed QC with appropriate action (patients not tested)
Utilization (number of tests per site or device)
• Tests billed versus tests purchased • Single lots of test and QC in use at any time
Compliance
• Untrained operators performing testing • Clerical errors or data entry errors during testing or result reporting • Medical record has results reported with reference ranges • Expired reagents and QC/reagent bottles and kits dated appropriately • Refrigerator temperature monitored • Proficiency testing successful • Action plan in response to site compliance deficiencies

Interdisciplinary communication

The management of POCT requires the development of a quality assurance program and clear communication of that program to everyone involved. The objectives of improved patient care through POCT and the path to achieving this goal need to be clearly defined. Likewise, the fundamentals of regulatory compliance and quality improvement must also be spelled out. Unfortunately, clinicians perceive POCT from a different perspective than the laboratory. Technology and nursing has a kind of "love−hate" relationship. Taking the optimistic view, technology is intricately linked to the science of nursing and physician practice. POCT provides more rapid clinical decision-making, moving patients through the system (the hospital or physician's office) more quickly; improving the efficiency of delivering care; and decreasing patient wait times. However, from the pessimistic viewpoint, technology detracts from the art of nursing and does not integrate well into the daily patient care responsibilities. Compliance with regulatory demands and quality assurance protocols is time- and labor-intensive for clinical staff and takes the focus of nurses and physicians away from the patient. Physicians are also experiencing increased pressure to examine more patients while conducting successful research programs, maintaining resident education, and developing unique programs in their discipline for academic advancement. Nurses are encountering increasing pressure to cross-train and diversify, take on more roles, multitask, and increase the use of unlicensed personnel for some aspects of patient care.

Nurses and physicians must be responsible for the physical, emotional, and spiritual care of the patient. These caring and nurturing roles are in direct contrast to the scientific rigors of the laboratory that include accuracy, precision, and quality focus.

Successful POCT management requires an appreciation of different viewpoints, mutual respect, and compromise. There are always multiple ways to achieve a goal. Conflict with POCT frequently arises from the laboratory, dictating how clinicians should act in response to a problem without considering all perspectives. As compliance issues or other differences of opinion arise, participants need to look beyond the paradigms of their discipline and think outside the box. In any field, there are shared sets of assumptions or paradigms. Paradigms determine what is taught, the methods, and how findings are interpreted. Nursing has one set of paradigms, the laboratory has another, and physicians have a third set of paradigms. When a compliance issue is noted, like an unapproved POCT device, the laboratory may interpret this as a willful breach of policies and failure to go through the POCT committee approval process. However, the physicians may perceive this only as an attempt to improve the care of their patients and improve turnaround time of results. They may not be aware of the stringency of laboratory regulations and the need for committee approval or device validation before using a POCT device. Nursing, on the other hand, was conducting the test, because the physician ordered it and was only following instructions. The problem here is a lack of understanding about the regulations governing POCT and a failure to communicate effectively the issues. A clear discussion of the POCT committee policies and the reasoning behind the policies will be more successful than dictating compliance. When staff understand why they must follow policies, they will be more likely to comply with QC performance, refrigerator temperature monitoring, and seeking approval before purchasing new POCT devices.

Self-management

POCT is a decentralized process, and the laboratory cannot be at every site 24 hours a day to monitor test performance. The laboratory has to delegate responsibility for POCT to the clinical staff and trust that nursing and physicians will properly manage the testing process. In this model, the laboratory takes a central oversight role for POCT, but the clinical staff takes responsibility for the day-to-day operations such as purchasing reagents, discarding outdated tests, validating staff competencies, and performing QC and other functions needed to maintain testing on the medical unit. This laboratory−clinical partnership is based on mutual respect and shared responsibility for POCT quality.

Successful POCT is based on self-management. Clinical units make a decision that faster testing will improve patient care and must allocate the resources necessary to support the testing, while the laboratory provides all of the policies, procedures, and information required for the staff to succeed and continuously improve their performance. One means of distributing POCT information to many sites within an institution is through a dedicated website for POCT. A website is easily accessible from anywhere within a health system with only a computer, web browser, and internet connection. An institutional POCT website may contain contact information for the lab director, point-of-care coordinator, and support staff as well as training checklists, policies and procedures, compliance reports, minutes of the POCT committee, current POCT projects, and links to the FDA laboratory safety tips or current CAP/Joint Commission accreditation checklists. A website could also contain a list of POCT contacts on each of the clinical units and frequently asked questions written in a language that the clinical staff can understand and relate. The website could contain compliance trends by unit of their performance monitors, so units can compare their performance to others and help prioritize their action plans. Self-management encourages clinical staff to take charge of their own testing.

Many institutions have adopted electronic document control systems that can be an alternative to creating a dedicated POCT website. Electronic document control systems allow the procedures to be available on the nursing units from any of the clinical workstation computers, so staff does not have to hunt for a hardcopy of a procedure when conducting testing. Electronic document systems remind staff for required annual review of policies and provide an easy means of distributing policy revisions to all the sites performing POCT simultaneously. Most importantly, POCT policies and procedures can be integrated with other nursing policies in format and wording, emphasizing the role of POCT in patient care rather than as a "laboratory" service.

Institutions with a large number of staff have also adopted electronic training and competency systems. These programs can track operator competency and send messages to those pending expiration of their training. Training/competency systems can utilize slides, video with sound, exams, and other tools to refresh staff on key points to remember when performing POCT and ensure that these points were received and understood. CLIA and accreditation agencies require six elements of competency to be evaluated annually including:

1. Direct observation of routine test performance
2. Monitoring the recording and reporting of test results (including critical results)

3. Review of intermediate test results, worksheets, QC records, proficiency test results, and preventive maintenance records
4. Direct observation of preventive maintenance and function check performance
5. Assessment of test performance using previously analyzed specimens or proficiency testing samples
6. Assessment of problem-solving skills

Many of these elements can be assessed through an electronic training/competency system with an exam that includes troubleshooting questions, but direct observation of test performance and comparison of test results requires one-on-one time of a staff trainer with each POCT operator. Observing test performance cannot be automated through an electronic training system.

Staff members who perform testing are wholly responsible for their success as well as their failure. By positioning the laboratory as a resource for POCT and distancing the laboratory from the performance aspects of the POCT program, staff members tend to help each other, communicate more about their issues, and work more as a team than when the laboratory is mandating compliance and dictating practice. Each unit can find unique solutions to issues that work best within the unit's workflow. Issues are brought to staff attention by the laboratory and staff is encouraged to inspect their own practice and determine the solution that operationally works best for them. For instance, two levels of QC must be analyzed each day of testing, but this can be accomplished in a number of ways. Nursing units should rotate the responsibility among different staff, but a nursing unit might choose to have the first shift run QC, because it works better into their patient rounds, while another unit might find that night shift works best when staff are not as busy. By facilitating communication between the POCT sites and the encouraging staff to solve their own problems in a regulatory compliant manner, the laboratory becomes a resource of information to help staff improve their own program. Staff can then find the best ways to integrate POCT into their current workflow without the laboratory interfering. This improves interdisciplinary relations between the clinical sites and the laboratory and promotes collegiality rather than animosity.

There are many POCT resources that are available to assist staff with managing POCT. A journal, *Point of Care: The Journal of Near-Patient Testing & Technology* (www.poctjournal.com), is dedicated to basic research, method validation data, regulations, and other topics related to POCT management and device technology. *The Journal of Analytical Laboratory Medicine* also publishes peer-reviewed research and offers case studies, focused studies, and laboratory reflections involving POCT. Several textbooks are also devoted to POCT [7,8], and the American Association for Clinical Chemistry (AACC) has a community forum, the AACC Artery, to discuss POCT issues (www.aacc.org/community/forums). AACC also offers a POC Bootcamp and certification program for coordinators who are managing POCT programs. There are also a number of regional point-of-care coordinator groups throughout the country, and their meetings, activities, and original articles are available on a POCT website (www.pointofcare.net). Point-of-care coordinators and staff involved in POCT thus have a variety of resources and ways to contact others involved in POCT to get answers to their questions, seek advice, and get feedback from staff who are experiencing similar challenges.

Analytical performance

Although regulatory compliance and management is a significant aspect of POCT, the analytical performance of devices also contributes to the overall quality of results and clinical applicability of a test. Poor testing will result when staff fail to follow manufacturer's instructions on a device with excellent analytical performance; it is the same as if staff do everything right, but picks a device with poor analytical performance. Technical performance and management practices both contribute to quality POCT. Therefore institutions must be concerned about picking the right test for the specific patient as well as ensuring that the test is conducted properly, and QC and quality assurance practices are followed.

The required performance characteristics of a device must match the clinical need of the patient and the question being asked by the physician. POCT devices are different methods than core laboratory instrumentation. Each method has unique bias, imprecision, and analytical interferences that may limit its clinical utility. Glucose meters, for instance, have greater imprecision and are susceptible to different interferences than central laboratory methods. Despite recommendations by the American Diabetes Association for agreement of glucose meters within 5% of a central laboratory method, none of the currently marketed glucose meters can meet these performance standards [9]. Glucose meters are thus not recommended for use in screening or diagnosis of diabetes [10,11]. The variability of glucose meters limits their use to management of patients already diagnosed with diabetes. CLSI recommends that glucose meters agree with a comparative central laboratory method within ± 12 mg/dL for results <100 mg/dL and $\pm 12.5\%$ for results ≥ 100 mg/dL [12]. Glucose meters are too variable for use in analyzing specimens collected after a glucose tolerance test for diagnosis of diabetes, and meter variability also limits the utility of meters in health fair and shopping mall screening programs. Device performance requirements can change with

the concentration of analyte and the clinical application (screening, diagnosis, or management).

Operators are a key part of device performance, and there are several studies indicating poorer performance by staff without laboratory training than operators with training. The CDC compared performance on proficiency testing samples sent to laboratories performing POCT [13]. Proficiency samples are specimens of unknown concentration analyzed like patient specimens where the results are graded and compared with all other laboratories performing the same test. The CDC noted significantly better performance on proficiency samples for medical technologists working in accredited hospital laboratories than nonlaboratory staff performing testing in physician office laboratories. Intermediary performance was seen at those sites performing testing with laboratory-trained operators. Training improves performance, and the Oregon Health Sciences University noted significant improvement in both the performance of glucose testing and interpretation of results after a standardized training program [14]. Performance not only improved immediately after training but continued to improve consistently for the following several months that were monitored by the study. Operators and the training of operators can thus affect the quality of POCT results as well as the interpretation and treatment decisions based on POCT results.

Standardization is an important aspect of successful POCT programs. Selecting one manufacturer for glucose meters and one kit for pregnancy testing simplifies quality management. With dozens of POCT sites and thousands of operators, increasing the number of different devices complicates the ability to manage the program and stresses available staff and resources. Validation, procedures, and training are required for each device for regulatory compliance. CAP also requires subscription to a proficiency-testing program. As the number of different devices multiplies, there are more procedures and training to maintain, and staff who rotate or test patients infrequently may not remember how to operate the test when required. For POCT, simplicity is fundamental. Fewer devices, limited testing sites, and reducing the number of operators simplify the management of testing and enhance compliance. With fewer devices and a smaller group of key POCT operators, it is easier to train staff and more economical to manage the program.

Method limitations

POCT methods are different from clinical laboratory methods and have their own biases and interferences. Clinical treatment protocols and pathways of care based on central laboratory methods may not necessarily be transferable to the same patient populations when using POCT results. As noted already, glucose meters may provide a faster glucose measurement, but the variability of the method may not allow the device to be used for diagnosis or screening of general patients, while central laboratory glucose results can be utilized for these situations. This is why clinical validation of a device on the intended population using routine staff operators at that location is so important before implementation of a test for patient care.

POCT devices are portable, so reagents and test strips may be exposed to varying environmental conditions compared with testing in a well-controlled laboratory. Visiting nurses travel to patient's homes, and tests can be exposed to cold in the winter and heat in the summer. Humidity can damage colorimetric test strips, like urine dipsticks. Altitude may also affect some tests that are sensitive to oxygen, like glucose and blood gas tests. Storage and environmental conditions are factors that need to be controlled to ensure quality test results. Tests and devices should be removed from vehicles when not in use to prevent freezing and overheating. Strip vials also need to be tightly recapped and tests stored in cool, dry places away from radiators and windows where the tests may be damaged from heat, light, and moisture.

Drugs, disease metabolites, and diet can affect POCT results in different ways compared with traditional laboratory methods. Some glucose strips are sensitive to salicylate, acetaminophen, and urea. Vitamin C in high doses can act as an electron carrier in POCT glucose reactions. Dietary constituents affect other POCT methods. Meat and peroxidase-containing vegetables, for instance, may give false-positive reactions in guaiac-based occult blood tests. Hydration status and drinking excess water can dilute urine, generating false-negative drug and pregnancy tests. Hemolysis of blood elevates potassium levels and may not be detected in a whole blood sample used for POCT compared with serum with laboratory analysis where hemolysis is evident as red color in the sample; so hemolysis can be overlooked with POCT, leading to falsely increased potassium results and the potential for misinterpretation and inappropriate clinical management.

Critical illness is another factor to consider with POCT. Patients presenting with extremes of physiology challenge the performance of POCT devices. Glucose meters originally developed for use in patient self-testing may perform differently when used in a hospital environment. Diabetic outpatients are ambulant and generally healthy compared with critical inpatients on oxygen therapy and various medications. Critically ill patients also have low hematocrits that can interfere with glucose methodologies. Manufacturers have been encouraged by the FDA to include a limitation in the meter package insert that "the performance of the test system has not been evaluated in the critically ill." While newer meters have received FDA approval for use in critically ill

populations, consumers are still warned of interferences with meter results when utilizing capillary fingerstick samples in patients with poor peripheral circulation. This limitation warns the consumer of the potential for interference in subpopulations of the critically ill that may show variations in results with certain sample types and conditions. Consumers should restrict use of glucose meters in order to adhere to package insert limitations, such as acceptable hematocrit and oxygen ranges, and prohibit use of capillary fingerstick samples from patients with poor peripheral circulation (i.e., diabetic ketoacidosis, nonketotic/hyperosmolar conditions, congestive heart failure stage IV, shock, and peripheral vascular disease) [15,16]. Blood can pool in the periphery and capillary samples in such patients may not reflect the physiology of central circulation. Currently, only one glucose meter has been FDA-cleared for use in critically ill patients using capillary fingerstick samples, but the analytical performance of this meter is significantly more variable than laboratory methods. Clinicians are cautioned to interpret POCT results with care in patients with rapidly changing physiologic conditions, particularly when analyzing capillary samples in critically ill patients despite FDA approval for use in these populations.

Use of venous or arterial samples may be a more acceptable alternative in patients with poor peripheral circulation, and capillary sampling is affected. Alternatively, hospitals may choose to use a different glucose methodology such as a blood gas analyzer or send a sample to the central laboratory [15]. However, delays in test turnaround may prohibit sending a sample to a central laboratory. Hospitals can also choose to use a glucose meter off-label by analyzing capillary samples despite the manufacturer warnings for critically ill patients. Caution should be taken, however, since off-label use shifts the CLIA-waived glucose meter to a high-complexity category requiring additional validation and documentation. CLIA high-complexity may further limit the staff who can perform testing, as hospitals frequently use patient care assistants, staff with only a high school education and on the job training, to perform glucose testing [15,17]. Under CLIA high complexity, staff with only a high school diploma would not be eligible to conduct glucose meter testing, and more advanced clinical staff, such as registered nurses or nurse practitioners, with additional laboratory training, experience, and licensure (in some states) may be required.

POCT employs unprocessed specimens. Whole blood is analyzed on POCT devices, whereas most laboratory methods require serum or plasma. Glucose, however, is unstable in whole blood. The specimen must be analyzed quickly after collection, or inhibitors of cellular glycolysis, like fluoride or oxalate, must be added to stabilize the glucose levels in the sample. Specimen additives, like fluoride and oxalate, can interfere with some POCT methods, so correlations of glucose meters against laboratory methods must quickly analyze a whole blood specimen on the glucose meter and either simultaneously collect a separate sample for laboratory analysis, or centrifuge and separate the remainder of the POCT specimen. Once separated from cells, glucose is stable in plasma/serum for several days refrigerated and longer if frozen. While use of whole blood for POCT and serum/plasma for laboratory analysis ensures appropriate specimen types for each methodology, the glucose concentration may not match between the two methods because of physiologic differences between whole blood and serum/plasma (Fig. 19.2).

Glucose distributes within the aqueous portion of blood. Since there is less water inside erythrocytes (73% water/27% lipids and protein) compared with the plasma portion of blood (93% water/7% lipids and protein), the glucose concentration will be lower inside red blood cells than plasma from the same patient specimen. The actual difference will depend on the hematocrit (concentration of erythrocytes in a sample). At a normal hematocrit of 45%, plasma is ~11% higher than whole blood. Patients with higher hematocrits will have greater difference between whole blood and plasma/serum glucose, while patients with lower hematocrits will have less difference. Method comparisons and validation of POCT devices must take into account these physiologic differences in specimen matrix when interpreting the agreement between different methods. To simplify interpretation, most

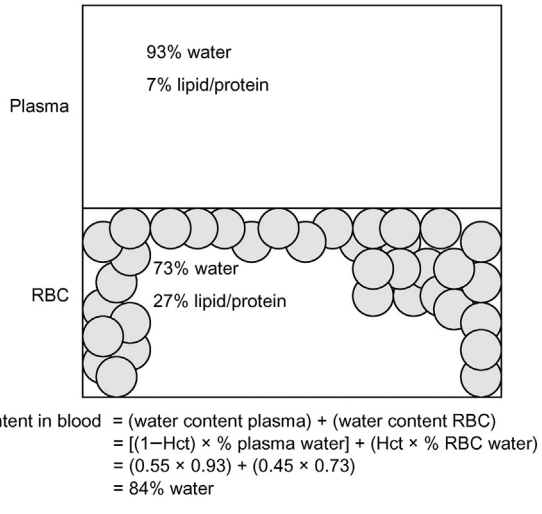

FIGURE 19.2 Whole blood to plasma differences. The physiologic water content in whole blood is a mixture of the plasma and erythrocyte red blood cell water and varies with the hematocrit or volume of red blood cells in blood. Analytes that follow water, like glucose, electrolytes, and some drugs, will show similar differences in concentration when measured in whole blood versus plasma.

manufacturers calibrate their glucose meters to read a plasma equivalent result despite accepting whole blood samples. Glucose meters should theoretically be comparable with central laboratory methods in patients with normal hematocrits. Differences in hematocrit are one reason why critically ill patients and neonatal populations with low and high hematocrits may show biases between the two methods, and why validation of POCT in the intended patient population is so important.

There are a variety of factors that can affect POCT differently from laboratory methods. These factors must be considered when implementing POCT or when interpreting the POCT literature. A device that works well on one medical unit and patient population may show different results in another patient population due to medication, diet, or operational differences between the two sites. Validation of POCT devices by staff operators on the intended patient populations will most likely uncover interferences and other potential problems before implementation and routine use of a device. When environmental effects or unexpected interferences are discovered, practices can be changed to control against test exposure or alternative devices can be selected, which do not experience the same interferences.

The potential for interference, operator, and environmental effects sets POCT apart from central laboratory methods. Results from POCT should be clearly separated from central laboratory test results in the patient's chart. As hospitals move toward electronic records, POCT result interfaces should distinguish the source of the test result for the ordering clinician. Clinical systems have the ability to overlay test results, so all glucose values or sodium values, for instance, can be viewed and trended together. From the clinician's perspective, seeing more information together on a computer screen saves time and prevents scrolling through result spreadsheets and multiple mouse clicks. However, differences in methodologies between POCT and central laboratory will cause results to jump around when plotted or trended together. This can lead to clinical confusion and chasing results where treatment is based on one result, but the next result comes back too low. Based on this, therapy is readjusted; then the next result is too high, so therapy is adjusted again. Combining results from multiple methods can lead to such clinically confusing trends, overtreatment, and frequent changes in treatment that would not occur if the individual methods were separated in the patient's medical record.

Other distinctions that should be identified in the medical record are calculated and measured results. Some blood gas analyzers measure hematocrit by conductivity and calculate hemoglobin by a common conversion (hemoglobin = hematocrit/3), while other analyzers measure hemoglobin spectrophotometrically and calculate hematocrit. Conductivity hematocrit is sensitive to protein concentration and can be biased in surgical and trauma patients who receive transfusions and volume replacement. So POCT results for hemoglobin and hematocrit should specify not only that result was performed point-of-care, but whether the result was calculated or measured. These are only a few of the interface challenges to consider because of the unique method differences and biases that can occur with POCT in some patient populations.

Risk management

POCT systems are not perfect. All devices have limitations. When used outside manufacturer recommendations or used improperly, incorrect results can be generated. Errors can be more likely with POCT because of the number of operators involved, the volume of tests being conducted, and the various locations where testing is performed. POCT is often delegated to the lowest level of staff who have minimal training and experience. Staff shortcuts, differences in operator technique, and failure to appreciate patient and preanalytic factors can all compromise test quality. POCT is chosen over laboratory testing, because it is rapid and convenient. POCT can be performed at a variety of locations with the opportunity for the device and the reagents to be exposed to heat, cold, and humidity. The number of operators, tests, and locations multiplies the complexity of managing the testing process in a quality manner. Environmental exposure, sample, and operator errors can all lead to incorrect results.

Risk management can reduce errors. Manufacturers employ risk management when developing new methods in order to document that common hazards or the potential for errors have been addressed by the device engineering and that the limitations have been outlined in the package insert and instructions for use. The FDA considers the manufacturer risk management plan when reviewing the device for market approval. This plan outlines how the device is intended to be used (use-case scenario) and how the manufacturer addresses or detects potential misuse. With POCT, a device may be brought to the patient's bedside for testing, or alternatively a sample may be collected and brought to a device in a spare utility room on the nursing unit for testing. Moving a sample away from the patient presents the potential to mix-up samples with other patients tested in that utility room, unless the sample is labeled appropriately. These two use-case scenarios present different opportunities for particular errors, such as specimen mix-up. Risk management examines each step in the testing process for weaknesses where errors may occur and defines actions that may be required to reduce, prevent, or detect those errors before a result is released and action is taken by clinicians. So

laboratories can learn to reduce their chance for test errors by adopting industrial risk management principles.

Testing liquid QC specimens in a manner like patient specimens have historically been utilized to prove the ability of a test system to achieve a test result with the expected level of quality; however, liquid controls have limitations. With POCT, analyzing a QC sample consumes a single-use test kit, and there is no guarantee that the next kit will perform comparably. Based on this, manufacturers have developed a number of control processes engineered into the test or actions required to be performed by the laboratory to achieve quality results. Newer devices have clot and bubble detection, volume detection to ensure adequate sample was applied, and internal controls to prove the viability of reagents such as internal controls on pregnancy, HIV, and drug tests. Reagents are being shipped with a temperature monitor to ensure the package has not been exposed to heat or cold temperatures outside of manufacturer specifications during shipping. Staff are expected to check the temperature monitor on receipt of each shipment and verify acceptability before attempting to place the kits in use for patient testing. Each POCT device and test kit is unique and may present different opportunities for error depending on how the device is used by the consumer. Applying risk management to trace the sample through the testing process can reveal hazards or potential sources for error and the actions that are required to prevent and detect those errors. CLSI has published a guideline for assessing the risk of errors from implementing unit use testing devices, titled "Quality Management for Unit-Use Testing" [18]. This document advocates the use of an error matrix to list and prioritize the frequency and severity of potential errors associated with testing devices. This guideline also emphasizes a shared responsibility between the manufacturer and the consumer of the testing device in developing appropriate control strategies to manage errors. Another CLSI document, EP 23-A, titled "Laboratory Quality Control Based on Risk Management" [19], outlines a strategy to develop an IQCP for the laboratory test based on risk management. An IQCP basically summarizes many of the quality activities a laboratory is already doing in a more formal manner. The IQCP is discussed in further detail in Chapter 5, Quality control. Manufacturers have been conducting risk assessments for years and must submit their data for FDA review when seeking market approval of new tests. CLSI EP23 and the IQCP introduce these industrial risk management principles into the clinical laboratory.

Summary

POCT is an increasingly popular means of delivering faster test results closer to the patient. As the number of devices and menu of tests expands, the POCT market can be expected to grow. The major concern with POCT is providing quality test results with multiple devices, at dozens of sites by thousands of operators. Management of POCT, therefore, requires organization. POCT management can best be organized by forming a POCT committee to supervise new test requests and set policies, standardizing and minimizing the number of devices, planning implementation through validation of devices and training of operators, and providing consistent laboratory oversight to comply with regulatory requirements. POCT is a different method and may not be freely interchangeable with laboratory results in clinical protocols. Each method has unique interferences, biases, and imprecision that can lead to disparate results in certain patient populations. The potential for method differences stresses the need to validate devices at the intended clinical sites by using clinical staff operators to test typical patients before the decision to implement a device for patient care. Newer devices are computerized and can automatically collect and transfer the test results and QC data necessary to document regulatory compliance. Interfaces of POCT results should distinguish POCT results from laboratory results in order to prevent clinical confusion that can occur from overlaying results with unique biases in certain patient populations and clinical situations. Many newer POCT devices also offer improvements in detecting common errors through internal control processes. Risk management offers a means for laboratory directors to determine the required actions and optimal control strategies to minimize risk of errors for any specific device in their healthcare setting and use-case scenarios. POCT has the potential to provide faster results and improve patient outcomes through quicker therapeutic intervention provided that the clinician understands the method limitations and when to use the devices in patient care appropriately. POCT is thus a complex system with many factors to consider and manage to obtain optimal benefits.

Self-assessment questions

1. What is the definition of point-of-care testing?

a. Testing conducted close to the site of patient care
b. Bedside testing
c. Portable testing in an ambulance or helicopter
d. All of the above

2. Which of the following tests are available from POCT devices?

a. Growth hormone
b. Dihydrotestosterone
c. HIV antibody
d. Renin

3. What are the advantages of POCT?

a. Larger sample
b. Faster turnaround time for test results
c. Less expensive than core lab testing
d. More precise than core lab instrumentation

4. Which regulations apply to POCT devices?

a. Federal CLIA regulations
b. State law
c. Private accreditation agency standards like The Joint Commission
d. All of the above

5. Which of the following are true?

a. POCT results can lead to wrong treatment, and care should be taken to guarantee quality.
b. POCT devices are so simple that they pose no risk to the patient if incorrectly performed or a wrong answer is generated.
c. POCT results are used only for screening patients, and results are always confirmed by a lab method.
d. Clinicians can purchase POCT devices from a local pharmacy without having to comply with laboratory regulations if the tests are used only on their own patients in an office practice.

6. The DHHS enforces CLIA standards in which way(s)?

a. Limiting the physician's medical license to practice
b. Stopping reimbursement from Medicare and Medicaid
c. Closing the laboratory or physician's office performing testing.
d. All of the above

7. POCT device connectivity and the POCT1 standard are important for what reason(s)?

a. Allows multiple devices to connect to a single data manager and share an interface with a laboratory or HIS
b. Allows collection and review of data from multiple sites
c. Facilitates implementation of new POCT devices through plug-and-play connections
d. All of the above

8. Limitations of POCT devices include which of the following?

a. Ability of physicians to rapidly treat patients
b. Environmental and drug interferences with rapid methods
c. Ease of use and training of the operator
d. Small sample volumes

9. Which of the following is a QC process?

a. A whole blood control above the medical decision limit for a test
b. A colored disk to check the optics of a spectrophotometric device
c. A separate control line that develops with each test on a pregnancy strip test
d. All of the above

10. What is risk management?

a. A requirement for FDA approval of new devices
b. An industrial process for defining potential errors in the use of a device
c. A means for clinical laboratories to prevent and detect errors
d. All of the above

Answers

1. d
2. c
3. b
4. d
5. a
6. b
7. d

Chapter 20

Applications of molecular techniques in the clinical laboratory

Allison B. Chambliss[1] and Mark A. Marzinke[2]

Learning objectives

After reviewing this chapter, the reader will be able to:

- Describe molecular techniques used in the evaluation of cancers.
- Explain the role of nucleic acid testing in the identification of common infectious pathogens.
- Identify the influence of genetics in the coagulation cascade.
- Understand regulatory considerations associated with molecular testing.

Advances in genomic technologies have exponentially increased knowledge of human genetics and have led to the identification of numerous inherited and acquired genetic variants. Characterization of such genetic variants is critical to the differential diagnosis of numerous disease states, the selection of treatment regimens, and the monitoring of treatment responses. Traditionally, variant detection has been performed in a targeted manner, thus limiting analysis to a predefined selection of sequence changes associated with a clinical phenotype. However, more recently, multiplexed and next-generation sequencing (NGS) technologies have allowed for broader exome- or genome-wide approaches to facilitate inherited or acquired variant identification.

Molecular methodologies have been utilized in the characterization of both native and foreign genomic sequences. For instance, molecular platforms are commonly employed in constitutional genomic testing, which can be used to characterize congenital or developmental disorders. Molecular applications to the diagnosis of inborn errors of metabolism are discussed in more detail in Chapter 48, Inborn errors of metabolism and newborn screening, of this book. In addition, molecular testing is widely used in the identification of infectious pathogens and in the characterization of viral drug resistance. The central backbone of molecular platforms is the polymerase chain reaction (PCR)-mediated amplification of native, foreign, or acquired DNA regions. PCR amplification may occur in a targeted, untargeted, or multiplexed manner. Amplicon quantification or detection may be achieved using a variety of oligonucleotide or sequencing-based approaches; a review of nucleic acid probes and PCR technology is found in Chapter 13, Nucleic acid analysis in the clinical laboratory. This chapter will discuss the current applications of molecular analysis as well as the clinical utilities, limitations, and regulatory considerations associated with these analytical approaches.

Molecular diagnostics

Somatic gene variants

Cancer progression may be associated with the acquisition of genetic variants, which may result in the alteration of DNA replication, cellular proliferation, or differentiation. Such somatic variants are typically identified in the laboratory via analysis of DNA extracted from formalin-fixed, paraffin-embedded tissue. As tissue biopsies are heterogeneous, cancerous regions often contain populations of various distinct clonal populations of tumor cells as well as "contamination" by normal cells. Thus pathological findings and postreview processing of tissue samples are critical to the identification of acquired genetic variants. Further, clinical assays must be sensitive enough to distinguish the targeted variant among a heavy background of nonvariant DNA.

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00020-X

There are a number of transcription factors and signaling pathways that control molecular processes within cells. For example, the MAP kinase/ERK pathway, also known as the Ras−Raf−MEK−ERK pathway, is a signaling cascade that modulates protein translation and cellular division. Activation of the Ras−Raf−MEK−ERK pathway is controlled via ligand binding to the signaling epidermal growth factor receptor (EGFR) molecule. Ligand binding results in intracellular EGFR phosphorylation and downstream activation of adapter molecules; it is through this process that the Ras protein can bind the activator guanosine triphosphate (GTP) and initiate the aforementioned signaling cascade. Genetic variations can lead to constitutive pathway activation, thus resulting in uncontrolled cellular proliferation; dysregulation of the cascade is a key factor in cancer progression. Therapies directed toward the EGFR molecule, such as tyrosine kinase inhibitors and monoclonal antibodies, have demonstrated promising activity in the treatment of several cancers. For instance, EGFR-targeted therapies are widely employed in the treatment of colorectal cancers, nonsmall-cell lung cancers, and squamous cell carcinomas of the head and neck.

Specific variations within the genes located downstream of EGFR can render the pathway constitutively active even if EGFR itself is inhibited. Consequently, tumors with these variants are unresponsive to EGFR-targeted therapies. For instance, the acquired V600E mutation of the *BRAF* proto-oncogene results in the substitution of glutamic acid for valine at position 600 within the protein chain, resulting in a constitutively active BRAF signaling molecule. There is a prevalence of approximately 10% for the *BRAF* V600E mutation in colorectal cancers, and the somatic variant predicts resistance to anti-EGFR monoclonal antibody therapies such as cetuximab and panitumamab. Further, there is an estimated frequency of 45% for this variant in papillary thyroid cancers (PTCs). PTCs carrying the *BRAF* V600E variant are associated with a more aggressive phenotype that may include extrathyroidal invasion, lymph node metastases, and tumor recurrence [1]. Similarly, variants in the *KRAS* oncogene downstream of EGFR are implicated in carcinomas of the lung and colon. As many as 40% of colorectal cancers involve mutations in *KRAS*, with approximately 90% of variants found in codons 12 and 13 [2]. Thus guidelines from the National Comprehensive Cancer Network include tissue genotyping for *KRAS* variants in all patients with metastatic colorectal cancer. Table 20.1 lists other representative oncogenic variants commonly assessed in the monitoring and treatment of various cancers.

Variants within the EGFR pathway were previously detected by direct sequencing methods such as Sanger sequencing or pyrosequencing for single-gene analysis; however, detection of these variants via NGS platforms is becoming more common [3]. As variants must be distinguishable from the background of normal genetic sequences, specific considerations should be taken into account with regard to the analytical limits of detection (LODs) of the methodological technologies used. The analytical LODs vary between the methods and the laboratories but typically fall within 5%−30%, which refers to the percentage of DNA from the extracted material that carries the genetic aberration. Thus the variant of interest

TABLE 20.1 Representative oncogenic mutations commonly assessed in cancer.

Oncogene	Chromosome location	Associated protein function	Type of mutation	Representative associated cancers
HER2/*neu* (*ERBB2*)	17q12	Receptor tyrosine kinase	Gene amplification	Breast, ovarian, gastric, colon
Ras family: *HRAS* *KRAS* *NRAS*	11p15.5 12p12.1 1p13.2	Signal transduction (GTP/GDP binding)	Point mutations	Pancreatic, colorectal, lung, melanoma, bladder
BRAF	7q34	Signal transduction	Point mutations	Colorectal, papillary thyroid, melanoma
c-myc	8q24.21	Transcription factor	Translocation	Lymphoma, leukemia
N-myc	2p24.3	Transcription factor	Gene amplification	Neuroblastoma
PIK3CA	3q26.3	Phosphorylation	Point mutations	Colorectal, ovarian, breast

will only be detected if its frequency among nonvariant tissue DNA meets or exceeds the assay LOD. For example, general LODs have been estimated as 15%−20% for Sanger sequencing, 5% for pyrosequencing, and 10% for melting curve analysis [4]. In addition to testing of the tumor tissue itself, genetic variants in genes such as *KRAS* may be detected in cell-free DNA (cfDNA) obtained from plasma samples. Analysis of cfDNA is discussed later in this chapter.

Loss of heterozygosity

Loss of heterozygosity (LOH) occurs when a somatic cell contains only one of the two traditional alleles at a genetic locus. LOH may be the result of the failure of homologous chromosomes to separate properly during mitosis (nondisjunction), recombination segregation of homologous chromosomes before separation, or the deletion of a chromosomal segment. Cancer may develop if the missing chromosomal region includes the genomic information encoding a tumor suppressor gene. Further, LOH may also present as copy neutral by uniparental disomy, which is the consequence of maternal or paternal chromosomal duplication with the concurrent loss of the other allele (the Knudson two-hit hypothesis) [5]. In these cases, cancer may arise if the nonfunctional allele of a tumor suppressor gene is inherited. LOH has been reported in numerous cancer types, such as melanoma and cancers of the breast, lung, prostate, and bladder. LOH is considered the most frequent molecular genetic alteration observed in human cancers [6]. Further, when present in the germline, uniparental disomy may be associated with such congenital diseases as Prader−Willi or Angelman syndromes.

Analysis of microsatellite targets is the primary methodological approach employed for LOH detection. Microsatellites are tandem repeats of one to six nucleotides scattered at a frequency of approximately 3% across the genome [7]. These repeat elements are unstable and are prone to mispairing during DNA replication. Wild-type mismatch repair (MMR) genes typically correct these replication errors, resulting in microsatellite stabilization in the genome of healthy patients. However, variants in MMR genes have been implicated in the pathogenesis of several cancers and result in variability with respect to microsatellite length, causing microsatellite instability (MSI). Germline alterations in MMR genes are the cause of hereditary nonpolyposis colon cancer (Lynch syndrome), which account for approximately 5% of all colon cancer cases. Thus the detection of MSI may reflect cancer-causing MMR variants and can, therefore, be used to identify the presence of LOH or allelic imbalances.

A targeted microsatellite can be analyzed via PCR amplification using primers flanking the targeted tandem-repeat region. Products are subsequently separated by size via gel or capillary electrophoresis. The absolute size of each microsatellite may be determined using an internal size standard, which employs an additional dye to provide accurate allelic size determination and eliminates the possibility of run-to-run electrophoretic variability. MSI is defined as a change of allelic length due to the insertion or deletion of repeating units. Thus by comparing nontumorigenic control DNA (i.e., from lymphocytes) to DNA isolated from solid tumor tissue from the same patient, MSI may be detected by shifts in allelic size from the normal control (Fig. 20.1). MSI may also be detected in cfDNA from genetic testing of blood. Importantly, microsatellite typing can detect copy-number neutral LOH, which is not possible with traditional karyotyping techniques or fluorescence in situ hybridization (FISH). The latter is a common technique used to visualize specific DNA sequences on chromosomes. MSI is associated with endometrial and bladder cancers, among others. Additional

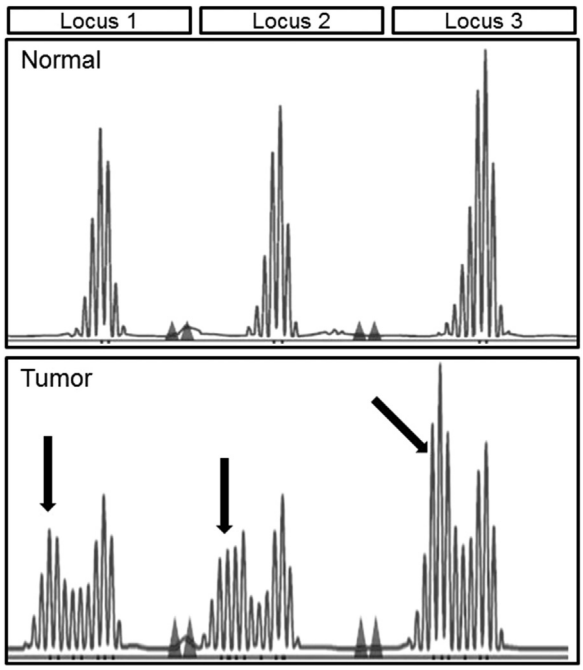

FIGURE 20.1 Microsatellite instability. Microsatellite instability, associated with many cancers, occurs when mismatch repair genes become mutated and cannot repair DNA mispairing errors. Resultant affected sequences from tumor tissue can be identified after targeted polymerase chain reaction amplification by a change in allele base pair length when compared with a nontumorous DNA control. This example for three targeted genome loci plots a frequency histogram of measured polymerase chain reaction product sizes measured by capillary electrophoresis (relative frequency on *y*-axis, allele size on *x*-axis). The tumor tissue DNA (*bottom panels*) shows additional product sizes, indicated by the black arrows, which are not present in the normal control DNA (*top panels*), indicating microsatellite instability. Data were collected via a microsatellite instability multiplex kit (Promega) and analyzed with GeneMapper software (Applied Biosystems/Thermo Fisher Scientific).

applications of microsatellite profiling outside of cancer include determination of parental origin of new mutations as well as engraftment testing by comparison of pre- and posttransplant samples of donor and recipient DNA.

Single nucleotide polymorphism (SNP) arrays are another common tool to assess LOH; these arrays are used for the genome-wide detection of copy-neutral LOH. This type of analysis involves assessment of a particular genotype (represented generally as homozygous AA, heterozygous AB, or homozygous BB) via single-base extension using labeled oligonucleotide probes at hundreds of thousands of known SNP locations simultaneously throughout the genome. SNP arrays may provide greater insight into the characterization of leukemias and other hematologic malignancies with characteristic chromosomal deletions. SNP arrays are also a common approach utilized for the assessment of LOH on chromosome arms 1p and 19q; the presence of LOH at these locations is diagnostic of oligodendroglioma in patients presenting with brain tumors. Similarly, LOH at chromosomes 1p and 16q is associated with a poor prognosis in patients with Wilms tumor, a renal malignancy observed in children [8]. Furthermore, upon detection of ultrasound abnormalities during fetal development, whole-genome SNP arrays provide a more rapid and high-resolution analysis of unbalanced germline chromosomal abnormalities in the fetus than traditional karyotyping.

Circulating tumor cells and cell-free DNA

Tumor cells enter the circulatory system when they break from primary tumors of epithelial origin. In cancer, circulating tumor cells (CTCs) may exist at a frequency of one per 5−10 million blood cells and may be collected and enriched for quantification. The Menarini Silicon Biosystems CellSearch platform, the only FDA-cleared test for the assessment of CTC at the time of this publication, is approved for use in patients with breast, prostate, and colorectal cancers. The assay uses a combination of immunomagnetic cell labeling and automated digital microscopy to negatively select for and quantify isolated tumor cells in 7.5 mL blood [9]. While tissue biopsies are risky and invasive, genetic testing from blood requires only a blood draw and is thus an attractive alternative for characterizing or monitoring the aforementioned cancers. Increased CTC counts are correlated with poorer prognosis and shorter survival rates in many cancers [10].

Tumor-derived extracellular DNA provides another target for the detection of characteristic genetic or epigenetic mutations. All patients, healthy and diseased, possess some portion of extracellular or cfDNA that is released upon apoptosis and circulates unbound from leukocytes or erythrocytes. The presence of such cfDNA was first described in 1948 by Mandel and Metais [11]. However, it was not until the 1990s that their discoveries were further extrapolated with the use of PCR to demonstrate that oncogenic variants could be detected in the plasma of cancer patients [12,13]. Presently, detection of variants in both proto-oncogenes and tumor suppressor genes, as well as LOH analysis (i.e., microsatellites, genetic aberrations), can be performed using plasma. Because plasma contains cfDNA both of cancerous and noncancerous tissue origin, appropriately specific and sensitive methods are required to identify malignant genetic material. Initial methods implemented for cfDNA analysis included allele-specific PCR amplification with direct sequencing; however, such methods often lacked sensitivity to detect the rare amounts of cfDNA in the plasma. More recently, single-molecule PCR, also known as digital PCR (dPCR), has been utilized due to its ability to detect a variant present in a very small fraction of the whole specimen. The principles behind dPCR are discussed later in this chapter.

In addition to cancer applications (i.e., monitoring of tumor burden, minimal residual disease, and molecular resistance), cfDNA has also revolutionized the field of fetal medicine. Inspired by the discovery of tumor-associated DNA in plasma, Lo and colleagues set out to determine whether, in the same manner, fetal DNA could be found in the plasma of the mother. In 1997 they discovered that a sequence from the Y chromosome was detectable in the plasma of pregnant women carrying male fetuses [14]. The fraction of fetal DNA in maternal plasma may approach 10% in the first and second trimesters and 20% in the third trimester [15]. Analysis of fetal DNA by liquid biopsy overcomes the risks and invasiveness of traditional sampling methods such as amniocentesis and chorionic villus sampling (CVS). The first clinical application of DNA-based noninvasive prenatal diagnosis came with the demonstration that fetal rhesus D blood group status could be identified in maternal plasma via real-time PCR (qPCR) [16]. Other applications include the detection of paternally inherited variants associated with thalassemias and cystic fibrosis. dPCR techniques can distinguish low abundance fetal genomic sequence from the primarily maternal genomic background. However, the detection of fetal chromosomal aneuploidies, such as trisomy 21, has proven more challenging, because it requires specific differentiation between the fetal and maternal chromosomes. One approach to circumvent this issue involves the assessment of an epigenetic allelic ratio via the analysis of differential DNA methylation between the maternal and fetal chromosomes. Currently, this approach is considered a laboratory-developed test.

Massively parallel sequencing (MPS) has made it possible to count millions to billions of DNA molecules in order to detect accurately the presence of a trisomic fetus.

Assays for the detection of trisomy 21, 13, and 18 by noninvasive methods are now commercially available. Importantly, the American College of Obstetricians and Gynecologists currently recommends that cfDNA testing be considered only for screening purposes, and all abnormal results should be confirmed by diagnostic testing via amniocentesis or CVS [17]. While cfDNA testing eliminates the invasiveness and risks of traditional prenatal screening, there also exist ethical concerns, as the ease of testing may encourage more those mothers with "increased risk" to undergo testing.

Genetic variants in hemostasis

The use of molecular diagnostic techniques in hematology laboratories has increased with both the improvement of analytical technologies as well as the identification of genetic factors affecting coagulation. The coagulation system functions to control bleeding through the generation of blood clots. The process is complex and dynamic and involves the activation, adhesion, and aggregation of platelets to generate ultimately cross-linked fibrin. Regulators of the involved pathways include several coagulation factors, which are generally serine protease (PR) enzymes or transglutaminases. Molecular assays serve to assess function along many various steps of the coagulation cascade.

Prothrombin polymorphisms

Prothrombin, also known as factor II, is the vitamin-K-dependent precursor to thrombin (factor IIa) at the culmination of the coagulation cascade. A well-characterized variant exists within the prothrombin gene on chromosome 11p11-q12 that is defined by a guanine-to-adenine (G > A) substitution at nucleotide 20210 in the 3′ untranslated region. The primary consequence of this genetic aberration is increased prothrombin accumulation with a resultant two- to threefold increased risk of venous thromboembolism. The prevalence of this variant is $<1\%-6\%$, and the frequency is dependent on ethnic background [18]. Of note, plasma prothrombin levels alone are insufficient to identify carriers of the defect due to the large inter- and intraindividual variabilities across populations. Thus genetic analysis is necessary.

PCR-based assays for prothrombin variant evaluation are widely performed using DNA obtained from whole blood; combined restriction digestion and agarose gel electrophoresis may be used for aberration detection. Techniques that are more modern include beacon-based or fluorescent probes using sequence-specific hybridization as well as high-resolution melting curve analysis. With regard to the melting curve analysis technique, PCR amplification precedes a gradual temperature increase, which results in the dissociation of the amplified product at a specific melting temperature dependent on the base pair sequence of the amplicon. The melting temperature is defined as the point at which the fluorescent dye (which is intercalated into double-stranded DNA) signal decreases following product dissociation. The G > A variant decreases the amplicon melting temperature from a wild-type control and readily allows for variant identification in the sample. Of note, other less-prevalent polymorphisms of the prothrombin gene have been described, including C20209T and A19911G. These variants are not as well characterized as G20210A. However, both polymorphisms are also thought to increase plasma prothrombin levels and heighten risk of venous thromboembolism.

Factor V Leiden polymorphism

Upstream of factor II in the coagulation cascade, activated protein C (APC) functions to degrade factors V and VIII, thus acting as a natural anticoagulant to balance thrombin production. A genetic polymorphism causing an arginine-to-glutamine substitution at nucleotide 1691 within factor V gene, which is located on chromosome 1q23, leads to a defect in the APC cleavage site. This amino acid substitution causes decreased factor V susceptibility to inactivation by APC and is associated with resistance to APC activity. The abnormal factor V protein is termed factor V Leiden (FVL) and is the most common cause of inherited thrombophilia in Caucasians, with as much as 5% of the population possessing heterozygosity for this polymorphism. Further, prevalence may approach 15% in some European and Middle Eastern countries, while the variant is typically not observed in African and Asian populations. The FVL point mutation may be detected using similar analytical approaches as the aforementioned prothrombin G20210A variant. Commercial assays often utilize PCR followed by target-specific hybridization with reporter fluorophores, such as a TaqMan probe-based approach; this methodology is described in more detail in Chapter 13, Nucleic acid analysis in the clinical laboratory. Based on measured fluorescent signal, allelic discrimination data analysis approaches determine whether the assayed sequence is wild type (or reference), heterozygous, or homozygous for the targeted variant.

Methods are also available to detect both the G20210A prothrombin variant and the FVL variant in the same reaction. This is achieved by multiplexed PCR of both affected genetic regions followed by similar target-specific hybridization methods. It is estimated that approximately 1 in 1000 Americans are doubly heterozygous for both FVL and G20210A, significantly increasing the risk of venous thromboembolism 20-fold over the general population [19]. For both FVL and

G20210A, screening in asymptomatic patients is typically limited to those with a strong family history of venous thromboembolism.

Nonmolecular approaches to identify the abnormal FVL factor are functional in methodological design. For example, APC resistance assays consist of diluting patient plasma into factor V-deficient plasma for the evaluation of activated partial thromboplastin time. Functional APC resistance assays may be used as a screen for FVL; however, positive results should be confirmed by genetic testing to confirm the diagnosis and determine hetero- or homozygosity in order to stratify thrombotic risk [20].

Methylenetetrahydrofolate reductase polymorphism

The 5,10-methylenetetrahydrofolate reductase (MTHFR) enzyme is responsible for the conversion of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate in the metabolism of folate. A mutation in the gene encoding for MTHFR represents the most common form of genetic hyperhomocysteinemia. This *MTHFR* polymorphism is characterized by a cytosine-to-thymine substitution at nucleotide 677, leading to an amino acid replacement of valine for alanine at codon 222. The mutation variably reduces MTHFR enzyme activity by rendering the enzyme more thermolabile. Variants may occur with frequencies as high as 40% in the general population [21]. Affected individuals may present with increased risk of venous thromboembolism and cardiovascular disease. Targeted genotyping assays for *MTHFR* may aid in the differential diagnosis of megaloblastic anemia, especially in the background of folate deficiency and elevated plasma homocysteine concentrations. Testing may also be indicated for individuals on medications known to affect folate metabolism (i.e., methotrexate). Mutational status is often measured using molecular probe-based approaches or melting curve analysis.

Nucleic acid testing in pathogen detection and monitoring

Nucleic acid testing has transformed the management of pathogen detection and monitoring in infectious diseases. In contrast to traditional culture methods, rapid molecular methods facilitate expedited result reporting and provision of clinical decision support. Further, in some cases, quantification of pathogen nucleic acids provides a means of monitoring infection progression in addition to monitoring response to therapy. While infectious diseases commonly assessed in the clinical laboratory are described in more detail in Chapter 54, Infectious diseases, of this book, this section will focus on nucleic acid testing for pathogens for which molecular technologies play a large role.

Hepatitis B virus

Hepatitis B virus (HBV) is a circular, partially double-stranded DNA virus from the hepadna family. HBV is the most common cause of acute hepatitis globally and is the most common form of chronic viral infection. The HBV surface antigen and other surface protein forms contain various molecular subdeterminants, which distinguish 10 genotypes (A-J) and >30 subtypes of the virus. In the United States, the A, B, and C genotypes are most prevalent. The complicated structure of HBV includes several enzymatically active sites that make viral reproduction error-prone, leading to a high frequency of viral mutations and yielding challenges in vaccination, diagnosis, and treatment. For example, a relatively common G > A point mutation at nucleotide 1896 inserts a stop codon in the place of tryptophan, thereby preventing the translation of a functional hepatitis B e antigen (HBeAg), rendering affected individuals' infections undetectable when using HBeAg immunoassay testing. This variant may be present in over 70% of patients in the United States with HBV type D [22]. Similarly, variants in the "a" determinant region of the HBV surface antigen (HBsAg), which is involved in the binding of antibodies against the antigen, may cause patients to test falsely negative when using the HBsAg immunoassay, which is the most widely used marker to assess an active HBV infection. Quantification of HBV DNA is critical to the diagnosis and management of infection, especially when serology testing is inconclusive.

HBV DNA assays are available for monitoring treatment responses and viral genotyping. For DNA analysis, most assays use qPCR techniques with LODs as low as 10 IU/mL. International units are used rather than the traditionally reported copies/mL due to the establishment of international reference material from the World Health Organization [23]. However, due to various methodologies used for HBV DNA quantification, conversion between IU/mL and copies/mL tends to differ amongst assays. Roughly, 1 IU/mL equates to approximately 5 copies/mL, though PCR-based quantification assays have demonstrated higher conversion factors than branched DNA (bDNA) assays. bDNA assays consist of a series of hybridization steps that result in a branched "sandwich" complex of probes and target sequence to amplify signal [24]. Accordingly, interpretation of viral load is somewhat controversial, and patients should ideally be monitored with the same assay. Some guidelines suggest a cutoff value of 20,000 IU/mL to diagnose the virus. However, a lower threshold is necessary for HBeAg negative individuals, such as those with the G1896A variant, who naturally have lower viral loads despite an aggressive disease course when chronically affected [25]. Thus serial monitoring of DNA levels is

considered more valuable than a cutoff threshold when determining treatment regimens. HBV genotyping is not widely performed, as further studies regarding the role of genotyping in the guidance of clinical decisions are necessary before it can be recommended for routine practice.

Hepatitis C virus

Hepatitis C virus (HCV) is a single-stranded RNA flavivirus that is transmitted primarily via blood. HCV may lead to chronic liver disease in over 50% of those virally infected. While immunoassay screening is often used as the first line of testing, HCV RNA testing assists in confirmation of active infection. Furthermore, in certain cases, molecular testing may be diagnostically indicated. For example, immunocompromised patients, such as those infected with Human immunodeficiency virus (HIV)-1, may not be seropositive for HCV but infected with the virus; thus immunoassays may result negative, while HCV RNA is detectable. Furthermore, because maternal antibodies can cross the placenta, qualitative molecular-based assays are more informative than serology in the detection of HCV RNA in the plasma or serum of infants born to HCV-infected mothers. RNA testing may also detect the virus earlier than immunoassays in any patient, as RNA is detectable as early as 1 week postexposure and several weeks prior to seroconversion, depending on the mode of transmission [26]. Such "qualitative" HCV RNA tests used for diagnosis commonly utilize conventional qPCR or transcription-mediated amplification, which, in contrast to traditional PCR, uses an isothermal reaction with RNA polymerase and reverse transcriptase (RT). Currently, available assays are detailed in Chapter 54, Infectious diseases; LODs may be as low as low as 5 IU/mL. Of note, RNAse activity of blood cells can lead to HCV RNA lability in whole blood, and rapid separation of serum is critical to avoid significant loss of HCV RNA and potential false-negative results [27].

For treatment, a quantitative viral load is typically assessed at baseline to predict the duration of treatment and the likelihood of sustained virologic response, which is defined as an undetectable viral load 24 weeks after completion of antiviral therapy. Commonly available formats for quantitative HCV RNA include both qPCR and bDNA assays. Quantitative assays also play a role in blood supply screening, which has significantly reduced the risk of HCV RNA transmission via transfusion reactions. While blood transfusion carried a high risk of 15%−20% for HCV infection prior to 1992, blood screening procedures have now reduced the risk dramatically to approximately 1 in 1 million transfusions [26].

HCV infection is genetically heterogeneous across individuals, with six major genotypes and over 100 subtypes identified. HCV genotyping assays serve to predict the course of infection and assist in determining treatment type and duration. Although the 5′ untranslated region is the most highly conserved portion of the HCV genome, it is frequently used as a target in all molecular HCV assays, including genotyping. Conversely, the NS5B nonstructural protein region of the HCV genome is the least well-conserved region, and more recently has been successfully used for viral genotyping. Common genotyping methodologies include reverse hybridization probe-based assays and direct DNA sequencing.

Human immunodeficiency virus type 1

HIV is an RNA lentivirus that is transmitted through the exchange of virus-containing fluids. Routes of infection include sexual contact, injection drug use, vertical transmission, and exposure to infected membranes or tissues. The type 1 virus (HIV-1) is the most common form worldwide and is the more virulent form than HIV-2. HIV-1 is characterized by extensive genetic heterogeneity, resulting in a variety of major phylogenetic groups (M, O, N) and M-group subtypes (A through K). The Centers for Disease Control and Prevention recommends that initial screening for HIV should be performed with an FDA-approved fourth-generation combination assay, which detects antibodies to both HIV-1 and HIV-2 as well as the HIV-1 p24 antigen [28]. However, RNA testing is indicated when serologic investigation is indeterminate or if an acute HIV infection is suspected. Virus may be detectable by the most sensitive molecular methods approximately 10 days after infection, possibly up to ten days prior to the fourth-generation immunoassays for the p24 antigen.

RNA quantification of HIV-1 viral load is primarily used for monitoring purposes in previously diagnosed HIV-1-infected individuals. Viral load testing can monitor response to therapy as well as predict time to progression to acquired immune deficiency syndrome (AIDS). Combinatorial antiretroviral (ARV) therapies seek to reduce viral loads below the LOD of currently available assays (20−50 copies/mL). Testing should be performed before therapy is initiated (baseline) and again at 2 and 8 weeks into treatment to assess response. Testing may then be performed every 3−6 months thereafter to evaluate continued therapeutic efficacy. If viral load exhibits a significant increase during therapy, HIV-1 resistance testing may be required (see below). While some individuals show persistently low but quantifiable levels of HIV RNA (<200 copies/mL but still detectable), these measurements are not necessarily indicative of virologic failure; the AIDS Clinical Trials Group defines virologic failure as a viral load of >200 copies/mL [29]. HIV-1 RNA quantification is typically achieved through qPCR or bDNA assays. FDA-approved assays for nucleic acid

TABLE 20.2 FDA-approved nucleoside reverse transcriptase inhibitors (NRTIs) for the treatment of HIV-1 and relevant resistance mutations in the HIV-1 reverse transcriptase (RT) gene.

NRTIs	Major HIV-1 RT mutations yielding resistance[a]	Notes
Zidovudine (ZDV/AZT) and stavudine (d4T)	T215Y/F, Q151M, T69ins	Thymidine analog mutations (TAMs) reduce susceptibility to these drugs
Lamivudine (3TC) and emtricitabine (FTC)	M184V/I	M184V is the most prevalent NRTI-associated mutation seen in HIV-1 treated patients
Tenofovir	K65R, T69ins	K65R confers significant cross-resistance to ABC, 3TC, and ddI
Abacavir (ABC)	K65R, L74V/I, Y115F, Q151M, T69ins	L74V may be present in combination with M184V
Didanosine (ddI)	K65R, L74V/I, Q151M, T69ins	The combination of d4T and ddI appears to select for TAMs more commonly than it selects for the L74V mutation

[a]*Mutations are described by a combination of letters and numbers, for example, M41L. The first letter (M) is the code for the amino acid in the wild-type virus. The number (41) identifies the position of the codon. The second letter (L) is the code for the new amino acid in the mutant sample. "ins" indicates an insertion.*

testing of HIV-1 are listed in Chapter 54, Infectious diseases, of this book. An additional technology, nucleic acid sequence-based amplification, is an isothermal method of RNA amplification that eliminates the need for thermocycling instruments and uses endpoint electrochemiluminescence or fluorescence detection for RNA quantification [30].

Viral drug resistance and genotyping

High rates of HIV replication and viral dependence on the error-prone HIV RT enzyme can lead to frequent introduction of viral mutations that often yield ARV drug resistance. To combat the rise of drug-resistant virus, combinatorial drug regimens are primarily used in the management of HIV, including inhibitors of CCR5-mediated viral entry, viral fusion, viral transcription, integration into the host cell genome, and protein assembly. However, viral resistance may occur in all of these ARV classes, thereby limiting the potential efficacy of treatment regimens. The likelihood of resistance is higher in certain ARV drug classes, such as nucleoside reverse transcriptase inhibitors (NRTIs)/nucleotide reverse transcriptase inhibitors and protease inhibitors. Thus there is immense clinical utility for antiviral resistance testing in HIV-1-infected patients, particularly in those who are on treatment regimens but not virally suppressed.

Traditional phenotypic assays measure the ability of the virus to grow among a variety of ARV drugs and concentrations. However, molecular assays are often cheaper, simpler, and provide a significantly quicker turnaround time; thus genotyping is the preferred method for evaluating resistance. The US Department of Health and Human Services recommends HIV drug resistance testing for individuals who have never before received therapy as well for those who are changing treatment regimens; however, this may not occur as standard of practice. Standard genotype-based drug-resistance testing involves detection of variants within the RT and PR genes. Assays assessing mutations in the integrase and gp41 (envelope) genes are also commercially available; however, the incidence of viral resistance in these genes is much lower. Automated sequencing methods are primarily used; upon isolation of the HIV-1 RNA from plasma, PCR amplification is performed followed by sequencing of the RT and PR genes. Most laboratories utilize commercial assays with corresponding software to assist in the interpretation of sequencing results. The International Antiviral Society—United States maintains and routinely updates lists of mutations associated with clinical resistance to HIV; the most recent report was published in 2019 [31]. As a representative example, Table 20.2 lists the NRTIs that are FDA-approved for the treatment of HIV-1 along with their majorly associated resistance mutations.

Assay approaches

Next-generation sequencing

While optimal for some applications, traditional sequencing methods are limited in throughput and are, therefore, not conducive to multigene panels. More recent technological advances in the early 2000s have led to the development of NGS, also known as MPS, which differs from

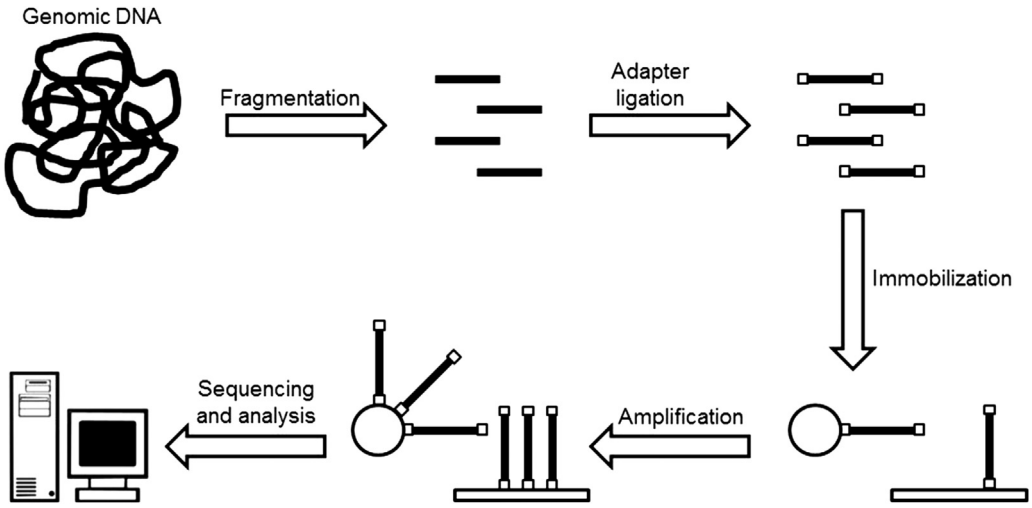

FIGURE 20.2 Next-generation sequencing general workflow. The general workflow of next-generation sequencing analysis is illustrated. Genomic DNA is first isolated, purified, and fragmented. Oligonucleotide adapters are attached to the ends of target fragments, and DNA is then immobilized to beads or sequencing slides. Fragments are then amplified clonally followed by parallel sequencing of the millions of clones, and resultant sequences are compared electronically against a reference genome. The whole genome may be sequenced, or smaller portions may be targeted, such as the exome or a preselected targeted gene panel.

traditional sequencing in that it uses parallel sequencing of millions of small DNA fragments to increase significantly throughput and speed of analysis. The technology has gained significant traction in the clinical laboratory and may be used in a number of ways. Notably, targeted NGS can provide both predictive and prognostic information in the routine care of patients with cancer. Further, NGS can also be used in the identification of germline variants associated with inherited diseases, identification of pathogens, analysis of circulating cfDNA, and gene discovery.

Though several technical platforms exist, NGS is generally a multiday process that first consists of a library preparation step in which the patient's DNA template is purified, amplified, fragmented, and then isolated onto solid surfaces such as slides or small beads (Fig. 20.2). Fragments are then amplified clonally followed by parallel sequencing of the millions of clones, and resultant sequences are compared electronically against a reference genome. The whole genome may be sequenced, or smaller portions may be targeted such as the exome or a preselected subset of genes ("hotspot" sequencing). Whole-genome sequence is typically reserved for gene discovery, including the characterization of unidentifiable diseases. Exome sequencing seeks to cover all coding regions of the genome. While the exome comprises only 1%–2% of the whole genome, it is estimated that it contains upward of 85% of disease-causing variants [32]. Exome sequencing may be indicated over more specifically targeted sequencing approaches when there are a large number of potential responsible genes in the patient's differential diagnosis or when obvious candidate genes have already been tested and were found to be normal. Targeted gene panels are selected when a particular disease is known or suspected, and the greater depth of coverage offered by these targeted panels increases the probability of detecting low-level heterogeneity or mosaicism. Notably, pipeline filters are often utilized to reveal only the clinically relevant or "actionable" variants.

Multiple commercial platforms are currently available for NGS analysis from a variety of vendors, including Illumina (HiSeq, MiSeq, and NextSeq series), Qiagen (GeneReader), and ThermoFisher Scientific (Ion Torrent), among others [33]. Considerations for choosing such a system include evaluation of read length, error rates, and run times. Notably, platforms vary with regard to gene coverage and may differ in terms of analytical sensitivity for specific variants. Thus inherent platform biases, combined with deviations in sample preparation and data analysis, can contribute to interlaboratory variability. Cost of testing and bioinformatics challenges remain hurdles in the wide implementation of NGS, though technological advances continue to decrease both.

Digital polymerase chain reaction

In the context of a dilute template DNA solution, such as in the case of cfDNA or fetal DNA in maternal plasma, the analytical sensitivity of conventional PCR is limited. Such limitations may be circumvented via the use of dPCR or single-molecule PCR. dPCR is performed through sample partitioning where template DNA is distributed broadly across thousands of reaction components. The physical dilution or partitioning of the sample occurs

to the extent that some compartments contain no template at all. Depending on the technical platform chosen, compartments may occur as microarrays, microfluidic disks, or small droplets of oil–water emulsions. Each partition behaves as an independent PCR reaction with the use of fluorescent probes to identify and quantify amplified target DNA. Data are analyzed in a binary way such that partitions containing product/fluorescent signal are considered positive ("1"), while partitions without detected signal are considered negative ("0"). Through the ratio of positive-to-negative reactions and Poisson statistics, very exact absolute template quantity can be determined. In this manner, copy number changes and minor allele fractions in a heavy background of wild-type DNA may be quantified. Applications are numerous in such areas as noninvasive prenatal diagnostics, liquid biopsies of solid tumor burden, and ultrasensitive viral load detection. While this method requires large-scale multiplexed PCR reactions, improvements in technologies such as microfluidics are making the technique more high throughput and suitable for routine use.

Universal biosensors for pathogen detection

The identification of unknown pathogens (bacteria, viruses, fungi, and protozoa) is challenging using conventional methods due to their often narrowly targeted nature as well as the long turnaround times associated with cultures. More recent technological advances have led to the development of universal pathogen detection platforms capable of identification and strain typing of a broad range of pathogens within the same assay. Abbott's IRIDICA universal biosensor (previously Ibis Biosciences) employs a series of broad-range primers for organism groupings, rather than particular species, to first PCR amplify species-specific genomic DNA. The broad-range approach of the primers allows for the inclusion of any species, even previously unknown organisms. Subsequent electrospray ionization mass spectrometry measures the mass-to-charge ratio (m/z) of the amplified product, which allows for the calculation of molecular mass for each amplicon. By comparing the resultant mass spectra to a database of known microorganisms, unknown pathogens can be matched and new, undescribed pathogens may be identified. The major advantage of this methodology is the ability to characterize multiple organisms simultaneously and without prior knowledge of microorganism identity. However, one caveat is that pathogen identification can only extend to what organisms are characterized in the reference library.

Regulatory considerations for molecular approaches

Clinically utilized molecular assays are subject to similar regulatory standards as other laboratory techniques, though they present their own set of challenges. The College of American Pathologists states that for molecular testing, nucleic acids must be extracted, isolated, and purified by commercially available or internally validated methods followed by measurement of nucleic acid quantity and purity. Internal quality control procedures should include the use of appropriate positive and negative controls in a similar matrix to patient samples. Laboratories must provide written guidelines for interpretation of results, which is often not straightforward with qualitative molecular assays or the detection of a novel genomic variant. Laboratory policies should be in place for the reporting of genetic findings unrelated to the intended purpose for clinical testing.

Regulations for NGS in particular pose unique challenges. "Positive controls" are typically chosen for one particular mutation or set of mutations and cannot encompass all possible mutations that could be recognized by the assay. In addition, Clinical Laboratory Improvement Amendments requirements for proficiency testing (PT) typically involve twice yearly assessments per assay. NGS assays may be defined in various manners, including a particular gene panel, exome analysis, or whole-genome analysis. The cost of running several PT samples per year may by any of these NGS assay definitions not be financially feasible for many laboratories. Alternatively, more affordable PT approaches that may become more prominent in the future include analytic/bioinformatics challenges in which electronic sequence information, rather than biological samples, is sent electronically to the laboratory. Such challenges may assess the laboratory's ability to accurately align, detect, and interpret the genetic information without having to use costly reagents and consumables. In general, developments in molecular technologies have initiated a shift from analyte-specific PT to methods-based PT due to the wide scope of genes now being assessed in clinical laboratories.

Limitations to molecular detection of allelic variants

Molecular diagnostic assays are accompanied by several technical and interpretative limitations that must be taken into consideration when used in the clinical laboratory. Sample quality comprises the first bottleneck of assay reliability. Nucleic acid extraction and sample preparation must be performed in sterilized environments to prevent contamination. For nucleic acids extracted from blood specimens, automated extraction methods are ideal for consistency of DNA sample preparation. For DNA obtained from solid tumors, the retrieval of DNA from formalin-fixed, paraffin-embedded tissue often leads to high levels of degradation and suboptimal sample quality. Resultant degraded samples may only allow for

amplification of small PCR amplicons (<200 base pairs). An additional barrier to biopsied tumor tissue is that isolated DNA will contain mixed populations of normal and cancerous cells. Thus assays must be sensitive enough to detect accurately very low levels of mutations in what may be a heavy background of normal sequences.

Aside from genome-wide approaches, a majority of molecular approaches are targeted to specific genes, gene regions, and known polymorphisms. It is imperative to recognize that such assays can detect only what they have been designed to recognize. Furthermore, bioinformatics challenges persist as advances in massive parallel sequencing assays yield more and more genetic information that requires large data storage capacity. In addition, questions still exist regarding how much information to transmit into the patient's medical record and how to best guide interpretation of that information. Finally, while costs per test are decreasing, many genetic tests remain expensive and may be deemed "investigational" by insurance companies and thus are not reimbursed.

Conclusions

This chapter has demonstrated the numerous applications of molecular techniques to the diagnosis and monitoring of patients in a variety of clinical disease states. Profound molecular breakthroughs in recent years have led to increased genotype−phenotype insights and their application in the clinical laboratory. However, with more knowledge come additional challenges in bioinformatics and test interpretation. Further collaborations among institutions and advancements in data analysis tools will soon allow for the routine testing for genetic mutations with broad, genome-wide approaches.

Self-assessment questions

1. Which of the following techniques will detect copy-number neutral LOH?
   a. FISH
   b. karyotyping
   c. MSI
   d. pyrosequencing

2. The most frequent molecular genetic alteration observed in human cancers is:
   a. point mutations
   b. LOH
   c. translocations
   d. gene deletions

3. Mutations of prothrombin and Factor V are best described as:
   a. point mutations
   b. gene insertions
   c. gene deletions
   d. gene duplications

4. Molecular detection of hepatitis may be indicated in patients who are:
   a. anemic
   b. under the age of 18
   c. obese
   d. immunocompromised

5 Standardized HIV-1 drug resistance genotyping assays target the following genes:
   a. CCR5 and integrase
   b. PR and RT
   c. RT and integrase
   d. CCR5 and RT

Answers

1. c
2. b
3. a
4. d
5. b

Chapter 21

Applications of mass spectrometry in the clinical laboratory

Learning objectives

After reviewing this chapter, the reader will be able to:

- Identify the advantages and disadvantages of mass spectrometry as a diagnostic tool.
- List three clinical small molecule and three clinical protein applications of mass spectrometry.
- Describe bottom-up and top-down approaches for clinical protein mass spectrometric assays.
- Describe the regulatory considerations associated with clinical mass spectrometric assays.

Mass spectrometry (MS), a technique in which the mass-to-charge ratio of a gas-phase ion is measured, has a long history in providing qualitative and quantitative measurements in analytical chemistry [1]. Most MS assays make use of isotopically labeled internal standards, which enable mass spectrometers to provide highly specific measurements. Mass spectrometers can be coupled to gas or liquid chromatographs to add orthogonal points of identification and further increase analytical and assay selectivity. The specificity of MS allows analytes to be measured accurately even in the presence of interfering substances (e.g., heterophilic or autoantibodies) or in the presence of structurally similar compounds that cannot be distinguished by immunoassay. Mass spectrometers are also capable of multiplexing, or measuring many analytes within a single analysis, and some parts of the testing process can be easily automated, both of which increase testing efficiency. A description of the analytical methodology is provided in Chapter 10, Mass spectrometry, of this book.

MS is an extremely versatile platform and offers many benefits as a measurement tool in laboratory medicine. In this chapter, we review the various applications of MS in the clinical lab as well as the challenges and the regulatory considerations associated with the implementation of this technique.

Mass spectrometric applications for measuring small molecules

Sample preparation for small molecule methods

Most MS methods require pretreatment of biological samples in order to introduce the sample into the mass spectrometer. For most methods currently deployed in clinical laboratories, sample preparation is used to concentrate an analyte of interest, dilute out interfering compounds, and/or change the composition of the sample to be more amenable for downstream chromatographic or MS analysis. Sample preparation for small molecule applications has been extensively reviewed elsewhere [2].

Gas chromatography-mass spectrometry (GC-MS) is generally limited to smaller, volatile compounds, and samples must be introduced in organic solvent. As a result, biological samples that will be analyzed by GC-MS are subjected to extraction, where the compound of interest is removed from the aqueous matrix and placed into an organic solution. A variety of techniques can accomplish this, including liquid−liquid extraction, solid phase extraction, and dilution. Extracted samples can be concentrated by evaporating some or all of the organic solvent. Extracts can also be chemically derivatized to increase the volatility of the analyte, improve the chromatographic peak shape, and increase the sensitivity of the method. Heat stable compounds that are generally nonpolar may not require derivatization prior to GC-MS analysis, but this process may be necessary for polar compounds. Derivatization reagents are often used for broad-spectrum drug screening methods, where compounds from a variety of chemical classes will be analyzed together, and for analysis of steroid hormones.

Depending on the type of chromatography being used, samples can be introduced into a liquid chromatography-

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00021-1

mass spectrometry (LC-MS) system in aqueous or organic solution. Liquid chromatography systems can be used with polar, nonpolar, and thermally labile compounds, so chemical derivatization is generally not necessary for LC-MS analysis. Still, it can be helpful to improve sensitivity for some analytes, like steroid hormones. Extraction is generally needed to remove proteins and lipids from serum and plasma, but is not absolutely required for matrices with lower protein content, like urine. In some cases, dilution of the specimen is all that is needed to achieve the desired sensitivity. In other cases, extraction followed by evaporation and reconstitution may be required to achieve optimal analytical sensitivity. The type of sample preparation that is selected will influence the degree of matrix interference, the frequency of source maintenance that is required, and ultimately the sensitivity of the method. These factors, as well as the cost of the preparation in technologist time, consumables, and solvents, can all influence the choice of sample preparation.

Qualitative and quantitative testing

Mass spectrometric testing used in diagnostics can be designed to operate qualitatively, for example, by identifying the presence but not the concentration of a compound of interest, or quantitatively, for example, by identifying both the presence and concentration of a compound of interest. Many factors can influence the choice to provide qualitative or quantitative results. Quantitative methods may require more extensive internal standardization and calibration and may be more expensive to develop, validate, and perform. In some clinical scenarios, like urine drug testing, quantitative results may not add value or may be misinterpreted, and qualitative results may be preferred. On the other hand, compounds that are expected to be present in a patient's sample, like steroid hormones and many other biomarkers, are generally measured quantitatively, and the numeric result is compared with a reference interval.

Toxicology

One of the first clinical applications of MS arose in part due to the 1981 accident on the U.S.S. Nimitz, in which cannabinoid metabolites were detected in urine samples collected from several crew members who were killed in the accident [3]. Intoxication was considered as a factor in the accident, but the presence of cannabinoids in the crew members' urine could not be used to determine unequivocally the timing of cannabis use. To prevent reoccurrence of this issue, the military enacted a zero-tolerance policy around drug use. As a consequence, increased demand for, and focus on, the accuracy of urine drug testing pushed laboratories to offer more specific confirmatory testing for presumptively positive immunoassay screens. Today, toxicological applications of MS have involved a variety of mass analyzers [quadrupole, ion trap, time of flight (TOF), and orbitrap] along with a variety of chromatography and ionization techniques [4]. Confirmation of drugs in biological fluids is an area where the specificity of MS is of particular importance, since the results can have medical and legal ramifications. Multiplexing of drug analytes is common in confirmatory mass spectrometric testing panels, which may contain a hundred or more drugs. Clinical testing is performed on a variety of biospecimens, including plasma, serum, urine, hair, and oral fluid. Other specimens may be used for specific purposes, for example, in screening newborns for in utero drug exposure. Confirmatory mass spectrometric results can be qualitative or quantitative. GC-MS and liquid chromatography tandem mass spectrometry (LC-MS/MS) are the most common techniques in laboratory medicine, with the use of LC-MS/MS growing quickly over the past decade. Most LC-MS/MS confirmation assays are targeted in nature, which increases the sensitivity of the analysis for compounds of interest. A more comprehensive review of toxicology-related applications can be found in Chapter 52, Toxicology and the clinical laboratory.

More recently, MS has been applied as a detection tool for novel psychoactive substances (aka "designer drugs" or NPS) [5]. NPS function similarly to known illicit drugs, but have slightly different structures; these differences lead to a legal grayzone, in which many of these compounds are often not explicitly illegal. Still, they can be dangerous, and pressure on the NPS market causes a continual shift in the exact drugs that are available. Because the targets change frequently and immunoassays can be costly and time-consuming to develop, many NPS can only be detected using MS. One of the most promising techniques used in this field is high-resolution MS, with a TOF or orbitrap mass analyzer coupled to upfront liquid chromatographic separation [5–7]. If data for all ions reaching the detector are collected, the data file can be analyzed retrospectively to detect specific compounds of interest. Though it is not as widely employed in laboratory medicine as the more traditional LC-MS/MS, high-resolution MS has much promise for emerging trends and public health threats.

Therapeutic drug monitoring

Therapeutic drug monitoring (TDM) is a type of personalized (or precision) medicine in which the blood concentration of a pharmaceutical agent is determined in an effort to ensure that the patient is experiencing the maximum benefit of the drug and to prevent toxicity (see Chapter 51: Therapeutic drug monitoring, for more detail).

While immunoassays are available for many drugs where TDM is suggested or required, there are a large number of drugs where commercial assays are unavailable, including antineoplastic agents like busulfan, anticonvulsants like rufinamide, antimicrobials like tazobactam and piperacillin, antifungals like itraconazole, and biologic drugs like infliximab. There are many other compounds, like antidepressants, that lack commercial immunoassays; in such cases, MS may be used to investigate the utility of TDM. One of the major advantages of mass spectrometric assays for the purpose of TDM is the specificity of the measurement in the presence of drug metabolites. Another major advantage is the ability to multiplex measurements of multiple drugs expected to be used to manage a patient's disease from a single injection. For many TDM applications, LC-MS/MS methods have been developed to quantitate drug concentrations from a blood matrix [4]. These methods are ideal for drugs like cyclosporine, in which immunoassays have variable cross-reactivity with active metabolites, potentially resulting in drastically different values [8]. In some cases, US Food and Drug Administration (FDA)-approved reagents for LC-MS/MS TDM assays are commercially available [9].

Endocrinology

After toxicology and TDM, measurement of hormones and related compounds usually makes up the next largest group of mass spectrometric methods in routine clinical laboratories. Given that many steroids share a common chemical backbone, immunoassays are prone to undesirable cross-reactivity [10,11]. In addition, some immunoassays lack the sensitivity to measure steroids in special populations. As a result of these factors, LC-MS/MS is often preferred for the measurement of testosterone in women, children, and hypogonadal men, and serves as a gold standard method for many other analytes (e.g., biogenic amines, 17-hydroxyprogesterone, aldosterone, and many more). From a laboratory perspective, one challenge associated with measuring endogenous compounds like those mentioned above is that matrix materials that are free of the analyte of interest must be acquired. These matrices can be produced from natural matrix, as is the case when serum is charcoal-stripped to remove steroid hormones from the matrix. Alternatively, surrogate matrices can be used, like bovine serum albumin in saline, which is created by the laboratory to mimic the protein content of the natural matrix. In many cases, these starting materials are expensive and may demonstrate significant lot-to-lot variability. Measurement of endogenous molecules adds an additional layer of complexity over exogenously derived molecules like drugs.

Newborn screening

Newborn screening targets and policies vary by state, and in some cases, testing is performed by dedicated state-run laboratories rather than hospital-based or associated laboratories. Due to the time-sensitive nature of newborn screening and the limited volume of sample that is collected for a large number of tests, the analytical sensitivity of MS is of particular value for this application [12,13]. Newborn screening is typically performed on dried blood spots rather than liquid samples, but similar to endocrinology testing, involves the detection of endogenously derived compounds present in abnormal amounts or patterns. Some compounds of interest like acylcarnitines are present as a number of closely related polymers, and specific tandem mass spectrometric data collection techniques called precursor ion scans are often used to detect these compounds. In many cases, newborn screening applications do not use gradient chromatography to separate analytes prior to introduction into the mass spectrometer. A variety of other biomolecules, including amino acids and organic acids are measured in newborn screening, and these analyses may be accomplished using traditional LC-MS/MS or GC-MS methods [12,13], refer to Chapter 48.

When an inborn error of metabolism is identified in newborn screening, treatment is often initiated, sometimes with pharmacologic agents, but very commonly with dietary restrictions. Mass spectrometric methods can also be used for routine monitoring of patients with known disease and can be helpful in ensuring that treatment regimens remain effective as the child grows. For patients with the most common amino acidopathy, phenylalanine hydroxylase deficiency, recommendations include keeping the diet low in phenylalanine and supplemented with tyrosine [14]. Similar to the TDM examples described above, patient compliance with dietary restrictions and supplementation can be monitored by measurement of amino acids in blood. Though many laboratories use liquid chromatography with UV detection to measure amino acids, LC-MS/MS offers a faster turnaround time, since analytes do not need to be completely resolved chromatographically [15]. This can be important for patients with inborn errors of metabolism like methylmalonic acidemia and maple syrup urine disease, who can become rapidly and acutely decompensated.

Trace elements

A variety of clinically relevant elements including lead, cobalt, chromium, zinc, and copper can be measured using MS. While many elements are tested infrequently, lead testing is commonly performed on children, because

lead has documented effects on development and the US Centers for Disease Control (CDC) has determined that there is no safe blood lead level in children [16]. Inductively coupled plasma mass spectrometry (ICP-MS) is the MS technique used for clinical metals testing. Similar to other MS applications, multiple metals can be measured simultaneously using ICP-MS, which can enable a laboratory to perform multiple analyses using a single workflow [17]. Samples for trace element testing are usually collected in certified metal-free tubes and ICP-MS testing can be performed in a room with limited access that is kept under positive-pressure to reduce environmental contamination. An overview of trace elements can be found in Chapter 46, Trace elements: functions and assessment of status through laboratory testing, of this book.

Mass spectrometry applications for measuring proteins

Although the mass spectrometric analysis of proteins and peptides is not very different from that of small molecules, the steps preceding analysis are more complex and currently represent a major bottleneck for translating these assays into the clinical laboratory. These steps are important, however, because biological matrices are complex mixtures of thousands of proteins, most of which are of low abundance. Strategies are needed to simplify the sample and enrich the protein or peptide of interest.

Techniques used in clinical proteomics

Bottom-up approach

A common approach for analyzing proteins by MS is bottom-up analysis. In this approach, proteins are enzymatically digested and peptides are used as a surrogate marker of the protein. Trypsin is commonly used for the digestion step because it reproducibly cleaves on the C-terminal (carboxy-terminal) side of arginine and lysine amino acid residues. The mass spectrometric analysis of peptides is similar to that of small molecules. Peptides are typically analyzed by LC-MS/MS. For purposes of quantitation, data are collected in a targeted manner. That is, the mass spectrometer only looks for certain peptides in an experiment called selected reaction monitoring or SRM (Fig. 21.1A). Here, the peptide precursor ion is selected and fragmented, and a specific product ion is detected. This precursor-product ion transition can be quantitated using internal standards and calibrators.

For the purposes of protein identification, data are collected in an untargeted manner (Fig. 21.1B). Because peptides fragment in a predictable manner (Fig. 21.2), MS/MS spectra obtained from a peptide can be searched against databases to identify proteins that are in the

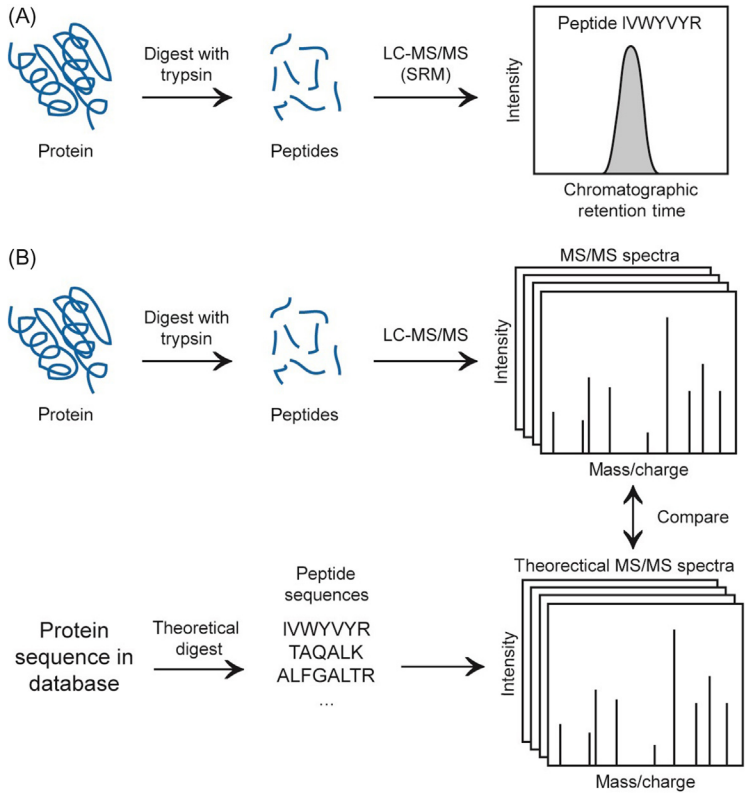

FIGURE 21.1 Targeted versus untargeted workflows for protein analysis. (A) In a targeted workflow, the mass spectrometer only looks for a specific peptide using selected reaction monitoring (SRM). (B) In an untargeted workflow, product ion spectra are generated from all peptides that enter the mass spectrometer. Because peptides fragment in a predictable manner, MS/MS spectra collected from a sample can be compared with theoretical spectra in order to identify peptides, and the corresponding proteins, in the sample.

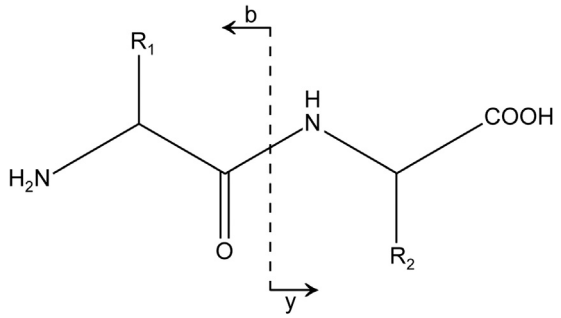

FIGURE 21.2 Fragmentation pattern of peptides. Under low-energy, collision-induced dissociation, peptides typically fragment at the peptide bond producing b- and y-ions, which contain the N-terminus and C-terminus, respectively.

sample or used for de novo protein sequencing. This approach is called "shotgun" proteomics and is used in discovery research to identify new biomarkers. This workflow is also being implemented for clinical purposes for the classification of amyloidosis, for example. The main advantages of using a bottom-up approach are that peptides ionize much more readily than large proteins because of their smaller size. The downside is that digestion introduces variability into the sample preparation step.

Top-down approach

In a top-down approach, intact proteins are measured. In some cases, proteins may be separated into smaller parts, either through reduction of disulfide bonds or dissociation of individual subunits, but the protein is not digested into peptides. The mass of the full-length protein or subunit, including posttranslational modifications, is measured. The advantage of the top-down approach is that the sample preparation step is simpler without proteolysis. In addition, different proteoforms and posttranslational modifications can be distinguished more easily by top-down analysis. The main disadvantage of this approach is that large proteins are harder to ionize. In addition, with electrospray ionization (ESI), large proteins may adopt many different charge states making mass spectra more complicated. Software programs are used to deconvolute the mass spectrum of multiply-charged species into a molecular mass (Fig. 21.3). Specific analytical platforms amenable to bottom-up or top-down approaches will be discussed later in this chapter.

Sample preparation

Many of the mass spectrometric methods employed to measure proteins rely on an upfront purification step to simplify the sample and enrich the protein or peptide of interest prior to analysis. Several strategies can be used for sample cleanup including solid-phase extraction, protein precipitation, ion-exchange isolation, liquid−liquid extraction, or depletion of high abundance proteins found in biological samples. A common strategy used in clinical assays is immunoaffinity enrichment. In this approach, antibodies that are immobilized to a solid support are used to purify the protein from the biological matrix. In bottom-up approaches, immunoaffinity enrichment can be performed at the protein or peptide level. That is, the protein can be purified first and then digested with trypsin. Alternatively, all proteins in a sample can be digested and then antipeptide antibodies are used to purify specific peptides. Purification of tryptic peptides from a digest is also known as the stable isotope standards and capture by antipeptide antibodies method [18].

Quantitation

As with small molecules, quantitation of proteins by MS is most often performed by the addition of internal standards. Ideally, isotopically labeled proteins would be used as internal standards and would be added early in the sample preparation process to control for the enzymatic digestion. However, labeled full-length proteins are expensive and usually not available. Instead, most bottom-up protein assays use stable isotope-labeled peptides that are added after digestion with trypsin. These peptides are chemically synthesized and include ^{13}C or ^{15}N heavy isotopes. Alternatively, some assays use cleavable, or extended, internal standards that include a proteolytic digestion site (Fig. 21.4). These labeled internal standards are added prior to trypsin digestion and provide a way to control for variation in the digestion step, though the digestion rate may not be representative of that of the full-length protein analyte.

Relative quantitation approaches may also be used. One example is spectral counting. When data are collected in an untargeted manner, proteins that are more abundant will produce more peptides and more MS/MS fragmentation spectra. Therefore the frequency of MS/MS events for a certain protein is used to determine its relative abundance in the sample. The advantage of relative quantitation is that it avoids the use of costly labeled internal standards and can be used when the identity of the protein(s) is not known. However, spectral counting is limited in terms of its accuracy, because the size of proteins and ionization efficiency of peptides can also affect the number of MS/MS events generated. Relative quantitation approaches are mostly used in research and discovery applications. However, one example of spectral counting being used in a clinical method is for the classification of amyloidosis, which is described in more detail below.

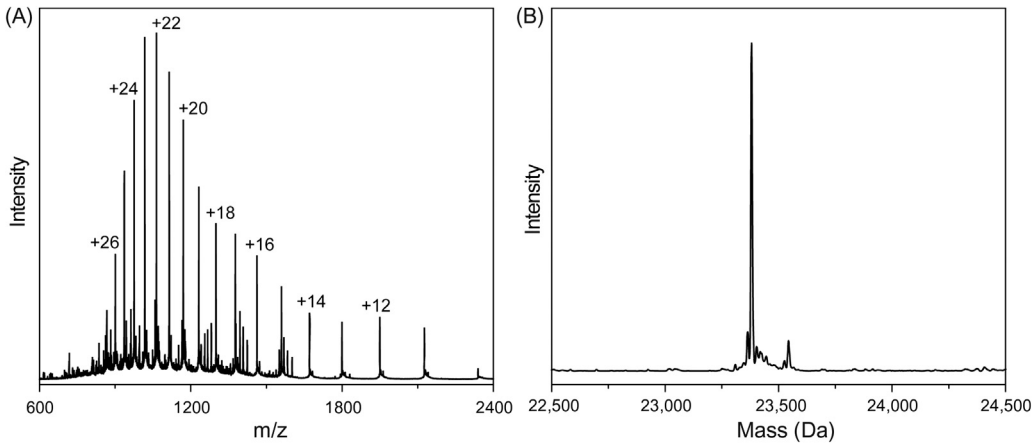

FIGURE 21.3 Electrospray ionization results in multiply charged protein ions. (A) When analyzed by liquid chromatography-electrospray ionization-Q-time-of-flight mass spectrometry, the intact kappa light chain of Daratumumab, an anti-CD38 therapeutic monoclonal antibody, appears as several multiply-charged ions. (B) Software is used to convert multiply charged ions into molecular mass, a process called deconvolution.

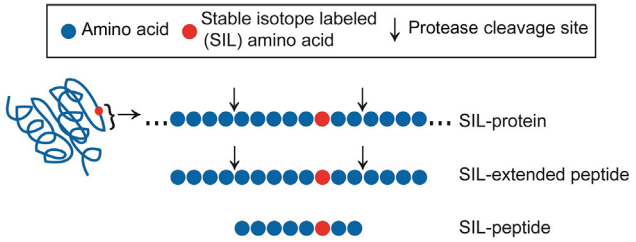

FIGURE 21.4 Internal standard strategies for protein quantification by mass spectrometry.

Instrumentation

Matrix-assisted laser desorption ionization (MALDI) and ESI are most often used for protein analysis because they are soft ionization techniques. This allows molecular ions to be obtained without extensive fragmentation during the ionization step, which is particularly important when ionizing large molecules. For protein analysis, triple quadrupole (QqQ), TOF, or orbitrap mass analyzers are often used. MALDI-TOF mass spectrometers are attractive for the analysis of intact proteins (i.e., top-down approach) because of their large mass range. ESI-QqQ is often used for targeted, quantitative analysis of peptides. ESI-Q-TOF and ESI-Q-Orbitrap systems are often used in the untargeted analysis of proteins, because they provide measurements with high resolution and high mass accuracy. Finally, nano- and microflow liquid chromatography systems are also common in protein analysis. These low-flow systems improve the sensitivity of the assay, because very small volumes of sample are delivered to the mass spectrometer, therefore reducing ion suppression. They also require smaller sample volumes. For more details on MS and ionization techniques, see Chapter 10, Mass spectrometry.

Examples of clinical protein mass spectrometric assays

A handful of MS-based protein assays are currently being used by clinical laboratories. Here, we provide examples that highlight the various approaches used and the reasons why MS is chosen over other techniques. Other examples are listed in Table 21.1.

Thyroglobulin

Thyroglobulin (Tg) is a 660-kDa protein that is produced by the follicular cells of the thyroid. Because thyroid tissue is the only source of Tg, Tg is monitored after total thyroidectomy or radioactive ablation to detect the persistence or recurrence of differentiated thyroid carcinoma. Most clinical laboratories use commercially available immunoassays to quantitate Tg. However, these assays are susceptible to interference by thyroglobulin antibodies (TgAb), which are present in 10%–30% of patients and typically result in falsely low Tg results.

MS has provided a solution to accurately measure Tg in the presence of TgAb. The TgAb interference is overcome because all proteins in the sample are digested with trypsin. Immunoaffinity enrichment is then used to purify Tg-specific peptides prior to their quantitation by LC-MS/MS. In patients without TgAb, MS measurements show excellent agreement to standard Tg immunoassays. In patients with TgAb present, MS-based Tg values tend to be higher than immunoassays [39].

Currently, a few major reference labs and academic centers offer Tg analysis by MS. All labs use the same general steps, that is, a bottom-up approach with immunoaffinity enrichment of Tg-specific peptides. However, there are differences in sample preparation, calibrators,

internal standards, LC-MS/MS platforms, and which Tg-specific peptide is used for quantitation. Despite these differences, the LC-MS/MS assays correlate well and efforts to harmonize the assays are ongoing [40].

Although MS is highly specific for the measurement of Tg and can overcome the aforementioned TgAb interference, the analytical sensitivity is not as good as currently available immunoassays. It is unclear if this difference in sensitivity is clinically relevant. Future work to evaluate the clinical sensitivity and specificity of these MS-based assays will be important in determining the impact of these tests on patient outcomes.

Insulin-like-growth-factor 1

Insulin-like-growth-factor 1 (IGF-1) is a 70 amino acid peptide hormone that is used to assess growth hormone (GH)-related disorders or to detect GH abuse for antidoping purposes. MS-based assays to measure IGF-1 were developed because immunoassays suffer from interference from IGF binding proteins and show poor agreement between platforms [23]. Several MS methods have been described. Currently, a small number of reference laboratories in the United States use a top-down approach to quantify intact IGF-1 using high-resolution mass spectrometers for analysis [24,25]. A bottom-up approach, which showed good agreement between different laboratories, is used to quantitate IGF-1 by World Anti-Doping Agency-accredited laboratories [23].

Monoclonal immunoglobulins (M-proteins)

Traditionally, electrophoretic methods (i.e., serum protein electrophoresis, capillary electrophoresis, and immunofixation) have been used to detect isotype M-proteins for the diagnosis and monitoring of multiple myeloma and other monoclonal gammopathies. However, with recent improvements in the treatment for multiple myeloma and the use of monoclonal antibody drugs, there is a growing need for more sensitive and specific laboratory tests. In addition, MS techniques, especially MALDI-TOF MS, could potentially offer higher throughput compared to electrophoretic methods.

Several MS-based methods have been developed to detect isotype M-proteins in serum and urine [35,41,42]. Currently, one reference lab in the United States is offering the MALDI-TOF assay as a replacement for serum immunofixation. Here, immunoaffinity enrichment is used to purify immunoglobulins from serum. In this assay, disulfide bonds are reduced in order to separate the heavy chains from the light chains, and the resulting mixture of intact heavy and light chains is analyzed by MS. The principle behind this approach is that each immunoglobulin has a unique amino acid sequence and, therefore, a unique mass. When overproduced, the M-protein will produce a “spike” in the mass spectrum that can be visualized above the polyclonal background (Fig. 21.5).

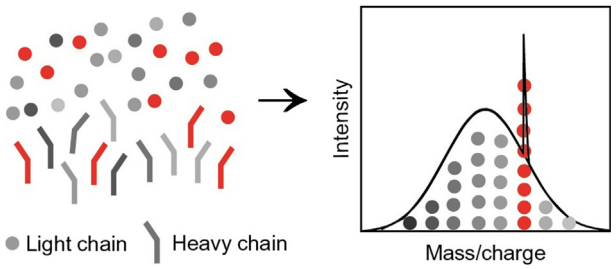

FIGURE 21.5 Monoclonal immunoglobulins can be visualized as a spike in the mass spectrum. In this assay, immunoglobulins are purified from serum or urine and are reduced to separate the light and heavy chains. When the sample is analyzed by matrix-assisted laser desorption ionization-time-of-flight mass spectrometry, the light chains generate most of the signal, since they ionize better than the heavy chains. The light chain from the monoclonal protein (*red*) can be detected as a spike above the polyclonal background (*gray*). The light chain has a specific amino acid sequence and, therefore, a specific mass and serves as a surrogate marker of the M-protein.

Classification of amyloidosis

Clinical management of amyloidosis is based on treating the underlying etiology and it is important to identify accurately the protein that is forming the amyloid deposits. An MS-based approach for classifying amyloidosis was described in 2009 [43] and is now being used by a few major reference laboratories in the United States. In this method, laser microdissection is used to cut out amyloid plaque from a tissue biopsy. Microdissected fragments are digested with trypsin, and the resulting peptides are analyzed by LC-MS/MS. The goal of this method is to identify the most abundant protein in the plaque; therefore the peptides are analyzed in an untargeted manner. Here, peptides are fragmented in the mass spectrometer and MS/MS spectra can then be searched against databases to identify the protein(s). Spectral counting is used to determine which protein(s) are most abundant in the sample. Laboratory professionals and pathologists review these results to determine if a known amyloidogenic protein is present. Results consist of an interpretive report, which indicates the presence and identity of the protein. This analysis is a significant improvement over immunohistochemistry techniques, which suffer from lack of sensitivity and specificity. In addition, the use of MS in this setting has identified previously unrecognized proteins in the formation of amyloid plaques [44].

Identification of microorganisms

The use of MALDI-TOF MS to identify microorganisms has drastically changed the clinical microbiology laboratory. This method is covered in more detail in Chapter 54, Infectious diseases, but we mention it here because the mass spectra generated in this assay are primarily comprised of highly abundant microbial proteins, such as ribosomal proteins [45]. Rather than trying to identify or quantitate the proteins in the sample, the mass spectrum is used as a "fingerprint" or "profile" of the microbe. The mass spectrum collected from a sample is searched against a database to identify organisms. "Fingerprint analysis" is also used in tissue imaging, which is discussed below in the "Future of clinical mass spectrometry" section.

Use of mass spectrometry in method standardization and harmonization

Standardization and harmonization of laboratory methods are important to ensure that different methods generate the same results when measuring the same sample. Harmonization refers to interlaboratory agreement or the "uniformity of test results when a reference method is not available" [46]. Standardization refers to agreement with the "true" value or the "uniformity of test results based on relation to a reference method" [46]. MS plays an important role in this area of laboratory medicine, because it directly detects molecules based on a well-defined physical property (i.e., mass). In addition, the use of isotopically labeled internal standards improves accuracy and precision and is a unique feature of the technique. Because of these advantages, isotope dilution MS is often used as a reference measurement method for a variety of analytes, including steroid hormones, drugs, metals/trace elements, and a few proteins. Please refer to the "Database of higher-order reference materials, measurement methods/procedures and services" [47], which is maintained by the Joint Committee for Traceability in Laboratory Medicine, for a full list of current reference measurement methods. Although no MS-based method has been fully standardized or harmonized according to recommended guidelines [48,49], progress has been made for some small molecules through the CDC's Hormone Standardization and Vitamin D Standardization Certification Program programs [50], for example.

Regulatory considerations for clinical mass spectrometry

The majority of MS-based assays currently deployed in clinical laboratories are considered laboratory developed tests (LDTs), which means the test is designed, manufactured, and used within a single laboratory [51]. The FDA has historically exercised discretion on regulating LDTs, with the regulatory oversight being provided by the laboratory's accrediting agency [51]. Recently, the FDA announced plans to regulate LDTs, and while the agency has not yet released final guidance, they have published a

TABLE 21.2 Guidelines pertaining to the design, development, validation, implementation, and use of mass spectrometry in laboratory medicine.

Title	Publisher	Publication year
Mass spectrometry in the clinical laboratory: general principles and guidance	CLSI	2007
Follow-up testing for metabolic diseases identified by expanded newborn screening using tandem mass spectrometry	AACC Academy (formerly NACB)	2008
Gas chromatography/mass spectrometry confirmation of drugs, 2nd edition	CLSI	2010
Liquid chromatography-mass spectrometry methods	CLSI	2014
Mass spectrometry for androgen and estrogen measurements in serum	CLSI	2015
Methods for the identification of cultured microorganisms using matrix-assisted laser desorption/ionization time-of-flight mass spectrometry	CLSI	2017
Newborn screening by tandem mass spectrometry, 2nd edition	CLSI	2017
Using clinical laboratory tests to monitor drug therapy in pain management patients	AACC Academy (formerly NACB)	2017

discussion paper summarizing the issues [52]. While the final guidance remains uncertain, it is clear that laboratories developing new LDTs will be subject to additional regulations. However, not all MS testing is developed by the laboratory. For example, there are several FDA-cleared/approved mass spectrometric devices for the purposes of neonatal screening, the identification of microorganisms, and the quantitation of exogenous and endogenous molecules, such as tacrolimus and vitamin D [53,54].

For laboratories utilizing LDTs, the increase in potential applications along with increased acceptance and awareness of the technique has spurned the development of several guidelines for best practices in MS method development and validation. Among other things, these guidelines describe experiments that should be conducted, provide suggestions for optimizing a method, and outline potential challenges that laboratories should consider in designing their methods. A full list of guidelines that may be useful for laboratories considering MS can be found in Table 21.2.

Challenges of implementing mass spectrometry in the clinical laboratory

Despite the advantages of MS over traditional techniques, there are many challenges associated with these assays. First, LDTs require a significant amount of time, money, and technical expertise to develop and validate [55]. There is a high upfront cost of instruments; technologists need to be well trained to prepare samples, operate the instruments and interpret data; and data analysis and reporting is time-consuming and may be manual. For protein analytes, the sample preparation step is one of the largest impediments to translating assays into the clinical laboratory. Regardless of the application, MS assays still require a substantial amount of manual input due to lack of automation. Because of these reasons, the use of MS, particularly for protein analytes, has largely been limited to reference laboratories and large academic centers.

Future of clinical mass spectrometry

Like many other techniques used in laboratory medicine, increasing automation is a goal for clinical MS and manufacturers are working to develop fully automated "black box" mass spectrometers. In this scenario, the entire MS analysis from sample preparation to result generation could be cleared by the FDA as a diagnostic test, which would make adoption of the technique much easier for laboratories with little experience. However, the mass spectrometer is programed only to run the analyses the manufacturer has validated; thus the laboratory may not have the option to develop and perform their own tests on the analyzer. Separately, software companies are working to improve the algorithms used to process MS data, a task that can be very time-consuming.

Mass spectrometers are also the primary tool for metabolomics, lipidomics, and proteomics research, in which hundreds of small molecules, lipids, or proteins/peptides

are measured [56]. The information from the MS analysis can be used to determine how disease-relevant biochemical pathways are functioning. Analysis of a pathway in patients with and without a target condition can identify candidate biomarkers that can be further validated. Highly accurate MS measurements can also be used to record the spatial distribution of various analytes within a tissue, thus creating an image based on the different masses collected [57]. MS is also being used in the operating room, including for the detection of surgical margins [58–60]. Though these analyses are currently only used for research purposes, they remain a point of interest for future applications of clinical MS. A variety of other potential applications have been reviewed more comprehensively in recent works [61].

Conclusion

Like any technique, MS has advantages and disadvantages. Developing and validating methods to the high standards required for diagnostic testing can be onerous and expensive. Data analysis is not always straightforward and may seem daunting for unexperienced laboratorians. However, MS enables laboratories to offer tests that they would otherwise have to send out and provides another tool with which the laboratory can contribute to patient care. When methods are validated with attention to best practices, MS can provide cost savings for laboratories, both directly in technologist time and indirectly in reduction of interferences from immunoassays, while also reducing the turnaround time. The arrival of automated mass spectrometers on the market, though still expensive, offer an opportunity for laboratories that do not have the technical capability or interest in LDT validation to still offer fast, selective, multiplexed analyses on their test menu.

Self-assessment questions

1. Which of the following is an advantage of mass spectrometry?
   a. Low sensitivity
   b. Low specificity
   c. Ability to multiplex
   d. Minor regulatory burden
2. What challenge is more often associated with measuring testosterone than with measuring cyclosporine?
   a. Sourcing testosterone-free matrix materials
   b. Sourcing reference materials for testosterone
   c. Detecting signal generated by testosterone
   d. Standardizing the assay against a reference material
3. Of the following applications, which would be most appropriate for analysis by ICP-MS?
   a. Illicit drugs
   b. Testosterone
   c. Phenylalanine
   d. Copper
4. Why does mass spectrometry help enable harmonization?
   a. Because everyone uses the same method to measure the analyte.
   b. Because everyone directly measures the analyte's signal.
   c. Because the ionization process is consistent across different mass spectrometers.
   d. Because many analytes can be detected in a single injection.
5. Which ionization technique is often used for the analysis of intact proteins?
   a. MALDI
   b. Electron ionization
   c. Fast-atom bombardment
   d. Atmospheric pressure chemical ionization
6. Which endopeptidase is commonly used in bottom-up analysis of proteins?
   a. Chymotrypsin
   b. Pepsin
   c. Trypsin
   d. Elastase
7. In low-energy, collision-induced dissociation, peptides typically produce which type of fragment ions?
   a. a- and b-ions
   b. b- and y-ions
   c. x- and y-ions
   d. Cations

Answers

Proteins: analysis and interpretation in serum, urine, and cerebrospinal fluid

Joesph R. Wiencek[1], Show-Hong Duh[2], and Robert H. Christenson[2,3]

[1]Department of Pathology, University of Virginia School of Medicine, Charlottesville, VA, United States, [2]Department of Pathology, University of Maryland School of Medicine, Baltimore, MD, United States, [3]Department of Medical and Research Technology, University of Maryland School of Medicine, Baltimore, MD, United States

Learning objectives

After reviewing this chapter, the reader will be able to:

- List the clinical indications for requesting or following specific protein measurements or protein electrophoresis.
- Discuss and sketch a conventional protein electrophoresis pattern, label each fraction, and list two proteins that comprise each region.
- Describe common analytical methods and biochemical techniques used in protein analysis.
- List and classify potential endogenous and exogenous interferences in protein analysis and interpretation.
- Explain the physiology of serum free light chains and list three reasons why testing is clinically important.
- Explain clinical and laboratory features for the following conditions: multiple myeloma, Waldenström macroglobulinemia, amyloid light-chain amyloidosis, cryoglobulinemia, Bence Jones proteinuria, and monoclonal gammopathy of undetermined significance.
- Describe a basic strategy for evaluating pathological and nonpathological protein electrophoresis patterns and problem-solving when potential interferences are suspected.t

Introduction

Analysis and interpretation of proteins in serum, urine, and cerebrospinal fluid (CSF) are essential components for care of patients. It is vital that the laboratory provides informed consultation concerning technical performance, reference intervals, and serum protein interpretations in disease and potential interferences such as the appearance of a therapeutic monoclonal antibody (t-mAb) on protein electrophoresis. Some important indications for clinicians requesting specific protein measurements and protein electrophoresis are the following:

1. workup and monitoring of patients for monoclonal gammopathy;
2. as part of the workup of patients with suspected or diagnosed multiple sclerosis (MS);
3. monitoring of patients to evaluate response to therapy and prognosis;
4. unexplained renal insufficiency or proteinuria;
5. hypogammaglobulinemia;
6. peripheral neuropathy;
7. clinical history of amyloid light-chain amyloidosis; and
8. further evaluation of patients having unexpected findings, for example, bone lesions on X-ray performed for unrelated indications.

Fig. 22.1 displays the major regions of the typical serum protein electrophoresis (SPEP or SPE) pattern for a normal individual. Table 22.1 lists various proteins and the corresponding SPEP region where they are located. Each region will be discussed in the order of their migration pattern on SPEP, from the anode to the cathode. Reference to some proteins will be made in the context of the "acute-phase response" (APR). This term refers to the dynamic changes in these protein concentrations in response to physiologic stresses such as inflammation, trauma, myocardial infarction, or cancer.

Prealbumin region

Prealbumin or "transthyretin" (TTR) serves as a transport protein for thyroid hormone thyroxine (T_4) and retinol binding protein 4 (RBP4) in serum and CSF. The name TTR originates from the combination of the root words *trans*ports *thy*roxine and *retin*ol, but occasionally is referred to as prealbumin, because it migrates faster than albumin (ALB) on protein electrophoresis. TTR is synthesized by both the liver and choroid plexus and appears more prominently on CSF

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00022-3

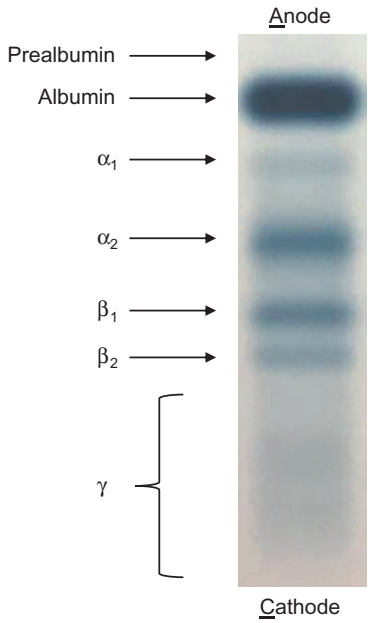

FIGURE 22.1 Normal serum protein electrophoresis pattern performed in an agarose matrix. The six typical fractions separated are indicated (albumin, α_1, α_2, β_1, β_2, γ).

protein electrophoresis than on SPEP except in patients receiving certain medications (e.g., salicylates). Since the concentration of TTR decreases with physiological stress, it is often referred to as a negative APR protein. Table 22.1 lists the characteristics of various proteins, including TTR, such as its relatively short half-life of 48 hours. The amino acid sequence of TTR contains a high proportion of essential amino acids, and this protein is rapidly degraded during nutritional deficit and serves as a reservoir for these amino acids. It is important for clinical laboratorians to know that prealbumin and TTR may be used interchangeably.

Another protein in the prealbumin region is RBP4. This protein functions in the transport of the all-trans form of the fat-soluble vitamin retinol (vitamin A). RBP4 has a short half-life and circulates as a dimer bound to TTR, which stabilizes the interaction between RBP4 and vitamin A and helps conserve this relatively small protein from renal excretion. The liver synthesizes RBP4 in response to retinol binding requirements. RBP4 is cleared via renal excretion and, therefore, renal insufficiency leads to increased concentrations. Recent studies have demonstrated that increased concentrations of RBP4 may be an additional risk factor for type 2 diabetes and cardiovascular diseases [1–3]. Decreased RBP4 concentrations occur with liver failure and in protein malnutrition.

Albumin region

ALB is the most abundant protein in plasma, normally accounting for approximately 60%–65% of total protein and 80% of oncotic pressure. At physiologic pH, ALB is negatively charged with many surface groups and contains both hydrophilic and hydrophobic binding sites. This allows ALB to function as a carrier protein for various substances, including divalent cations, bilirubin, free fatty acids, and hormones such as thyroxine and estrogen, along with drugs such as penicillin, phenytoin, and warfarin. ALB also functions as an amino acid reservoir, entering cells by pinocytosis where ALB is available for degradation into constituent amino acids for the synthesis of cellular proteins. ALB's low isoelectric point (pI) confers an intense negative charge at the physiologic pH of 7.4 and migrates anodally on conventional SPEP (see Fig. 22.1). The ALB band can be used as the reference point in SPEP pattern interpretation.

The liver synthesizes ALB, and reduction of over 90% of the liver's functionality is necessary to decrease substantially the serum ALB concentrations. For this reason, acute hepatic disease is rarely a cause of decreased ALB. In inflammatory disease, serum ALB decreases, because synthesis is inhibited by the cytokines interleukin-1 (IL-1) and interleukin-6 (IL-6), and/or tumor necrosis factor-α (TNF-α). Given that there is an acute decrease in ALB concentrations in the inflammatory state, ALB is often referred to as a negative APR. The primary cause of hyperalbuminemia is dehydration; false hyperalbuminemia may also result from keeping a tourniquet on for too long during phlebotomy.

The interpretation of ALB on SPEP or urine protein electrophoresis (UPEP) is an important consideration in evaluating the renal status of a patient. ALB normally is the most predominant protein excreted in urine, because it is the most abundant plasma protein and also because it is not entirely reabsorbed by the renal tubules. Less abundant and smaller proteins may pass through the glomeruli, but most are almost entirely reabsorbed by the proximal tubules.

The size threshold for passage through the glomerulus is approximately 50 kilodaltons (kDa), only slightly less than ALB's molecular weight (67 kDa). ALB's strong negative charge at physiologic pH of 7.4 is important in minimizing its excretion through the kidney, because the glomerular basement membrane is also negatively charged, resulting in the electrical repulsion of ALB.

In a healthy state, any ALB that passes through the glomerulus is almost totally reabsorbed by the proximal tubule by active transport through receptor-mediated endocytosis. When there is an injury to the glomerular basement membrane and/or the renal tubules, substantial amounts of ALB and other proteins that are normally reabsorbed are excreted into the urine and can be visualized on UPEP. In nephrotic syndrome, where the amount of protein (mainly ALB) passing through the glomerulus increases to exceed the maximum capacity of tubular

TABLE 22.1 Characteristics of major proteins separated by serum protein electrophoresis.

Location on gel electrophoresis	Protein	Half-life	Molecular weight, g/mol	Isoelectric point	Normal reference interval (mg/dL)	Acute-phase protein	Comments
Anode (charge +)							
Prealbumin	TTR	48 h	54,000	4.7	20–40	Yes, ↓	Transport protein, nutrition marker
	RBP4	12 h	21,000		2.4–6.7		Nutrition marker, binds to TTR
Albumin	ALB	19 d	66,000	~5.0	3500–5200	Yes, ↓	Transport protein, maintains oncotic pressure and amino acid reserve
	A1AT	4 d	54,000	4.8	90–200	Yes, ↑	Genetic deficiency can result in emphysema or cirrhosis
α_1	AGP (orosomucoid)	5 d	40,000	3.5	50–120	Yes, ↑	Binds hormone and cationic drugs (function not fully known)
	Hp	2 d	85,000	4.1	30–200	Yes, ↑	Binds to hemoglobin and decreased in hemolysis
α_2	A2M	5 d	800,000	5.4	130–300	Yes, ↓	Proteolytic enzyme inhibitor, increased in nephrotic syndrome
	Cp	4.5 d	160,000	4.4	20–60	Yes, ↑	Antioxidant, contains copper, and decreased in Wilson's disease
β_1	Tf	7 d	77,000	5.7	200–360	Yes, ↓	Iron transport protein; increased in iron deficiency anemia
β_2	C3		180,000		90–180		Complement factor
	B2M	2 h	11,800		< 0.27		Assess renal tubular function and tumor marker
	IgG	24 d	160,000	6–7.3	700–1600		Long-term defense and most abundant serum immunoglobulin
γ	IgA	6 d	170,000		70–400		Active in secretions and increases in B-cell tumors
	IgM	5 d	900,000		40–230		First immunoglobulin to increase (respond) after infection
	CRP	18 h	120,000	6.3	< 0.5	Yes, ↑	Robust and nonspecific APR protein
Cathode (charge −)							

A1AT, α_1-Antitrypsin; *A2M*,α_2-macroglobulin; *AGP*, α_1- acid glycoprotein; *ALB*, albumin; *B2M*, β_2 microglobulin; *C3*, complement 3; *Cp*, ceruloplamin; *CRP*, C-reactive protein; *Hp*, haptoglobin; *IgA*, immunoglobulin A; *IgG*, immunoglobulin G; *IgM*, immunoglobulin M; *RBP4*, retinol binding protein 4; *Tf*, transferrin; *TTR*, transthyretin; α_2, alpha 2; β_1, beta 1; β_2, beta 2; γ, gamma.

resorption, damaged glomeruli will allow 3 g or more of protein to be excreted in urine over a 24-hour period [4]. The loss of ALB leads to reduction in oncotic pressure and excess fluid buildup in tissues. This may lead to the synthesis of large proteins such as α_2-macroglobulin (A2M) and apolipoproteins as a compensatory response to maintain oncotic pressure. This results in the increase in the peak size of the α_2 region of the SPEP.

Two additional patterns in the ALB region to be cognizant of when interpreting protein electrophoresis patterns are from patients with analbuminemia or bisalbuminemia. Analbuminemia (OMIM 103600) is a rare autosomal recessive disorder characterized by low concentrations of ALB and the absence of an ALB band on SPEP. The disorder is accompanied by mild symptoms of edema and fatigue. Bisalbuminemia or alloalbuminemia appears as a doublet in the ALB region and may be inherited or acquired (Fig. 22.2). The inheritance pattern of bisalbuminemia is through an autosomal codominant pattern and is considered relatively benign. Cases of the acquired form are described in patients receiving high doses of β-lactam antibiotics or those with pancreatic disease.

α_1 Region

The major protein in this region is α_1-Antitrypsin (A1AT). A1AT functions as a "broad spectrum" inhibitor for trypsin, elastase, and several other proteases released by neutrophils. A1AT can also inhibit members of the clotting cascade. Synthesized in the liver, A1AT rises rapidly in response to the increased concentrations of IL-6 and other proinflammatory cytokines. A1AT is a robust positive APR protein that may function to attenuate proteases and other substances that are released during inflammation. Catabolism of A1AT occurs via receptors located on hepatic parenchymal cells, which bind A1AT-protease complexes.

A decrease in α_1 globulins may be indicative of A1AT deficiency. The gene coding for A1AT (termed "Pi") is polymorphic, and there are over 75 genetic variants or isotypes. Although many of these variants are associated with reduced concentrations of A1AT, the most clinically important is the Z allele denoted as PiZ. The homozygous PiZ genotype (e.g., PiZZ) occurs in 1 in 6700 live births of individuals having northern European ancestry. Approximately 90% of these individuals develop emphysema between the second and fourth decades of life. However, many individuals go undiagnosed, especially in patients with chronic obstructive pulmonary disease. Individuals who are heterozygous or homozygous for the PiZ allele have an increased incidence of cirrhosis and hepatocellular carcinoma.

Detection of PiZ and other variants of A1AT can be accomplished by isoelectric-focusing electrophoresis (IEF); this is considered the biochemical gold standard test for establishing the diagnosis of A1AT deficiency. However, caution must be taken, because if plasma is not separated expeditiously from cellular material, leukocytes may release elastase and other proteases that can bind with A1AT and change electrophoretic mobility. This in vitro binding may also affect immunochemical measurement. In severe cases of A1AT deficiency, there may be an absence of the α_1 region on SPEP. Additional confirmatory tests may include targeted genotyping, protease inhibitor IEF, mass spectrometry, or gene sequencing. Treatments include transfusion of purified A1AT, aerosols, liver transplantation, and, perhaps in the future, gene therapy.

α_1-Acid glycoprotein (AGP), also termed "orosomucoid," is synthesized by the liver and in granulocytes and monocytes. Catabolism of AGP occurs via a receptor-mediated mechanism involving hepatic parenchymal cells. The physiologic function of AGP is incompletely understood, but the protein is known to bind progesterone and other hormones, as well as drugs, such as lidocaine, propranolol, and phenobarbital. AGP is a positive APR protein and has been used for monitoring ulcerative colitis.

(B) The serum protein electrophoresis trace created with a densitometer from the patient with bisalbuminemia. Image credit UVA Clinical Chemistry Fellow Kwabena Sarpong, PhD.

α_2 Region

Haptoglobin (Hp) irreversibly binds free hemoglobin (Hb) as one of its several physiological functions. The Hp protein is synthesized by hepatic parenchymal cells as two heavy chains and two light chains. There are two Hb binding sites per Hp molecule. Only a small amount of in vivo hemolysis is necessary to deplete Hp; for this reason, Hp measurements are clinically useful as a sensitive biomarker of intravascular hemolysis. It may also be used to rule out in vitro hemolysis. After binding to Hb, the larger Hp−Hb complex is less likely to be filtered by the glomerulus, so this binding presumably protects the renal tubules from Hb-induced injury. The Kupfer cells of the liver rapidly clear the complex. Hemolysis does not induce Hp synthesis; however, production is stimulated by inflammation. Although complexation of free Hb appears to be an important function, the Hp−Hb complex is a powerful peroxidase and may cause cytotoxicity to macrophages. In addition, Hp functions as a bacteriostatic agent by binding Hb and deprives iron-requiring bacteria of this element. Hp also inhibits cathepsin B released by phagocytes. Anhaptoglobinemia (OMIM 614081) occurs in approximately 1 in 1000 births and is linked with difficulties in iron (Fe) metabolism and toxicity in patients with chronic hemolysis secondary to malaria.

α_2-Macroglobulin (A2M) is a large, 800-kDa protein synthesized primarily by hepatic parenchymal cells. A2M's major function involves inhibition and complexation of a broad spectrum of proteases. A2M also inactivates kinins and members of the complement and fibrinolytic pathways. A2M is a binding protein for insulin and other small peptides as well as for divalent cations such as zinc. Clearance of A2M is through receptors on hepatic cells. A2M concentrations in children are higher in adults; women tend to have higher concentrations than men. A2M concentrations are increased in the nephrotic syndrome because of induction of this protein's synthesis by the liver, presumably as a compensatory response to maintain oncotic pressure when ALB and other proteins are lost by urinary excretion. A2M synthesis is decreased by the release of IL-1; the protein is a negative APR protein. A2M binds to prostate-specific antigen (PSA) with higher affinity than α_1-antichymotrypsin (ACT). However, the A2M-PSA complex is rapidly cleared from circulation, and 70% of circulating PSA is present in the ACT-PSA complex.

Ceruloplasmin (Cp) is a ferroxidase enzyme synthesized and catabolized by hepatic parenchymal cells. Cp carriers more than 95% of plasma copper. The primary physiologic role for Cp is to facilitate oxidation−reduction reactions in plasma such as the ferric (Fe III) to ferrous (Fe II) conversion of Fe—an essential part of Fe metabolism. The main clinical use for Cp measurements is in screening for Wilson's disease (OMIM 277900), also termed hepatolenticular degeneration. Wilson's disease is an autosomal recessive condition that reduces the activity of an intracellular ATPase. The estimated prevalence of Wilson's disease is 1 case per 30,000 live births in most populations. In the absence of this enzyme, copper is transported to the liver, but the metal is not subsequently bound to Cp. The result is the deposition of copper in hepatic parenchymal cells, in the brain, and in the periphery of the iris also known as "Kayser−Fleischer" rings. Kayser−Fleischer rings appear in approximately 95% of patients with this disorder. Usually, symptoms of Wilson's disease begin in the second or third decades of life, presenting as acute or chronic hepatitis, neurologic symptoms, renal tubular acidosis, or hematologic abnormalities. Cp concentrations are greatly decreased in Wilson's disease. However, Cp is a positive APR protein, so interpretation can be confounded by conditions such as inflammation and pregnancy. The definitive diagnosis of Wilson's disease requires demonstration of increased tissue copper on biopsy and/or analysis of ATP7B gene mutations.

β Region

The β region on SPEP typically contains two distinct bands referred to as β_1 and β_2. The β_1 band is mostly comprised of β-lipoprotein (low-density lipoprotein, LDL) and transferrin (Tf). Very low-density lipoprotein may appear also in the pre-β region. LDL is the most anodal protein in the β_1 region and appears as an anodal "feathery edge." An increase in peak size in this region may indicate the body is not properly breaking down lipids such as seen in conditions of hyperlipoproteinemia or familial hypercholesterolemia. The β_2 band mostly contains complement proteins such as complement component 3 (C3).

β_1 Region

Tf is the most abundant protein in the β_1 band. It is a single-chain protein that binds and transports Fe in circulation. Tf is synthesized in the liver and reticuloendothelial system and has a half-life of approximately 7 days. Tf catabolism is mediated by binding to receptors on hepatic parenchymal cells. Tf is a negative APR protein that is also decreased in chronic liver disease, malnutrition, renal insufficiency, and protein-losing enteropathies. As shown in Table 22.2, Tf is increased with pregnancy, estrogen therapy, and particularly Fe deficiency.

Tf can be measured by immunoassay or estimated using its predictable relationship with total iron-binding capacity (TIBC) according to the following equation:

$$\text{Tf} = 0.70 \times \text{TIBC (mg/dL)} \quad \text{or} \tag{22.i}$$

$$\text{TIBC} = 1.43 \times \text{Tf (mg/dL)} \tag{22.ii}$$

TABLE 22.2 Effects of various hormones and conditions on proteins.

Condition	TTR	ALB	A1AT	AGP	Cp	Hp	Tf	C3	CRP
Inflammation or trauma	D	D	I	I	I	I	D	I(D)(N)	I
Androgens	N	N	I	I	I	I	I	I	N

Chronic hepatocellular disease	D	D	N(D)	N(D)	N	D	D	N	N or I
Malnutrition	D	D	N(D)	N(D)	N(D)	N(D)	D	N(D)	N
Iron deficiency	N	N	N	N	N	N	I	N	N
Hemolysis, in vivo	N	N	N	N	N	D	N	N	N
Nephrotic syndrome	D	D	D	D	N(D)	I,D	0	N	N
Adrenal glucocorticoids	I	N	N	I	I	I	N	N(I) N	

A1AT, α_1-Antitrypsin; *AGP*, α_1-acid glycoprotein; *ALB*, albumin; *C3*, complement 3; *Cp*, ceruloplasmin; *CRP*, C-reactive protein; *D*, decreased compared with normal; *Hp*, Haptoglobin; *I*, increased compared with normal; *N*, within normal limits; *Tf*, transferrin; *TTR*, transthyretin.

Tf's primary clinical use is for the assessment of Fe status. Normally, approximately 70% of Tf binding sites are saturated with Fe, leaving excess capacity. In Fe deficiency anemia, the Fe concentration decreases, while the Tf protein and TIBC increase. The increase in Tf concentration may lead to an increase in β_1 on SPEP and should prompt investigation into the patient's Fe status if possible.

High saturation of Tf indicates possible hemochromatosis, an autosomal recessive condition, which results in abnormally high absorption of Fe and Fe deposition in the pancreas, heart, liver, joint linings, and gonads. Deposition results in scarring that can lead to progressive tissue injury. Although genetic analysis is the definitive means for diagnosis, increased Fe saturation of Tf may be considered a useful screen. CSF contains two forms of Tf: the form normally found in serum and a desialated isoform termed the "tau protein," Beta Trace Protein or β_2-Tf. The tau protein is abundant in CSF and migrates independently of the intact (sialated) Tf on conventional electrophoresis. Occasionally, there is a clinical question involving the origin of a fluid (e.g., from the nose or ear) and the identification of tau protein by electrophoresis and immunofixation electrophoresis (IFE) with Tf antisera may help determine if the fluid source is CSF. Carbohydrate-deficient Tf is another form of Tf monitored in chronic alcoholics. In nephrology, tau protein is typically termed Beta Trace Protein; high plasma levels of this protein occur in renal failure, inflammation, and tumors, and urine levels have been used to assess residual renal function in dialysis patients.

β_2 Region

C3 is the most abundant protein in the β_2 region of SPEP. C3 has the highest concentration of all complement proteins and represents a functional link between the classical and alternative pathways for the activation of the complement systems. C3 synthesis occurs at several locations, including hepatic parenchymal cells (induced by cytokines and TNF-α), and by fibroblasts and monocytes (induced by endotoxin). C3 is activated by hydrolysis into forms that bind to membranes and other entities, including immunoglobulins. In biliary obstruction, C3 concentrations are proportional to bilirubin increases for reasons that are poorly understood. In focal glomerulosclerosis, increased C3 concentrations are associated with a favorable prognosis. Decreased C3 concentrations increase the risk of infection. Pathologically decreased C3 concentrations may be due to a genetic deficiency or to consumption from autoimmune diseases such as systemic lupus erythematosus (SLE). Electrophoretic variants may be misinterpreted as a monoclonal protein (M-protein) unless definitive identification or quantitation is performed. C3 is a positive APR protein. The appearance of C3 in the β_2 region of quality control material on SPEP may appear degraded, which is attributed to C3 being labile.

γ Region

Immunoglobulin G (IgG), Immunoglobulin A (IgA), Immunoglobulin M (IgM), Immunoglobulin D (IgD), and Immunoglobulin E (IgE) represent the preponderance of protein in the γ electrophoretic region labeled in Fig. 22.1. This region on protein electrophoresis is broad and diffused in appearance. Typically, no demarcated bands should be identified in the healthy population. In general, IgG migrates in the gamma region, IgA migrates to the beta region and the more anodal (early) gamma region, and IgM also tends to migrate toward the anodal

portion of the gamma region. In addition, although some of the immunoglobulins are polymers of similar molecules, all are composed of monomers having two heavy (~55 kDa) chains and two smaller light chains (each ~23 kDa). The G, A, M, D, and E identities of immunoglobulins are defined by the amino acid sequence of the heavy chain, which are signified by the Greek letters γ, α, μ, δ, and ε, respectively. Disulfide bonds covalently bind two like heavy chains; each heavy chain is also covalently bound to a light chain, as indicated in Fig. 22.3. Terminology describing immunoglobulin structure divides the molecule into the Fab fragment (Fig. 22.3), the hinge region joining the heavy and light chains, and the Fc region.

There are two types of light chains for all immunoglobulins. They are known as kappa and lambda and are denoted by the Greek letters κ and λ, respectively. Each κ and λ light chain has a different constant region and a variable region specific for the myriad of antigens that may be encountered. The Fab fragment forms the antigen-binding site, as shown in the upper part of Fig. 22.3. Both light chains for an individual immunoglobulin molecule are either κ or λ; an individual immunoglobulin molecule never mixes one of each. In humans, κ light chains predominate on immunoglobulins in a 3κ:1λ ratio. Free light chains (FLCs) in serum have a different κ:λ ratio of approximately 0.26:1.65. However, recent literature cautions the transference of this ratio on select analyzer platforms without proper verification [5]. The interpretation of the ratio should also be considered in the context of renal status [6]

Immunoglobulins are synthesized mainly in lymph nodes and in blood by plasma cells—a fully differentiated B cell that produces a single type of antibody. A naïve B lymphocyte bears antigen receptors specific for a single chemical structure on its surface. Upon interaction with the target antigen, the cell is activated and proliferates into a clone of identical plasma cells that can secrete clonotypic antibodies with specificity identical to the surface receptor that first triggered the activation leading to the clonal expansion. The interaction of antibodies with cells and complement occurs at the Fc region and varies according to the type and subtype of immunoglobulin heavy chain. The Fab region of the light chain is responsible for interaction with specific antigen, and the hinge region controls the relationship between the Fc and Fab parts of the molecule.

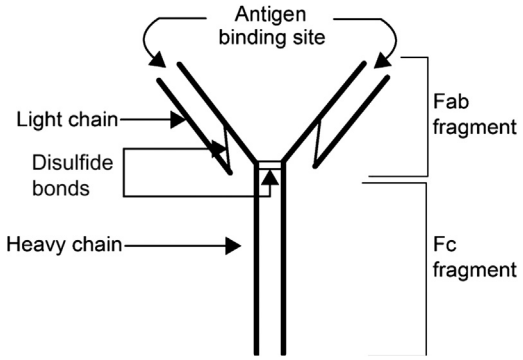

FIGURE 22.3 General structure of immunoglobulin monomers with the Fab and Fc fragments indicated. The hinge region is between the Fab and Fc components.

The γ region of SPEP patterns normally shows homogeneous, diffuse protein staining (Fig. 22.1). However, in the conditions of immunodeficiency, this region can be nearly absent in protein and has a "washed-out" appearance. Examples of such conditions are bone marrow suppression seen in X-lined agammaglobulinemia (OMIM 300755) or "Bruton agammaglobulinemia," an immunodeficiency state characterized by profoundly low concentrations of serum immunoglobulins of all classes. Treatment with plasmapheresis using ALB for fluid replacement can also have a substantial effect on the SPEP pattern, where ALB staining predominates and all of the other regions are rather featureless because of protein removal. Conversely, any reactive or inflammatory process may lead to the increase in immunoglobulins and a polyclonal appearance in the γ region. Patients with autoimmune deficiencies can show abnormal immunoglobulin patterns on SPEP such as polyclonal hypergammaglobulinemia, hypogammaglobulinemia, oligoclonal banding, and occasional monoclonal or triclonal immunoglobulins bands.

IgG is the most abundant immunoglobulin in serum, comprising approximately 75% of total staining in the γ SPEP region. IgG is responsible for long-term physiologic protection from infection accounting for the majority of neutralization of bacterial and viral antigens. Total IgG is comprised of four subtypes termed IgG_1 (65%), IgG_2 (25%), IgG_3 (6%), and IgG_4 (4%). IgG crosses the placenta; neonates have only maternal IgG_1, and adult concentrations of IgG are not reached until approximately 3 years of age. IgG_1 and IgG_3 activate killer monocytes through binding of their Fc receptors on phagocytic cells. The response of many IgG-producing clones to various antigens gives rise to the polyclonal response and homogeneous staining normally observed in the γ region (Fig. 22.1). In particular, increased IgG_4 subclass concentrations give a distinct narrow, smooth, bell-shaped increase in the anodal γ region and can be falsely interpreted as a malignant M-protein [7].

IgA comprises approximately 10%–15% of total immunoglobulins. IgA exists as two subtypes: IgA_1, which predominates (~90%) in the blood, and IgA_2, which predominates (~60%) in mucosal secretions. In the blood, IgA is found mainly as a monomer, while in the mucosal tissues, IgA is almost exclusively a dimer.

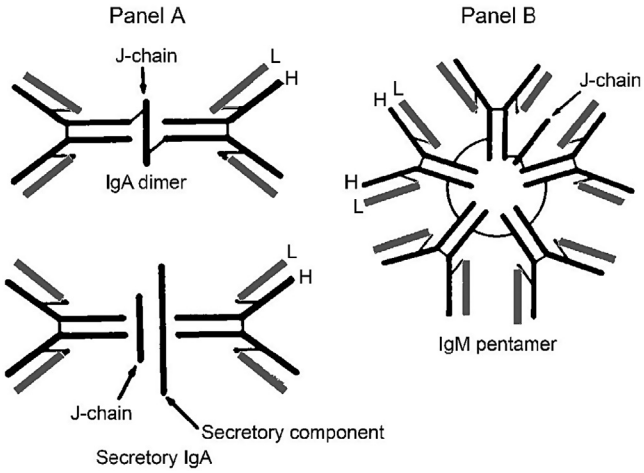

FIGURE 22.4 (A) Structure of immunoglobulin A dimer and the secretory immunoglobulin A subtype containing the secretory component. (B) Structure of the immunoglobulin M pentamer in which the monomers and the J chain are connected by disulfide bonds.

IgA is the major immunoglobulin in tears, saliva, sweat, milk, and also gastrointestinal and bronchial secretions. Secretory IgA has a molecular weight of 380 kDa and consists of two IgA molecules plus a secretory component of 70 kDa and a J chain of 16 kDa (Fig. 22.4 Panel A). The secretory component is thought to enhance solubility in secretions and nonplasma fluids. Increases in IgA frequently observed in liver disease may create a connection or "bridge" of the anodal γ region to the β region on SPEP; this appearance is commonly referred to as β-γ bridging (i.e., beta−gamma bridging).

IgM comprises approximately 10% of total immunoglobulins. IgM is the largest immunoglobulin; as shown in Fig. 22.4 Panel B, the protein exists as a pentamer having a molecular weight of 850 kDa. Along with the five monomeric IgM molecules, the pentamer contains a J chain; disulfide bonds connect the J chain and the monomers. IgM as the transmembrane form is found on the surface of early B lymphocytes and is the most primitive immunoglobulin; after antigen stimulation, some of the B cells differentiate into plasma cells, producing IgM antibodies that are excreted into blood, whereas other cells undergo class switching to form plasma cells of a different class and produce antibodies of that class. IgM is, thus, the first-responder immunoglobulin after antigen assault.

IgD is a monomeric immunoglobulin in plasma and is active on the cell surface of B lymphocytes; its function is incompletely understood. IgD is not measured routinely in clinical laboratories, but antisera are available for particular applications such as IFE (see the section "Immunofixation electrophoresis" for details). IgD is labile on storage, so sample handling and measurement must be completed expeditiously.

IgE is the lowest concentration immunoglobulin and is monomeric in plasma. IgE attaches rapidly to the membranes of mast cells by its Fc region. Cross-linking of two IgE molecules by antigen causes release of histamine, heparin, and vasoactive amines by mast cells. IgE's activity is essential in the allergic reactions associated with urticaria, hay fever, and asthma. Sensitive immunoassays are necessary for quantification, because IgE's plasma concentration is very low ($\leq$214 kU/L for individuals $\geq$18 years old).

C-reactive protein (CRP) has a structure similar to immunoglobulins; key characteristics are shown in Tables 22.1 and 22.2. The term CRP was coined because the protein binds to the polysaccharide coat of *Escherichia coli*. CRP is the most robust positive APR protein, and normal CRP concentrations have a high negative predictive value for infection. The measurement of CRP is recommended over erythrocyte sedimentation rate to detect acute-phase inflammation. The measurement of CRP by highly sensitive methods (hsCRP) can be helpful for estimating the long-term risk of cardiac events. Concentrations of hsCRP in mg/L at $<$1.0, 1.0−3.0, and $>$3.0 carry a relative low, moderate, or high risk of event, respectively. The Justification for the Use of Statins in Primary Prevention: An Intervention Trial Evaluating Rosuvastatin trial demonstrated that patients with elevated hsCRP benefit from statin therapy regardless of LDL concentrations [8].

Standard analytical techniques

Proteins in the clinical laboratory are commonly measured by immunochemistry-based techniques. Specific protein measurement by immunochemistry is based on the in vitro formation of an immune complex by reaction of the protein antigen of interest with a specific antibody (Ab). When the protein antigen is present at high enough concentration (usually in the mg/dL range), immune complexes form an immunoprecipitin. Particle size of the immunoprecipitin is sufficiently large to cause increased turbidity that scatters incident light and results in a decreased signal at the detector. The unbound antigen or Ab does not cause turbidity. Varying the protein antigen concentration when the Ab concentration is held constant forms the immunoprecipitin curve (see Chapter 12, Immunoassays). This curve comprises three distinct areas: (a) Ab excess; (b) area of equivalence; and (c) antigen excess. The immunoprecipitin signal decreases at increased antigen concentrations that passed the area of equivalence; analytical strategies must be in place to detect and avoid antigen excess, because use of this region of the curve will lead to falsely low results at high antigen concentrations.

Turbidimetry and nephelometry

Turbidimetry (immunoturbidimetry) and nephelometry (immunonephelometry) measurements are commonly used to quantify immune-complex precipitates by their ability to interact with incident light. For turbidimetric measurements, the detector is oriented at a straight-on 180-degree angle relative to the incident light source. With this experimental design, the decrease in light intensity is quantified and the amount of light passing through the solution to the detector is inversely proportional to the concentration of protein antigen in the sample. Quantification is accomplished by comparing the signal from the sample with that of a standard curve. Nephelometry detects immune-complex precipitates by their ability to reflect light, a phenomenon termed "Rayleigh light scattering." Because nephelometry measures light scatter, the light detector is oriented at an angle (e.g., 30 or 90 degrees) relative to the incident light source. The amount of light reaching the detector in nephelometry is directly proportional to the quantity of protein antigen in the sample. Quantification is accomplished by comparing the signal from samples with a standard curve.

Radial immunodiffusion

Radial immunodiffusion measurements are performed using gel plates containing a homogeneous distribution of specific Ab for the antigen of interest. Wells are cut in the gel, into which the patient's sample is pipetted. Antigen from the sample diffuses radially until a critical proportion of Ab and protein antigen is achieved (the equivalence point), whereupon a precipitin ring is formed. A standard curve is used, because the area of the precipitin circle (at equilibrium) is directly proportional to the concentration of the protein antigen. An alternative quantification strategy is the Fahey–McElvy modification, in which the diameter is read after a fixed time. The Fahey–McElvy method may produce erroneous results when antigens have multiple forms of differing molecular weight.

Calculated results

The Quotient of ALB (Q albumin) is useful for assessing the integrity of the blood–CSF barrier. The calculation is as follows:

$$Q\ \text{albumin} = 1000 \times \left[\text{CSF albumin}/\text{serumalbumin}\right] \tag{22.iii}$$

All CSF ALB is derived from diffusion or passage into the central nervous system (CNS) from blood, because synthesis occurs only in the liver. Normally, the serum concentration of ALB is approximately 500-fold greater in serum than in CSF. However, disruption of the blood–CSF barrier by inflammation or other process results in increased leakage of ALB in blood into the CSF. The greater the disruption of the blood–CSF barrier, the higher the Q albumin. The Q albumin normal reference interval is <9.

The IgG index is a calculation that "corrects" the relative amount of IgG in CSF for that in serum by normalizing with the Q albumin. The IgG index is calculated as follows:

$$\text{IgG index} = \frac{\text{CSF IgG}/\text{serumIgG}}{Q\ \text{albumin}} \tag{22.iv}$$

Since IgG can be synthesized by plasma cells on either side of the blood–CSF barrier, the IgG index is useful for assessing abnormal IgG production within the CNS. The accepted normal reference interval is 0.30–0.70. Increased values indicate elevated intrathecal synthesis of IgG in the CNS.

Quantitative assessment of proteins

Serum protein electrophoresis

ALB and globulin proteins are two major protein groups in serum. The SPEP test separates these two protein groups on the basis of size and charge properties into the six major regions: ALB, α_1, α_2, β_1, β_2, and γ. The gel matrix most commonly utilized in this technique is agarose; however, cellulose acetate may also be used, but tends to show lower resolution. SPEP performed on an agarose system is typically buffered at pH 8.6. After electrophoresis, the proteins are fixed in the gel that is bonded on a clear Mylar plastic backing. The SPEP pattern is visualized using a general dye-binding protein stain such as Amido black or Coomassie blue. The gel is further dehydrated and scanned.

Most gels may hold up to 30 patient samples. Each gel should include two levels of quality control to be assessed in the same manner as a patient specimen. Densitometry is performed with instrumentation that scans the SPEP pattern, as shown in Fig. 22.5. Incident light passes through the clear Mylar backing of the fixed and stained gel to the detector. However, areas of the gel containing fixed and stained proteins block the incident light. The relative intensity of the incident light at the detector is plotted versus gel position to form the pattern. Software in the densitometer quantifies the proportion of total protein staining represented by each SPEP region. It is important to note that following electrophoresis, fixation, and staining, a direct visual inspection of the gel is an essential component of protein electrophoresis studies, because subtleties occur, which are not resolved on standard densitometric scanning. M-proteins or other

abnormal findings will lead to additional and more sensitive testing such as subtyping by IFE or immunosubtraction. Through a case example, these techniques will be expanded upon in the subsequent text of this chapter.

UPEP is based on the same separation principles as SPEP. However, the concentration of protein in urine specimens is normally far lower than in serum; therefore preconcentration of samples is required before UPEP. Random or 24-hour urine specimens may be used in the analysis. Densitometric UPEP patterns are sometimes helpful for quantifying protein excretion and for monitoring the presence of monoclonal banding, particularly the excretion of κ or λ light chains in urine (e.g., Bence Jones protein defined as a monoclonal or immunoglobulin light chain found in the urine, with a molecular weight of 22–24 kDa) [9]. CSF electrophoresis is usually performed like SPEP; however, more sensitive IEF (i.e., isoelectric focusing) methods are available. CSF specimens generally have low protein content, so samples require either preconcentration before analysis or use of more sensitive stains (e.g., silver stain).

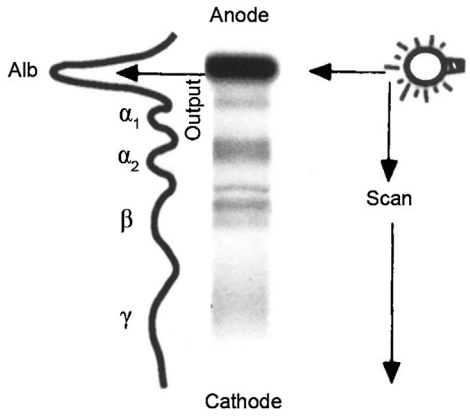

FIGURE 22.5 Sketch of the experimental design for densitometry. A scan of a normal SPEP is indicated. As the incident source scans the gel, the intensity of light passing through the gel and reaching the detector varies according to the staining intensity, resulting in the output shown.

Case example

A 70-year-old African American male presents to the emergency department with complaints of fatigue, spinal column pain, and frequent emesis. The care team orders complete cell counts (CBC), comprehensive metabolic panel (CMP), urinalysis, and protein electrophoresis. His select CBC, CMP, and urinalysis results are listed in Table 22.3, and his SPEP is shown in Fig. 22.6.

This is a classic example of a patient presenting with nonspecific findings such as fatigue and bone pain. Laboratory results of decreased Hb and increased blood urea nitrogen, creatinine, total protein, and calcium are all concerning for someone with a plasma cell disorder. Additional diagnostic testing was performed, and a diagnosis of multiple myeloma (MM) was determined.

Immunofixation electrophoresis

IFE is able to characterize further or subtype M-proteins identified on SPEP such as the one identified in the recent case example. This technique takes advantage of Ab specificity for antigens and their ability to fix (e.g., immunoprecipitate)

TABLE 22.3 Results of clinical laboratory testing for case example.

Select laboratory tests		Result	Reference interval	Units
CBC	WBC	5.6	4.8–10.8	K/μL
	RBC	2.6	4.0–5.4	M/μL
	Platelets	162	145–499	K/μL
	Hemoglobin	8.6	12.0–16.0	g/dL
	Hematocrit	25.3	36.0–47.0	%
CMP	BUN	40	7–18	mg/dL
	Creatinine	4.5	0.5–1.2	mg/dL
	Calcium	10.2	8.5–10.2	mg/dL
	TP	10.5	6.1–8.0	g/dL
	ALB	2.7	3.5–4.8	g/dL
Urinalysis	Protein	28.0	< 30.0	mg/dL

proteins in a gel matrix. IFE is performed after the specimen is subjected to electrophoresis in the same process as SPEP but in multiple lanes. After electrophoresis is complete, each isolated electrophoretic lane is then overlaid with specific antiserum that reacts with the protein antigen(s) of interest. The antiserum precipitates the specific protein of interest, fixing it in the gel matrix. After washing away unreacted reagent and unfixed proteins, the gel is stained and the fixed immune precipitates are identified. The additional protein from the Ab-antigen IFE reaction enhances sensitivity for detection by magnifying the intensity of staining several fold.

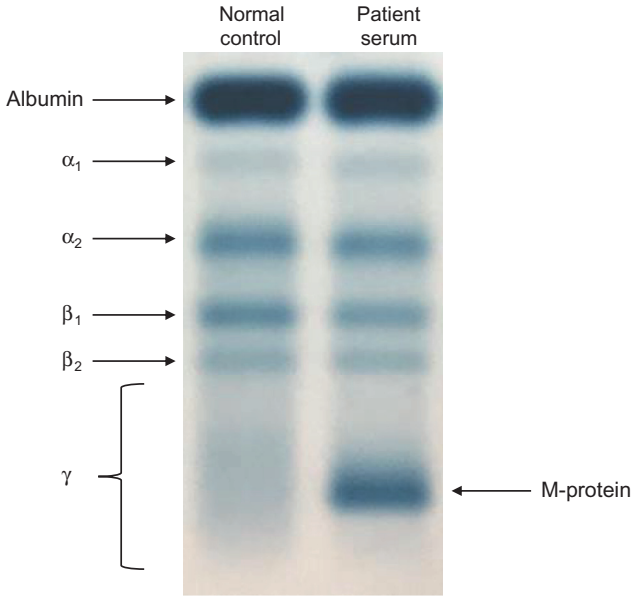

FIGURE 22.6 Control (normal) serum protein electrophoresis pattern *(left lane)* and serum protein electrophoresis of the patient's serum from the case example showing a monoclonal gammopathy *(right lane)*.

IFE of serum is typically performed using specialized gels in which electrophoresis is performed simultaneously in six adjacent lanes for each specimen. Following separation and placement of the template cutout, the first lane is overlaid with a general protein fixative and may be used as a reference. Each of the second through sixth lanes is overlaid with respective antisera against the IgG, IgA, and IgM heavy chains, and then κ and λ light chains, respectively. The IFE gel from the case example shows the characterization of the M-protein as an IgG λ (see Fig. 22.7).

IFE of urine requires electrophoresis of the patient's preconcentrated urine specimen in multiple lanes. Generally, the same six-lane specialized gels (Fig. 22.8) as for serum IFE are used. Since the focus of urine IFE is often detection of Bence Jones proteinuria, a general fixative is typically overlaid in the first (leftmost) lane; free κ (unbound to heavy chain), total κ, free λ, and total λ are overlaid in the second through fifth lanes, respectively. The last lane can be used to assess urine excretion of any heavy-chain components identified on serum IFE.

IFE of CSF typically requires specimen concentration or sensitive stains, and uses the same specialized gels as are used for serum IFE. CSF IFE is usually performed to assess the presence of oligoclonal banding, defined as multiple bands of IgG identity migrating in the γ region. The strategy for CSF IFE typically includes a general fixative in the first lane and IFE with IgG, κ, and λ antisera in separate lanes. Fig. 22.9 shows that IFE of CSF enhances the ability to detect oligoclonal bands due to its greater sensitivity compared with conventional electrophoresis and staining (see the section "Multiple sclerosis and cerebrospinal fluid electrophoresis").

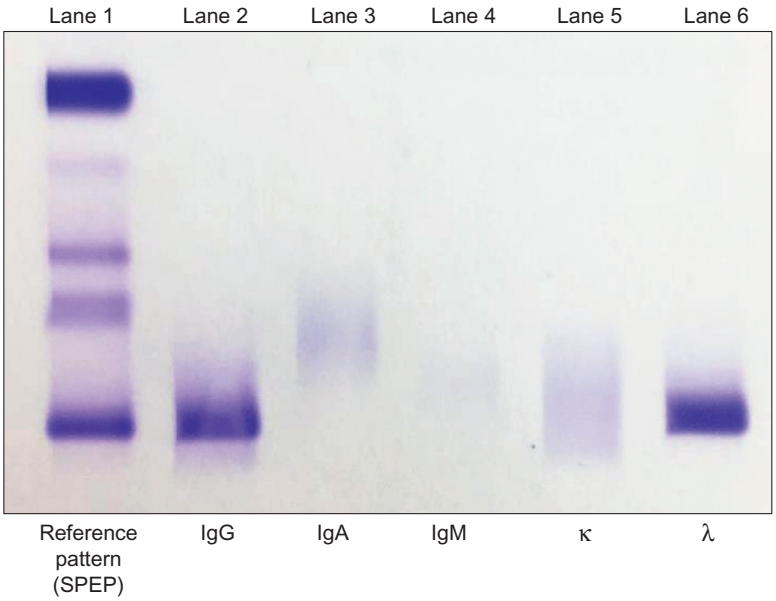

FIGURE 22.7 Six-lane immunofixation (immunofixation electrophoresis) gel of the case example in which a general fixative is applied to the *leftmost lane* (reference pattern). Each of the remaining lanes is overlaid with specific antisera for γ (immunoglobulin G), α (immunoglobulin A), and μ (immunoglobulin M) heavy chains, and κ and λ light chains as indicated. In lanes 2–6, only the protein of interest is fixed for staining and visualization. Note that the identity of the monoclonal protein is immunoglobulin G, with λ light chain.

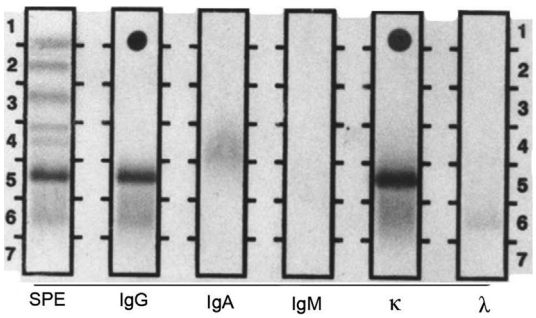

FIGURE 22.8 Another typical six-lane immunofixation (immunofixation electrophoresis) gel, in which a general fixative is applied to the *leftmost lane*. Each of the remaining lanes is overlaid with specific antisera for γ (immunoglobulin G), α (immunoglobulin A), and μ (immunoglobulin M) heavy chains, and κ and λ light chains as indicated. In lanes 2–6, only the protein of interest is fixed for staining and visualization. Note that the identity of the monoclonal protein is immunoglobulin G, with κ light chain.

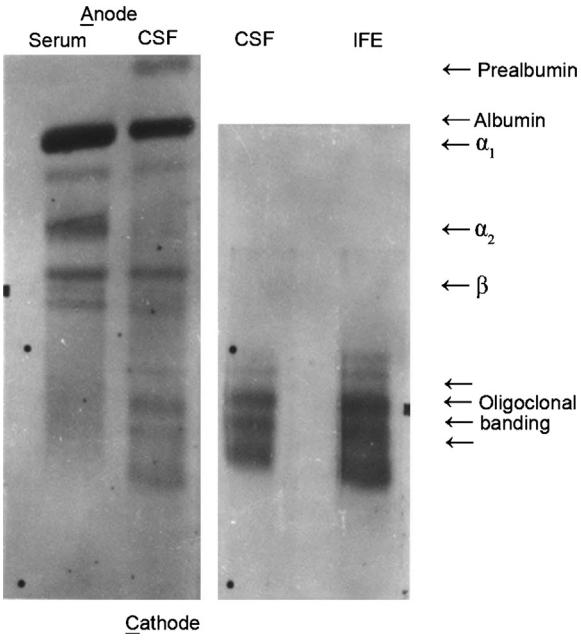

FIGURE 22.9 The *leftmost lanes* show serum and cerebrospinal fluid electrophoresis patterns for a patient with multiple sclerosis; note the presence of oligoclonal banding in the cerebrospinal fluid. The prealbumin band stains prominently in the cerebrospinal fluid lane. In the *rightmost two lanes*, the cerebrospinal fluid was immunofixed with immunoglobulin G antisera. Note the greater intensity of the immunofixed lanes. Cerebrospinal fluid applied to the *rightmost lane* was subject to more preconcentration prior to electrophoresis.

Capillary zone electrophoresis

Capillary zone electrophoresis (CZE) is an efficient, sensitive, and versatile analytical method that is based on combining zone electrophoresis, isoelectric-focusing electrophoresis, and isotachophoresis (see Chapter 8, Chromatography and electrophoresis). CZE systems have

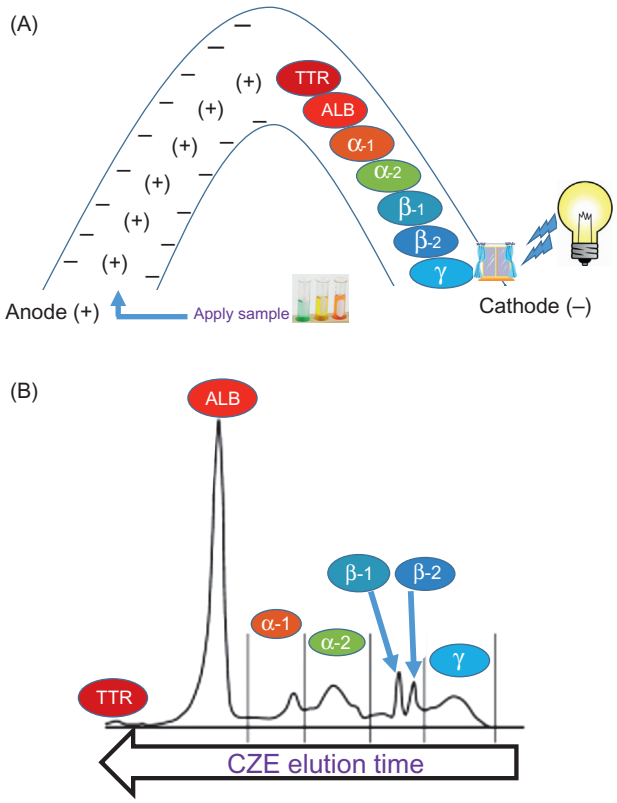

FIGURE 22.10 *Panel A:* Sample is applied into the capillary tube and migrates through the charged environment, with the positively charged proteins passing through the column most easily. Detection of the proteins is possible through a window in the column. *Panel B:* The protein pattern resulting from capillary zone electrophoresis showing the direction of elution from the column. Note that it is similar to the serum protein electrophoresis pattern displayed in Fig. 22.5.

been investigated for clinical use for several decades, and there are various instruments available for assessing protein regions in serum and urine. Rather than a gel-based technology, CZE utilizes a liquid-based system that separates proteins in a strong negatively charged environment, as shown in Fig. 22.10A. As shown, the sample is aspirated into the anodal end of a fused silica capillary, where the negative charge on the interior of the capillary applies a strong endosmotic flow of cations toward the cathode. The proteins travel through the capillary at a rate proportional to the intensity of their net positive charge with a flow of negatively charged proteins such as the ALB moving slowest and positively charged proteins such as immunoglobulins moving through the column more quickly (Fig. 22.10A). As the protein fractions exit the capillary system, they are detected by absorbance, commonly at 200–215 nm, through a window in the column. This results in the electropherogram shown in Fig. 22.10B. There is a strategy to identify M-proteins in which specific antisera are added to the specimen of interest. The specific antisera remove the M-protein targeted by

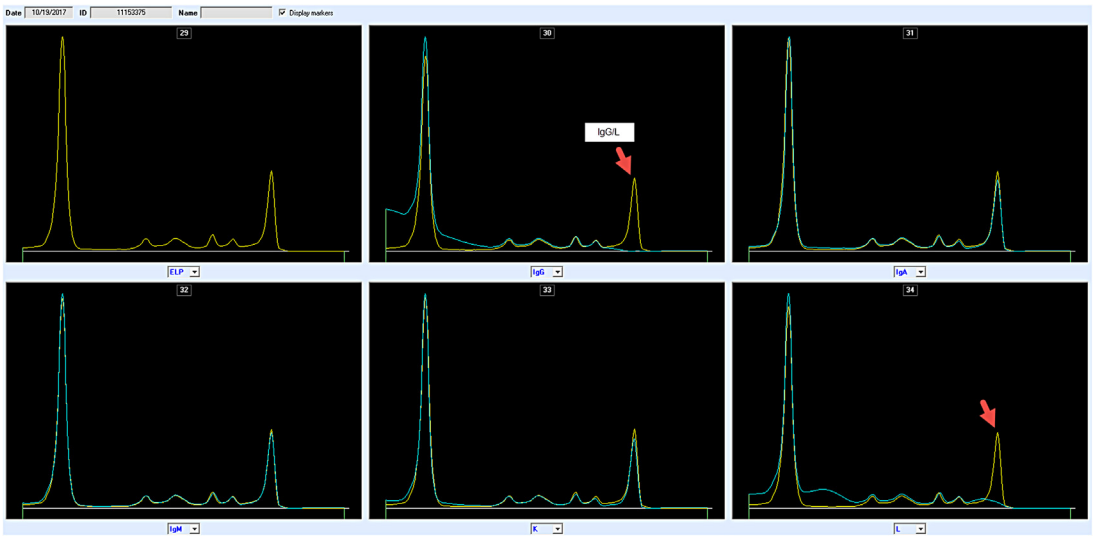

FIGURE 22.11 Typical capillary zone electrophoresis immunosubtraction panels (Sebia, Capillarys) from the case example in which a general capillary pattern is depicted in the *leftmost lane* (reference pattern). Each of the remaining lanes is treated with antibodies against γ (immunoglobulin G), α (immunoglobulin A), and μ (immunoglobulin M) heavy chains, and κ and λ light chains. Then capillary zone electrophoresis is performed to determine which heavy and/or light chains are removed/subtracted. The reference pattern is applied to panels 2–6. Electrophoretic shifts of bounded proteins can be seen in the albumin region of panels 2 and 6. This characterizes the monoclonal protein as immunoglobulin G, with λ light chain.

the antisera by precipitation, which is eliminated from the sample. This technique is commonly referred to as immunosubtraction. CZE before and after immunosubtraction eliminates the monoclonal band, and measurement of the area difference allows quantification of the precipitated M-protein. The CZE trace and immunosubtraction for the case example are shown in Fig. 22.11.

Automated CZE methods are gradually being adopted in the clinical laboratory. Recently, an international survey of 774 laboratories from 38 countries revealed 31.4% ($n = 238$) are currently utilizing CZE for serum protein measurement versus the remainder, who predominantly perform analysis by agarose gel electrophoresis [10]. The migration to CZE from SPEP is likely due to CZE offering relatively straightforward automation, generally improved precision, and overall faster turnaround times than conventional SPEP. However, CZE measurements do not provide a physical gel for visual inspection, although computer generated or "digital gels" can be provided by current software. In addition, the absorbance detection of CZE results in various interferences and the immunosubtraction technique requires additional training and experience. The overall cost per test is more expensive than traditional gel electrophoresis. These limitations may delay adoption of CZE, and labs will need to weigh their options such as volumes and reimbursements.

Mass spectrometry

The use of mass spectrometry to identify, isotype and quantitate M-proteins may be on the horizon for the clinical laboratory. Mass spectrometry has shown better analytical sensitivity and specificity in the detection of M-proteins than SPEP or CZE. Recent studies by Mills et al. [11] have demonstrated the utility of M-protein assessment using nanobody enrichment coupled to matrix-assisted laser desorption ionization-time of flight also known as "MASS-FIX." As of 2018, MASS-FIX is offered clinically as a laboratory-developed test at a single referral lab in the United States. The method is capable of performing rapid analysis (<1 minute per patient), but the 2.5-hour sample preparation is a recognized limitation.

Mass spectrometry may also assist in monitoring therapeutic monoclonal antibody (t-mAb) treatments in patients with MM. Patients with comigrating IgG κ malignant M-proteins and IgG κ therapeutic monoclonal antibody (t-mAb) on IFE could benefit from the specificity offered by mass spectrometry. A recent pilot study demonstrated mass spectrometry was able to differentiate accurately 100% of samples ($n = 192$) containing t-mAb, an endogenous M-protein, or both regardless of migration patterns observed on IFE. This work highlights the growing use of mass spectrometry in this area and the potential elimination of false-positive results due to t-mAb interferences [12]. In the future, mass spectrometry may be the method of choice for protein measurement. However, upfront instrument costs as well as the required instrument expertise may keep SPEP and CZE as frontline tests for several years to come.

Serum free κ and λ light chains in serum and urine

Free κ and λ light chains may appear on protein electrophoresis at high concentrations. There are four major indications for FLC testing in the evaluation and management

of MM and related clonal plasma cell disorders: screening, prognosis, monitoring for recurrence, and monitoring therapeutic response. Screening for clonal plasma cell disorders (including MM) by simultaneous analysis of SPEP and examination of the serum FLC assay negates the need for screening by 24-hour urine studies. However, it is important to note that once diagnosis of a plasma cell disorder is made, 24-hour urine studies are required for all patients. The serum FLC assay results are of major prognostic value in virtually every plasma cell disorder, including monoclonal gammopathy of undetermined significance (MGUS), smoldering myeloma, active myeloma, immunoglobulin light-chain amyloidosis, and solitary plasmacytoma. Quantitative monitoring of patients with oligosecretory plasma cell disorders (including patients with AL amyloidosis, oligosecretory myeloma, and nearly two-thirds of patients who had previously been deemed to have nonsecretory myeloma) is accomplished by examination of results from serum FLC measurements. In addition, measurement of FLC is essential in acute leukemia patients and patients with oligosecretory myeloma. Finally, serum FLC measurement is a requirement for monitoring and evaluating clinical response, according to the *International Myeloma Working Group (IMWG) Uniform Response Criteria for Multiple Myeloma* [13].

β_2 Microglobulin

As a tumor marker, β_2-microglobulin is used to provide independent information about prognosis and tumor burden. β_2-microglobulin is not a diagnostic biomarker, because it is nonspecific for malignancy or other disease processes.

Three staging criteria for prognostic interpretation of β_2-microglobulin values are available from "*International Staging System for Multiple Myeloma*" [14].

1. Stage I criteria require serum β_2-microglobulin to be $<$3.5 mg/L (296 nmol/L) and serum albumin $>$3.5 g/dL (35 g/L or 532 μmol/L; median survival 62 months).
2. Stage II criteria fits neither stage I or III (median survival 45 months).
3. Stage III criteria requires serum β2-microglobulin to be $>$5.5 mg/L (465 nmol/L; median survival 29 months).

Other indications to measure β_2-microglobulin are to assess tubular dysfunction in renal tubular disease.

Interferences

Analytical interferences are common to all areas of the clinical laboratory. Interferences may be due to a natural or pathological process or may be from some exogenous compound such as medications or medical therapies. Multiple interferences for both agarose gels and capillary-based methods for protein determination have been well characterized by McCudden et al. [15]. However, unrecognized interferences are a common source of laboratory error and may lead to additional testing, inappropriate treatments, or even misdiagnosis. Therefore it is imperative for the laboratorian to be aware of the type of interferences currently identified with their technology and how to mitigate or eliminate them if possible. Table 22.4 summaries several interferences that can be encountered during review of protein electrophoresis.

Endogenous interferences

Many common interferences that affect SPEP and CZE are endogenous. The two most frequent patterns identified are fibrinogen and hemolysis. It is important to recognize the various sources and develop strategies to avoid false interpretations. A commonly encountered analytical interference on SPEP and CZE is fibrinogen. Fibrinogen is a large, 340-kDa glycoprotein readily converted into fibrin by thrombin in the final steps of the coagulation cascade. Fibrinogen is typically removed from serum specimens, although patients with coagulation disorders or patients on anticoagulation therapy may contain traces of fibrinogen. On occasion, plasma samples may also be submitted for SPEP or CZE analysis. Specimens containing fibrinogen will have an abnormal band that migrates to the β/γ region. Such a band virtually always requires an IFE or immunosubtraction, to avoid misidentifying the band as an M-protein. If the analyzed specimen was heparinized plasma, diligent use of either of these techniques (IFE or immunosubtraction) can help confirm possible abnormalities seen on SPEP or CZE.

Hemolysis is a widely characterized interferant in the clinical laboratory. Lysed or "hemolyzed" red blood cells release high cellular concentrations of Hb, potassium, magnesium, iron, phosphate, lactate dehydrogenase, and aspartate aminotransferase. Hb causes a spectral interference in most absorbance-based methods and may be identified by visual inspection of the plasma or serum sample, or by the generated hemolysis indices reported by most automated chemistry analyzers. On SPEP, the α_2/β_1 regions may show discrete bands attributed to sample hemolysis. Similar to fibrinogen interference, specimen examination or an IFE should be performed to avoid false interpretation of the abnormal pattern. Causes of hemolysis may be due to various in vivo or in vitro processes.

Elevated serum concentrations of polyclonal IgG_4 subclass may mimic or resemble an M-protein. This interference may also be referred to as monoclonal gammopathy mimicry. The endogenous increase is due to IgG_4-releated disease (IgG_4-RD), a syndrome of unknown etiology. On SPEP and CZE, a characteristic focal band can be seen bridging the β/γ regions of patients with IgG_4-RD. The pattern can appear polyclonal on IFE or immunosubtraction

TABLE 22.4 List of common interferences encountered during protein electrophoresis.

Interference	Method affected	Action for resolution	Frequency
Fibrinogen	SPE/IFE (both capillary and agarose gel methods)	Thrombin treatment, ethanol precipitation, preabsorption of antisera	Common
Contrast/radio-opaque dyes	Capillary electrophoresis	IFE is unaffected	Uncommon
Antifungals (5-fluorocytosine)	Capillary electrophoresis	IFE is unaffected	Uncommon
Antiboiotics	SPE (capillary and agarose gel)	IFE is unaffected	Uncommon
Hemolysis	SPE (capillary and agarose gel)	IFE is unaffected	Common
Heterophilic antibodies	IFE (capillary and agarose gel)	Clinical awareness/education	Rare
Polyclonal IgG_4 subclass mimics	IFE (capillary and agarose gel)	Clinical awareness/education	Rare
Monoclonal therapies	SPE/UPE/IFE (capillary and agarose gel)	Clinical awareness/education, migration shift assays, and mass spectrometry	Rare, but may become significant in the future

IFE, Immunofixation electrophoresis; *IgG*, immunoglobulin G; *SPE*, serum protein electrophoresis; *UPE*, urine protein electrophoresis.
Modified from reference C.R. McCudden, J.F.M. Jacobs, D. Keren, H. Caillon, T. Dejoie and K. Andersen, Recognition and management of common, rare, and novel serum protein electrophoresis and immunofixation interferences, *Clin. Biochem.* **51**, 2018, 72–79,

with both κ and λ bands staining similarly. This may lead to confusion with clonality, and IEF should be performed to differentiate. Human antianimal antibodies (HAAAs) and heterophile antibodies are known but relatively rare endogenous interferences on SPEP [15]. Human antimouse antibodies are the most common subclass of HAAAs. Exposure to farm animals or medical treatments with animal proteins may elicit an immune response and formation of HAAAs. No previous exposure is necessary for the development of a heterophile antibody. Heterophile antibodies are IgM class immunoglobulins. Although HAAAs are nonpathological, they may give the false appearance of an M-protein and may lead to incorrect classification as MGUS.

Endogenous proteins in the β and γ region can also be possible sources of interference and confusion. Proteins in the β_1 and β_2 region may mask or hide M-proteins. Patients presenting for the first time with clinical indications of MM but no demarcated band on SPEP or CZE may require an IFE or immunosubtraction to rule out a β region, M-protein. Unfortunately, M-proteins in this region can also be difficult to quantitate, and these limitations should be shared via comments or alerts to clinicians. As described early in this chapter, proteins such as Tf can also mimic an M-protein in the β_1 region and may lead to additional testing such as IFE. Finally, CRP is commonly misinterpreted for an M-protein. During an inflammatory response, CRP can show up as a band in the γ region; however, since CRP does not react with heavy-chain or light-chain antisera, the band is absent on IFE.

Exogenous interferences

It has been observed that exogenous compounds, such as radiocontrast dyes, medications, and more recently m-tAb, can affect the interpretation of SPEP or CZE. These compounds may interfere with the spectral absorbance in CZE, leading to a falsely abnormal band, or directly affect the interpretation by the presence of a quantifiable m-tAb. The list of exogenous interferences continues to grow with the gamut of current and new drugs, supplements, and treatments being given to patients.

Radiopaque chemicals or "agents" absorb at $\sim$200 nm, the same wavelength utilized by CZE. This often leads to the detection of an additional spike or band, which may be concerning for the presence of an M-protein. The α_2 or less commonly the β_2 regions are mostly affected by the radiopaque agents. Fortunately, the abnormal pattern can be further investigated by IFE or immunosubtraction, but the additional analysis is expensive and can take away important resources (e.g., time). Laboratories performing CZE may want to educate clinicians about the possible interference and make further recommendations about timing appropriate specimen collection whenever possible. These radiopaque chemicals do not interfere with conventional SPEP agarose gels.

Some antifungal and antibiotic medications can elicit abnormal patterns on CZE. Interference from 5-fluorocytosine on CZE may be seen at the end of the γ region of patients with immunosuppression and renal failure.

Similar to the radiopaque chemicals, 5-fluorocytosine absorbs around the 200-nm wavelength utilized in CZE. This pattern increases the suspicion of an M-protein and IFE or immunosubtraction should be performed to confirm. An abnormal band between α_2 and β_1 is associated with piperacillin. Other medications such as ceftriaxone and sulfamethoxazole produce abnormal bands or spikes but appear on CZE in regions less associated with M-proteins (e.g., prealbumin and ALB).

Interference from novel monoclonal therapies is a growing concern for clinicians and laboratorians. Treatments with targeted monoclonal antibodies are becoming common for patients with MM and other plasma cell disorders. Therapeutic doses of daratumumab, siltuximab, elotuzumab, and newer t-mAbs can appear on SPEP and CZE as a small M-protein. Most t-mAbs identified by IFE or immunosubtraction are IgG_1 κ. The half-life of many of these biologic drugs can cause interferences several weeks after infusion and may be misleading to the clinician who might be expecting partial or complete response from therapy.

Several approaches may help to alleviate t-mAb interference. The most practical method involves collaboration with other clinical departments. For example, the hospital pharmacy may provide lists of patients receiving immunotherapy to the laboratory or the laboratorian performing signouts can examine the medical record when bands suspicious for immunotherapy are present on SPEP or CZE. This allows the laboratory to track and provide comments where appropriate. An additional approach involves the use of a commercially available methodology that utilizes antidaratumumab antibodies to decipher comigrating malignant M-protein from daratumumab. Similar approaches are being investigated with other t-mAbs; however, the rate of t-mAb development and wide clinical use is expected to increase and it will be challenging for vendors and laboratorians to keep up. Another effective approach to this complex solution involves the use of mass spectrometry analysis. The exact mass of the specific t-mAb can alleviate concerns of M-protein identify and more importantly help to eliminate other endogenous and exogenous interferences. However, these methods are not considered mainstream yet and until a better approach is readily available to minimize or remove m-Ab interference, and cooperation between the clinical laboratory and medical community will be essential to patient care.

Protein analysis and interpretation

Protein electrophoresis examples

Fig. 22.12 displays selected protein patterns that may be encountered in clinical practice. The normal pattern is shown in the first lane of Fig. 22.12. As with any clinical assay, inclusion of appropriate controls is a fundamental part of SPEP and UPEP interpretation.

The glomerular UPEP pattern in Lane A is typically quite featureless except for the obvious ALB band and a faint band in the β_1 region. Mechanistically, this pattern results when negatively charged ionic repulsion at the basement membrane of the glomerulus is compromised and allows ALB and other low-molecular-weight, negatively charged proteins to pass through the glomerulus, overwhelm the protein resorbing mechanisms, and pass into the urine. This pattern typically depicts ALB and TRN in the β_1 region, but λ and κ light chains can migrate in the β region too. If there is high clinical suspicion and increased serum FLC, a UPEP IFE may be performed. Nonselective proteinuria (Lane B) typically indicates a lack of the kidney's ability to filter and

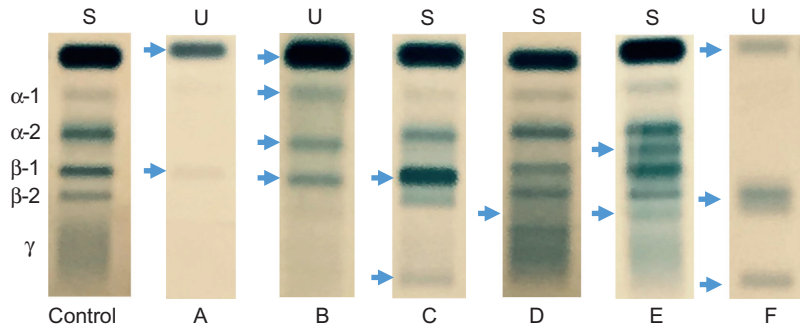

FIGURE 22.12 Examples of various protein electrophoresis patterns encountered in clinical practice. U represents urine and S represents serum. *Control Lane:* serum protein electrophoresis of Normal Serum. *Lane A*: glomerular urine protein electrophoresis pattern. Arrows point to characteristic albumin band and faint band in β_1 region (typically transferrin). *Lane B*: nonselective urine protein electrophoresis pattern, showing excretion of nearly all serum protein fractions (highlighted by the arrows). *Lane C*: serum protein electrophoresis, showing biclonal band. The arrow in the β_1 region points out a monoclonal-protein comigrating with proteins of this region. The arrow in the γ region highlights a second, faint band. *Lane D*: serum protein electrophoresis, showing $\beta-\gamma$ bridging (*arrow*). Note there is a faint band in the γ region just to the γ side of the arrow. *Lane E*: serum protein electrophoresis, showing a hemoglobin band migrating between the α_2 and β_1 regions (*arrow*). There is also a fibrinogen band (*arrow*) due to incomplete coagulation of the specimen. *Lane F*: a complicated urine protein electrophoresis showing albumin excretion due to glomerular injury, a band in the γ region that is an intact immunoglobulin from serum (extremely high, >4 g/dL) that "overflowed" into urine, and bands in the β region due to Bence Jones proteinuria.

TABLE 22.5 Association of the various immunoglobulin subtypes with multiple myeloma.

Protein	Frequency of association with MM, %	Bence Jones proteinuria, %	Mean age of occurrence (years)
IgG	50	60	65
IgA	25	70	65
IgD	2	100	57
Free light chains only	20	20	56
None detected	<1	0	-
Bi-clonal	1	-	-
IgM	1	50–100	-

IgA, Immunoglobulin A; *IgD*, immunoglobulin D; *IgG*, immunoglobulin G; *IgM*, immunoglobulin M; *MM*, multiple myeloma.

resbsorb both small- and large-molecular-weight proteins. In addition, the negative charge repulsion mechanism to conserve ALB is compromised, and virtually all fractions of the SPEP pass into urine. Lane C shows a biclonal monoclonal gammopathy pattern (see arrows). As shown in Table 22.5, approximately 1% of MM patients demonstrate a biclonal banding pattern. These bands should be characterized by IFE for monitoring. β-γ bridging (arrow Lane D of Fig. 22.12) is frequently observed in liver disease patients. Note there is also a faint band in the γ region that is an indication for performing IFE. Lane E is an SPEP pattern, showing two possible misleading interferences highlighted by the arrows. First, there is an Hb band migrating between the α_2 and β_1 regions (upper arrow). There is also a fibrinogen band (arrow right below the β_2 region) due to incomplete coagulation or collection of the incorrect specimen type. IFE of this SPEP would identify no corresponding M-proteins. Lane F is a complicated UPEP, showing ALB excretion due to glomerular injury; in addition, there is a band in the γ region that is an intact immunoglobulin from serum (extremely high, >4 g/dL) that "overflowed" into urine, and bands in the β region due to the Bence Jones proteinuria. The legend of Fig. 22.12 details the characteristic findings for each.

Acute-phase response

APR proteins respond to cytokine release and physiologic stresses such as inflammation, infection, trauma, myocardial infarction, or tumors. The increase or decrease in protein concentration in these situations leads to their further characterization. Proteins that increase with such stresses are termed "positive APR proteins"; those that decrease are termed "negative APR proteins." The APR classification of several proteins is listed in Table 22.1. "Acute" is actually a misnomer, because the APR proteins also persistently respond in chronic conditions such as rheumatoid arthritis and SLE. Many other conditions and therapies may affect the APR proteins and the corresponding SPEP pattern, including endocrine status and administration of steroid hormones, as shown in Table 22.2.

Monoclonal gammopathies

M-proteins are detected in approximately 5% of patients older than 50 years and in approximately 8% of patients >70 years. Once an M-protein is detected, characterization and temporal monitoring of the specific protein are important for clinical care. Table 22.6 lists laboratory and other investigative tests useful for screening and diagnosis of MM. Laboratory tests include SPEP and UPEP, IFE or immunosubtraction in serum and urine, serum FLC measurement, as well as routine laboratory studies including CBC, serum creatinine, electrolytes, calcium, lactate dehydrogenase, and β_2-microglobulin [16]. SPEP and IFE are considered the first-line tests for the workup of MM. If MM is suspected, a bone marrow sample should be collected and examined. If an M-protein is detected through SPEP, UPEP, or pathological FLC ratio and the plasma cell count is higher than or equal to 10%, a diagnosis of MM is made [15]. In addition, if any of the following three criteria are met, a diagnosis of MM is made [16]:

- 60% or greater clonal plasma cells on bone marrow examination;
- serum FLC ratio of 100 or greater of either involved or uninvolved κ or λ light chain, provided the absolute concentration of the involved light chain is at least 100 mg/L (the "involved" FLC, either κ or λ, is the one that is above the normal reference range; the "uninvolved" FLC is the one that is typically in, or below, the normal range); and

- more than one focal lytic lesion on magnetic resonance imaging (MRI) that is at least 5 mm or greater in size.

MM is also diagnosed in patients with $<10\%$ plasma cells that also have an M-protein of more than or equal to 3 g/100 mL. In patients with nonsecretory MM, the diagnosis is dependent on the bone marrow findings of $>30\%$ bone marrow plasma cells or plasmacytoma detection [16,17].

When plasma cell clones multiply beyond normal control, an M-protein can be identified on SPEP as a darkly staining area, frequently (but not exclusively) in the γ region, as illustrated in Fig. 22.13. M-protein disorders can be conceptualized as a disease continuum spanning from the asymptomatic "MGUS" condition, to "smoldering" myeloma, which has some features of malignancy, all the way to the full-blown MM malignancy. Criteria and definitions of this continuum are listed in Table 22.7 [18]. Pathological findings associated with M-proteins include amyloid light-chain amyloidosis (termed "primary amyloidosis" or AL amyloidosis) and light-chain deposition disease (LCDD). Monoclonal plasma cell disorders include IgG, IgA, IgM, and occasionally IgD or IgE classes; also the disorder can involve AL amyloidosis, Waldenström macroglobulinemia (IgM), MGUS, and B-cell lymphoma. In addition, monoclonal gammopathy may also secrete κ or λ light chains only, without an associated heavy chain component. In these cases, the measurement of serum FLCs is particularly important for assessment of patients; Table 22.8 lists criteria for the continuum of light-chain M-protein that includes MGUS, idiopathic Bence Jones protein, and light-chain MM.

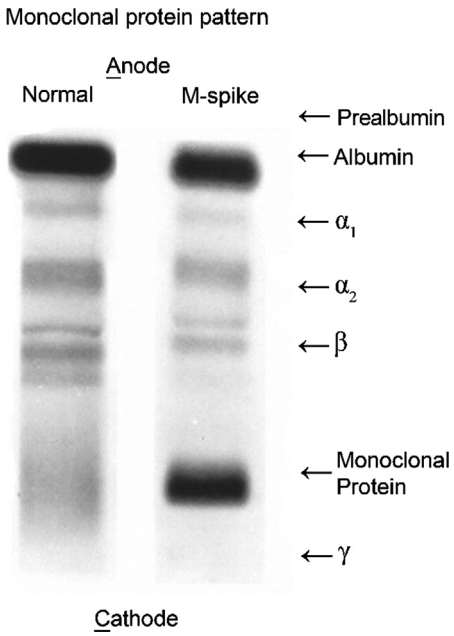

FIGURE 22.13 Control (normal) serum protein electrophoresis pattern *(left lane)* and serum protein electrophoresis showing a monoclonal gammopathy *(right lane)*.

Detection of an M-protein in serum or urine typically leads to further studies including the collection and examination of a bone marrow biopsy. The prevalence of various immunoglobulin subtypes in patients with MM is displayed in Table 22.5.

If MM and smoldering myeloma are ruled out and the M-protein is attributed to MGUS, then temporal

TABLE 22.7 Diagnostic laboratory focused criteria for immunoglobulin G and immunoglobulin A monoclonal gammopathies[a] including: monoclonal gammopathy of unknown significance,[b] smoldering myeloma, and symptomatic myeloma.

MGUS[c]	Smoldering multiple myeloma	Symptomatic myeloma
(all three criteria must be met)	**(both criteria must be met)**	**(all three criteria must be met)**
• M-protein in serum <3.0 g/dL • Bone marrow clonal plasma cells <10% and low level of plasma cell infiltration in a trephine biopsy (if done) • No related organ or tissue impairment (no end organ damage including bone lesions)	• M-protein in serum >3.0 g/dL and/or bone marrow clonal plasma cells >10% • No related organ or tissue impairment Absence of end-organ damage such as lytic bone lesions, anemia, hypercalcemia, or renal failure that can be attributed to a plasma cell proliferative disorder	• Clonal bone marrow plasma cells ≥ 10% • Presence of serum and/or urinary evidence of monoclonal protein (except in patients with true nonsecretory multiple myeloma) • Evidence of end-organ damage that can be attributed to the underlying plasma cell proliferative disorder, specifically: Hypercalcemia: serum calcium >11.5 mg/dL Renal insufficiency: serum creatinine >2 mg/dL or estimated creatinine clearance <40 mL/min Anemia: normochromic, normocytic with a hemoglobin value of >2 g/dL below the lower limit of normal or a hemoglobin value <10 g/dL Bone lesions: lytic lesions or severe osteopenia attributed to a plasma cell proliferative disorder or pathologic fractures

[a] *Occasionally patients with IgD and IgE monoclonal gammopathies have been described and are considered to be part of this category.*

[b] *Unless specifically distinguished, when the terms MGUS and multiple myeloma are used in general, they include IgM MGUS and light-chain multiple myeloma, respectively.*

[c] *Note that conventionally IgM MGUS is considered a subtype of MGUS.*

Adapted from reference International Myeloma Working Group consensus criteria for response and minimal residual disease assessment in multiple myeloma: Diagnosis, Staging & Monitoring, IMWG Publications. <http://imwg.myeloma.org/international-myeloma-working-group-consensus-criteria-for-response-and-minimal-residual-disease-assessment-in-multiple-myeloma/>, 2016 (accessed 01.12.18).

monitoring is clinically indicated. This is because a substantial proportion of patients with MGUS evolve into more serious conditions including MM. MGUS accounts for approximately 60% of unexpected discovery of M-proteins. The frequency of occurrence varies with age and is 1%–2% of individuals >50 years old, 3%–4% of individuals >70, and reportedly 10% in people >80 years of age. Patients diagnosed with MGUS require periodic monitoring with serum and urine studies, because the disease progresses in about 24% of these individuals [19], as shown in Fig. 22.14. Treatment of patients with MGUS is not recommended until laboratory or other abnormalities progress or symptoms of MM develop, because these patients may remain stable for years [16,17].

Multiple myeloma

MM is a malignancy that was first described in 1848 and is characterized by a proliferation of plasma cells of a single clone leading to a subsequent excess of monoclonal protein in serum (80% of cases) and/or urine (60% of cases). MM represents approximately 15% of all hematologic malignancies; it is the most common hematologic malignancy in African Americans and is the second most common in Caucasians. The lifetime risk of MM in the United States is about 0.76%. MM is a malignancy of plasma cells and may show clinical signs and symptoms including bone pain, pathologic fractures, weakness, malaise, hypercalcemia, spinal cord compression, renal failure, plasmacytoma, and neuropathies. Also, MM is characteristically associated with anemia. MM patients frequently have thrombocytopenia and leukopenia and impaired humoral immunity, which predisposes MM patients to infections, especially with encapsulated organisms such as *Pneumococcus*. The American Cancer Society estimates that about 30,770 new cases of MM in 2018 and that approximately 12,770 deaths were attributed to MM in that year. Table 22.7 shows the diagnostic criteria for symptomatic myeloma according to the IMWG [18].

For patients with symptomatic MM, chemotherapy is a first-line treatment. If the patient is classified as having asymptomatic MM, treatment is typically delayed until

TABLE 22.8 Diagnostic laboratory focused criteria for light-chain monoclonal gammopathies including light-chain monoclonal gammopathy of unknown significance.

Light-chain MGUS	Idiopathic Bence Jones proteinuria	Light-chain multiple myeloma[a]
(all criteria must be met)	**(all criteria must be met)**	**[the same as multiple myeloma (see Table 22.7) except no evidence of immunoglobulin heavy-chain expression]**
• Abnormal free light-chain ratio (<0.26 or >1.65) • Increased level of the appropriate involved light-chain (increased kappa free light chain in patients with ratio >1.65 and increased lambda free light chain in patients with ratio <0.26) • No immunoglobulin heavy-chain expression on immunofixation • Clonal bone marrow plasma cells <10% • Absence of end-organ damage such as CRAB that can be attributed to the plasma cell proliferative disorder	• Urinary monoclonal protein on urine protein electrophoresis ≥500 mg/24 h and/or clonal bone marrow plasma cells ≥10% • No immunoglobulin heavy-chain expression on immunofixation • Absence of end-organ damage such as CRAB that can be attributed to the plasma cell proliferative disorder	• Clonal bone marrow plasma cells ≥ 10% • Presence of serum and/or urinary monoclonal protein (except in patients with true nonsecretory multiple myeloma) • Evidence of end-organ damage that can be attributed to the underlying plasma cell proliferative disorder, specifically: Hypercalcemia: serum calcium >11.5 mg/dL Renal insufficiency: serum creatinine >2 mg/dL or estimated creatinine clearance <40 mL/min Anemia: normochromic and normocytic with a hemoglobin value of >2 g/dL below the lower limit of normal or a hemoglobin value <10 g/dL Bone lesions: lytic lesions or severe osteopenia attributed to a plasma cell proliferative disorder or pathologic fractures

CRAB, Hypercalcemia, renal insufficiency, anemia, and bone lesions; *MGUS*, monoclonal gammopathy of unknown significance.

[a]*Note that light-chain multiple myeloma is considered a subtype of multiple myeloma. Unless specifically distinguished, when the terms MGUS and multiple myeloma are used in general, they include IgM MGUS and light-chain multiple myeloma, respectively.*

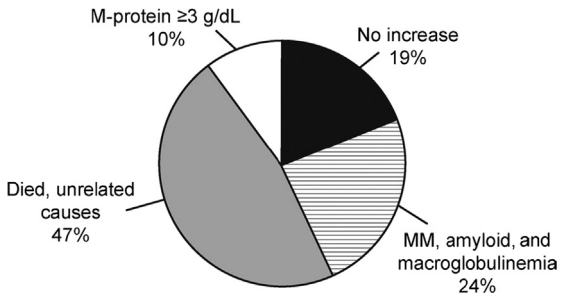

FIGURE 22.14 Findings at 20–35 years (median 22 years) in 241 patients initially presenting with monoclonal gammopathy of unknown significance. *Adapted from P.M. Ridker, E. Danielson, F.A.H. Fonseca, J. Genest, A.M. Gotto, J.J.P. Kastelein, et al., Rosuvastatin to prevent vascular events in men and women with elevated c-reactive protein,* New Engl. J. Med. ***359*** *(2008) 2195–2207.*

disease clinically progresses, for example, serum or urine concentrations of the M-protein substantially increase. Although no cure for MM is currently known, treatment results in improved patient outcomes including better survival, less pain, and fewer complications. The 5-year relative survival rate for MM is 46.6%, with younger patients showing better treatment response than the elderly [17]. Assessing treatment response is central to prognostication and management of MM patients. Table 22.9 displays the criteria indicating treatment response [18]. Serum FLC measurements, urine and serum agarose gel or capillary electrophoresis, quantification of the amount of protein comprising the M-protein in serum and urine, and IFE or immunosubtraction of serum and urine are all recommended measurements along with bone marrow examination and clinical criteria.

Laboratory testing is also important for temporal monitoring MM patients. Table 22.10 shows the criteria and laboratory support required for assessing disease progression or relapse according to current guidelines [18]. Serum FLC measurement, protein electrophoresis, IFE of serum and urine, and routine laboratory analysis play an important role in MM monitoring.

TABLE 22.9 International Myeloma Working Group uniform response criteria.

Response subcategory	Response criteria
Stringent complete response	Complete response as defined below plus • Normal free light-chain ratio • Absence of phenotypically aberrant plasma cells by multiparameter flow cytometry
Complete response	• Negative immunofixation on the serum and urine • Disappearance of any soft tissue plasmacytomas • <5% bone marrow plasma cells
Very good partial response	• Serum and urine M-protein detectable by immunofixation but not on electrophoresis OR • >90% reduction in serum M-protein plus reduction in 24-h urinary M-protein by >90% or to <100 mg/24 h
Partial response	• >50% reduction of serum M-protein and reduction in 24-h urinary M-protein by >90% or to <200 mg/24 h

Adapted from reference International Myeloma Working Group consensus criteria for response and minimal residual disease assessment in multiple myeloma: Diagnosis, Staging & Monitoring, IMWG Publications. <http://imwg.myeloma.org/international-myeloma-working-group-consensus-criteria-for-response-and-minimal-residual-disease-assessment-in-multiple-myeloma/>, 2016 (accessed 01.12.18).

TABLE 22.10 International Myeloma Working Group uniform response criteria: disease progression and relapse.

Relapse subcategory	Relapse criteria
Progressive disease	Requires at least one of the following • >25% increase in serum M-protein in 3 months (absolute increase must be >0.5 g/dL) • >25% increase in urine M-protein in 3 months (absolute increase must be >200 mg/24 h) • >25% increase in the difference between the involved and uninvolved free light-chain concentrations [applicable only to patients without measurable serum and urine M-protein (absolute increase must be >10.0 mg/dL)] • >25% increase in bone marrow plasma cell percentage (absolute percentage must be >10%) • Development of new bone lesions or soft tissue plasmacytoma • Development of hypercalcemia
Clinical relapse	Requires at least one of the following: • Development of new bone lesions or soft tissue plasmacytoma • Increase in size of existing plasmacytomas or bone lesions • Any of the following attributable to myeloma: Development of hypercalcemia Development of anemia (drop in Hemoglobin >2.0 g/dL) Rise in serum creatinine
Relapse from complete response	Requires at least one of the following • Reappearance of serum or urine M-protein by immunofixation or electrophoresis • Development of >5% plasma cells in the bone marrow • Appearance of any other sign of progression (e.g., new plasmacytoma and new lytic bone lesion)

Adapted from reference International Myeloma Working Group consensus criteria for response and minimal residual disease assessment in multiple myeloma: Diagnosis, Staging & Monitoring, IMWG Publications. <http://imwg.myeloma.org/international-myeloma-working-group-consensus-criteria-for-response-and-minimal-residual-disease-assessment-in-multiple-myeloma/>, 2016 (accessed 01.12.18).

Waldenström macroglobulinemia and immunoglobulin M multiple myeloma

IgM monoclonal gammopathies can present as several conditions including MGUS, smoldering Waldenström macroglobulinemia, and IgM MM. See Table 22.11 for criteria for their distinction [20]. Waldenström macroglobulinemia is the clinical expression of lymphoplasmacytic lymphoma, in contrast to the plasma cell proliferation in IgM MM that is associated with the secretion of high amounts of circulating monoclonal IgM protein. It is important to recognize that not all IgM

TABLE 22.11 Diagnostic laboratory focused criteria for Immunoglobulin M monoclonal gammopathies including smoldering Waldenström macroglobulinemia, Waldenström macroglobulinemia, and immunoglobulin M myeloma. For immunoglobulin M monoclonal gammopathy of unknown significance criteria, see Table 22.7

Smoldering Waldenström macroglobulinemia	Waldenström macroglobulinemia	IgM multiple myeloma
(Both criteria must be met)	**(All three criteria must be met)**	**(All three criteria must be met)**
• Serum IgM monoclonal protein ≥ 3 g/dL and/or bone marrow lymphoplasmacytic infiltration $\geq$ 10% • No evidence of anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly that can be attributed to the underlying lymphoproliferative disorder	• IgM monoclonal gammopathy (regardless of the size of the M-protein) • $\geq$10% bone marrow lymphoplasmacytic infiltration (usually intertrabecular) by small lymphocytes that exhibit plasmacytoid or plasma cell differentiation and a typical immunophenotype (e.g., surface IgM^+, $CD5^{+/-}$, $CD10^-$, $CD19^+$, $CD20^+$, and $CD23^-$) that satisfactorily excludes other lymphoproliferative disorders including chronic lymphocytic leukemia and mantle cell lymphoma • Evidence of anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly that can be attributed to the underlying lymphoproliferative disorder	• Symptomatic monoclonal plasma cell proliferative disorder characterized by a serum IgM monoclonal protein regardless of size • Presence of 10% plasma cells on bone marrow biopsy • Presence of lytic bone lesions related to the underlying plasma cell disorder and/or translocation *t*(11;14) on fluorescence in situ hybridization

IgM, Immunoglobulin M; *M-protein*, monoclonal protein.

Adapted from reference R.A. Kyle, "Benign" monoclonal gammopathy—after 20 to 35 years of follow-up,*Mayo Clin. Proc.* **68** (1993), 26–36..

monoclonal gammopathy is Waldenström marcroglobulinemia. In fact, the minority, only 15%, of IgM M-proteins are Waldenström macroglobulinemia, 55% are MGUS, and 25% are related to other lymphoproliferative disorders including chronic lymphocytic leukemia and other B-cell lymphomas. IgM MM only comprises 1%–2% of IgM monoclonal gammopathies.

The median age of onset for Waldenström macroglobulinemia is 63–68 years; clinical features include headache, dizziness, hepatomegaly, splenomegaly, anemia, and mental status changes; peripheral neuropathy occurs in approximately 5% of patients. Hyperviscosity, caused in large part by the high molecular weight of the IgM pentamer, is also a clinical feature and is related to the visual changes, retinal hemorrhage, and oral mucosal bleeding symptoms. Plasma viscosity must exceed fivefold that of water to produce symptoms, and values of ≥ 6 typically occur with plasma IgM concentrations >5 g/dL. Patients with plasma IgM concentrations of ≤ 4 g/dL are typically asymptomatic, so plasma viscosity measurements are not indicated. Waldenström macroglobulinemia differs from MM clinically in other important ways, including:

1. less bone pain and fewer lytic lesions;
2. fewer bacterial infections; and
3. greater incidence of serum hyperviscosity. Some textbooks state that virtually all patients have Bence Jones proteinuria. However, Fin et al. [7] reported that approximately 50% of patients excrete FLCs.

Cryoglobulinemia

Cryoglobulinemia is characterized by the presence of proteins that precipitate at temperatures cooler than normal body temperature (some at temperatures as high as 35°C). Cryoglobulins can be classified into three types.

1. Type I features an associated monoclonal protein (25% of all cases).
2. Type II mixes a monoclonal component and other proteins (25% of cases).
3. Type III is composed of mixed polyclonal proteins (50% of cases).

Patients with types II and III disease often have associated immune-complex disease.

Preanalytical factors are essential to detecting cryoproteins. Specimens from patients with suspected cyroglobulins must be maintained at 37°C throughout transportation to the laboratory and during specimen processing. If

temperatures are not appropriately maintained, cryoglobulins may precipitate out during the clotting process. After the sample clots, samples should be refrigerated at 4°C for 72 hours before assessing the presence of cryoprotein. Upon finding a cryoglobulin, the protein should be redissolved in saline warmed to 37°C, and then studied by, for example, electrophoresis and IFE for confirmation and characterization.

Serum from hepatitis C patients frequently demonstrates a type II cryoglobulinemia, which is typically IgM directed against polyclonal IgG. Hepatitis C may produce glomerulonephritis, leading to a combination of serum monoclonal proteins and renal failure that is not a consequence of light-chain deposition, light-chain casts, or amyloid.

Amyloidosis

AL amyloidosis, or "primary amyloidosis," is characterized clinically by peripheral neuropathy, carpal tunnel syndrome, congestive heart failure, nephrotic syndrome, enlargement of the tongue, and malabsorption. Most AL amyloidosis cases do not have evidence of plasma cell myeloma or lymphoma. However, most of these patients have a subtle B-cell disorder in which the cells produce the amyloidogenic light chains that are characteristic of the disease. The amyloid material consists of unbranched fibrils having a diameter of approximately 10 nm; 95% of the fibril proteins consist of λ light chains and 5% amyloid P-protein, arranged in a β-pleated sheet structure. The fibrils demonstrate distinctive staining with Congo red, which are salmon pink in color and show green birefringence under polarizing light. The amyloid material is deposited in blood vessels and also in the thin membranous mesangium of the kidney in a nodular or diffuse pattern.

Nonimmune forms of amyloidosis may be systemic and involve multiple organs. Unlike AL amyloidosis, some forms of true amyloid neither contain immunoglobulin components nor are associated with a monoclonal gammopathy. Therefore some patients with MGUS may also have an amyloid component that is coincidental and not causally related. Amyloid A (AA) amyloidosis, also termed "secondary AA amyloidosis," is a nonimmune form that is associated with chronic infection or inflammatory diseases such as rheumatoid arthritis, osteomyelitis, or granulomatous ileitis. Amyloid deposition in various tissues including the kidney results from the production of the amyloidogenic acute-phase protein serum AA during chronic inflammation. Appropriate treatment of the underlying chronic infection or inflammatory disease can slow down or even halt the progression. There are also familial forms of amyloidosis in which mutations of plasma proteins (e.g., TTR) are deposited in tissues. More than 50 different mutations in TTR are known in connection with this type of amyloidosis. Rarely, mutations also occur with other proteins including apolipoprotein Al, gelsolin, fibrinogen, and lysozyme and can cause familial amyloidosis.

Light-chain deposition disease

LCDD is associated with renal insufficiency and proteinuria or the nephrotic syndrome. This condition occurs when there is deposition of immunoglobulin light chains (typical ratio: $\kappa > \lambda$; 9:1) in the kidney along the tubular basement membrane of the distal tubules and loops of Henle. The thickened basement membrane shows characteristic diffuse immunofluoresence staining for λ and/or κ light chains. A large proportion (35%–40%) of LCDD patients meet criteria for MM. Microscopy on renal biopsy typically shows glomerular lesions that are described as nodular glomerulosclerosis with strongly periodic acid—Schiff-positive mesangial nodules; these lesions are similar to those observed in diabetic nodular glomerulosclerosis. Although LCDD is similar in some respects to amyloid, there is no "P" component, no staining with Congo red, and polarization shows no effect.

LCDD is a subset of conditions termed "monoclonal immunoglobulin deposition disease" that includes immunoglobulin light- and heavy-chain deposition disease (LHCDD) and heavy-chain deposition disease (HCDD). LHCDD mainly involves deposition of IgG-κ and IgG-λ components, whereas HCDD involves deposition of the γ heavy chain and no light-chain component.

Multiple sclerosis and cerebrospinal fluid electrophoresis

MS is a demyelinating disease that typically affects the brain, optic nerve, and spinal cord. Although advances in radiologic technology, such as MRI, have become increasingly important for diagnosis, 90%–95% of MS patients show oligoclonal banding on CSF agarose electrophoresis and IFE (Fig. 22.9). Oligoclonal banding is useful for diagnosis after other causes of banding such as CNS syphilis, chronic meningitis, and subacute sclerosing panencephalitis are excluded. The Q albumin is typically not increased in MS patients, because the disease does not often show increased permeability of the blood–CSF barrier. IgG index studies are less sensitive but are also considered useful for diagnosis and monitoring.

Because monoclonal proteins in serum may traverse the blood–CSF barrier and produce banding in CSF, performing electrophoresis on concomitant serum and CSF is important to avoid false-positives. IFE with IgG antisera allows more sensitive detection of oligoclonal banding. In addition to the conditions listed above, Guillain–Barré

syndrome, SLE, and bacterial meningitis may show bands in the CSF. Measurement of CSF FLC in the future may serve as an alternative to the labor-intensive IEF used for oligoclonal banding [21].

Summary

The analysis of proteins remains a critical component to laboratory medicine. Serum from patients being assessed for suspected MM and other cancers described herein is initially screened by SPEP or CZE. The interpretation of the initial SPEP or CZE pattern may lead to more sensitive diagnostic procedures such as IFE and serum FLCs. It is important that laboratorians understand the basic protein electrophoresis patterns and know the various exogenous and endogenous interferences that may affect patient's results. The introduction of m-tAb has also contributed to the overall success in the treatment and survival of these patients but presents unique challenges to the clinical laboratory. Current and future laboratorians will need to engage clinical partnerships in other areas of medicine to manage these new obstacles.

Self-assessment questions

1. Prealbumin is which of the following?
   a. A protein rich in nonessential amino acids
   b. A protein that migrates closer to the cathode than ALB
   c. The precursor protein for ALB
   d. The same protein as TTR
   e. The major plasma binding protein for copper
2. Which of the following proteins is a protease inhibitor?
   a. C-reactive protein
   b. A1AT
   c. Transferrin
   d. Haptoglobin
   e. Fibrinogen
3. A band is visualized in the γ on SPEP. However, on IFE, no band that reacts with IgG, IgA, IgM, or κ or λ antisera is identified. Which of the following is a possible cause?
   a. The band is possibly IgD.
   b. The specimen may be heparinized plasma, so the band could be fibrinogen.
   c. The band could be transferrin.
   d. a–c are possible
4. Which of the following is a difference between nephelometry and turbidimetry measurements?
   a. The immunoprecipitin curve is not relevant to nephelometry measurements, whereas turbidimetry depends on this curve.
   b. Turbidimetry is based on Rayleigh scattering, whereas nephelometry is not.
   c. Detection of nephelometry signals is typically made at a 30% offset angle from the incident light source, whereas turbidimetry is at a 180-degree angle.
   d. Turbidimetry is more difficult to adapt to spectrophotometric equipment compared with nephelometry.
   e. All of the above are differences between nephelometry and turbidimetry.
5. Which is a calculation that can be used for assessing the integrity of the blood–CSF barrier?
   a. IgG index
   b. Globulin calculation
   c. Q albumin
   d. TIBC
   e. IgG synthesis rate
6. Which of the following is a correct difference between Waldenström macroglobulinemia and multiple myeloma?
   a. More visual disturbances occur with Waldenström macroglobulinemia.
   b. More bone pain and more lytic lesions occur with Waldenström macroglobulinemia.
   c. A greater incidence of serum hyperviscosity occurs with Waldenström macroglobulinemia.
   d. a and c are correct differences between Waldenström macroglobulinemia and multiple myeloma.
   e. a–c are correct differences between Waldenström macroglobulinemia and multiple myeloma.
7. Which of the following is a diagnostic criterion for asymptomatic (smoldering) myeloma?
   a. $<10\%$ plasma cells in bone marrow aspirate
   b. No evidence of lytic bone lesions
   c. No reduction in uninvolved serum immunoglobulins
   d. No light chains excreted in urine
8. Which of the following is correct about amyloidosis?
   a. The majority of AL amyloidosis cases do not have evidence of plasma cell myeloma or lymphoma.
   b. Immunoglobulin components are a characteristic of all forms of amyloidosis.
   c. The fibrils in AL amyloidosis demonstrate distinctive staining with Congo red that is salmon pink in color, but no color is observed under polarizing light.
   d. AA amyloidosis is also termed "primary amyloidosis."
   e. Serum AA deposition is the principle cause of renal injury in AL amyloidosis patients.
9. Which of the following is a negative acute-phase protein?
   a. A1AT
   b. Haptoglobin
   c. Ceruloplasmin
   d. Orosomucoid
   e. None of the above

10. Measurement of FLC is an addition to laboratory medicine that aids in the evaluation and management of multiple myeloma and related clonal plasma cell disorders. Which of the following makes FLC assay different from and advantageous over the electrophoretic assays?
    a. FLC assay identifies the light-chain type of the monoclonal protein more effectively than electrophoresis.
    b. FLC assay can be used for screening, prognosis, monitoring for recurrence, and monitoring therapeutic response, all more effectively than electrophoresis.
    c. FLC assay can be used in the quantitative monitoring of nearly two-thirds of patients who had previously been deemed to have nonsecretory myeloma.
    d. FLC assay negates the need of immunofixation study on urine specimen.
    e. All of the above.
11. Which of the following medications may appear on conventional agarose SPEP?
    a. Sulfamethoxazole
    b. 5-Fluorocytosine
    c. Piperacillin
    d. Siltuximab
    e. Hydroxycobalamin
12. Which of the following type of cyroglobulins may be seen in serum of patients with Hepatitis C?
    a. Type I
    b. Type II
    c. Type III
    d. Type IV
    e. Type V

Chapter 23

The complement system

Maria Alice V. Willrich

Department of Laboratory Medicine and Pathology, Division of Clinical Biochemistry and Immunology, Mayo Clinic, Rochester, MN, United States

Learning objectives

1. Define the different pathways for activation of the complement cascades.
2. Differentiate the assays used for assessment of complement function and quantitation, as well as assays used for the measurement of autoantibodies and activation fragments of complement.
3. Apply the various test combinations for aiding in diagnosis of complement disorders or monitoring complement consumption.
4. Classify the disorders associated with complement abnormalities as acquired or genetic in terms of underlying pathology.
5. Propose tests utilization approaches for the various complement disorders.

Introduction

The complement system is part of our innate immune response and consists of a number of precursor cell-bound or soluble proteins. To date, over 50 circulating proteins, enzymes, proenzymes, cofactors, and control proteins have been described, with an additional 15 cell-associated proteins involved in signaling, clearance, and phagocytosis. The complement system was discovered in 1891 and named alexin. In 1899 it was renamed complement, given its role in complementing the functions of the cellular immune system and antibodies. The complement system is responsible for infection and inflammation control by directly killing bacterial pathogens via cell lysis, or tagging infected cells or pathogens with opsonins for downstream removal by phagocytes. Anaphylatoxins released with complement activation will promote inflammation and increase vascular permeability for innate immune cell passage. In addition, immune complex clearance and tagging of cell debris and DNA fragments are some of the complement system's main housekeeping roles.

With the advent of eculizumab, a complement inhibitor that targets component C5, proper complement testing for diagnoses, and therapeutic monitoring are warranted. Outside the study of rare immunodeficiencies, which may have genetic and acquired causes, the complement system has been recognized to be involved in many conditions beyond infection. Complement testing should be considered when there is suspicion of primary immunodeficiencies presenting in the form of angioedema or recurrent pyogenic infections, or family history of complement deficiencies. Autoimmune diseases such as systemic lupus erythematosus (SLE), a disease in which increased amounts of immune complexes are generated, are often associated with hypocomplementemia. Thus testing patients throughout the SLE disease course is common. Testing is also indicated when there is tissue injury that can potentially be mediated by the complement system, such as graft rejection, organ damage observed in kidney glomerulopathies, or intravascular and extravascular hemolysis present in conditions such as hemolytic uremic syndrome (HUS) or paroxysmal nocturnal hemoglobinuria (PNH). However, with so many circulating and cell-associated proteins, understanding which tests are important is challenging and requires further understanding of the complement system to optimize test utilization and interpretation.

Overview of the complement system

In physiological conditions, complement is the first line of defense and surveillance of the immune system. Complement provides a mechanism for continuous immune surveillance through a network of soluble and bound proteins that work together to achieve molecular pattern-based immune recognition, thereby triggering a complement response when microbial pathogens, foreign antigens, or danger-associated molecular patterns (DAMPs) are recognized. The complement system circulates pattern-recognizing molecules (PRMs), including C1q, mannose-binding lectin (MBL), ficolins, and properdin, which are able to recognize pathogen-associated molecular patterns (PAMPs) or DAMPs for autoactivation and initiation of a serine protease cascade. This cascade,

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00023-5

also known as the complement cascade, results in opsonization and potential lysis of the target microbe [1–4].

Complement components are secreted primarily by the liver. Exceptions are C1q (secreted by brain microglia, immature dendritic cells, monocytes, and macrophages), C7 (monocytes, macrophages, endothelial cells, fibroblasts, and central nervous system cells), properdin (mainly produced by neutrophils), and factor D (FD, synthesized by adipocytes). There are three main pathways for complement activation, and these are the classical pathway (CP), the lectin pathway (LP), and the alternative pathway (AP) (Fig. 23.1). The CP is activated by an antigen–antibody immune complex or C-reactive protein (CRP), whereas the LP is activated directly by PAMPs such as mannose-containing bacterial surfaces. The AP is constitutively active at low levels and can be activated by spontaneous hydrolysis of C3 when a potential threat is detected. All three pathways are unique in the types of PRMs that activate the complement cascade; however, all lead to formation of an amplification loop mediated by enzymatic complexes called convertases. The C3 convertase is able to initiate opsonization of complement targets. Opsonization is the process of tagging molecules for removal or phagocytosis with antibodies (e.g., IgG) or complement fragments. Opsonization more commonly involves the C3b fragment, which is generated after C3 convertase-mediated C3 cleavage. Activated C3 convertase subsequently favors formation of a C5 convertase that will initiate cell lysis via formation of a membrane attack complex (MAC). The anaphylatoxins C3a and C5a have potent inflammatory effects and promote chemotaxis. They are released after C3 and C5 cleavage, respectively. Complement activation is controlled by a set of membrane-bound and fluid phase regulators to prevent overactivation.

The three complement activation pathway cascades are described in detail in the next sections.

The classical pathway

The complement CP is activated through the PRM C1q [5]. Endogenous C1q activators include IgM and IgG immune complexes, surface-bound pentraxins (such as CRP), β-amyloids fibrils, and tissue-damaged elements from apoptotic cells [6–8]. Exogenous C1q activators consist mostly of molecular patterns on pathogen surfaces such as bacterial porins [2]. C1q binds to two C1r and two C1s serine proteases to form a $C1qC1r_2s_2$ pentamer. The C1 complex in circulation is able to recognize PAMP or DAMP activators through C1q. When the target is bound to C1q, it initiates a conformational change in the complex, allowing C1r to autocleave in order to self-activate and, in turn, activate C1s (Fig. 23.2). Activated C1s subsequently cleaves C4 to generate C4a (released to circulation) and C4b (opsonizing) fragments. C4 cleavage by surface-bound C1 complex will result in activators being tagged with C4b. The surface-bound C4b recruits C2, which is cleaved by the C1 complex to release a C2b fragment (to circulation) and a C2a serine protease fragment; the latter remains associated with C4b.

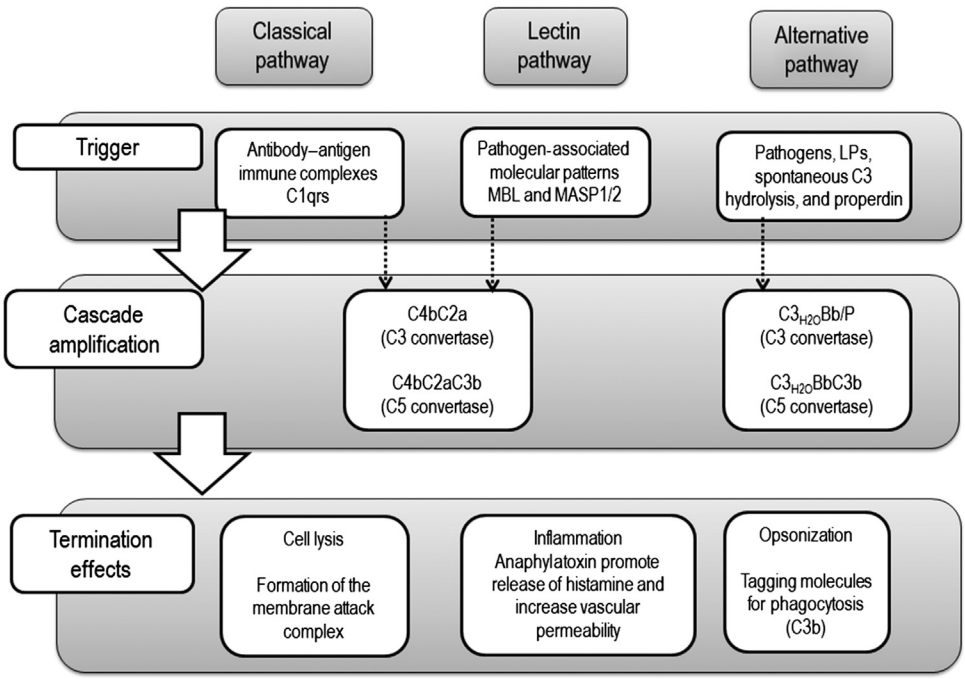

FIGURE 23.1 Overview of complement system. The complement pathways have unique pattern-recognizing molecules that recognize the different threats and trigger the cascade activation. All pathways converge to the formation of potent convertase complexes that target C3 and C5. The complement cascades effects include opsonization, inflammatory responses, and cell lysis via formation of the MAC.

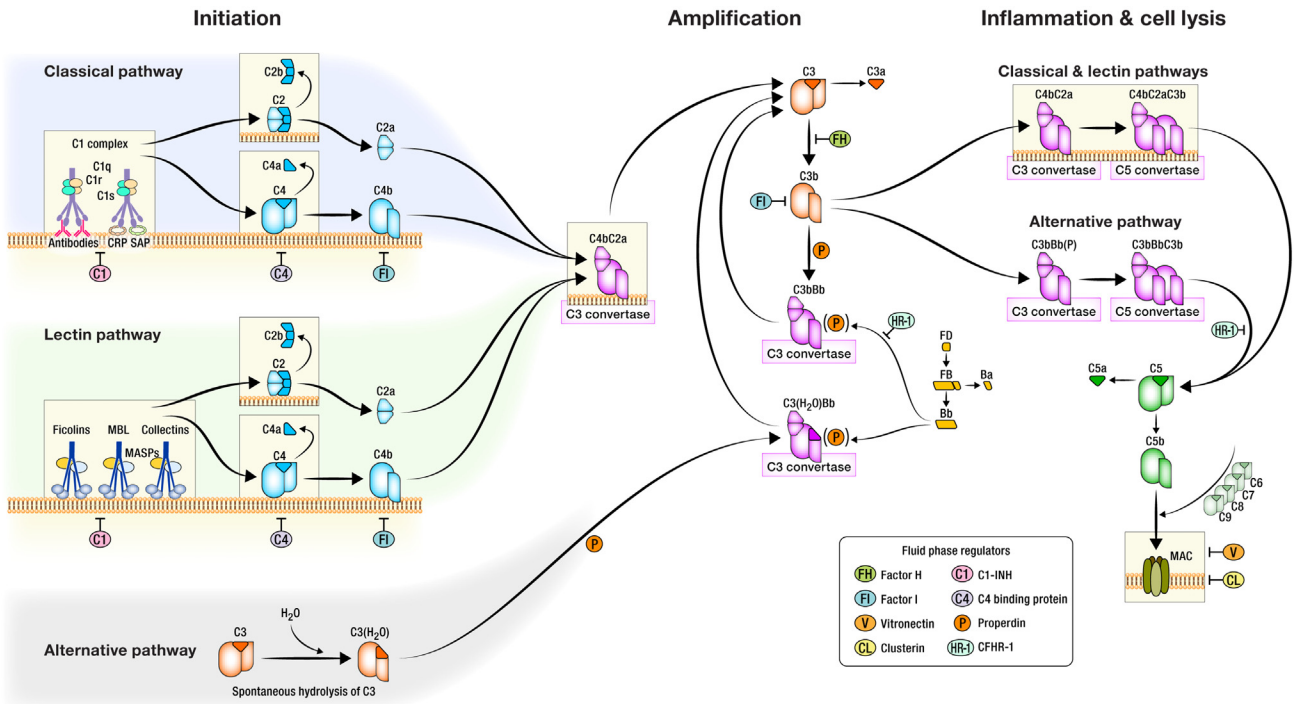

FIGURE 23.2 The complement cascades. Complement initiation, amplification, regulation, and formation of the terminal complement complex. *Initiation, top*: Classical pathway initiation via C1q and the C1 complex to form the C3 convertase (C4bC2a). *Initiation, middle*: Lectin pathway initiation via ficolins, mannose-binding lectin, and collectins to form the C3 convertase (C4bC2a). The roles of C1 inhibitor, C4BP, and factor I in regulating classical pathway and lectin pathway initiation are highlighted. *Initiation, bottom*: Alternative pathway initiation via the "tick-over" mechanism (spontaneous hydrolysis of C3) to form the alternative pathway C3 convertase $C3_{H2O}Bb$. *Amplification*: The amplification loop shows the role of properdin in complement initiation and amplification. The roles of factor I, factor H, and CFHR1 (HR-1) in regulation of complement amplification are highlighted along with the role of factor D and factor B in complement cascade amplification. *Inflammation and cell lysis*: The role of the amplification loop in generating the C5 convertases is shown along with the C5 convertase formation of the terminal complement complex. *Adapted from A. Frazer-Abel, L. Sepiashvili, M.M. Mbughuni, M.A. Willrich, Overview of laboratory testing and clinical presentations of complement deficiencies and dysregulation. Adv. Clin. Chem. 77 (2016) 1–75 [9] with permission of the Mayo Clinic Foundation, retainer of the copyrights for publication.*

The formation of the surface-bound C4bC2a protease complex is also known as C3 convertase. The C3 convertase plays a central role in complement signal cascade amplification and activation of the terminal pathway (TP). First, it cleaves C3 into C3a and C3b. C3a is an anaphylatoxin, and its generation starts a series of proinflammatory events. Similar to C4b, C3b is an opsonin, a molecule that tags complement targets for opsonization, facilitating phagocytosis and removal. It also acts as a surface for complement cascade amplification through factor B (FB) and FD from the AP (Fig. 23.2). Since all three complement activation pathways converge by assembling a C3 convertase, which has a high affinity for C3, C3b serves as the major opsonizing agent of the complement system.

The lectin pathway

Collectins and ficolins are the PRMs that activate the LP. They recognize membrane glycoprotein and acetylated glycolipid patterns on pathogen membrane surfaces. Once bound to activating surfaces, collectins (MBL or collectin LK) or ficolins recruit mainly MBL-associated serine protease 1 (MASP1) and MBL-associated serine protease 2 (MASP2), which are proteases structurally similar to the C1r and C1s enzymes from the CP. MASP1 binding to target surfaces results in autoactivation and subsequent activation of MASP2, which in turn will trigger cleavage of C4 and C2 to yield C4a, C4b, C2a, and C2b fragments. As in the CP, C2b and C4a fragments are released into circulation; whereas the C4b opsonin is capable of recruiting C2a to form a surface-bound LP C3 convertase identical to the CP C3 convertase, but containing C4bC2a [4].

The alternative pathway

The AP is the dominant complement surveillance method using a tick-over mechanism for complement activation, where spontaneous hydrolysis of a buried thioester bond in C3 releases a $C3_{H2O}$ fragment. This fragment has C3b-like properties. $C3_{H2O}$ binds to FB to form a proconvertase complex, $C3_{H2O}FB$ (Fig. 23.2). FB in the proconvertase complex is then cleaved by FD to release an

inactive Ba fragment and a Bb serine protease fragment, which associates with $C3_{H2O}$ to yield a soluble AP C3 convertase, $C3_{H2O}Bb$. The soluble C3 convertase is similar to the CP or LP C3 convertases in that it also cleaves C3 to generate a C3b fragment, but in this case, the fluid phase convertase makes a C3b fragment that must diffuse in search of complement-activating PAMP or DAMP targets or any reactive or unprotected surface. C3b generated from CP and LP C3 convertases is also able to recruit FB and FD to form the AP surface-bound C3 convertase (C3bBb), facilitating cross talk of CP, LP, and AP during complement cascade amplification.

In the AP, the PRM properdin is the only positive regulator of complement and has the capability to adhere C3bBb onto activating cell surfaces, forming a C3bBbP convertase (Fig. 23.2). Properdin can also bind to soluble C3b, $C3_{H2O}$, $C3_{H2O}Bb$, and C3bBbP, thereby substantially increasing their liquid phase stability and the likelihood of reacting with a nearby surface where assembly of a C3 convertase can occur. Target-bound properdin can recruit circulating C3b, $C3_{H2O}$, $C3_{H2O}Bb$, or C3bBb components to surfaces where these AP cascade proteases are stabilized. In the end, the AP omits components C1, C2, and C4, and is thought to be the dominant mechanism for complement amplification through C3, FB, FD, and properdin. Due to its ability to act as an amplification loop, the AP is often credited with nearly 80%−90% of total complement activation through FB and FD, even when the initial signal comes from C3b fragments produced by a C3 convertase from the CP or the LP.

The terminal pathway

Once the complement system is activated and C3 convertase is abundant, the TP is activated when C3b is high enough that CP, LP, or AP C3 convertases are able to bind additional C3b fragments, shifting the substrate specificity of the convertases from the C3 to the C5 component. In principle, excess C3b converts C3 convertases to C5 convertases [1]. C5 convertases then cleave C5 to yield C5a and the C5b fragments. C5a is the most potent anaphylatoxin generated by the complement system. C5b associates with C6 and C7, forming a soluble or surface-bound C5b-7 complex able to bind C8 and multiple C9 proteins to yield a soluble or surface-bound MAC (Fig. 23.2). The MAC in circulation is also known as the terminal complement complex, and can be held in the soluble form by the binding of vitronectin or clusterin yielding sC5b-9, and controlling the lytic properties of the MAC.

Complement regulation

With such a powerful system directed to lysis and opsonization, it is important that complement also has mechanisms for host cell protection. Complement regulation occurs through a number of soluble and membrane-bound proteins able to suppress complement activation at multiple checkpoints. Key molecules involved in complement regulation include C1 inhibitor (C1-INH), factor H (FH), complement factor H-like protein 1 (FHL-1), factor I (FI), factor H-related proteins (CFHRs), C4-binding protein (C4BP), CD46 [membrane cofactor protein (MCP)], CD55 or decay-accelerating factor, and carboxypeptidase-N.

Nonspecific CP and LP activation is prevented by the acute phase reactant C1-INH, which performs direct inhibition of the C1r/C1s or MASP1/MASP2 proteases in the CP or LP, respectively, to cause irreversible inactivation of these serine proteases in the absence of appropriate PRMs for complement activation with covalent binding and subsequent removal from circulation. When C1r/C1s and MASP1/MASP2 proteases are activated, regulatory checkpoints then shift to regulation of C3 and C5 convertase activities. At this point, key complement regulators include FH, FI, C4BP, CD55, and CD46 (Fig. 23.2). FI regulates all C3 and C5 convertases from all pathways through proteolytic inactivation of C3b and C4b, where FI is the direct inactivating enzyme. FI has a number of cofactors that direct its action. CD55 is a cell-bound regulator that facilitates accelerated decay of complement convertases through competitive binding of C3b and C4b. More tailored regulation of CP and LP convertases also occurs through C4BP (Fig. 23.2), with the ability to speed decay of CP/LP C3 convertase by binding to C4b to cause displacement of C2a or by acting as a cofactor for FI to aid in C4b proteolytic inactivation.

FI and FH are essential inhibitors of the AP C3 and C5 convertases, which also occur in order to keep in-check complement activation through the tick-over mechanism.

FH is a humoral complement regulator that plays an important role in distinguishing self from nonself. By binding to host cell surface glycans such as glycosaminoglycans (GAGs), FH localizes onto self surfaces where it protects host cells from complement by inhibition of AP C3 and C5 convertases. FH inhibits AP C3 and C5 convertase by acting as a cofactor for FI and also through competitive binding to C3b and FB in order to accelerate AP convertase decay. FH has high homology with many related proteins with similar or antagonistic roles in complement regulation. FHL-1 is an alternatively spliced version of FH where the C-terminus is truncated. Like FH, FHL-1 also recognizes self-specific molecular patterns, with a decay-accelerating activity for convertases and a cofactor role for FI to suppress complement activation on host surfaces. Complement factor H-related (CFHR) proteins 1 through 5 are proteins encoded by separate genes with some homology to FH. These proteins have the

ability to bind C3b and distinguish between self and nonself surfaces. The role of CFHR proteins in complement regulation is poorly understood and ranges from complement activation through competition with FH binding on host cell surfaces to complement regulation through inhibition of C3 and C5 convertases. CFHR-1 can bind to C3b in the C5 convertase and inhibit C5 cleavage, thereby inhibiting MAC formation. CFHR-1 also inhibits C3 convertase by inhibiting Bb binding to C3b.

Finally, carboxypeptidase-N is a protease able to cleave and inactivate the complement anaphylatoxin peptides C3a and C5a. While removal of the terminal desArg from C3a by carboxypeptidase-N eliminates the anaphylatoxin activity of C3a, C5a retains some of its activity after cleavage [10]. CD59 is glycophosphatidylinositol (GPI)-anchored protein expressed by host cells and functions to inhibit formation of the MAC on host cell surfaces [11]. Another important complement regulator is vitronectin, which regulates MAC formation by binding to C7.

Assays in the clinical laboratory

Serologic complement assays

Measurement of the complement system proteins in serum or plasma can be divided into four main categories:

1. measurement of complement function or lytic activity,
2. quantitation of complement components,
3. detection of autoantibodies against complement components, and
4. quantitation of activation fragments or split products.

CH50 and AH50 are the most common functional assays to measure CP and AP functions, respectively. LP function assays are also available, although not as common in the clinical setting as the assays for CP and AP given the more limited clinical utility. These assays are performed in serum samples and require the complement cascade to be activated in vitro; the reactions progress until the formation of a measurable MAC occurs. In a few assay formats, antibodies targeting the neoepitope of C5b-9 are used, while in others, the lytic effect of MAC is measured. Reports are usually in % activity or arbitrary units.

For quantitation of complement components, there are a number of automated and manual methods available, which measure the amount of antigen in the sample, most commonly reported in mass units such as milligrams per milliliter or micrograms per deciliter. Detection of autoantibodies to complement components will aid in differentiating genetic from acquired conditions. Finally, the quantification of activation products gives an estimation of the activation state of the pathways and determines if a complement protein is reduced due to either increased consumption or decreased synthesis. The complement cascades are dependent on calcium and hence using citrate or EDTA as chelating agents prevents in vitro complement activation. Serum is the required specimen when functional assays are carried out, and plasma samples are recommended when studying the activation fragment concentrations.

Preanalytical considerations

As the heat labile fraction of the immune system, complement activation in vitro has been the main challenge to overcome by researchers and scientists. Complement components of the CP are activated by immunoglobulins or immune complexes, and the AP can be activated by spontaneous hydrolysis of C3. Even the clotting process has been known to activate complement cascades; therefore, for activation fragment assays, plasma is the preferred sample source. Both degradation by temperature and consumption of complement components after in vitro activation will lead to falsely low function measurements and falsely high concentrations of activation fragments, respectively, thereby complicating the assessment of complement dysregulation. While preanalytic handling can lead to falsely abnormal results, it is far less likely that such issues could lead to falsely normal results.

If more than one component is measured as low, it is important to look for poor sample handling, use of IV catheters or other underlying disease states that could be causing chronic complement activation. A possible complement autoantibody, deficiency in a control protein, malnutrition, protein-wasting states, or age (newborn state) may also contribute to abnormal results. An additional consideration is that complement assays may be ordered by physicians in several conditions where standard treatment includes plasmapheresis or plasma exchange. The procedure itself, if traumatic, may activate complement, and the results will not necessarily reflect what is going on with the patient's complement system. Thus it is recommended to collect blood prior to plasma exchange whenever possible. Abnormal complement functional tests or low complement concentrations inconsistent with the clinical history should be verified with a new blood draw. It is recommended to freeze specimens immediately postcollection. Long-term stability is optimal when the sample is kept at $-70^{\circ}C$ prior to testing [12].

Postanalytical challenges

In addition to the preanalytical challenges associated with complement lability, proficiency testing is another area that suffers from complement poor stability. Most analytes are not regulated by proficiency testing agencies, such as the College of American Pathologists or the Food and Drug Administration (FDA), and a range of assays

are available as laboratory developed tests. Commercial proficiency testing is primarily available only for the major laboratory tests CH50, C3, and C4. Thus alternative assessment of performance with split blind samples is a common practice to address the lack of commercial proficiency testing. However, this approach has contributed to the lack of standardization or harmonization in reporting practices. To address this, the International Complement Society (www.complement.org), under the International Union or Immunological Societies, has sponsored a proficiency testing program under INSTAND (Society for Promoting Quality Assurance in Medical Laboratories e. V.). Since many assays are neither standardized nor harmonized, which means the reference intervals and performance between methods are often not interchangeable across laboratories, the assays are evaluated on a qualitative or semiquantitative scale for agreement and consensus. Ideally, individuals who require serial testing should be monitored within the same laboratory, and when crossing healthcare institutions, the comparison of test results should be minimal or reviewed in the qualitative or semiquantitative scale, with understanding of the differences between methodologies and reference intervals.

Given the complexity of testing and relationship to so many different clinical diseases, several tests are needed for a comprehensive overview of complement function. A panel approach is usually required to isolate a complement disorder within the CP, LP, or AP. Examples of such panels can be found from a number of clinical laboratories that specialize in complement or specific complement-related diseases.

Methods for analysis of complement function or activity

The study of complement system function may be performed using manual radial immunodiffusion (RID) hemolytic assays, or using automated methods such as liposomal lysis and ELISAs. Hemolytic functional assays are based on the ability of complement to induce red blood cell (RBC) lysis after formation of an MAC; these assays shape the initial approach to complement testing.

RID is a simple and versatile method, without the need for sophisticated instrumentation, and requires a small sample volume for testing. RID employs an agarose gel containing antiserum to a given complement component, when the goal is to assess complement component concentrations. Alternatively, RID agarose gels may contain heterologous RBCs from sheep, rabbit, or chicken for functional hemolytic assays. For both forms of the assay, wells are punched onto the gel, and samples are applied and allowed to diffuse passively for a given amount of time, usually in the scale of 12−36 hours. On an RBC agarose gel, hemolysis will be observed around the samples' wells. The diameter around the well is proportional to complement function. RID may be affected by variations in temperature, humidity, and incubation time. The manual nature of the technique makes it labor intensive, and incubation periods range from hours to days.

For CH50 functional testing, sheep RBCs are coated with antirabbit IgM antibodies, with or without IgG. The animal RBCs coated with IgM will trigger the activation of the CP. The dilution of patient's serum needed to lyse 50% of RBCs is then determined, hence the origin of the test name. The assay requires the presence and functionality of all proteins of the CP and TP. Deficiency in C1 or C2−C8 will result in no-to-little lysis of RBCs, with observed hemolysis of less than 5%. C9-deficient patients may have residual CH50 function, with less than 30% of RBCs hemolyzed. A low CH50 result may occur due to congenital complement deficiencies, increased consumption of complement components evidenced by infection or acute flares in autoimmune diseases, such as SLE, with abundant immune-complex formation, or insufficient synthesis of complement components (e.g., hepatic diseases). In the AP function assay, or AH50, a buffer is used to block the activation of the CP and LP (Mg EGTA is used to chelate calcium, necessary for the activity of CP and LP, but not AP). Rabbit or guinea pig RBCs are then used to spontaneously activate the AP. The assay requires all components in the AP and the TP. Patients with defects in the regulatory proteins FH, FI, or in the components FB and FD have a constitutively active AP, resulting in consumption of the early components of the pathway. When laboratory testing is performed during the acute phase of the disease, AH50 activity is often low. Little or no lysis is observed for deficiencies of C3−C9, FD, and FB.

As a second line of testing, the functionality of individual complement components may be tested by mixing a patient's serum with complement-depleted serum using similar approaches as CH50 and AH50 assays. If CH50 is decreased and AH50 is within reference intervals, a physician may try to identify the CP-deficient component: C1, C2, or C4, and specific functional tests may be ordered for each component. If hemolysis occurs after mixing a patient's serum with complement C2-depleted serum, for instance, it becomes evident that the C2 is present in the patient's serum and functional. If, on the other hand, the mixing study did not *complement* the deficient serum and there is still little or no hemolysis, this is evidence that the C2 is missing or nonfunctional in the specimen of interest.

ELISAs may be designed as functional assays that measure neoepitopes generated after complement activation. Fig. 23.3 shows conventional ELISA methods for measurement of the activity within the CP, LP, and AP. Three ELISA systems are illustrated. For the CP, IgM is

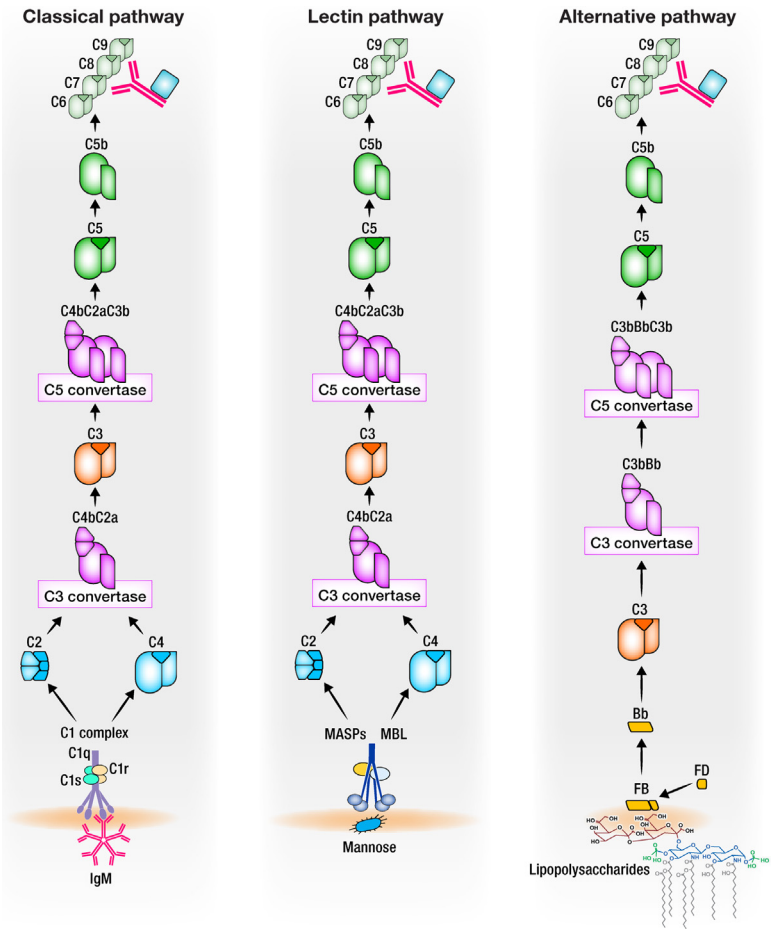

FIGURE 23.3 ELISA assays are available to measure function of classical, lectin, and alternative pathways of complement as described in [13].

coated on the solid-support ELISA plate. For the LP, mannan is on the plate, and, for the AP, lipopolysaccharides are from Gram-negative bacteria. The CP and LP assays use diluted sera 1:101, while the AP assay uses a 1:18 dilution. The LP function assay also uses antibodies to C1q to block the CP, and AP is minimized using the higher dilution schemes. These characteristics make the assays pathway-specific. In all of the tests, the complement system in a patient's serum will be activated, the respective cascades amplified to create C3 and C5 convertases, and ultimately the MAC. The conjugate antibody is common for all assays, and it targets neoepitopes generated after the formation of the MAC (alkaline phosphatase conjugated antihuman C5b-9) [13].

Another automated method for complement function analysis is the liposome enzymatic assay. Briefly, a liposome containing glucose-6-phosphate (G6P) and a hapten on its surface are used as the first reagent. A second IgM-containing reagent, which targets the hapten on the surface of the liposome, creates an artificial immune-complex. In the presence of patient sera, which are added after the formation of the aforementioned complex, the CP should be triggered when in contact with the immune-complex created by the reagents. The CP progresses up to the creation of the MAC, which is anchored on the surface of the liposome, creating holes in it. G6P is exposed after the liposome is lysed by the MAC, and an enzymatic reaction using nicotinamide adenine dinucleotide can be measured on several automated platforms, with absorbance measured at 340 nm (Fig. 23.4). This assay is FDA-approved for measurement of CP activity.

Complement component concentrations

Complement component concentrations are the second most common complement assessment after CH50 and AH50. Low complement can signal consumption and clearance of immune-complexes or inflammation, as seen in flares of autoimmune disease activity. C3 and C4 are routinely measured in most laboratories using nephelometric or turbidimetric approaches. Both nephelometric and turbidimetric measurements utilize the formation of antibody–antigen immune-complexes to determine protein concentrations. When the antigen to be measured, such as C1-INH, C3, C4, and C5, FB and FH are in equilibrium with the antibodies to the complement

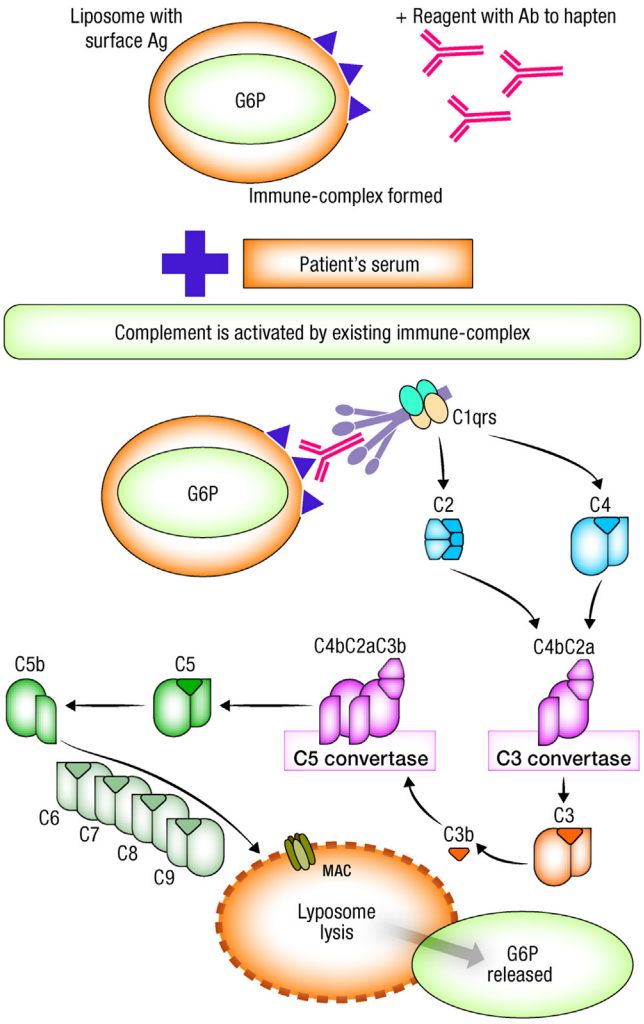

FIGURE 23.4 Illustration of complement functional assay to measure the activity of the classical pathway using a liposome colorimetric method. Reproduced with permission of the Mayo Clinic Foundation, retainer of the copyrights for publication.

component, immune-complexes are formed that can then be measured using light scattering approaches. Nephelometric methods quantitate an analyte based on the light scatter from immune-complexes at an angle, while turbidimetry allows for antigen quantitation based on changes in the transmission of light with an in-line detector. The outputs of both methods are directly proportional to concentrations of the complement component of interest.

It should be mentioned that particles, solvent, and macromolecules all scatter light and affect light transmission, which means lipoproteins and chylomicrons are problematic interfering substances for both nephelometry and turbidimetry. Lipemic samples can generate signal above the background despite lack of antigens of interest, and therefore cannot be tested. It is not common practice to ultracentrifuge specimens to remove lipemia because of the poor stability of the samples and potential risk of complement activation. Issues confounding the measurement of many complement components in serum are that the antibodies used by most diagnostic laboratories react with the parent, intact molecules, as well as many of their cleavage, activation fragments. This is common for C3, FB, and C4. C4 is also an acute phase reactant, and can double concentrations within 24 hours after trauma or acute inflammation. Therefore it should be kept in mind that the measurement returned by such methods will not distinguish if the component was cleaved in the patient, or not. For such questions, functional tests and analysis of the specific split products are indicated.

Manual methods for measuring complement component concentrations, such as RID, are still considered relevant, particularly for C2. RID measurement of antigen concentrations also relies on the formation of immune-complexes, as with the aforementioned methods; however, in this instance, a precipitin ring will be observed between the antiserum against a specific complement component mixed with the agarose gel, and the complement component in patient serum. The diameter between sample and precipitin ring will be compared with standards for quantitation. ELISA assays are not only set up as functional assays, but also commonly used for measurement of complement components, particularly for lower abundant proteins. In addition, ELISA approaches overcome some of the interferences observed with the turbidimetric and nephelometric approaches.

Complement activation products

Complement activation may be assessed by measurement of complement activation fragments or split products, which reflect the stimulation of any of the activating pathways. The main challenge for analysis of the activation fragments is to stabilize the sample, so that complement activation is inhibited in vitro. Plasma samples are required for the majority of the tests in this category, especially when performed by reference laboratories, because time to analysis and transportation play a significant role in accidentally activating the complement system in vitro.

The main methodologies available for analysis of activation fragments are ELISAs or fluid phase immunoassays using electrochemiluminescent detection approaches [14], which may use polyclonal or monoclonal antibodies against the many different unique epitopes to each of the specific fragments. Cross-reactivity is a challenge, and different assay manufacturers do not use antibodies for the same targets, making study results inconsistent and reference intervals very different, all of which should be taken into consideration when interpreting results.

Autoantibodies to complement components

Given the heterogeneity in autoimmune response to complement, the main methods used to detect autoantibodies to complement proteins are the aforementioned immunoassay strategies (e.g., ELISA and electrochemiluminescence). Analytes of interest stem from the identification of a role of anti-C1q autoantibodies in the pathogenesis of lupus nephritis (LN) and in hypocomplementemic urticarial vasculitis. Autoantibodies to C1q and C1-INH are usually measured by ELISA, and testing is most commonly performed in the setting of autoimmune diseases and acquired angioedema (AAE), respectively. Antibodies to FH are another common target for laboratory analysis. These autoantibodies have been measured with a standardized ELISA validated in an international multicenter study. When utilizing testing for complement autoantibodies, most assays are designed to detect only IgG autoantibodies. Of note, autoimmunity to complement components themselves can result in disease manifestations. This is particularly true of the autoantibodies associated with the kidney, such as C3 nephritic factors (C3Nefs) or autoantibodies to FH, which are also associated with atypical hemolytic syndrome and with AAE (antibodies to C1-INH).

C3Nefs are IgG and IgM autoantibodies that bind directly to C3 convertase of the AP. These molecules are very heterogeneous. In order to accurately measure C3Nefs, a stable C3 convertase must be generated in vitro; this would allow for autoantibody capture. This complex would not progress to cleave C3 and change into a C5 convertase. The gold standard laboratory method for C3Nefs testing is a hemolytic assay that measures whether patient-purified IgGs can stabilize preformed membrane-bound C3 convertase from the AP. Another approach is to measure the C3Nefs via surrogate, by indirect electrophoresis-based detection, which infers the presence of C3 convertase stabilizing molecules when C3 breakdown products are detected in serum. The latter, however, does not correlate with direct hemolytic assays according to proficiency testing reports. C4 nephritic factors are autoantibodies against the CP and LP C3 convertases, which require similar methodologies for measurement; however, these autoantibodies are very rare. These are currently manual, labor-intensive laboratory developed tests, only offered by very few reference laboratories.

Complement genetic testing

The complement serological tests are not always sensitive or specific enough to aid in diagnosis of the rare complement deficiencies or conditions with complement dysregulation such as atypical hemolytic uremic syndrome (aHUS) or PNH. Identifying if the defect is genetic or acquired is helpful in many conditions for treatment decisions. For instance, patients with a large deletion in FH are at higher risk for developing autoantibodies to FH. Patients without genetic variants have better prognostic outcomes in aHUS than the ones with complement variants, which are at higher risk for relapses. Genetic tests for complement-related genes are usually performed by next generation sequencing (NGS). Given that complement proteins have high homology, copy number variation and detection of large deletions is necessary in addition to NGS. Genetic analyses are beyond the scope of this chapter, but comprehensive information can be found in the references list [15–17].

Disorders associated with complement deficiency or dysregulation

Complement deficiencies

Increased susceptibility to infection was the first recognized clinical outcome of having a complement deficiency. Since those initial investigations, an increase in infection has been associated with deficiencies with almost every complement component. This ranges from the apparently more common and often benign deficiency in MBL to the severe outcomes of deficiencies in properdin. Individuals with complement component deficiencies, largely presenting in childhood, experience more frequent and severe infections involving pyogenic bacteria. Warning signs for a complement-mediated primary immunodeficiency include meningococcal meningitis in patients >5 years of age; other recurrent bacterial infections, especially *Pneumococcus*; autoimmune manifestations; angioedema without urticaria; and renal and ophthalmic inflammatory disorders. As a deficiency in any of a number of complement components that can result in similar infectious presentation, diagnosing the specific deficiency can be complicated.

The prevalence of MBL deficiency has been reported to be around 10% in European populations. Often without clinical symptoms, the most common presentations of disease are development of autoimmune disease or more frequent and severe infections. Deficiencies in C2 are most common in Caucasians, occurring at a rate of 1:10,000 to 1:20,000, resulting in autoimmune manifestations or infection, particularly streptococcal pneumonia. There are two forms of C2 deficiency: Type I C2 deficiency, found in over 90% of patients resulting from a complete lack of C2 protein synthesis (messenger RNA is present but no translation), and Type II C2 deficiency resulting from an intracellular protein secretion defect [18]. C4 deficiencies can also be associated with autoimmune or infectious presentations. C4 is encoded by two different genes in the

major histocompatibility complex on human chromosome 6. Seventy-five percentage of the population has two *C4A* and two *C4B* genes; however, the total sum of *C4A* and *C4B* genes in an individual can range from zero to eight or more copies, giving this protein a wide range of concentrations and an even wider range of functionality among the general population. Most of the partial C4 deficiencies are without consequence, although deficiency of *C4A* is associated with a 15% incidence of SLE.

Deficiencies in the AP or TP of complement are the most clinically significant for recurrent infections. Deficiencies in properdin, the only positive regulator in complement and the only component that is X-linked, result in severe and sometimes fatal infections. Similarly, deficiencies in components C3, C5, C6, C7, and C8 are strongly linked with susceptibility to pyogenic infections, particularly *Neisseria* [19]. Recommended testing for complement deficiencies is listed in Table 23.1.

Complement in autoimmune diseases

Disease presentations

Clearance of immune-complexes is an important housekeeping role of the complement system, mediated by activation of the CP and its PRM C1q. A close connection between complement deficiencies and autoimmune diseases exists, and complement is said to have a dual role. The first is that an impaired complement system is not as effective in clearing immune-complexes, and hence complement deficiencies are associated risk factors to development of autoimmune diseases, for example, SLE, primary Sjögren's syndrome (pSS), and RA [26]. The second role, in contrast to the first, is that the increased presence of large immune-complexes in autoimmune diseases demands large complement supply, and frequently depletes complement components for clearance of immune-complexes. Active states of disease are associated with hypocomplementemia, and increased ratio of activation fragments of the components of the CP. C1q deficiency is associated with 55%−75% of SLE cases. These patients present with several characteristics that may distinguish them from patients with sporadic SLE: early age of onset (~5 years of age), lower frequency of anti-dsDNA antibodies, prominent photosensitivity, and fewer renal symptoms [27,28]. In addition, the ratio of females to males is roughly equal for C1q deficiency-associated SLE, unlike sporadic SLE, which is more prevalent in females.

The renal manifestations of SLE, known as LN, are associated with more severe disease morbidity and mortality. In epidemiological studies, it was found that, among other factors, hypocomplementemia has prognostic significance for the development of LN. Autoantibodies against C1q have been reported in over 30% of SLE patients with LN. The presence of anti-C1q autoantibodies alone or in combination with anti-dsDNA and low complement has been shown to have strong association with renal involvement in SLE [29,30]. In addition to anti-C1q antibodies, autoantibodies to C3 and C3Nefs may have a role in LN [31]. CP activation is found in RA, polyarteritis nodosa, hypersensitivity vasculitis, rheumatoid vasculitis, SLE vasculitis, and mixed cryoglobulinemia, among many other conditions. In SLE, pSS, and RA, measurements of C3 and C4 have been used to monitor disease activity. A low result in C4 or both C3 and C4 is suggestive of active disease, and may help stratify patients' risks. Given that C3 is the most abundant complement component, and C4 is a protein coded by genes with different copy numbers, a decreased concentration below reference intervals is a significant finding. Although C3 and C4 measurements are widely available and have proved useful for most patients, a number of conditions can cause low C3 and C4, leading to lack of specificity.

Hereditary and acquired angioedema

Hereditary angioedema (HAE) is caused by a deficiency in the C1-INH, the PRM of the CP. C1-INH deficiency stems from heterozygous variants in the *SERPING1* gene (chromosome 11, q12-q13.1). Over 200 variants have been described, and the vast majority are inherited in an autosomal-dominant fashion. Links between specific variants and disease severity have not been identified; therefore the burden of disease may vary in individuals with similar pathogenic variants. HAE affects approximately 1 in 50,000−100,000 individuals. It is characterized by recurring episodes of unpredictable acute nonpitting edema attacks without urticaria or pruritus, predominantly affecting the cutaneous and/or mucosal tissues. The onset of disease symptoms usually occurs in the second decade of life. While the frequency of angioedema attacks is highly variable, most acute attacks occur at least once a month and last 1−5 days, incapacitating the patients for ~1−2 months per year.

The most debilitating manifestations of HAE include abdominal pain and vomiting due to gastrointestinal swelling or asphyxiation due to laryngeal swelling, but attacks can also occur in the face, hands, feet, or urogenital track. Attacks of the hands or feet are generally unilateral. Although acute attacks are spontaneous, numerous triggers have been reported; examples include stress, trauma, certain pharmacological exposures, infection, or inflammation. If HAE is unrecognized, abdominal attacks may lead to unnecessary surgical procedures. Furthermore, asphyxiation may be fatal and is the predominant cause of death in these patients.

TABLE 23.1 Laboratory testing indicated in several clinical conditions with complement involvement.

	Characteristics	First tier assays and findings	Second tier assays and findings	Genetic testing
Complement deficiencies	Individual components or control proteins are low or absent. Gene variants are usually involved.	CH50 and AH50 may be decreased.	If only CH50 is low: test for C1, C4, and C2 (function and concentrations). If only AH50 is low: test for FD, FB, and properdin. If both CH50 and AH50 are low: test for C3, C5, C6, C7, C8, and C9 (function and concentrations). If both CH50 and AH50 are normal: test for LP function.	Sequence gene coding for low serological results is recommended, but not mandatory, once the phenotypical presentation is characterized.
SLE, RA, and other autoimmune diseases. Monoclonal gammopathies and HCV infections	Increased immunoglobulin production (with or without cryoglobulinemia) or immune-complex formation will lead to CP over-activation. Deposits of immune-complexes in the kidneys are common.	CH50, C3, and C4. Common results in the setting of hypocomplementemia are low CH50 and low C4, with normal or low C3. Type II cryoglobulinemia presents with low C3 and very low or absent C4.	C1q function and concentration. Autoantibodies to C1q are associated with lupus nephritis. Activation products of C3 and C4 can provide estimates of disease activity in SLE.	Not usually required.
Immune-complex-mediated MPGN and C3 glomerulopathies	Rare kidney diseases with deposits on the glomerular basement membrane. Immune-complex-mediated MPGN results from infectious processes, autoimmune diseases, or monoclonal gammopathies, whereas C3 glomerulopathies are differentiated into C3 glomerulonephritis or dense deposit disease using electron microscopy.	CH50, AH50, C3, C4, factor B, factor H, and sC5b-9. Expected findings are decreased function and concentration, with increased activation fragments (sC5b-9).	Immune-complex-mediated MPGN: CP involvement may be evident when activation products (e.g., C4d) are tested. C4 nephritic factors have been reported. C3 glomerulopathies: strong involvement of AP. Activation fragments such as Bb and sC5b-9 as well as C3 nephritic factors and antibodies to FH are recommended tests.	Genetic causes of C3G include variants of C3 complement gene and regulatory proteins (*CFH*, *CFI*, *MCP*, *CFHR5*, and *CFHR3−1*) [20–25]. Allele variants for *CFH* and copy number variation for the *CFHR* cluster have been reported.
Age-related macular degeneration	Complement components C3, C5, and MAC have been found in eyes retina, contributing to oxidative stress and formation of drusen.	Aqueous fluid measurements usually include evaluation of cytokines (IL-6, IL-10, and VEGF), but there is no routine measurement of serum complement assays.	In the event of concomitant MPGN, testing for factor H and anti-FH autoantibodies may be of value.	Y402H polymorphism in *CFH* is a lead predictor of risk for AMD, followed by CFHR1−5, C3, CFI, CFB, C2, and C9.
Atypical hemolytic uremic syndrome	This heterogeneous, rare disorder with presentations of nonimmune hemolytic anemia, thrombocytopenia, and renal impairment has strong AP involvement.	A panel of assays including CH50, AH50, C3, C4, FB, Bb, FH, and sC5b-9 will provide information to discern between CP and AP involvement. Patients with aHUS had lower CH50, C3, and FB when compared with secondary non-aHUS TMA, and a	Other conditions such as TTP may activate the alternative pathway and result in increased levels of C3a, C5a, and sC5b-9, although not to the same extent as in aHUS. Normal FH, FI, CD46, FB, and C3 concentrations do not exclude aHUS diagnosis, since	Sequencing *CFH* and copy number variation for *CFHR1*, *CFHR3*, *CFHR4*, sequencing *CFB*, *CFI*, *C3*, *CD46*, and THBD.

(*Continued*)

TABLE 23.1 (Continued)

	Characteristics	First tier assays and findings	Second tier assays and findings	Genetic testing
		combination of assays using FB ≤ 20.9 mg/dL and CH50 ≤ 56% led to a sensitivity of 75% with increased specificity of 89%. Additional serological findings may include low AH50, low FH, or FI concentrations. Reduced C3 is found in only 30%–50% of patients with aHUS, TTP, and *Shiga toxin* HUS.	some variants may lead to a functionally impaired protein without a detectable change in concentration. In such instances, functional testing, when available, or genetic analysis can serve as an effective way to detect variants in complement pathway genes.	
Paroxysmal nocturnal hemoglobinuria	PNH is an acquired hematologic disorder characterized by nocturnal hemoglobinuria, chronic hemolytic anemia, thrombosis, pancytopenia, and, in some patients, acute or chronic myeloid malignancies. PNH affects erythroid, granulocytic, and megakaryocytic cell lines. The abnormal cells in PNH have been shown to lack (GPI)-linked proteins in erythroid, granulocytic, megakaryocytic, and, in some instances, lymphoid cells.	CH50, the Ham's test or flow-cytometry panel.	Flow cytometry can detect the presence or absence of GPI-linked proteins in granulocytes, monocytes, erythrocytes, and/or lymphocytes. A partial list of known GPI-linked proteins include CD14, CD16, CD24, CD55, CD56, CD58, CD59, C8-binding protein, alkaline phosphatase, acetylcholine esterase, and a variety of high-frequency human blood antigens.	Variants in the phosphatidylinositol glycan A gene have been identified consistently in patients with PNH, thus confirming the biological defect in this disorder.

Notes: Functional assays for factor B, factor D, and properdin are not available. MBL deficiency frequency is reported as 10% in individuals of European descent and frequently goes without clinical manifestations. Screening is indicated only in the context of symptoms, such as repetitive infections, when CH50 is normal. *AAE*, Acquired angioedema; *aHUS*, atypical hemolytic uremic syndrome; *AMD*, age-related macular degeneration; *AP*, alternative pathway; *CP*, classical pathway; *FB*, factor B; *FD*, factor D; *FH*, factor H; *FI*, factor I; *GPI*, glycophosphatidylinositol; *HAE*, hereditary angioedema; *LP*, lectin pathway; *MPGN*, membranoproliferative glomerulonephritis; *PNH*, paroxysmal nocturnal hemoglobinuria; *SLE*, systemic lupus erythematosus; *THBD*, thrombomodulin; *TMA*, thrombotic microangiopathy; *TTP*, thrombotic thrombocytopenic purpura; *VEGF*, vascular endothelium growth factor.

TABLE 23.2 Laboratory features consistent with hereditary and acquired angioedema subtypes.

	Type I HAE	Type II HAE	AAE
C1-INH concentration	Low	Normal/high	Low
C1-INH function	Low	Low	Low/normal
C4 concentration	Low	Low	Low
C1q concentration	Normal	Normal	Low
Anti-C1-INH antibodies	Absent	Absent	Present
C3 concentration	Normal	Normal	Normal
Family history	Yes	Yes	No

AAE, Acquired angioedema; *C1-INH*, C1 esterase inhibitor; *HAE*, hereditary angioedema.

It has been demonstrated that HAE attacks may be attributed to the role of C1-INH in the contact activation pathway, where it controls bradykinin release through inhibition of factor XIIa [32]. In HAE, there is insufficient C1-INH to negatively regulate bradykinin release and stop angioedema attacks from occurring. The mechanism of HAE attacks is distinct from an allergic angioedema, as it is not mediated by histamine release via mast cell activation. Therefore HAE patients are unresponsive to antihistamines or corticosteroids.

There are two main types of HAE that are attributed to C1-INH deficiency (Type I HAE) or dysfunction (Type II HAE); impacted individuals can have C1-INH activities ranging from $<20\%$ to 50% of normal. Type I HAEs, representing approximately 85% of patients, are associated with low circulating concentrations of C1-INH, leading to a concomitant decrease in C1-INH function. In Type II HAEs, normal or elevated concentrations of functionally inactive C1-INH are produced. The relative proportion of Type I and Type II HAEs may differ based on geographical location. A third HAE subtype with unknown prevalence termed "HAE with normal C-INH" has been described. Although poorly characterized, a minority of these patients is known to harbor a mutation in factor XII; the disease origin for the remainder of patients remains unknown. Factor XII is the zymogen form of factor XIIa, and plays a key role in bradykinin production as part of the contact system.

Angioedema due to C1-INH deficiency can also be acquired during adulthood in the fifth decade of life or later [33]. The prevalence of AAE is extremely low and is estimated at 10% of HAE [34]. AAE is frequently associated with monoclonal gammopathies or lymphoproliferative disease, different types of cancer, and autoimmune diseases. AAE may be caused by development of anti-C1-INH autoantibodies that act to reduce the functional activity or increase the catabolism of C1-INH.

For patients exhibiting symptoms associated with HAE, evaluation of pertinent family history in combination with laboratory results for C1-INH function and concentration, C4 concentration, and C1q concentration can assist in HAE diagnosis and determination of HAE type (Table 23.2). Identification of low C1-INH function and low C4 concentration supports the diagnosis of HAE, and was found to have 98% specificity toward C1-INH deficiency and a negative predictive value of 95% [35]. C4 is decreased owing to excessive consumption through CP in the absence of inhibition by C1-INH. Due to low disease prevalence, false positive results are common; therefore repeated testing is recommended to confirm findings [36]. The C1-INH concentration assay can be used to distinguish Type I HAE, with low C1-INH concentration, from Type II HAE characterized by normal or elevated concentration. Furthermore, serum C1q concentrations can be used to differentiate HAE from AAE forms of angioedema, as the latter is characterized by decreased C1q antigen concentration [37] and autoantibodies against C1-INH. Genetic analysis for *SERPING1* variants status may also help exclude HAE [33].

Atypical hemolytic uremic syndrome

The HUS is a form of thrombotic microangiopathy (TMA) characterized by a triad of nonimmune hemolytic anemia, thrombocytopenia, and renal impairment. This TMA is often due to the infectious *Shiga* toxin producing *Escherichia coli* with the most common serotype 0157: H7, a clinical presentation that includes watery or bloody diarrhea. A more rare form of HUS has become more prevalent in recent years in individuals without known *Shiga toxin*-producing infections. These individuals usually had recurrent disease associated with a more severe clinical course and worse outcomes. Patients fitting this clinical phenotype are diagnosed as having atypical HUS

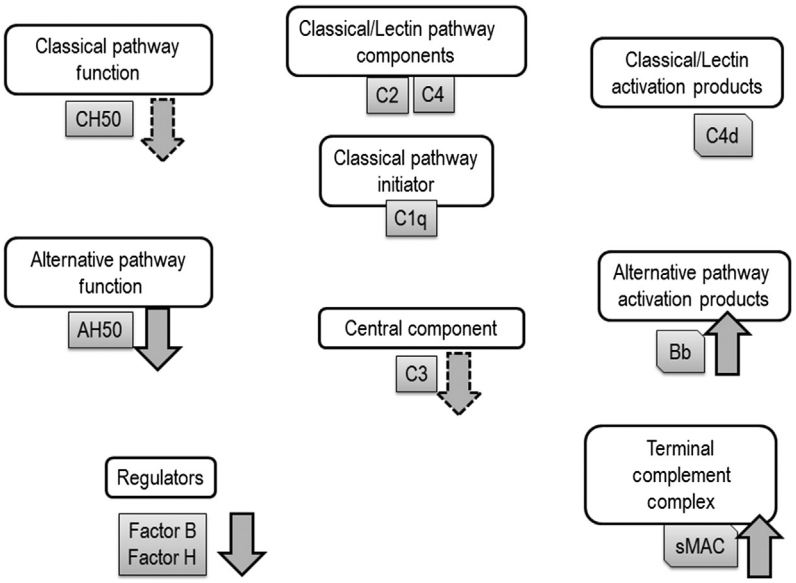

FIGURE 23.5 Expected pattern of findings for alternative pathway dysregulation. Complement alternative pathway function will be decreased, as well as concentrations of the components of the alternative pathway, due to increased in vivo consumption of those early components or regulators, and there is accumulation of the activation fragments, suggesting in vivo cleavage above reference intervals. C3 may or may not be decreased. If it is decreased, it may also impact the CH50 assay, which relies on the C3 available to measure the classical pathway function. A combination of findings or only a few of the analytes may be decreased/increased, as the sensitivity/specificity of the assays may vary with methodology used, and time of collection in relation to symptoms presentation. Evaluating for the presence of autoantibodies and genetic variants is also recommended.

or complement-mediated TMA. The incidence of the far less common atypical form of HUS (aHUS) in Europe is estimated at 2 per million population per year. aHUS is a rare and highly heterogeneous disorder that may appear during childhood or adulthood. The majority of patients incur irreversible renal damage, progress toward end-stage renal disease, or die within the first year of diagnosis when treated with plasma exchange or infusion. Over 80% of aHUS cases are not linked to family history of the disease, and therefore are considered sporadic. Approximately, half of sporadic cases are known to occur subsequent to a trigger event such as common infections or pregnancy. The inherited form of the disease is associated with a particularly poor outcome and has complex underlying genetics with frequent and rare variants and copy number variations of complement genes [38].

aHUS has also been called complement-mediated HUS and is a result of hyperactivation of the AP. The pathophysiologic mechanism involves increased continuous spontaneous hydrolysis of C3 to C3b, leading to tissue deposition of C3b, MAC formation, and subsequent tissue injury. This may be a result of genetic variants in complement-related genes or acquired autoantibodies to complement components. Over 100 variants in complement pathway proteins have been described, which account for $\sim$50%–60% of aHUS cases; however, additional causative mechanisms are yet to be uncovered. The known variants include gain-of-function variants of complement pathway activators (complement C3 and FB) and loss-of-function variants of regulators (FH, CD46, FI, and thrombomodulin). Pathogenic variants are found in only about half of the cases of aHUS. The penetrance of most variants is low, suggesting the requirement for other genetic or acquired factors for phenotypic expression of the disease, for instance, the association of FH autoantibodies with a deletion of *CFHR1* and *CFHR4* in addition to variable copies of deleted *CFHR1* and *CFHR3* genes. The autoantibodies inhibit FH function by binding and blocking the C-terminus, thereby impairing its ability to bind endothelial cell surfaces, sialic acids, and C3b.

In patients with clinical presentation characteristic of aHUS, lab features can be used for diagnosis and as a guide for treatment decisions [39]. In an initial workup, a distinction must be made between aHUS and infection-induced HUS or thrombotic thrombocytopenic purpura (TTP), as the disease management differs based on these distinctions, in particular with regard to the use of eculizumab, approved for aHUS treatment but not TTP. Immunodetection of the *Shiga toxin* in stool is consistent with infection-induced HUS. A laboratory finding of a significant decrease in ADAMTS13 activity ($<$10% of normal plasma) is consistent with TTP and can be used to distinguish it from aHUS. The serum complement profile for aHUS should reflect preferential activation of the AP and complement consumption with accumulation of the activation fragments from the AP, without CP/LP involvement (Fig. 23.5). In a recent study, patients with aHUS had lower CH50, C3, and FB, when compared with secondary non-aHUS TMA, and a combination of assays using FB $\leq$20.9 mg/dL and CH50 $\leq$56% led to a sensitivity of 75% with increased specificity of 88.9% and a diagnostic odds ratio of 24 [40]. Additional serological findings may include low AP function (AH50) or low FH or FI concentrations [41]. Reduced C3 is found in only 30%–50% of patients with aHUS, TTP, and *Shiga toxin*-related HUS. Other conditions such as TTP may activate the AP as well, and result in increased levels of C3a, C5a, and sC5b-9, although not to the same extent as in aHUS.

TABLE 23.3 Serologic assays that may be used as a panel to evaluate AP dysregulation in aHUS.

Test	Utility
CH50	Measurement of total complement function, triggered by an immune-complex. The assay requires complete activation of the classical pathway all the way to the formation of the membrane attack complex. If any of the components are decreased, CH50 measurement can be affected.
C4	C4 is a component of the classical and lectin pathways exclusively. If C4 concentrations are reduced, it suggests those pathways are involved. It does not participate in the alternative pathway. Standard assays for C4 do not distinguish between the parent component and its activation products. C4 is also an acute phase reactant, with concentrations that can double within 24 hours after trauma or acute inflammation. The measurement returned by such methods will not distinguish if the component was cleaved in the patient, or if a decreased result is due to a C4 deficiency.
C4d	C4d is a stable activation product of C4, further indicating classical or lectin pathway dysregulation, and C4 consumption.
AH50	Measurement of alternative pathway function. The most common method available utilizes an ELISA plate coated with lipopolysaccharides and proprietary buffers to block activation of the classical and lectin pathways. The complement proteins in patient's serum are activated by the presence of lipopolysaccharides. C3 hydrolysis initiates the cascade that ends with the formation of the sC5b-9 terminal complement complex. The detection antibody used for this test targets a neoepitope, only exposed on the sC5b-9 complex.
C3	The central component of the classical, lectin, and alternative pathways. This assay and other standard assays for C3 do not distinguish between the parent component and its activation products. Since C3 is the most abundant complement protein, a decreased result is a significant finding.
FB	Activator of the alternative pathway, binding to deposited C3b or hydrolyzed C3. Requires activation by factor D to form the alternative pathway C3 convertase complex, which cleaves additional C3 to C3b.
Bb	FB is activated by factor D and generates two activation fragments, Ba and Bb. Bb will bind to a deposited C3b molecule and create the AP C3 convertase, C3bBb.Measurement of soluble Bb indicates activation of the alternative pathway by FB and factor D.
FH	Complement FH regulates the alternative pathway of complement activation to prevent damage to self. It binds to glycosaminoglycans on cell surfaces through its central part (short consensus repeats SCRs 6–8) and its carboxyl-terminus (SCRs 19–20). The amino-terminal part competes with FB for binding to C3b and acts as a cofactor for factor I to inactivate C3b to iC3b, whereas the C-terminus binds to C3b and its cleavage fragment C3d. FH also enhances the dissociation of the C3bBb complex, limiting the alternative pathway activity.
sMAC	The terminal complement complex or soluble membrane attack complex is formed by C5b, C6, C7, C8, and C9 (C5b-9). The term "soluble" refers to the MAC in circulation in the fluid phase, when bound to one of its control proteins, vitronectin or clusterin. The MAC is responsible for anchoring on the cell membrane and promoting cell lysis when the control proteins are released from its structure. The ELISA assay available utilizes a capture monoclonal antibody to the C9 ring of sMAC, and detection antibodies conjugated with HRP that bind to antigens of the sMAC complex. High concentrations of sMAC are associated with dysregulation of alternative pathway.
Antibodies to FH	The autoantibodies inhibit FH function by binding and blocking the C-terminus of the molecule, thereby impairing its ability to bind endothelial cell surfaces, sialic acids, and C3b.

aHUS, Atypical hemolytic uremic syndrome; *AP*, alternative pathway; *FB*, factor B; *FH*, factor H; *HRP*, horseradish peroxidase; *MAC*, membrane attack complex; *sMAC*, soluble membrane attack complex.

Normal FH, FI, CD46, FB, and C3 concentrations do not exclude aHUS diagnosis, since some variants may lead to a functionally impaired protein without a detectable change in concentration. In such instances, functional testing, when available, or genetic analysis can serve as an effective way to detect variants in complement pathway genes. Several groups have performed retrospective analysis and demonstrated panels with high specificity for complement-mediated TMA [42,43], aHUS, and C3 glomerulonephritis (C3GN). An example of analytes to be used in such panels is described in Table 23.3.

Paroxysmal nocturnal hemoglobinuria

PNH is a rare clonal bone marrow disorder occurring at a population-level incidence of 5–10 in a million and affecting primarily young adults [44]. It is enriched in certain populations, including patients with intravascular hemolysis or hemoglobinuria, bone marrow failure, or

unexplained thrombosis, which are diagnostic features for PNH. PNH develops as a result of loss of GPI-anchors from cell membranes, resulting in untethering of membrane inhibitors of complement, thereby rendering the cells more susceptible to complement-mediated destruction.

RBCs express the essential complement regulatory protein CD59 on the plasma membrane via a GPI anchor, and its presence inhibits the formation of the MAC, thereby protecting cells from autologous complement-mediated destruction. In PNH, the synthesis of phosphatidylinositol tails required for anchorage of CD59 to the plasma membrane of RBCs is impaired due to a somatic mutation in the X-linked gene, phosphatidylinositol glycan class A. The absence of the critical CD59 leads to abrogation of inhibitory mechanisms, allowing complement activation, transversion of the MAC through the lipid bilayer, and subsequent destruction of RBCs. Consequently, PNH patients experience chronic intravascular hemolysis and numerous associated morbidities including hemolytic anemia, venous/arterial thrombosis, and smooth muscle dystonia. In addition, bone marrow failure can progress to aplastic anemia in the most severe cases. Occurring in approximately half of patients, thromboembolism is the most severe complication of PNH, and the primary cause of death. Prior to the approval of eculizumab, supportive therapies such as blood transfusions and stem cell transplantation were the mainstays of treatment in these patients, and were associated with poor quality of life and significant morbidities. With the emergence of novel therapies, the outlook for PNH is much improved.

Flow cytometry-based quantification of GPI-linked proteins in granulocytes, monocytes, RBCs, and/or lymphocytes is used as a diagnostic assay for PNH, an improvement which avoiding the problems associated with RBC-based diagnostic methods (Ham's test), in which recent hemolytic episodes or recent transfusions can give false-negative results. Flow cytometry-based methods are strongly preferred over the alternative methods, as flow provides superior specificity, quantitation, and sensitivity. A partial list of known GPI-linked proteins includes CD14, CD16, CD24, CD55, CD56, CD58, CD59, C8-binding protein, alkaline phosphatase, acetylcholine esterase, and a variety of high-frequency human blood antigens.

Complement in C3 glomerulopathies

C3 glomerulopathies is an umbrella term to define C3 deposition in the kidney without the presence of immunoglobulins, as it is observed in C3GN and dense deposit disease (DDD). This is in contrast to immune-complex-mediated membranoproliferative glomerulonephritis (MPGN). The C3G conditions are thought to be a result of complement dysfunction in the AP and differ from classical postinfectious glomerulonephritis, where immune-complexes are present and CPs or LPs are involved. The differentiation between C3GN and DDD is made using electron microscopy, according to the pattern observed in the glomerular basement membrane. Despite phenotypic differences, these glomerular diseases share dysfunction of the AP as the defining pathophysiology. As such, the diagnostic approach to these disorders should be similar. The causal abnormality in the complement pathway, genetic or acquired, may not be clear until an abrupt event, such as infection or pregnancy, activates complement exponentially, in an uncontrolled manner.

Genetic causes of C3G include variants of C3 and regulatory proteins (*CFH, CFI, MCP, CFHR5*, and *CFHR3-1*). Acquired forms of the disease are associated with the presence of C3Nefs that bind and stabilize the C3 convertase, increasing its half-life almost 10-fold, from seconds to minutes or hours, and blocking its dissociation; therefore the enzyme is active continuously, promoting complement activation. This will in turn lead to C3 consumption and decreased serum C3 concentrations. There have also been reports of C4 nephritic factors that act through a similar mechanism, stabilizing the CP and LP C3 convertases [45].

In the context of renal disease, reduced C3 is found in 40%−75% of patients with C3G and approximately 60% of atypical postinfectious glomerulonephritis. Significantly decreased C3 concentrations may be found in deficiencies of FH, FI, or the presence of C3Nefs. Reduced concentrations of FB are associated with increased concentrations of Bb and Ba activation fragments, and are consistent with AP C3 consumption. AH50 is commonly decreased. Anti-FH antibodies should also be assessed, and the sC5b-9 is elevated in 9% of DDD patients and 50% of C3GN patients. Conversely, a normal FB concentration and reduced C4 may reflect CP activation if genetic deficiency of C4 is excluded, and point the diagnosis toward immune-complex-mediated MPGN.

Complement and other conditions

Monoclonal gammopathies

Autoimmune diseases often result in polyclonal elevation of the immunoglobulins repertoire, and the relationship of the excess of immune-complexes with the complement system has been reviewed. Monoclonal gammopathies may have a similar impact on the activation of the complement system, since the monoclonal proteins may also deposit in organs and tissues (e.g., light-chain amyloidosis, multiple myeloma, and kidney). Tissue biopsy

immunohistochemistry studies often reveal the presence of immunoglobulin deposits as well as complement C3b and C4. The monoclonal immune-complexes may trigger activation of the CP and the TP. Patients with renal damage owing to the accumulation of the monoclonal protein in the glomeruli are classified with monoclonal gammopathies of renal significance, a reclassification compiling all renal disorders caused by a monoclonal immunoglobulin.

Cryoglobulinemia

Cryoglobulins are proteins that precipitate when cooled and dissolve when heated. In most cases, monoclonal cryoglobulins are IgM or IgG. They are classified as follows: type I (monoclonal: IgG, IgM, IgA, or rarely monoclonal light chains); type II (mixed: two or more immunoglobulins, of which one is monoclonal); and type III (polyclonal: in which no monoclonal protein is found). The monoclonal protein or mixed immunoglobulins precipitate in cooler vessels, such as earlobes and extremities, causing damage due to poor perfusion leading to infarction or ischemia, leg cramps, acrocyanosis, Raynaud's phenomenon, ulcers, and purpura. The temperature at which the cryoglobulin precipitates is more important than the amount of protein. Most commonly, mixed cryoglobulins (type II) consist of monoclonal IgM with rheumatoid factor activity and polyclonal IgG. Type II cryoglobulinemia is notably likely to present with complement abnormalities, with low concentrations of C3 and very low or absent C4. The monoclonal proteins deposition in tissues or the precipitation of cryoglobulins may activate the complement system via CP, LP, or AP, leading to low results being reported for CH50, AH50, or LP functional assays. Patients with mixed cryoglobulinemia frequently have vasculitis, glomerulonephritis, or lymphoproliferative or chronic infectious processes, like hepatitis B or hepatitis C infections. Measurement of low C3 and low/absent C4 are characteristic in type II cryoglobulinemia.

Hepatitis C virus infections

Viruses have been shown to attenuate complement activation, and interactions of hepatitis C virus (HCV) and the host immune surveillance system may play a role in viral persistence. Serum C3 is depleted in HCV-infected cirrhotic patients, and complement activation has also been reported, with decreased C4 activity in chronically infected HCV patients. In addition, HCV infection is associated with mixed cryoglobulinemia (type II cryoglobulinemia), and the HCV core antigen has been detected in cryoprecipitates. There is a structural similarity between C1q and HCV, which could explain the finding. In addition to CP involvement, LP is involved as MBL binds to HCV envelope proteins and also contributes to complement activation. The HCV infection with cryoglobulinemia is complicated in the presence of B-cell proliferation and extrahepatic disease manifestations such as leukocytoclastic vasculitis, arthropathy, neuropathy, and MPGN [46,47]. In HCV-infected individuals, testing for the presence of cryoglobulins is recommended and may suggest development of extrahepatic complications [48].

Complement in age-related macular degeneration

Age-related macular degeneration (AMD) is the leading cause of irreversible blindness in the developed world [49] A variant in *CFH*, Y402H, was found to be the lead predictors of risk for AMD [50–52]. Since that initial connection, polymorphisms in a number of other complement genes have been connected to AMD [53,54]. In addition to *CFH*, polymorphisms in *CFHR1–5*, *C3*, and rare variants of *CFI* [55,56] have been described to be risk factors in AMD, whereas variants in *CFB*, *C2*, and *C9* were found to be protective, and associated with decreased risk for AMD [54].

Complement components C3, C5, and MAC were actually found in the eye before the genetic connection was made [57]. The finding of the complement components, as well as other inflammatory markers, in the drusen lesions of AMD have reinforced the notion that AMD is driven by an inflammatory response with improperly controlled complement activation. The area of the eye where the drusen and complement deposition is found is, by definition, an area of possible high oxidative stress, which is believed to be a key trigger for the complement activations. The current treatments for AMD center around the inhibition of the provascular signaling molecule vascular are endothelium growth factor [58], but recent work has shown that the efficacy of the treatment is modulated by complement [59]. Many of the treatments on the horizon for AMD now focus on modulation of the AP of complement [60,61]. Currently, complement testing is not common for AMD. Testing for the genetic polymorphisms associated with AMD has been suggested as a diagnostic predictor of AMD risk, but without clear treatment stratification, the utility of such testing has been questioned. With the interest in complement-targeting therapeutic in AMD, the likelihood that complement analysis will be utilized in the future is high.

Complement therapeutics

Therapeutics for hereditary angioedema

The primary treatment goals for Type I and II HAEs are to reduce disease morbidity through reduction of the frequency, duration, and severity of angioedema attacks, and to avoid mortality by preventing occurrence or

progression of laryngeal edema. There are currently five commercially available, FDA-approved therapies that effectively treat acute HAE attacks, including C1-INH replacement therapies and drugs targeting the bradykinin pathway. C1-INH replacement therapy restores functional C1-INH concentrations to the normal range and can be derived in two ways: through purification from plasma (Berinert, CSL Behring GmbH, and Cinryze, Shire ViroPharma Inc.) or production of recombinant protein (Ruconest, Salix Pharmaceuticals). Bradykinin pathway-targeting drugs include the plasma kallikrein inhibitor, ecallantide (Kalbitor, Shire Pharmaceutical), and the bradykinin B2-receptor antagonist, icatibant (Firazyr, Shire Pharmaceutical). Ecallantide prevents kallikrein-mediated bradykinin release from high molecular weight kininogen, thereby reducing swelling. Icatibant, acting downstream of ecallantide, renders the bradykinin B2 receptor inaccessible to bradykinin. Of note, Berinert, Cinryze, and Firazyr may be self-administered by the patients or by their family members, thereby reducing the burden of disease by allowing for an earlier intervention and preventing unnecessary healthcare expenditures by averting emergency room visits and hospitalizations.

Although there are significant differences in treatment approaches for AAE versus HAE, there is evidence that AAE patients may also benefit from C1-INH replacement therapy. While effective in some cases, the rapid turnover rate of C1-INH in some AAE patients may require higher doses, or they may be resistant to treatment with plasma-derived C1-INH altogether. Efficacy of icatibant, and on a smaller scale, of ecallantide has also been demonstrated in AAE.

The C5 inhibitor

Eculizumab (Soliris, Alexion Pharmaceuticals), a humanized monoclonal hybrid IgG2/4κ antibody therapeutic directed against C5, is FDA-approved for treatment of PNH and aHUS, and has orphan-drug designation status for treatment of refractory myasthenia gravis and neuromyelitis optica. Eculizumab inhibits the terminal complement pathway through simultaneous blockade of the generation of the potent prothrombotic and pro-inflammatory molecule, C5a, and the formation of the MAC initiator, C5b [62,63]. Since all paths of the complement cascade converge at the point of C5 activation, eculizumab is thought to have a broad potential application and is being clinically evaluated in many other disorders with complement overactivation [64].

In PNH, eculizumab has become the standard of care, proving to be a safe and effective therapy with long-lasting effects, potentially enabling patients to become transfusion-independent and extending their survival. Eculizumab dosing regimen prescribed for an average adult diagnosed with PNH is 600 mg weekly for the first 4 weeks, followed by 900 mg for the fifth dose 1 week later; then, 900 mg every 2 weeks thereafter. In aHUS, it is prescribed for an average adult at 900 mg weekly for the first 4 weeks, followed by 1200 mg for the fifth dose 1 week later, then 1200 mg every 2 weeks thereafter. As compared with plasma exchange, eculizumab may facilitate better disease control and tolerability, and can be beneficial as a first-line treatment in children who have high risk of complications from plasma exchange and patients with recurrent aHUS (with or without transplantation).

The drawbacks of eculizumab therapy are associated with its potentially life-threatening side effects, variations in response profiles, and the cost of treatment. Patients treated with eculizumab are at an increased risk of susceptibility toward life-threatening infections such as *Neisseria meningitides*; to prevent these, vaccinations and, in some cases, prophylactic antibiotic treatment are recommended. In addition, PNH patients harboring a rare polymorphism of the complement receptor 1 gene were found to be more likely to remain transfusion dependent in spite of eculizumab therapy, and exhibited suboptimal response to eculizumab [65]. As another major drawback, being potentially a lifelong therapy with a price tag of nearly $6000 per 300 mg vial, the cost of eculizumab may limit its use in routine clinical practice worldwide and may amount to ~$100,000 or ~$500,000 annually in children or adults, respectively [66].

Monitoring eculizumab therapy can be accomplished by clinical monitoring of the patients undergoing therapy. In PNH, clinical parameters used to assess treatment outcome include stable hemoglobin concentrations with reduction of hemolysis, decreased blood transfusion requirements, improved quality of life, and reduced frequency of thromboembolic events. In aHUS, the use of eculizumab is usually initiated after poor response to plasma exchange. Successful response to eculizumab therapy includes normalization of thrombocytopenia, resolution of the TMA, and improvement of renal function measured by creatinine or estimated glomerular filtration rate. However, if the clinical response to therapy is only partial, for example, with normalization of some of the parameters but not others, one may wonder if eculizumab is adequately blocking C5. In those situations, the availability of laboratory testing can be helpful to guide whether a dose increase or shorter infusion intervals of eculizumab should be considered.

On the other end of the spectrum, it has been proposed that a group of patients without pathogenic variants and normalization of all hematologic and renal parameters (no evidence of microangiopathic hemolytic anemia, no thrombocytopenia, and stable renal function for over 3 months), could benefit from dose deescalation or therapy discontinuation. For these patients, assessment of

complement blockage status in conjunction with disease monitoring would be valuable. Complement activity of <10% for the AH50 assay or results below the reference intervals for C5 function or CH50 on the liposome methods are indicative of therapeutic concentrations of eculizumab >100 mcg/mL, and seem like suitable assays to monitor eculizumab therapy. C5 concentrations may be measured along with any of the functional tests, especially in cases of poor response to eculizumab, and it will help exclude a complement C5 deficiency; in the presence of eculizumab, C5 concentrations will be elevated [67]. Importantly, nephelometric or turbidimetric assays to measure C5 concentration use antibodies as reagents that may not distinguish between free and eculizumab-bound C5; therefore C5 concentration assays alone should be used to monitor complement control. Eculizumab quantitation may also be measured using immunoassay or mass spectrometric techniques for therapeutic drug monitoring.

Future directions

The indications for complement testing have expanded beyond the traditional evaluation of complement deficiencies to a series of other indications that include kidney diseases, TMAs, and autoimmune diseases. With complement therapies gaining the spotlight, the clinical laboratory specialized in this testing has regained relevance and may be able to contribute significantly to patient care with a diverse array of tests, targeting the complement system.

Acknowledgments

The author would like to thank colleagues Ashley Frazer-Abel, Ph. D. (University of Colorado Denver, CO), Lusia Sepiashvili, Ph.D. (The Hospital for Sick Children, Toronto, CA), and Michael Mbughuni, Ph.D. (US Department of Veterans Affairs Hospital, Minneapolis, MN), for their contributions to the study of the complement system and for writing a thorough review with the author in 2016 that served as the basis for this chapter.

Self-Assessment Questions

1. The Classical Pathway recognition molecule is
   a. C1 qrs complex [right answer]
   b. C1 inhibitor
   c. Mannose binding lectin
   d. Pathogen associated molecular patterns
2. The alternative pathway is triggered by
   a. C1 qrs
   b. C3 spontaneous hydrolysis
   c. Ficolins
   d. Factor B
3. The classical pathway is dependent on two metals to activate the cascade and proceed until the formation of the terminal complement complex. Which are they?
   a. Aluminum and lead
   b. Sodium and Potassium
   c. Calcium and Magnesium
   d. Calcium and Potassium
4. In order to measure the classical pathway complement function or activity, the best specimen type is:
   a. EDTA plasma
   b. Citrate plasma
   c. Serum
   d. Urine
5. In order to measure complement activation fragments in circulation, the best specimen type is:
   a. EDTA plasma
   b. Citrate plasma
   c. Serum
   d. Urine
6. What is the immunoglobulin that activates the complement system most efficiently? And what is the one that does not activate complement, respectively?
   a. IgG and IgA
   b. IgD and IgM
   c. IgM and IgG1
   d. IgM and IgG4
7. What is the complement defect associated with hereditary angioedema?
   a. C1 qrs
   b. C1 inhibitor
   c. C4 concentration
   d. C2 concentration
8. The most common acquired autoantibody to complement components, present in atypical hemolytic syndrome and C3 glomerulopathies is:
   a. Antibodies to Factor B
   b. Antibodies to Factor H
   c. C4 nephritic factors
   d. Antibodies to C1q
9. Eculizumab is a monoclonal antibody therapy that targets and blocks a component of the complement cascade. Which is it?
   a. C3
   b. C5
   c. C5b-9
   d. C4

Learning objectives

After reading this chapter, the reader will be able to:

- Describe pathological and nonpathological hemoglobin physiology.
- List biochemical and molecular methods used in hemoglobin analysis.
- Compare quantitative and qualitative methods to detect hemoglobin variants.
- Recognize differences between targeted and comprehensive molecular assays.
- Formulate problem-solving skills to assist in evaluating difficult hemoglobin cases.

Introduction

Hemoglobin (Hb) is the iron-containing protein within red blood cells (RBCs; erythrocytes), responsible for oxygen transport and delivery. In most vertebrates, functional Hb is a tetramer, consisting of four globular protein subunits organized as two heterodimers (Fig. 24.1 and Table 24.1). Each heterodimer is composed of one alpha or alpha-like globin subunit and one beta or beta-like globin subunit. Each of the four subunits surrounds a central heme group that contains iron and binds one oxygen molecule. Hb is often recognized for its cooperative binding; as each individual Hb monomer reversibly binds to one molecule of oxygen, the shape of the tetramer shifts, increasing the affinity for oxygen binding by neighboring subunits.

There are three normal Hbs detected in systemic circulation: adult hemoglobin (HbA), fetal hemoglobin (HbF), and HbA_2 (Table 24.1). All three of these Hb tetramers have two alpha globin subunits. The HbA tetramer consists of two alpha and two beta subunits, which are encoded by two alpha globin genes (*HBA1* and *HBA2*) and one beta globin gene (*HBB*), respectively. The "A" indicates adult, and HbA comprises >90% of normal Hb in children and adults. In contrast, in HbF, the alpha subunits pair with two gamma globin subunits, beta-like globins encoded by two gamma globin genes (*HBG1* and *HBG2*). The "F" indicates fetal, and HbF is the primary species of Hb present in utero (after the first trimester; Fig. 24.2) and at birth. HbA_2 is a minor Hb species, built from two alpha and two delta globin subunits, which appears at birth and is consistently present in normal individuals at a relative concentration of ~2.0%–3.5% of total Hb. The ratios of these three types of Hb are altered in certain pathophysiological states, including sickle cell anemia (increased HbF) and certain thalassemias (increased HbA_2).

The process by which the proportions of the major Hb subunits change over time in an individual is referred to as developmental switching (Fig. 24.2). During embryogenesis, there are primitive forms of Hb, including zeta globin (alpha-like) and epsilon globin (beta-like) subunits. Both of these globins are important during gestation in order to support the oxygen requirements of an embryo. After approximately 9 weeks of development, embryogenesis is complete and the Hb species transition into those that are required to support the increased oxygen demands of the fetus. During this phase of gestation, HbF becomes

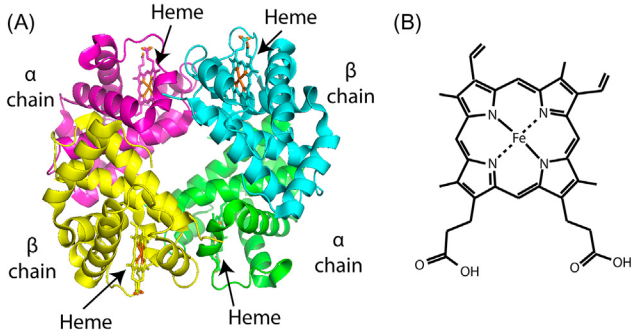

FIGURE 24.1 Hemoglobin structure. (A) Functional hemoglobin is a tetramer, consisting of four globular protein subunits organized as two heterodimers. the primary form of Hb found in fetal circulation. At birth, HbF rapidly decreases and is replaced with HbA. In adulthood, HbF normally persists as approximately 1%–4% of total adult Hb.

Around 5%–7% of the world's population carries one or more clinically important mutations or deletions affecting the globin genes (Table 24.2). It is, however, also important to note that the Hb genes are highly polymorphic and rare structural variants, which are collectively frequent, can be clinically insignificant. Pathological Hb abnormalities are broadly categorized into two forms: structural hemoglobinopathies and thalassemias. Structural hemoglobinopathies occur when there is a mutation, leading to a structurally abnormal Hb subunit. These hemoglobinopathies are most commonly caused by point mutations that lead to an amino acid change in the primary protein sequence. In the United States, sickle cell disease, a structural hemoglobinopathy caused by mutations in the beta globin gene, is the most common inherited blood disorder and leads to production of a variant Hb termed HbS. Approximately 10% of African Americans carry an HbS allele. In HbS, a missense mutation causes the substitution of a valine for glutamic acid in the sixth amino acid (Glu6Val) of the beta globin gene *HBB*. The mutated HbS polymers reduce red cell deformability and distort erythrocytes into the characteristic sickle-shaped cells that can occlude blood vessels, particularly in patients homozygous for the mutation (HbSS) (Fig. 24.3). The clinical significance of various hemoglobinopathies varies by the specific abnormalities. For example, patients with HbC disease have a variant Hb caused by a mutation in the same amino acid of the beta globin gene as HbS. However, in HbC, there is substitution of lysine for the glutamic acid at the sixth amino acid (Glu6Lys) of the beta globin gene, and this change is associated with less clinical severity than sickle cell disease. The hemoglobinopathies are generally associated with a spectrum of phenotypic severity depending on how many gene mutations are involved. For example, heterozygous hemoglobinopathy mutations do not typically have immediate clinical symptoms, but homozygous mutations [sickle cell disease (HbSS)] compound heterozygous mutations (HbSC disease), or hemoglobinopathies with a coincident thalassemia can manifest with a range of clinical phenotypes.

Thalassemias, in contrast to the structural hemoglobinopathies, are defined by a quantitative decrease in the

TABLE 24.2 Commonly detected abnormal hemoglobin variants.

	Subunit composition	Clinical indication
HbS	αα$\beta^{*}\beta^{*}$ *Indicates Glu6Val mutation	Not pathological in heterozygous cases; homozygous indicates sickle cell disease
HbC	αα$\beta^{*}\beta^{*}$ *Indicates Glu6Lys mutation	Not pathological in heterozygous cases; often occurs as a compound heterozygous genotype with HbS; homozygous shows a mild-to-moderate anemia
HbE	αα$\beta^{*}\beta^{*}$ *Indicates Glu26Lys mutation	Not pathological in heterozygous cases; considered a thalassemic hemoglobinopathy; homozygous shows a mild-to-moderate anemia
HbH	β_4	Detected only when two or more α genes are deleted
HbBarts	γ_4	Specific to pediatric patients; detected only when two or more α genes are deleted

For more details, see Refs. [1–3].

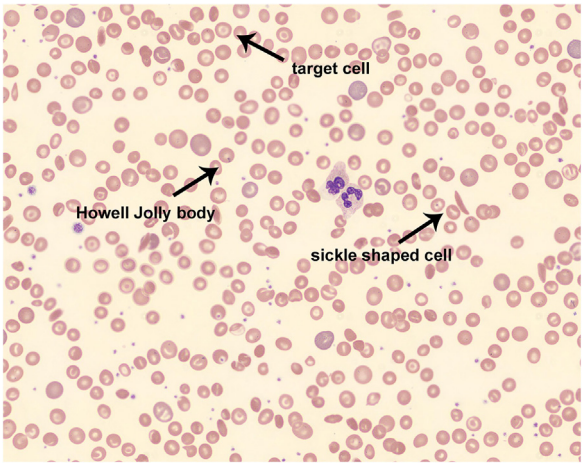

FIGURE 24.3 Peripheral smear from a patient with sickle cell disease illustrates the spectrum of red blood cell findings in this disorder, including sickle cells, target cells, Howell–Jolly bodies, and polychromasia.

overall amount of an Hb subunit. The thalassemias are classified according to the affected globin chain(s). Alpha-thalassemia, for example, occurs when there is a decreased concentration of alpha globin; beta-thalassemia occurs when there is a decreased concentration of beta globin. Thalassemias are most commonly caused by multiexon deletion mutations that can occur due to nonhomologous recombination events, but can also be due to individual point variants that reduce the structural integrity and stability of the transcript or the protein. The latter are considered thalassemic hemoglobinopathies and include Hb Constant Spring and HbE, two hemoglobinopathies more frequently found in individuals of Chinese and Southeast Asian ancestries. Clinically, thalassemias are classified according to the severity of the symptoms as thalassemia minor (asymptomatic), thalassemia intermedia (nontransfusion-dependent anemia), and thalassemia major (transfusion-dependent, severe anemia).

Detection of Hb abnormalities relies heavily on the clinical laboratory. A variety of biochemical and molecular techniques are applied for characterization of hemoglobinopathies. Diagnostic testing for Hb disorders is frequently performed in the evaluation of anemia and microcytosis, pulmonary hypertension, and preoperative anesthesia evaluation, but testing is also increasing in volume due to implementation of prenatal and population-based screening programs. For example, while a heterozygous mutation may be clinically asymptomatic, it can have important consequences for preconception and prenatal screening, particularly in high-risk demographic populations. Prenatal and postnatal testing are also complicated by the fact that, because of developmental switching of Hbs, detection of clinically severe hemoglobinopathies can be delayed until after the first trimester (if the mutations are in the alpha genes) or after birth (if the mutations are in the beta genes). Proper laboratory diagnosis is crucial for characterizing the different forms of hemoglobinopathies with important implications for prevention and treatment.

Blood smears and cell counts

The first indication of a hemoglobinopathy is frequently an abnormality in a complete blood count (CBC). The CBC test incorporates a number of hematologic parameters important for the evaluation of a hemoglobinopathy. The key components of the CBC for detection of hemoglobinopathies are the red cell indices, which include Hb, hematocrit (HCT), RBC count, mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and red cell distribution width (RDW). A CBC generally also includes a white blood cell (WBC) count and a platelet count.

Hb abnormalities that lead to decreased erythrocyte stability can cause a general anemia, identified in the

laboratory by a decrease in Hb and HCT. A manual differential may show a range of phenotypic erythrocyte abnormalities. Blood smears from patients with sickle cell trait (HbAS) are usually entirely normal, occasionally with a small number of target cells; however, patients with sickle cell anemia (HbSS) can show sickle cells, target cells, anisocytosis, polychromasia, basophilic stippling, and nucleated red cells. A blood film from a patient with Hb C disease may show a large number of target cells, microcytosis, and characteristic Hb C crystals. In the thalassemias, the reduced production of Hb also leads to a uniformly reduced cell volume called microcytosis (low MCV) with hypochromasia (reduced MCH). The RBC count can be increased as a compensatory mechanism. In these patients, the RDW, which measures the degree of variation in erythrocyte size, often remains normal. The blood films from a patient with thalassemia trait may show target cells, elliptocytes, and basophilic stippling.

In assessing patients with anemia and a low MCV, it is critical to consider the potential for iron deficiency, also characterized by anemia and low MCV but frequently with a low RBC count and an increased RDW. Testing specific for assessing an individual's iron status should be performed and may include ferritin, transferrin, and total iron binding capacity. Thalassemias can be distinguished from iron deficiency anemia by the RBC count (usually increased in thalassemia and decreased in iron deficiency) and red cell width (usually normal in thalassemia and decreased in iron deficiency).

The RBC findings are critical to the characterization of a hemoglobinopathy, and a CBC should always be integrated into the testing strategy for hemoglobinopathies, regardless of the other tests used. While CBC findings alone are not diagnostic of Hb abnormalities, the CBC findings play a critical role in their ability to help the provider assess the severity of a hemoglobinopathy.

Case Example 1

A 22-year-old African American male who was diagnosed at birth with sickle cell disease presents to his primary care physician with complaints of fatigue and unbearable leg muscle pain. His CBC results are listed in Table 24.3.

Are these results expected for an individual with HbSS (homozygous genotype)?

TABLE 24.3 Laboratory results for Case Example 1.

Hematologic parameter (units)	Result	Reference interval
WBC ($10^3/\mu L$)	11.2	4.3–10.0
RBC ($10^6/\mu L$)	6.0	4.4–5.6
Hb (g/dL)	9.8	13.0–18.0
HCT (%)	30	38–50
MCV (fL)	99	81–98
MCH (pg)	27.5	27.3–33.6
MCHC (g/dL)	34.0	32.2–36.5
Platelet count ($10^3/\mu L$)	220	150–400

Complete blood count remarkable for elevated white cell count, red cell count, and mean corpuscular volume with accompanying decrease in hemoglobin and hematocrit.
Hb, Hemoglobin; *HCT*, hematocrit; *MCH*, mean corpuscular hemoglobin; *MCV*, mean corpuscular volume; *RBC*, red blood cell; *WBC*, white cell count.

Case 1 Resolution

HbS is defined by the substitution of a valine for glutamic acid in the sixth amino acid of the beta globin protein (Table 24.2). Sickle cell disease occurs when both genes have this point mutation and the pathological consequences are significant. HbS has a propensity to polymerize within the erythrocyte, which decreases the flexibility of the membrane and leads to a sickling shape. The altered conformation of the erythrocyte is less flexible and therefore does not retain the mobility necessary to traverse the vasculature. Overall, this results in vaso-occlusive episodes (sometimes called sickle cell crises) and hemolytic anemia.

The CBC results described here are expected for a patient with sickle cell disease. Hb and HCT are decreased as a result of the anemia; WBCs are increased from inflammation; MCV and RBC count are increased as physiological attempts to compensate for the anemia. Palliative care should be used to help relieve this patient of their symptoms. The CBC findings are likely not severe enough to warrant blood transfusion; however, the decision when to give transfusions to these patients can depend on the patient's subjective symptoms and nonlaboratory-based vital sign measurements (i.e., heart rate and blood pressure).

Biochemical techniques

Quantitative measurement of hemoglobin variants

The relative concentrations of the various reference and Hb variants have clinical relevance; therefore accurate quantification of Hb species assists in the proper diagnosis of these Hb abnormalities. A normal Hb profile has a relative globin ratio of approximately 96% HbA, 1% HbF, and 3% HbA_2 (Fig. 24.4 and Table 24.1).

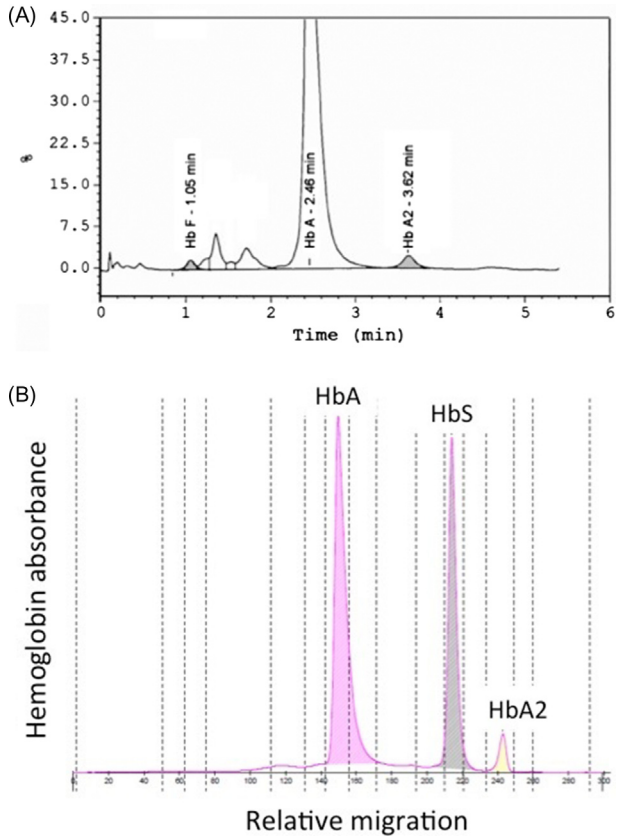

FIGURE 24.4 Representative high-performance liquid chromatogram from an adult with no detectable hemoglobin variants (A) and capillary zone electropherogram from an HbS carrier (B).

Abnormalities in the Hb profile are defined either as a disruption in this ratio or as a visual indication of a quantifiable species not observed in normal individuals.

High-performance liquid chromatography (HPLC) and capillary zone electrophoresis (CZE; sometimes referred to as CE) are the two primary methods used by clinical laboratories to measure Hb species. Both techniques require small amounts of sample and can be performed by automated methods, making them amenable to high-or low-volume laboratory workflows. Some laboratories employ one or more methods in their protocol for detection of hemoglobinopathies. Choice of method depends on the function of the laboratory and its testing algorithm. It is important to note that both HPLC and CZE are generally considered screening methodologies; therefore separate techniques, including alternative electrophoresis methods and molecular testing methods, are often used as confirmatory tests. Depending on the patient population served by a clinical laboratory and the indication for testing, laboratories may have different algorithms for testing. For example, some laboratories employ a screening method (HPLC or CZE) and only perform confirmatory testing on samples that screen positive, while other laboratories may evaluate all samples by multiple methods without requiring a positive screening result. The latter workflow is advantageous for high-risk populations, because certain alpha-thalassemias are not distinguishable from normal individuals by the screening methods alone (HPLC or CZE).

High-performance liquid chromatography

The classical method used by clinical laboratories to separate and quantify Hb variants is cation exchange HPLC (Fig. 24.4A). In this method, a small amount of red cell lysate is injected, and positively charged Hb is retained on a negatively charged silica-based column. Hb species are eluted from the column using a liquid mobile phase with phosphate buffers that have a gradient of salt concentrations and pH to decrease the affinity of the Hbs to the column. The eluted Hb is detected with absorbance wavelengths for maximal Hb detection (415 nm). Retention time, or the time it takes to elute from the column, is used to distinguish the major Hb species. The areas under the individual chromatographic peaks are integrated and compared to the total area under all peaks to quantify the corresponding percent Hb concentration. HPLC runs are preceded by priming and calibration of the instrument, which involves calibration factors containing HbA_2 and HbF that must measure at expected values.

HPLC allows quantification of the three normal Hbs, including HbF and HbA_2, as well as a large number of other Hb variants. Common and rare Hb variant profiles using HPLC are well defined, and libraries of chromatograms have been published to facilitate interpretation. Interpretation can be complicated by the biological background "noise" caused by posttranslationally modified and degraded Hb species. These modifications can produce small or shifted peaks, sometimes coeluting with other Hbs. For example, glycated HbS can elute in the HbA window. In addition, since HbE coelutes with HbA_2, the two cannot be differentiated using this technique. HbH and Bart Hb, which are clinically significant Hbs causing alpha-thalassemia, may elute too quickly from a column depending on the specific methods used and preclude their quantitation. Interestingly, many laboratories use HPLC-based assays to quantify Hb A1c for the management of diabetes mellitus. The presence of variant Hbs can be observed when the assay for Hb A1c is performed, and is sometimes the first indication a patient carries a variant Hb.

Capillary zone electrophoresis

CZE is a relatively recent technique compared with HPLC for the detection of abnormal Hbs, but its use by the clinical laboratory has significantly increased over the last decade. Hb separation and quantification is

particularly amenable to this technique. In CZE, separation is based on movement of charged molecules (the Hb fractions) in a silica-based capillary tube in an alkaline buffer, containing electrolytes that create an electroosmotic flow. Hb absorbance is monitored at the base of the capillary to detect migrating Hb species. The resulting peaks are divided into zones that are defined by their migration relative to HbA; the threshold position for HbA is established at the beginning of each run using control material and must be determined for each capillary. Thus samples must contain some amount of HbA to characterize the migration pattern of the other Hb components. Samples without endogenous HbA, including homozygous beta globin mutations and fetal samples, must be mixed with a reference sample, containing HbA to establish and identify the migration pattern. The results from the mixed and unmixed samples are compared to identify the unknown peaks and to determine the relative Hb concentrations in the sample lacking HbA. The data output from CZE is called an electropherogram, and, unlike HPLC, there is generally very little background noise to distinguish from relevant Hb species (Fig. 24.4B). CZE also allows clean separation of HbE from HbA_2 and facilitates easier detection of HbH and HbBart.

Case Example 2

A 6-month-old female child presented with progressive pallor and failure to thrive. On examination, she had significant hepatosplenomegaly. A CBC showed a severe anemia (Table 24.4) with marked anisopoikilocytosis (variable cell size and shape), and she was referred for further investigations. Hb HPLC showed a markedly increased HbF and absent HbA. Both parents were found to have raised HbA_2 fractions on HPLC around 6% (normal range 2.0%–3.5%; Fig. 24.5). What is the most likely diagnosis in the child? Is this the likely cause of the child's anemia? What is the most likely cause of the elevated HbA_2 in the parents?

TABLE 24.4 Laboratory results for Case Example 2.

Hematologic parameter (units)	Result	Reference interval
WBC ($10^3/\mu L$)	15.2	4.3–10.0
RBC ($10^6/\mu L$)	4.3	4.4–5.6
Hb (g/dL)	8.9	13.0–18.0
HCT (%)	32	38–50
MCV (fL)	74	81–98
MCH (pg)	29.1	27.3–33.6
MCHC (g/dL)	33.6	32.2–36.5
Platelet count ($10^3/\mu L$)	220	150–400

Complete blood count remarkable for elevated white cell count with accompanying decrease in red cell count, mean corpuscular volume, hemoglobin, and hematocrit.
Hb, Hemoglobin; *HCT*, hematocrit; *MCH*, mean corpuscular hemoglobin; *MCV*, mean corpuscular volume; *RBC*, red blood cell; *WBC*, white cell count.

Case 2 Resolution

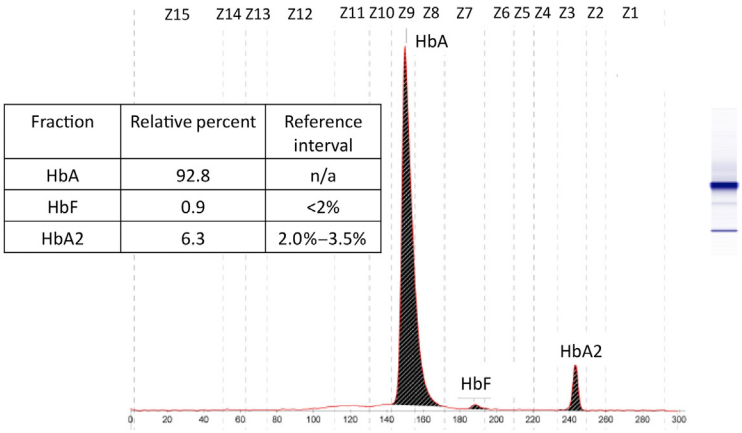
HbA_2 is a tetramer of two alpha and two delta globin subunits. Elevated HbA_2, as seen in the parents of the child, occurs in beta-thalassemia due to decreased production of beta globin. This causes a molar excess of free alpha globin subunits available to bind delta globin. The net result is an elevated relative percentage of HbA_2. The findings in this case suggest single-gene beta globin deletions in each of the parents. Single-gene beta globin deletions are not pathological, but they are important to diagnose as prenatal precautions. More severe forms of beta-thalassemia, as seen in this child, are referred to as beta-thalassemia major and occur when both beta globin genes have deleterious mutations that result in the absence of or significant decrease in beta globin synthesis. Rather than elevated HbA_2, the most striking Hb profile abnormality in beta-thalassemia major is a significant decrease in or complete absence of HbA with no accompanying variant peak. A chronic hemolytic anemia occurs in beta-thalassemia major, leading to blood transfusion dependence, which often results in iron overload. Resulting multi-organ damage is common.

Case Example 3

A 7-year-old African American female was brought to her pediatrician because her parents have noticed that she becomes out of breath when playing with peers and frequently complains of muscle cramps. Her records indicate that she was diagnosed as a carrier for HbS via newborn screening shortly after birth. Her pediatrician ordered a CBC and Hb profile evaluation (Table 24.5). Are the results consistent with the patient's diagnosis as a carrier for HbS?

Case 3 Resolution

In HbS carriers, the HbA:HbS ratio is approximately 60:40 (Table 24.6). Distinguishing between HbS trait and HbS with a concurrent beta-thalassemia can be difficult in the neonatal and early postnatal periods because the elevated concentration of HbF can mask the expected ratio between HbA and HbS observed in adults. If there is an underlying beta-thalassemia, the ratio decreases and the relative concentration of HbS is greater than that of HbA. Reviewing the relative percentages of Hb species in this child shows that her HbA is 28%, while her HbS is



Fraction	Relative percent	Reference interval
HbA	92.8	n/a
HbF	0.9	<2%
HbA2	6.3	2.0%–3.5%

FIGURE 24.5 Capillary zone electropherogram shows an elevated HbA_2, which is indicative of beta-thalassemia. Migration identification zones are indicated with "Z" followed by a number.

TABLE 24.5 Laboratory results for Case Example 3.

Hematologic parameter (units)	Result	Reference interval
WBC ($10^3/\mu L$)	13.2	4.5–13.5
RBC ($10^6/\mu L$)	5.7	4.0–5.2
Hb (g/dL)	8.6	11.5–15.5

HbA_2 (%)	5.2	2.0–3.5
HbS (%)	58.8	0
IEF interpretation	HbS and HbA present	

Complete blood count remarkable for elevated red cell count and mean corpuscular volume with accompanying decrease in hemoglobin and hematocrit. HbS was detectable by biochemical methods, and HbA_2 was elevated.
Hb, Hemoglobin; *HbA*, adult hemoglobin; *HbF*, fetal hemoglobin; *HCT*, hematocrit; *IEF*, isoelectric focusing electrophoresis; *MCH*, mean corpuscular hemoglobin; *MCV*, mean corpuscular volume; *RBC*, red blood cell; *WBC*, white cell count.

58.8%; HbA_2 and HbF are also elevated (5.2% and 7.0%, respectively; Table 24.5). Paternal and maternal Hb profiles are reviewed to help clarify the lineage: mother was a known HbS carrier; father had previously screened normal. On retesting, the father was shown to have an elevated HbA_2 (4.8%). Molecular testing confirmed that this child inherited one mutated beta globin gene from each parent, one with a point mutation conferring HbS and the second with a promoter mutation conferring a beta-thalassemia. In patients with this genotype, the clinical severity is inversely proportional to the concentration of HbA (higher percent HbA correlates with less severe presentation). Events that stress the body (illness and extended physical activity) can push the body into crisis where transfusion and/or hospitalization are necessary.

Qualitative measurement of hemoglobin variants

In addition to those Hb variants above, a large number of less common variants have been described in various ethnic populations (several are listed in Table 24.7). A conceptually straightforward approach to Hb variant detection is asking the question, "Does a simple biophysical challenge or basic separation technique qualitatively show anything different about an individual's results that may reflect their endogenous Hb?" These assays have historically been fundamental for intersecting Hb abnormalities with the clinical laboratory. Importantly, many of these techniques still play a large role in the laboratory assessment of Hb.

Slab gel electrophoresis

There are three types of electrophoresis that are commonly used to separate and visualize Hb species: acid, alkaline, and isoelectric focusing. Each of these techniques applies a small amount of lysed red cells to a polymer matrix for separation using an electric charge. The process is largely manual and semiquantitative; scanning densitometry is used to assess the Hbs present and lacks the precision to provide the attenuated details offered by HPLC and CZE. However, slab gel electrophoresis methods are useful confirmatory techniques for abnormalities detected using HPLC or CZE. In addition, isoelectric focusing electrophoresis (IEF) offers clinical information unable to be resolved using aforementioned biochemical methods.

TABLE 24.6 Distinguishing features between phenotypes remarkable for HbS.

Hemoglobin profile	Clinical severity	Hematocrit and hemoglobin	Red cell morphology	Hemoglobin profile quantification
AS	Normal	Normal	Rare sickle cell	HbA 60%; HbS 40%
SS	Marked	Low	Target cells; 20%–30% sickle cells	HbS 80%–95%; HbF 2%–20%
S/β^0-Thalassemia	Moderate to marked	Low	Hypochromic; microcytic; target cells; rare sickle cells	HbS 80%–95%; HbF 1%–15% F; HbA_2 3%–6%
S/β^+-Thalassemia	Mild to moderate	Low/normal	Slightly microcytic; target cells; rare sickle cells	HbS 55%–75%; HbA 10%–30%; HbF 1%–10%; HbA_2 3%–6%
SC	Mild to moderate	Low/normal	Slightly microcytic; rare sickle cells	HbS ~50%; HbC ~50%

β^0-Thalassemia indicates a complete gene deletion in a single beta gene; β^+-thalassemia indicates a mutation that decreases expression of a single beta gene.

Hb electrophoresis exploits the migration changes in Hb species when subjected to various pH environments and an electric field. It can be performed under acidic (pH 6.0–6.2; performed on citrate agar or an appropriate agarose gel) or alkaline (pH 8.0–8.6; generally performed on cellulose acetate) conditions. As the name implies, a red cell hemolysate is applied to wells on one end of a slab of gel, and an electric field is then applied to force the Hbs to migrate across the gel. Depending on whether acid or alkaline conditions are used, and the type of gel, the Hbs become charged, such that their charge-based migration patterns are predictable between the cathodal (negatively charged) and anodal (positively charged) ends of the gel. Visualization of the migrated Hb species is accomplished using a nonspecific protein stain (generally Ponceau S), which is sufficient, since 98% of the protein within a red cell corresponds to Hb, and scanning densitometry. A small, but noticeable band corresponding to carbonic anhydrase will also be detected. Neither acid nor alkaline electrophoresis provides a complete resolution of normal Hb species from common pathological Hb species (Fig. 24.6A and B). For example, while using alkaline electrophoresis, HbA_2 comigrates with HbC and HbE; on acid electrophoresis, HbA comigrates with HbA_2, HbE, HbD, and HbG. Consequently, both types of electrophoresis are functionally equivalent, but can provide complementary data in the investigation of an Hb abnormality. There are commercially available kits to detect Hb using acid or alkaline electrophoresis.

The third type of slab gel electrophoresis, IEF, is considered the biochemical gold standard for Hb abnormality detection and has two main advantages over acid and alkaline electrophoresis. First, because IEF separates proteins based on their molecule-specific isoelectric point (pI), the resolution of various Hb species is more refined than alkaline or acid gel electrophoresis. Second, IEF uses a heme-specific stain such as o-dianisidine rather than a nonspecific protein stain, which enables the technique to be more analytically sensitive and specific. IEF can detect small concentrations of HbH, the beta globin homotetramer that serves as the pathological indicator of alpha-thalassemia. HbH is often undetectable by other biochemical techniques (including CZE and HPLC).

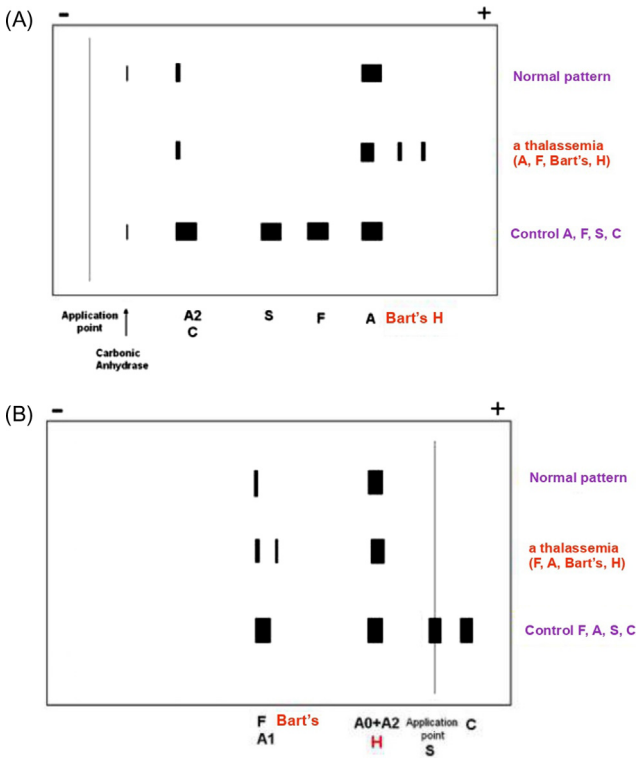

FIGURE 24.6 Diagram of normal and common variant hemoglobin migration in alkaline (A) and acid (B) electrophoresis.

Sickle solubility test

The sickle solubility test is a qualitative screening assay for sickling Hbs. This test exploits the inherent propensity for deoxygenated (deoxy-) HbS to polymerize and precipitate out of solution under conditions where deoxy-HbA remains soluble. In this assay, an aliquot of red cells is lysed in a reducing environment buffered to enhance the insolubility of deoxy-HbS. The appearance of a cloudy, opaque precipitate indicates a positive result. In general, the test will be positive when the concentration of HbS (or another sickling Hb) is greater than approximately 20%, which means that both homozygous and heterozygous carriers will be detected. Although the sickle solubility test cannot differentiate between homozygous and heterozygous genotypes, it is frequently used for screening at smaller volume hospitals, emergency department settings, and for screening blood donors for the presence of HbS.

Unstable hemoglobins

The biophysical properties of certain Hb variants make them more susceptible to oxidation relative to HbA. Assays for unstable Hb exploit this difference by detecting precipitates or inclusions that form when a whole blood lysate is exposed to heat or isopropanol, which enhance oxidation and destabilize the Hb bonds. These

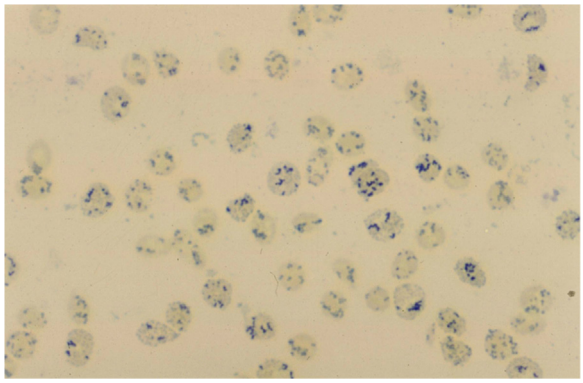

FIGURE 24.7 Red blood cell smear stained with bromocresol blue is remarkable for Heinz bodies. Concurrent biochemical analysis indicates that this individual has HbH disease, a form of alpha-thalassemia.

inclusions are called Heinz bodies and can also be detected by evaluating whole blood smears with supravital stains such as methyl violet and bromocresol blue (Fig. 24.7). Heinz bodies are also seen physiologically in G6PD deficiency, a genetic disorder that causes hemolytic anemia.

Case Example 4

A 28-year-old pregnant Filipino female presents for wellness prenatal screening. Her CBC results indicate a mild microcytic anemia (MCV = 72), which encourages her physician to order an Hb screening panel. The laboratory analyzes the sample using CZE and isoelectric focusing. No abnormalities are detected using CZE, but the IEF demonstrates an HbH concentration of <2% (Fig. 24.8). What is this indicative of?

Case 4 Resolution

Alpha-thalassemia occurs when there is a decreased synthesis of alpha globin, which disrupts the normal molar ratio of alpha to beta globin subunits and leads to a relative excess of beta globin. The free beta globin subunits form homotetramers, called HbH, which are inherently unstable and precipitate to form inclusion bodies within the red cell. The clinical severity of alpha-thalassemia is directly proportional to the number of alpha globin genes deleted. While single-gene deletions are usually silent, two-gene deletions may cause mild microcytic anemia, and three-gene deletions can lead to moderate or severe hemolytic anemia (known as HbH disease). Notably, four-gene deletions cause a condition termed hydrops fetalis in which excess fluid builds up in the fetus before birth in addition to anemia and other organ abnormalities. Most affected fetuses are stillborn or die shortly after birth.

Traditionally, the laboratory has detected HbH disease using biochemical methods because HbH concentrations

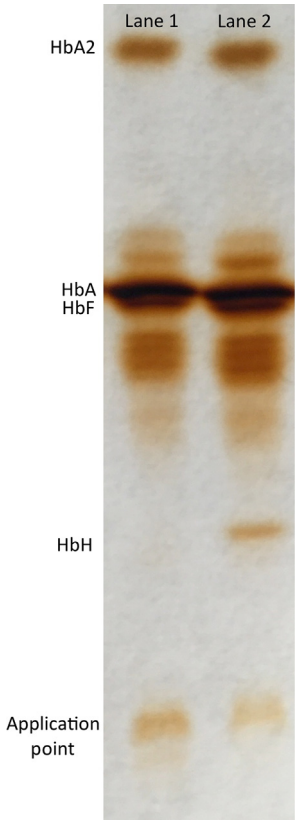

FIGURE 24.8 Isoelectric focusing electrophoresis of normal control (Lane 1) and patient remarkable for HbH of <2% (Lane 2). Major hemoglobin species and application point are appropriately marked; remaining bands are posttranslationally modified and degraded hemoglobin species.

are considerably elevated in these patients (~5%–15%). However, low concentrations of HbH (<2%) may be identified using IEF and indicate two-gene deletions. This patient has an MCV and an HbH concentration consistent with deletion of two alpha globin genes. There is no immediate medical concern for her, but because she is seeking prenatal care, paternal testing should be performed. If the father has evidence of a hemoglobinopathy, particularly one or more alpha globin gene deletions, genetic counseling services should be offered.

Mass spectrometry

Detection of Hb abnormalities using mass spectrometry is a relatively new application that has not been widely adopted in the clinical laboratory. There are various methods for mass spectrometry, but the general principle involves bombarding the sample with a laser beam and assessing the mass-to-charge ratio of produced ions. Mass spectrometry offers enhanced sensitivity and specificity for detection of variant Hbs, but the implementation of this method in the clinical laboratory can be costly and time-consuming.

Currently, Hb profiling by mass spectrometry has been most successful for newborn screening because of the amenability to small sample volumes, including the dried blood spots used in the newborn screen. Mass spectrometry also has invaluable utility for harmonization and standardization efforts. Standardization allows clinical thresholds to be universally adopted. For Hb variant analysis, this is most important for quantification of HbA_2, by which between-method standardization would allow for the endorsement of international beta-thalassemia diagnostic guidelines. The International Federation for Clinical Chemistry (IFCC) has supported a standardization program for HbA_2 that includes a scientific working group. Standardization requires a reference method, a certified reference material, and defined analytical performance expectations. The working group has made successful progress in developing an isotope dilution tandem mass spectrometry assay that quantifies HbA and HbA_2, allowing for the calculation of $\%HbA_2$, which is the recommended unit of measurement. This method meets the working group defined performance specifications and has the ability to assign primary calibrator values that could vastly improve comparability of results.

Molecular techniques

Although some Hb defects can be acquired or occur de novo, most Hb disorders are caused by inherited genetic defects. The majority of Hb disorders are autosomal recessive, and individuals heterozygous for a variant are generally asymptomatic. Molecular methods are often a crucial complement to hematologic and biochemical methods after a presumptive identification of a hemoglobinopathy and/or thalassemia. Laboratory determination of the underlying mutation(s) has utility in establishing a definitive diagnosis in cases where the hematologic phenotype is complex and also has utility in elucidating carrier status for genetic counseling.

There are greater than 1600 Hb variants that have been catalogued on a publicly available globin gene server database (HbVar: http://globin.cse.psu.edu). These variants range from single-nucleotide substitutions to chromosomal deletions and duplications. Thus a variety of molecular techniques must be employed to detect the various types of mutations seen in hemoglobinopathies. Current molecular methods can be separated into targeted assays that are designed to detect recurrent variants and methods suited for the identification of unknown or less common variants. Regardless, many of the methods start with an amplification step by PCR followed by one or more of an assortment of methods available for product detection. Each method has its own advantages and

disadvantages, and the most appropriate laboratory approach depends on both available technical expertise as well as the type and variety of Hb variants likely to be encountered in the relevant patient population.

The vast majority of cases submitted for laboratory analysis are for postnatal detection of variants; therefore DNA can be extracted from peripheral blood leukocytes. For in utero diagnosis, DNA can be extracted from chorionic villi obtained between gestational weeks 10 and 13, amniocytes obtained in the second trimester of pregnancy, or, most recently, from cell-free fetal DNA in maternal circulation.

Targeted assays for known variants

PCR-based techniques used for Hb variant identification include gap-PCR, allele-specific oligonucleotide hybridization or dot-blot analysis, reverse dot-blot analysis, allele-specific PCR, amplification refractory mutation system, high-resolution melt curve analysis, restriction enzyme analysis, and multiplex ligation-dependent probe amplification (MLPA). An efficient strategy for identifying common variants is to simultaneously detect multiple mutations using a multiplex assay. Several of the above methods have been designed as multiplex assays.

Gap-PCR

While more than 100 molecular forms of alpha-thalassemia have been identified, more than 90% of variants are comprised of a common set of deletions (the exact percent varies by population). This has led to the development and widespread adoption of gap-PCR for alpha-thalassemia diagnostics, a method that multiplexes detection of the seven most common alpha globin deletions: −3.7, −4.2, -FIL (Filipino deletion), -THAI (Thailand), -MED (Mediterranean), −20.5, and -SEA (Southeast Asian, Fig. 24.9). As several of the names imply, each deletion was initially described in a specific demographic. However, as global populations are increasingly mobile, there has been an increased incidence of alpha-thalassemia beyond the first-described populations. Gap-PCR can also be utilized to detect beta-thalassemia, delta−beta-thalassemia, hereditary persistence of fetal hemoglobin (HPFH), and the rare gamma−delta−beta-thalassemia.

Gap-PCR can be multiplexed within a single tube that contains a pool of various PCR primers specific for sequences of the genome that flank each individual deletion. The name gap-PCR is derived from the fact that each pair of primers spans the targeted deletion ("gap") breakpoints, such that a product of the expected size is only produced if the deletion is present (Fig. 24.9); without the deletion, the primers flank a region too large to amplify. PCR products are typically detected by standard agarose gel electrophoresis. A limitation of gap-PCR is that it can only detect targeted deletions. If a novel deletion is present that is outside the region of interest targeted by the primer mix, gap-PCR results will be normal. Thus, if there is a high clinical suspicion of alpha-thalassemia, a normal gap-PCR result may be reflexed to an alternative molecular method.

Case Example 5

As part of a routine annual physical exam, an 18-year-old Caucasian male had a CBC performed, which was remarkable for an increased red cell count and decreased MCV (Table 24.8). Further investigation by HPLC showed normal HbA_2 (2.5%), and inclusion body studies noted three or four "possible" HbH inclusions. Gap-PCR was performed to determine if the abnormal red cell indices were due to an Hb abnormality, and it was determined that the patient's genotype is −−SEA/aa. What does this result mean for the patient?

Case 5 Resolution

Alpha-thalassemia disorders are common, with estimations suggesting approximately 5% of the worldwide population carries an alpha-thalassemia variant. Absent or decreased production of the alpha chain of Hb causes alpha-thalassemia, and the severity can range from asymptomatic to lethal. There are two alpha globin genes on each chromosome 16 for a total of four alpha globin genes. Although the presence of four genes complicates

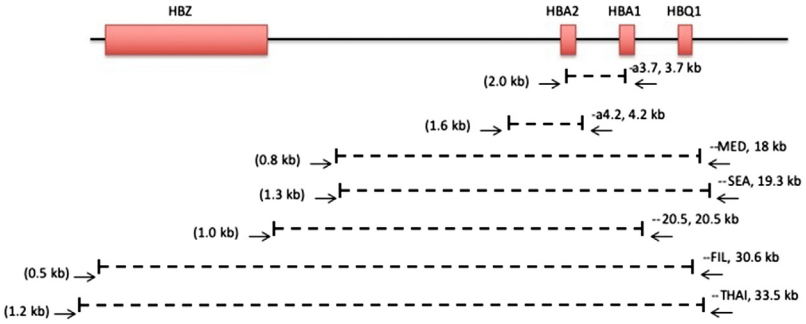

FIGURE 24.9 Gap-PCR schematic for alpha-thalassemia. Dashed lines: portions removed by each deletion. Arrows: primer locations that flank each deletion. The approximate size of each gap-PCR product is shown to the left of each deletion in parentheses.

TABLE 24.8 Laboratory results for Case Example 5.

Hematologic parameter (units)	Result	Reference interval
WBC ($10^3/\mu L$)	8.2	4.3–10.0
RBC ($10^6/\mu L$)	6.2	4.4–5.6
Hb (g/dL)	14.0	13.0–18.0
HCT (%)	42	38–50
MCV (fL)	67.5	81–98
MCH (pg)	23.1	27.3–33.6
MCHC (g/dL)	33.3	32.2–36.5
Platelet count ($10^3/\mu L$)	280	150–400

Complete blood count remarkable for elevated red cell count with decreased mean corpuscular volume, and mean corpuscular hemoglobin.
Hb, Hemoglobin; *HCT*, hematocrit; *MCH*, mean corpuscular hemoglobin; *MCV*, mean corpuscular volume; *RBC*, red blood cell; *WBC*, white cell count.

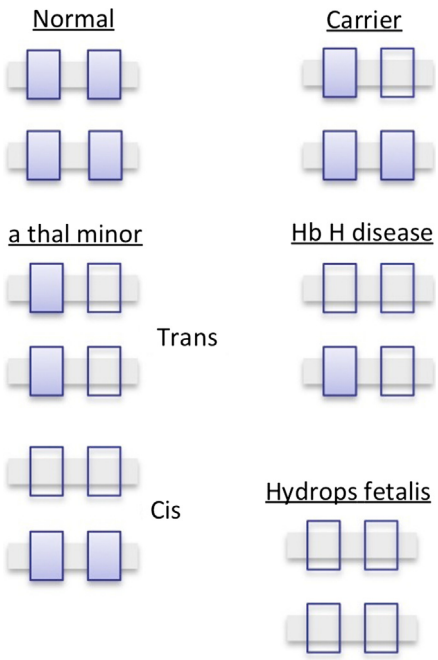

FIGURE 24.10 Four alpha globin genes are depicted. Filled boxes: normal gene. Open boxes: deletion. Note the cis and trans configurations for alpha-thalassemia minor.

genotypic characterization, phenotypes typically correlate with the number of nonfunctional genes. In this case, the patient has an SEA deletion, which involves deletion of two alpha globin genes. Since two alpha globin genes remain intact in this patient, the most significant clinical manifestations for this patient will be mild hypochromic microcytosis.

For genetic counseling purposes, it is important to determine whether the two deletions occur on a single chromosome (−−/aa, cis configuration) or whether one gene is mutated on each chromosome (−a/−a, trans configuration; Fig. 24.10). The cis configuration is at increased risk for producing offspring with HbH disease or hydrops fetalis, because one chromosome entirely lacks functional alpha globin genes. The −−SEA deletion is a cis deletion, and it is historically most prevalent in Southeast Asia where HbH disease and hydrops fetalis are more common. Thus this patient should be counseled that he is at risk for transmitting the −−SEA chromosome to offspring. In the patient's family, there was no history of anemia, and the family was unaware of Southeast Asian ancestry. This case highlights that the incidence of alpha-thalassemia is increasing globally and that molecular determination of the underlying genetic defect has significant implications.

Assays to detect unknown variants

Nonsequencing methods

Historically, a molecular method that has been widely used and does not involve DNA amplification is Southern blot hybridization, which is still utilized in certain contexts. It is particularly helpful when screening for large deletions or rearrangements, and is indispensable for identifying novel deletions. Prior to the advent of PCR, fluorescence in situ hybridization (FISH) analysis was also used to detect large alterations, though FISH probes have much less utility for detecting novel changes. Another alternative method is an array, which can be a single-nucleotide polymorphism (SNP) or comparative genomic hybridization array. Both methods can be used to detect large-scale alterations, such as deletions, and can also detect unknown deletions. For more information on these technologies, please refer to Chapter 13, Nucleic acid analysis in the clinical laboratory.

Two PCR-based methods for detecting unknown mutations exploit altered single-stranded DNA conformation and include denaturing gradient gel electrophoresis (DGGE) and single-strand conformation polymorphism analysis. An advantage of these methods is that they can detect a single-nucleotide change as well as small insertions and deletions. Although these methods are still viable, they require technical expertise and are labor-intensive, which increases overall turnaround time. Thus many laboratories have discontinued these methods in favor of sequencing.

Multiplex ligation-dependent probe amplification

Another PCR-based method that can detect uncommon and novel large rearrangements and copy number

alterations is MLPA. This method relies on multiplex probes that are available as a kit for either the alpha or beta globin gene clusters, or laboratories can design a custom probe mix. An advantage of this method is that the necessary instrumentation, including PCR and capillary electrophoresis, is typically available in clinical molecular labs. Briefly, DNA probes are tiled across a region of interest, hybridized to patient DNA, and then amplified selectively, such that PCR product abundance is proportional to the copy number of the target sequence. Products are separated by capillary electrophoresis, and analysis involves comparing a patient's relative peak abundance to characterized controls. A limitation of this method is that it does not identify specific breakpoints for detected alterations. Since definitive identification of the mutation is a key for genetic counseling, one approach that can be used is to screen with MLPA and follow up positive cases with sequencing.

Chain-terminating dideoxynucleotide sequencing (Sanger sequencing)

The relatively small size of the beta and two alpha globin genes makes them quite amenable to amplification and sequencing. Sequencing is an ideal technique for the detection of single-nucleotide changes as well as small insertions and deletions. An advantage of sequencing is that it can readily detect novel mutations as well as those previously described. A challenge with sequencing is that uncharacterized variants may be identified. The international globin gene server database (HbVar: http://globin.cse.psu.edu) is a valuable resource when novel variants are encountered, and family studies can also help elucidate whether an identified variant is pathogenic.

Case Example 6

A 24-year-old African American female is referred for investigation of hypochromic microcytosis with a normal HbA_2 and elevated HbF (Table 24.9). Initial molecular tests for alpha-thalassemia by gap-PCR are unremarkable, as are subsequent sequence analysis studies of the *HBB*, *HBA1*, and *HBA2* genes. MLPA is used to investigate a possible beta globin gene cluster deletion, and a large deletion (13.4 kb) is identified that encompasses the delta and beta genes. What is the reason for the microcytosis in this case? What values from the Hb screen are particularly noteworthy?

TABLE 24.9 Laboratory results for Case Example 6.

Hematologic parameter (units)	Result	Reference interval
WBC ($10^3/\mu L$)	11.2	4.5–13.5
RBC ($10^6/\mu L$)	4.8	4.0–5.2
Hb (g/dL)	12.6	11.5–15.5
HCT (%)	33	35–45
MCV (fL)	68.5	77–95
MCH (pg)	20.9	25.0–33.0
MCHC (g/dL)	38	32.2–36.5
Platelet count ($10^3/\mu L$)	358	200–450
HbA (%)	92.2	n/a
HbF (%)	5.3	<2
HbA_2 (%)	2.5	2.0–3.5

Complete blood count remarkable for decreased mean corpuscular volume and mean corpuscular hemoglobin. Fetal hemoglobin was elevated by biochemical methods, and HbA_2 was normal.
Hb, Hemoglobin; *HbA*, adult hemoglobin; *HbF*, fetal hemoglobin; *HCT*, hematocrit; *MCH*, mean corpuscular hemoglobin; *MCV*, mean corpuscular volume; *RBC*, red blood cell; *WBC*, white cell count.

Case 6 Resolution

This case illustrates several features characteristic for individuals heterozygous for delta/beta-thalassemia. Specifically, HbF concentrations are increased in the context of a normal HbA_2. The MCH and MCV are decreased to a lesser extent than is typically observed in other beta-thalassemias, which is due to increased gamma chain synthesis. The delta/beta deletion causes an imbalance between the synthesis of alpha and nonalpha chains that manifests as mild microcytosis. Although there is a wide range of observed HbF concentrations in delta/beta-thalassemia carriers, the notable finding is that HbF is modestly elevated and HbA_2 is normal. HbF is also increased in HPFH; however, the increase is generally more significant in HPFH (up to 35%). Another distinction between HPFH and delta/beta-thalassemia is that HPFH is not associated with microcytosis. Furthermore, HbF in HPFH patients is typically distributed equally within RBCs (pancellular), which contrasts the heterogeneous HbF distribution found in delta/beta-thalassemia. These findings point to a diagnosis of delta/beta-thalassemia, but family studies and molecular analysis are highly useful for confirmation. Identification of the underlying mutation is also helpful for additional family studies that may be clinically indicated.

Next-generation sequencing

Massively parallel sequencing or next-generation sequencing (NGS) has been rapidly adopted in clinical laboratories for numerous applications that range from prenatal screening for chromosomal aneuploidies to

treatment selection in oncology. A key advantage of NGS is that it is capable of detecting single-nucleotide changes, insertions and deletions, structural rearrangements, and larger copy number alterations. Many factors from assay design to bioinformatics processing affect what information can be gleaned from a test, but there is no doubt that NGS can be effectively used in clinical practice.

To date, there have been few studies that have utilized NGS for the detection of Hb disorders. However, the potential to consolidate testing for Hb disorders to a single methodology is both powerful and appealing. As described above, molecular detection of the varied types of mutations that underlie Hb disorders requires numerous methods that are labor-intensive and technically demanding. Although NGS is challenging both technically and interpretively, there is much interest in a single method that is capable of detecting the entire complement of molecular alterations.

There has also been significant interest in prenatal screening and diagnosis of thalassemia. This has partially been prompted by the continuous adoption of prenatal aneuploidy screening from cell-free DNA in maternal circulation in the general obstetric population. There have been limited studies of prenatal screening for thalassemia from cell-free DNA, but several have reported success. As NGS continues to be widely implemented in clinical laboratories, it will likely be applied to screening and diagnostic purposes in both prenatal and postnatal patient populations.

Self-assessment questions

1. An adult with a normal hemoglobin profile would be expected to have the following hemoglobin species detected:
   a. HbA only
   b. HbA and HbA_2 only
   c. HbA and HbF only
   d. HbA, HbF, and HbA_2 only
2. Quantitative biochemical techniques are better than qualitative ones for detecting which of the following disorders?
   a. alpha-thalassemia
   b. beta-thalassemia
   c. hemoglobin Barts
   d. sickle cell disease
3. To distinguish between an HbS carrier and an HbS carrier with concurrent beta-thalassemia, it is important to evaluate which of the following?
   a. the ratio of HbS to HbF
   b. the absolute value of HbS
   c. the ratio of HbA to HbS
   d. the relative percent of HbA_2
4. At the molecular level, the most common cause of alpha-thalassemia is which of the following?
   a. deletion
   b. insertion
   c. point mutation
   d. premature stop codon
5. Which of the following is a feature of beta-thalassemia minor?
   a. decreased HbA_2
   b. hypochromic RBC
   c. increased HbF
   d. microcytic RBC
6. Chain-terminating dideoxynucleotide or Sanger sequencing is best suited for detecting single-nucleotide changes and small insertions and deletions. Which thalassemic disorder is most commonly caused by a molecular defect detectable by Sanger sequencing?
   a. alpha-thalassemia
   b. beta-thalassemia
   c. gamma−delta-thalassemia
   d. hemoglobin H disease

Chapter 25

The complete blood count and white blood cell differential

Alisha D. Ware
Department of Pathology, The Johns Hopkins University School of Medicine, Baltimore, MD, United States

Learning objectives

After reviewing this chapter, the reader will be able to:

- Describe the morphology and function of red blood cells.
- Describe the morphology and function of subtypes of white blood cells.
- Describe the morphology and function of platelets.
- Describe laboratory methodologies for hematologic measurements.
- Understand the disorders that commonly cause abnormal complete blood count and/or differential results.
- Recognize common laboratory errors that occur on hematology analyzers.

The cellular components of the peripheral blood

The peripheral blood contains three main cellular components: red blood cells (RBCs, erythrocytes), white blood cells (WBCs, leukocytes), and platelets (thrombocytes).

Red blood cells

RBCs are the most numerous component of the peripheral blood [1,2]. Their primary role is in respiration of the body's tissues. A normal RBC count is $4.5-6.0 \times 10^{12}$/L in adult men and $4.0-5.0 \times 10^{12}$/L in adult nonpregnant women [3]. Normal RBCs are $\sim 7-8$ μm in diameter and are shaped like a biconcave disc, with a central pallor that comprises approximately one-third of the cell's diameter (Fig. 25.1) [2,4]. On a Romanowsky or Wright–Giemsa stain, RBCs appear pink or red [2]. Mature RBCs lack nuclei and contain hemoglobin, a protein composed of iron that transports oxygen and carbon dioxide [1]. The life span of a normal RBC is ~ 120 days in systemic circulation [4].

Reticulocytes are circulating immature, nonnucleated RBCs newly released from the bone marrow [1,2,4]. These cells take 1–2 days to mature in the circulation. Reticulocytes contain ribosomal proteins and RNA, which may be visualized with supravital stains, such as methylene blue [2,5]. On a Romanowsky or Wright–Giemsa stain, reticulocytes appear polychromatic, or blue-gray (Figure 25.1) [2,4]. The presence of reticulocytes and nucleated red blood cells (nRBCs) in the peripheral blood corresponds with the bone marrow's ability to increase RBC production in response to physiologic stress, although immature nRBCs and reticulocytes are not abundant and infrequently found in the circulation of a healthy individual [1,5].

Platelets

Platelets are anuclear fragments of megakaryocyte cytoplasm [2,4]. A normal platelet count is $150-450 \times 10^9$/μL [3,6,7]. Typically, mature platelets are between 1.5 and 3 μm in size. They contain azurophilic granules, which are comprised of substances necessary for coagulation and inflammatory reactions (Fig. 25.1) [4]. Immature platelets are larger in size (4–7 μm) and may be increased in association with increased platelet loss or peripheral destruction. Giant platelets (>10 μm in size) may be seen in hereditary disorders or neoplastic conditions [4].

White blood cells

WBCs carry out the body's immune functions [1,4]. Circulating WBCs in a healthy individual include neutrophils, lymphocytes, monocytes, eosinophils, and basophils. A normal WBC count in healthy adults is $4.5-11.0 \times 10^9$/L [3,8]. Neutrophils, also known as polymorphonuclear neutrophils (PMNs), are the most abundant subtype of circulating WBCs in healthy individuals (40%–75%) [2,3]. Mature PMNs are 10–15 μm in size. They have

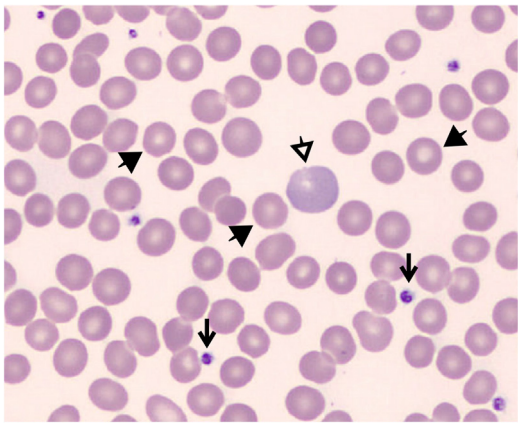

FIGURE 25.1 Wright's stain of a peripheral blood smear. Red blood cells (thick arrows) show central pallor that comprises approximately one-third of the cell's diameter. Reticulocytes (open arrow) may be present in small numbers in normal circulation. Platelets (thin arrows) are typically the smallest circulating cellular component, and they contain numerous azurophilic granules.

granular cytoplasm and a segmented nucleus with two to five lobes connected by a thin nuclear filament (Fig. 25.2A). Band forms, which are less mature neutrophils, contain a single-lobed U-shaped nucleus (Fig. 25.2B) [2,4]. PMNs play a vital role in the body's defense against bacteria and fungi [2,4]. Other immature forms, including metamyelocytes, myelocytes, and promyelocytes, may be seen, circulating in low numbers (<0.5% of circulating leukocytes). An increase in myeloid precursors at various stages in the peripheral blood, termed left shift, may be seen in cases of severe infection, hematopoietic neoplasms, or in other pathologic states [2,4].

Lymphocytes measure 7−15 μm and typically comprise 20%−45% of circulating WBCs [2,4]. Mature lymphocytes have scant pale blue cytoplasm and a round-to-oval nucleus with mature chromatin (Fig. 25.2C) [2−4]. Reactive or large granular lymphocytes have more abundant cytoplasm and fine azurophilic granules. Lymphocytes are involved in defense against viral infections and also play a role in chronic inflammatory conditions [4].

Monocytes are the largest normal circulating cells (12−20 μm) and typically comprise 2%−10% of circulating WBCs. They have gray-blue cytoplasm with an indented or reniform nucleus (Fig. 25.2D). Reactive or neoplastic monocytes may contain azurophilic granules or vacuoles within the cytoplasm [2−4]. Monocytes are important antigen-presenting cells, and are vital in immune modulation and defense against pathogens [4].

Eosinophils comprise approximately 1%−6% of circulating WBCs. They have characteristic brightly eosinophilic (orange-red) cytoplasmic granules and a bilobed nucleus (Fig. 25.2E) [2,4]. Eosinophils are approximately

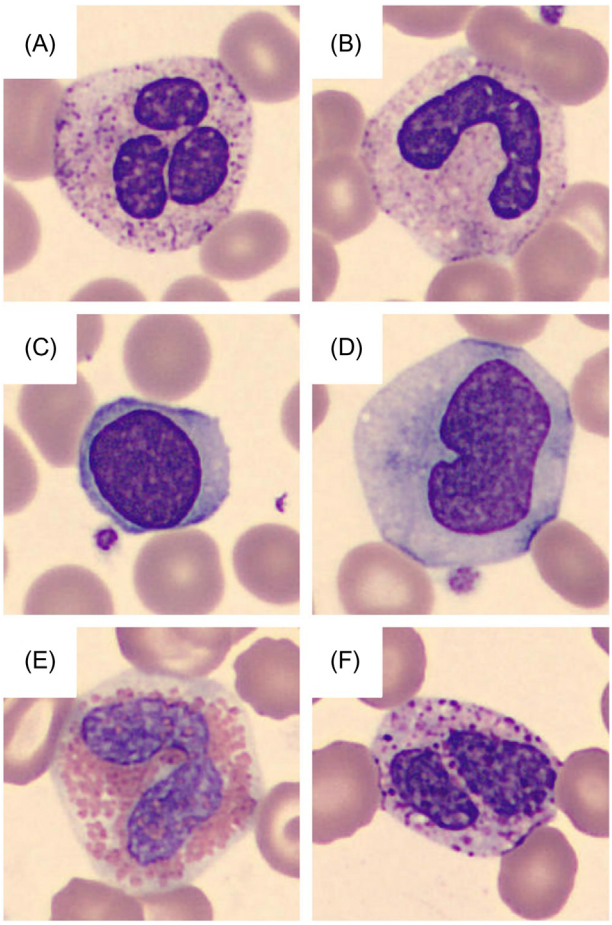

FIGURE 25.2 White blood cell morphology on a Wright's stain of a peripheral blood smear. Segmented neutrophils (A) are typically the most frequent white blood cell type in normal circulation. Band neutrophils (B), which are less mature, are also frequently seen. Lymphocytes (C) are smaller white blood cells with less abundant basophilic cytoplasm. Monocytes (D) have a folded or kidney bean-shaped nucleus and abundant blue-gray cytoplasm. Eosinophils contain numerous orange-red cytoplasmic granules and a bilobed nucleus (E). Basophils (F) also commonly have a bilobed nucleus; however, they contain numerous basophilic granules that may obscure the nucleus.

10−15 μm in size [3,4]. A relative and/or absolute increase in circulating eosinophils is primarily associated with allergic disease, parasitic and fungal infections, and some neoplastic conditions [2,4].

Basophils play a role in allergic disease and infections. In a healthy individual, basophils comprise <1% of circulating WBCs. They are 10−15 μm in size and are characterized by dense purple granules that often obscure the segmented nucleus (Fig. 25.2F) [2,4].

Blasts are immature cells that may be of myeloid or lymphoid lineage, or, rarely, of erythroid or megakaryocytic lineage. Blasts characteristically have a high nuclear-to-cytoplasmic ratio, fine chromatin, and prominent nucleoli (Fig. 25.3). Myeloid blasts may show cytoplasmic granules or Auer rods; however, it is often

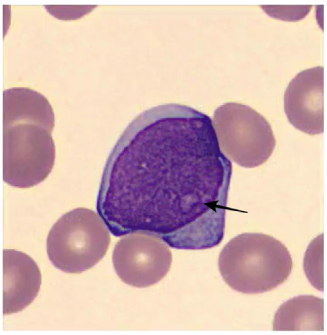

FIGURE 25.3 Blast morphology on a Wright's stain of a peripheral blood smear. Blasts are characterized by a high nuclear-to-cytoplasmic ratio, fine chromatin, and prominent nucleoli (arrow).

difficult to determine blast lineage on morphology alone. Blasts should be exceedingly rare in the circulation, an increase in circulating blasts is concerning for acute leukemia or other bone marrow disorder, and prompt evaluation by flow cytometry is warranted [2,4].

The complete blood count and white blood cell differential

The complete blood count (CBC) is one of the most commonly ordered laboratory tests. A blood sample for a CBC should be collected in an ethylenediaminetetraacetic acid (EDTA) tube. EDTA is an anticoagulant that functions by chelating calcium and other metal ions, thus preventing the enzymatic reactions of the coagulation cascade. Its use allows for preservation of the cellular components of the peripheral blood for laboratory evaluation [9]. Components of the CBC include the RBC and platelet count and indices, and the WBC count with or without the WBC differential. Abnormalities in results will typically generate an alert, termed a flag. Review of a peripheral blood smear may be required to confirm flagged results [1,4,5,10,11]. Table 25.1 shows the reference ranges for the CBC count and WBC differential.

TABLE 25.1 Typical reference ranges for complete blood count and white blood cell differential in healthy adults [2,3,8].

CBC component	Reference range
White blood cell count	$4–11 \times 10^9$/L
Neutrophils	40%–75%
Lymphocytes	20%–45%
Monocytes	2%–10%
Eosinophils	1%–6%
Basophils	<1%
Red blood cell count	$4.5–6 \times 10^{12}$/L (males)
	$4–5 \times 10^{12}$/L (females)
Hemoglobin	14–17.5 g/dL (males)
	12–15 g/dL (females)
Hematocrit	41%–50% (males)
	35%–45% (females)
Mean corpuscular volume	80–96 fL
Mean corpuscular hemoglobin	27–33 pg
Mean corpuscular hemoglobin concentration	33–35 g/dL
Red blood cell distribution width	11%–15%
Platelet count	$150–450 \times 10^9$/L
Mean platelet volume	9–13 fL

CBC, Complete blood count.

Laboratory techniques used in the complete blood count

Modern hematology analyzers use several methods for cell counting, including impedance, conductivity measurements, light scatter, and fluorescence [5]. Impedance, also known as the Coulter principle, involves passing individual blood cells through an analyzer channel. As each cell passes through the analyzer, an electrical pulse is generated. The number of pulses generated correlates with the cell count, while the height of the electrical pulse correlates with cell volume [5,10,12]. Conductivity measurements with high-frequency electromagnetic current provide information on internal structure, including nuclear-to-cytoplasmic ratio, nuclear density, and cytoplasmic granularity [5]. Flow cytometry methods can be used to assess cell count and volume by light scatter characteristics [1,5,10,11]. Fluorescent dyes may be used to label specific cell types, including reticulocytes, platelets, and WBCs, for quantification [1,5,12].

The red blood cell and platelet counts and indices

In a CBC, the RBC count, hemoglobin, mean cell volume (MCV, also known as mean corpuscular volume), hematocrit, mean corpuscular hemoglobin (MCH), mean corpuscular hemoglobin concentration (MCHC), and red blood cell distribution width (RDW) are reported, as are the platelet count, mean platelet volume (MPV), and platelet distribution width (PDW).

Red blood cell and platelet counts

One analyzer channel is most commonly used for both RBC and platelet detection, with volume parameters set to differentiate the two cell types. Anucleate cells with a volume of 2–30 femtoliters (fL) are classified as platelets, whereas those with a volume of 40–250 fL are classified as RBCs [5]. This methodology may lead to misclassification of abnormally sized cells. Large platelets may be classified as RBCs, causing a false increase in the RBC count and decrease in the platelet count. Similarly, fragmented RBCs (schistocytes) or microcytic RBCs may be classified as platelets, causing a falsely elevated platelet count and a spuriously low RBC count [1,5]. In such cases, a review of the peripheral blood smear and the patient's clinical history is warranted in order to evaluate the cause of abnormal cellular morphology. Common variations in RBC shape are discussed in Table 25.2, and common causes of microcytosis are described below (see "Abnormal red blood cell count or indices" section).

Fluorescent platelet count

Some automated hematology analyzers offer a fluorescent channel for platelet counts, which improves the accuracy of platelet quantification in thrombocytopenia, when large platelets are present, and in instances in which there are interferences from microcytic RBCs or RBC and/or WBC fragments. The fluorescent platelet channel may be automatically employed by flagged platelet counts, or based on laboratory-specific predetermined parameters [13]. Fluorescent dyes, such as oxazine, thiazole orange, or polymethine, are used to stain the nucleic acids within the cells. The platelets are analyzed via flow cytometry, using laser light to categorize cells as platelets based on size (based on forward light scatter) and fluorescence intensity. This method is also used to determine the immature platelet fraction and differentiate abnormal platelets, RBCs or fragments, and reticulocytes [13–15].

Reticulocyte count

Reticulocytes are commonly measured by fluorescence following staining with a fluorescent dye, such as new methylene blue, oxazine, auramine O, polymethine, and thiazole orange, which binds to residual RNA in the immature RBCs. The cells are then passed through a detector for quantification [1,5].

TABLE 25.2 Common variations in red blood cell shape [2–5].

RBC abnormality	Morphologic characteristics	Associated conditions
Sickle cells	Boat-shaped or sickle-shaped RBCs	Sickle cell disease
Target cells	Targetoid RBCs	Thalassemia, sickle cell disease, hemoglobin C trait or disease, iron deficiency, and liver disease
Ovalocytes	Long axis is 1–2 times length of short axis	Folate and vitamin B_{12} deficiency
Elliptocytes	Long axis is >2 times length of short axis	Hereditary elliptocytosis, thalassemia, hemoglobin S or C trait, cirrhosis, iron deficiency anemia, and megaloblastic or myelophthisic anemia
Stomatocytes	Slit-like central pallor	Hereditary stomatocytosis, acute alcohol ingestion, cirrhosis, obstructive liver disease, and Rh null disease
Echinocytes (burr cells)	Blunt spicules evenly distributed on the RBC membrane	Liver or renal disease, pyruvate kinase deficiency, and artifact
Acanthocytes	Irregular thorny spicules on the RBC membrane	Postsplenectomy, pyruvate kinase deficiency, hemolytic anemia, renal disease, thalassemia, and abetalipoproteinemia
Schistocytes	Fragmented RBC without central pallor	Microangiopathic hemolytic anemia
Spherocytes	RBC without central pallor	Autoimmune hemolytic anemia and hereditary spherocytosis
Bite cells	Bitten apple appearance	Heinz body anemia and G6PD deficiency
Blister cells	Vacuole on the peripheral RBC membrane	Heinz body anemia and G6PD deficiency
Dacryocyte	Teardrop-shaped RBCs	Bone marrow infiltration or fibrosis, megaloblastic anemia, hemolytic anemia, and hypersplenism

G6PD, Glucose-6-phosphate dehydrogenase; *RBC*, red blood cell.

Hemoglobin

Hemoglobin is measured spectrophotometrically following conversion of the molecule to cyanomethemoglobin [1,5,16]. Following RBC lysis, potassium ferricyanide oxidizes the ferrous ion of hemoglobin to the ferric ion of methemoglobin. Methemoglobin is then converted to cyanomethemoglobin following the addition of potassium cyanide. Absorbance at 540 nm is measured, and the intensity of this signal corresponds to hemoglobin concentration [5]. Hemoglobin is reported in grams per deciliter (g/dL). A normal hemoglobin measurement is 14−17.5 g/dL for adult males and 12−15 g/dL for adult females [3].

Mean corpuscular volume and mean platelet volume

The RBC MCV is a measure of the average volume of the RBCs in a given blood sample. The MCV is typically calculated from the RBC histogram, which is plotted by the hematology analyzer (Fig. 25.4A). The *x*-axis of the histogram corresponds to the RBC volume, measured in fL, and the *y*-axis corresponds to the percentage of RBCs at each specific volume. The volume that corresponds to the peak of the curve equals the MCV [1,5]. Like the MCV, the MPV measures the average volume of the platelets. Determination of MPV is analogous to the measurement of MCV (Fig. 25.4B) [1,5].

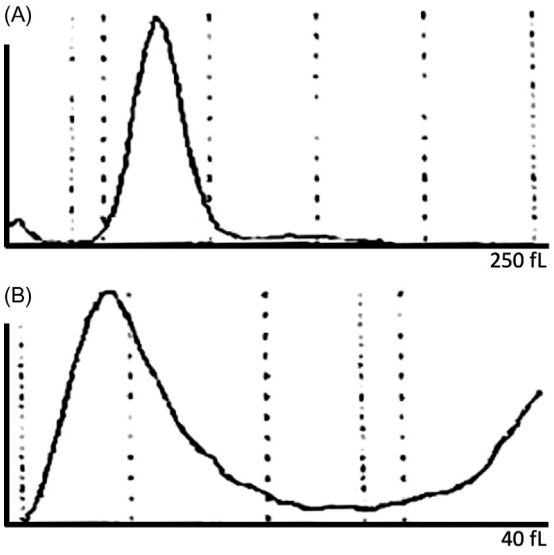

FIGURE 25.4 Red blood cell (A) and platelet (B) histograms produced by a hematology analyzer. The *x*-axis corresponds to cell volume in fL, and the *y*-axis corresponds to the percentage of cells at each specific volume. The mean cell volume of a red blood cell is defined by the volume that corresponds to the peak of the red blood cell histogram curve, and the mean platelet volume equals the volume that corresponds to the peak of the platelet histogram curve.

Hematocrit

The hematocrit is the percentage of packed RBCs in the whole blood [17]. The hematocrit has the implied units of L/L, although it is usually reported as a percent. Prior to the use of modern analyzers, the hematocrit was measured by centrifuging a tube of blood, and measuring the proportion of RBCs, which would settle to the bottom of the tube, to the total volume of blood. On modern hematology analyzers, the hematocrit is a calculated value [5,18,19]. A simple equation to calculate the hematocrit percent is to multiply the RBC count (in cells/L) by the MCV (in fL).

$$\text{Hematocrit} = \text{RBC Count}\left(\text{in RBCs/L}\right) \times \text{MCV(in fL)}$$

Sample calculation for an RBC count of 4.68 × 10^{12}/L and an MCV of 84.8 fL:

$$\text{Hematocrit} = 4.68 \times 10^{12}/\text{L} \times 84.8 \times 10^{-15}\text{L} = 0.397 \text{ L/L(or 39.7\%)}.$$

Mean corpuscular hemoglobin and mean corpuscular hemoglobin concentration

The MCH and MCHC are also calculated on hematology analyzers. MCH, reported in picograms (pg), is a measure of the average amount of hemoglobin in the RBCs [5,18,19]. It can be calculated by dividing the hemoglobin (in g/L) by the RBC count. MCHC measures the average concentration of hemoglobin in the RBCs, and is calculated by dividing the hemoglobin by the hematocrit. Like hemoglobin, the MCHC is reported in g/dL.

$$\text{MCH(pg)} = \text{Hb} \div \text{RBC count}$$

Sample calculation for an RBC count of 4.68 × 10^{12}/L and a hemoglobin of 133 g/L:

$$\text{MCH(pg)} = 133\text{g/L} \div 4.68 \times 10^{12}/\text{L} = 28.4 \text{ pg}$$

$$\text{MCHC}\left(\text{g/dL}\right) = \text{hemoglobin} \div \text{hematocrit}.$$

Sample calculation for a hemoglobin of 13.3 g/dL and a hematocrit of 0.397:

$$\text{MCHC}\left(\text{g/dL}\right) = 133\text{g/dL} \div 0.397 = 33.5\text{g/dL}.$$

Red blood cell and platelet distribution widths

The RDW and PDW are measures of the degree of variation in RBC or platelet size, respectively, in a sample. The RDW and PDW are essentially coefficients of variation of the RBC or platelet volume, and they are expressed as a percentage.

The white blood cell count and differential

Modern hematology analyzers most often report either a three- or five-part WBC differential. Three-part analyzers often use impedance to categorize WBCs as granulocytes, "MID" or intermediate-sized cells (monocytes, eosinophils, and basophils), or lymphocytes; categorization is based on cell size [10,11]. Features such as radiofrequency conductivity may be utilized to provide additional information about WBCs, such as internal complexity or granularity [10]. Five-part analyzers frequently use light scatter by flow cytometry techniques to quantify WBCs and differentiate them by cell size and complexity. As with impedance, cell counts correspond to the number of times the light source is interrupted. A cell's forward scatter is proportional to cell size, while right-angle side scatter correlates with a cell's internal complexity. Side fluorescence correlates with the amount of nucleic acid found within a cell. Each cell type has a distinctive light scatter and fluorescence pattern, which is measured by the analyzer to produce a WBC differential (Fig. 25.5). A five-part analyzer is able to categorize WBCs as neutrophils, lymphocytes, monocytes, eosinophils, or basophils [1,10,11]. Although a three-part analyzer may provide sufficient information in many clinical settings, most laboratories are now using five-part analyzers that provide a more sensitive WBC measurement and greater accuracy in the WBC differential [10,11]. Basophils may be measured via a separate channel in which RBCs and WBCs are lysed, leaving behind the basophils, which are resistant to cell lysis, and bare nuclei of the lysed WBCs [1,12].

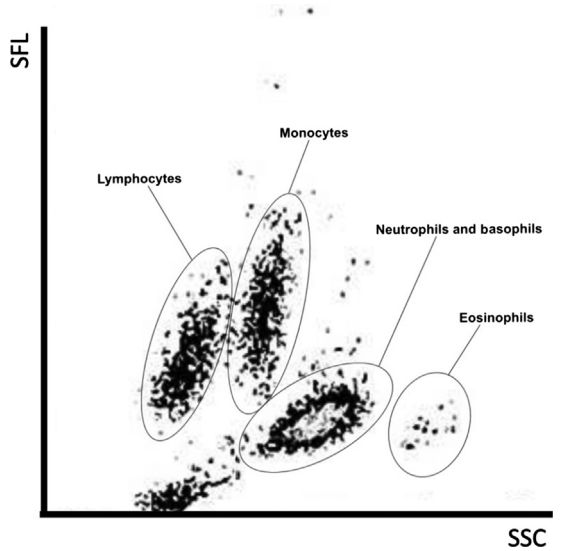

FIGURE 25.5 White blood cell differential plot produced by a five-part white blood cell differential analyzer. Right-angle light scatter, or side scatter, on the *x*-axis corresponds to a cell's internal complexity, while side fluorescence correlates with the amount of nucleic acid within a cell. Each cell type has a distinctive light scatter and fluorescence pattern, as noted on the plot, which is measured by the analyzer to produce a white blood cell differential.

Interpretation of abnormal results for the complete blood count or white blood cell differential

Most modern hematology analyzers will provide an alert, frequently termed a "flag," for abnormal results [5,10,11]. Common reasons for flagged CBC and/or WBC differential results include, but are not limited to, abnormally high or low values, blasts (immature cells), increased immature granulocytes (WBC left shift), atypical lymphocytes, nRBCs, or platelet clumps [10]. Some of the common causes of abnormal CBC and WBC differential results are discussed below. Evaluation of a peripheral blood smear is an essential component in the diagnostic workup of abnormal CBC results, and will be discussed in further detail in the sections to follow.

Abnormal red blood cell count or indices

Anemia

Anemia is defined by the World Health Organization as a hemoglobin concentration of less than 12 g/dL in nonpregnant women, less than 11 g/dL in pregnant women, and less than 13 g/dL in men [5]. Anemia is typically described as microcytic, normocytic, or macrocytic, and can stem from many etiologies including blood loss, bone marrow disorders, genetic disorders, or increased peripheral destruction of RBCs. Microcytic RBCs are abnormally small in size and have a lower than normal MCV ($<$80 fL) due to insufficient production of hemoglobin. Microcytic anemia may occur in iron or copper deficiency, thalassemias, hemoglobinopathies, or bone marrow disorders [1,4,5,20,21]. Normocytic anemia, in which RBCs are normal in size (80−100 fL), may be observed in cases of acute blood loss, RBC destruction, or RBC underproduction. Anemia of chronic disease and sideroblastic anemias may cause normocytic or microcytic anemia. Macrocytic anemia, which is associated with an abnormally elevated RBC MCV ($>$100 fL), may be due to megaloblastic anemia (vitamin B_{12} or folate deficiency), myelodysplastic syndrome, acute blood loss, liver disease, drugs, or alcoholism [2,5,20,21]. In addition to the RBC count and indices, RBC morphology may also aid in determining the cause of anemia (see "Interpretation of the peripheral blood smear" section below). Treatment of anemia involves addressing the underlying cause of disease.

In iron deficiency, the RBCs are microcytic and hypochromic with a low MCHC. The deficiency may be

caused by inadequate intake or decreased absorption of iron, or due to blood loss (i.e., chronic gastrointestinal bleeding). In more advanced disease, the transferrin saturation and ferritin concentrations are low, which may aid in the diagnosis. On bone marrow biopsy, a Prussian blue iron stain will show depleted iron stores [4,5,20,21]. The RDW may be normal or elevated in iron deficiency anemia [1,4,20,21]. The treatment for iron deficiency anemia involves replenishing iron stores with oral supplements or dietary modification [21].

Anemia of chronic disease is a frequent cause of anemia, particularly in hospitalized or chronically ill patients. It most commonly causes normocytic normochromic anemia; however, progressive cases may result in microcytic hypochromic anemia. Anemia of chronic disease may occur in the setting of any chronic disorder, including inflammatory or autoimmune disorders, infections, and malignancy. In anemia of chronic disease, hepcidin, an important regulator of iron homeostasis, is upregulated, which leads to defective iron transport from the gut and inadequate incorporation of iron into erythroid precursors. Laboratory analysis typically reveals a low serum iron, normal or high ferritin, and normal or increased bone marrow iron stores [4,5,20].

Thalassemias cause microcytic hypochromic anemia due to decreased alpha or beta globin chain synthesis. Alpha-thalassemia is caused by deletions of one or more of the four alpha chain genes on chromosome 16, with disease severity corresponding to the number of deleted loci. Beta-thalassemia is caused by mutations in the beta globin gene on chromosome 11. Delta−beta-thalassemia is caused by deletions of segments of DNA on chromosome 11 that involve both the beta and delta globin genes. Disease severity in thalassemia depends on the genetic abnormality, the number of genes deleted or affected, and the presence of a concurrent hemoglobinopathy (i.e., sickle cell disease). Thus a patient with thalassemia may have microcytosis without anemia or may have severe anemia. A diagnosis of thalassemia requires additional laboratory evaluation, including, but not limited to, high-performance liquid chromatography or hemoglobin electrophoresis. However, CBC findings, including a normal or increased RBC count, low MCV, low to normal MCHC, and a normal or increased RDW, can aid in the diagnosis of thalassemia [4,20].

Sideroblastic anemia may result from one of several hereditary or acquired disorders, all of which impair heme synthesis and lead to an abnormal increase in mitochondrial iron. RBCs in sideroblastic anemia may be normochromic and normocytic, or they may be hypochromic and microcytic [4,5,20]. Congenital forms of sideroblastic anemia include X-linked sideroblastic anemia, caused by a mutation in the δ-aminolevulinic acid (ALA) synthase gene leading to a defect in early heme synthesis; X-linked sideroblastic anemia with ataxia, which is caused by a variant in the gene that encodes the ABCB7 transporter protein that leads to defects in heme synthesis or in iron−sulfur biogenesis; and Pearson marrow-pancreas syndrome, which is characterized by large deletions or duplications in mitochondrial DNA, lactic acidosis, exocrine pancreatic insufficiency, and sideroblastic anemia [5,20]. Clonal bone marrow disorders, such as myelodysplastic syndrome with ring sideroblasts, can lead to sideroblastic anemia [5,20,22]. Sideroblastic anemia may also result from drug or toxin exposure, including but not limited to isoniazid, due to inhibition of pyridoxine metabolism; lead poisoning, which inhibits δ-ALA dehydratase and heme synthase; and chronic alcohol abuse, which is directly toxic to erythroid precursors. Serum iron and ferritin concentrations are usually increased [4,5], and a bone marrow examination will show increased iron stores and ring sideroblasts [4,5,20].

RBC underproduction is usually characterized by normocytic normochromic anemia with a paradoxically low or normal reticulocyte count. Causes include pure red cell aplasia, aplastic anemia or other bone marrow syndrome, or bone marrow infiltration by a pathologic process such as tumor, granulomas, histiocytes in storage pool disorders, or fibrosis. Congenital forms of pure red cell aplasia may cause normocytic normochromic anemia; however, they frequently cause macrocytic anemia [4,5,20]. Acquired pure red cell aplasia typically results in a transient decrease in hemoglobin of ∼1 g/dL, and is most frequently due to Parvovirus B19 infection, which is selectively cytotoxic to erythroid precursors. Other viral infections and some therapeutic drugs (i.e., azathioprine, cephalothin, chloramphenicol, dapsone, diphenylhydantoin, isoniazid, and procainamide) may lead to a similar clinical picture. Patients with a hemolytic disorder, such as RBC enzyme deficiencies, membrane abnormalities, hemoglobinopathies, or malaria infection, may also undergo an aplastic crisis with profound anemia. Rarely, antierythropoietin antibodies may form following treatment with erythropoietin; in this case, the red cell aplasia will persist despite discontinuation of erythropoietin therapy, and immunosuppression may be required. Diseases such as thymoma, hematologic malignancies, and autoimmune disorders may lead to chronic acquired pure red cell aplasia; in this case, red cell aplasia is thought to be due to an underlying autoimmune phenomenon. Chronic renal failure may lead to RBC underproduction due to decreased erythropoietin production by the kidneys [20].

Normocytic normochromic anemia may also be seen in the setting of marked RBC loss, such as that seen following hemorrhage or an episode of hemolytic anemia. A reticulocytosis is typically observed 3−5 days following hemorrhage. Hemolytic anemia may be caused by hemoglobinopathies (i.e., sickle cell disease or hemoglobin C

disease) or unstable hemoglobin, intrinsic RBC defects (i.e., hereditary spherocytosis, hereditary elliptocytosis, or hereditary pyropoikilocytosis), RBC enzyme defects (i.e., glucose-6-phosphate dehydrogenase or pyruvate kinase deficiency), plasma factors (i.e., alloantibodies or autoantibodies or drug–antibody complexes), paroxysmal nocturnal hemoglobinuria, mechanical or thermal RBC damage (i.e., microangiopathic hemolytic anemia or following severe thermal burns), or infection (i.e., malaria, babesiosis, and bartonellosis). Other laboratory findings in hemolytic anemia may include reticulocytosis, a decreased RBC life span, increased erythropoietin, indirect hyperbilirubinemia, low haptoglobin, and jaundice/icterus [5,20,21]. In microangiopathic hemolytic anemia, schistocytes are frequently seen on the peripheral blood smear [5,6].

Macrocytic anemia may be observed in bone marrow disorders that result in ineffective hematopoiesis, such as Diamond–Blackfan syndrome [4,5,20], congenital dyserythropoietic anemia [21], and myelodysplasia, or in megaloblastic anemia (vitamin B_{12} or folate deficiency) [4,20,21]. When macrocytic anemia results from a bone marrow disorder, the reticulocyte count is usually low and the RDW is normal [20]. Megaloblastic anemia is caused by vitamin B_{12} and/or folate deficiency, and may result from inadequate dietary intake or decreased gastrointestinal absorption. In patients with vitamin B_{12} deficiency, homocysteine and methylmalonic acid concentrations are markedly increased, while patients with folate deficiency will show increased homocysteine concentrations [21]. Hypersegmented neutrophils are also often seen in megaloblastic anemia [4]. Macrocytic anemia may also be seen following hemorrhage, hemolysis, or treated anemia due to an increase in reticulocytes; in this case, the RDW and reticulocyte count are elevated. Therapeutic drugs, such as those that inhibit DNA synthesis, anticonvulsants, and oral contraceptives, may also cause macrocytic anemia [4,20].

Polycythemia

An increased hemoglobin, referred to as polycythemia, may be seen in myeloproliferative neoplasms (MPNs), such as polycythemia vera (PV), in patients with chronic respiratory disease, or in patients who smoke [4,5]. The hematocrit and RBC count are also elevated in this condition. Patients may present with sequelae of the increased RBC mass, such as hypertension, thrombosis, and bleeding, which can be fatal. Patients with PV may also show leukocytosis and/or thrombocytosis in the early polycythemic phase, and, as the disease progresses, cytopenias often develop due to bone marrow fibrosis [5,20]. A bone marrow biopsy and molecular or cytogenetic testing (i.e., testing for the JAK2 V617F mutation observed in most cases of PV) may be warranted to evaluate polycythemia [5,20,22,23]. Treatment for patients with PV involves reducing the risk of thromboembolic complications and may include anticoagulant therapy, cytoreductive agents, or therapeutic phlebotomy [22,23].

Increased red cell distribution width

An increase in the RDW corresponds to increased variation in RBC size. This can be observed in patients with iron deficiency anemia, myelodysplastic syndrome, megaloblastic anemia, mechanical or thermal RBC injury, or in patients who have been recently transfused [4,5,20].

Abnormal platelet count or indices

Thrombocytosis

Increased platelets, or thrombocytosis, can be caused by reactive conditions, such as infection, inflammation, neoplasms, or iron deficiency. Thrombocytosis can also be seen in MPNs, other malignancy, following splenectomy, or during recovery of thrombocytopenia [2,4,5,24]. In the setting of infection, thrombocytosis is often accompanied by leukocytosis, and anemia may also occur. With resolution of infection, the platelet count often normalizes [25]. In contrast, thrombocytosis associated with an MPN, such as essential thrombocythemia (ET), is typically extreme and persistent, with platelet counts often exceeding 800×10^9/L [22,25]. When an MPN is suspected as the cause of thrombocytosis, a bone marrow biopsy and/or molecular or cytogenetic testing (i.e., for JAK2, MPL, or CALR mutations that are seen in ET and other MPNs) may be necessary to fully characterize the disorder [20,22,26,27]. Patients with thrombocytosis are at risk for thrombotic, vascular, and bleeding complications, which may be life-threatening [27]. Patients with thrombocytosis may also present with pseudohyperkalemia due to excessive leakage of potassium from the platelets during or after blood collection [28].

Thrombocytopenia

The term thrombocytopenia refers to a platelet count of $< 150 \times 10^9$/L. Conditions such as bone marrow and/or genetic disorders, infections, increased peripheral destruction, increased splenic sequestration, and certain medications are common causes of thrombocytopenia [2,4–7]. The manifestations of thrombocytopenia depend on the severity of the decreased platelet count. Patients may experience easy bruising when platelets are mildly decreased; however, severe thrombocytopenia (platelets $<$ 10,000/μL) greatly increases the risk for spontaneous mucocutaneous bleeding and life-threatening intracranial hemorrhage or gastrointestinal bleeding [7]. Patients may undergo platelet transfusions for severe thrombocytopenia

or for mild-to-moderately decreased platelet counts in the setting of a surgical procedure or trauma [6].

Diseases or malignancies that involve the bone marrow, such as aplastic anemia, myelodysplastic syndrome, or marrow infiltration by a malignant, infectious, or reactive process, as well as some toxins and drugs (i.e., chemotherapeutic agents, antimetabolites, chlorothiazides, estrogens, ethanol, and ionizing radiation), can lead to suppressed or ineffective thrombopoiesis [5,6]. There are many genetic disorders associated with thrombocytopenia, which typically present in pediatric patients (Table 25.3) [4–6]. Viral infections such as influenza, human immunodeficiency virus (HIV), Epstein–Barr virus (EBV), human herpesvirus-6, and hepatitis C have been shown to cause thrombocytopenia via deleterious interactions with megakaryocytes and/or platelets. Bacterial and protozoal infections have also been associated with thrombocytopenia [5,6,29].

Peripheral destruction of platelets may occur due to immune or nonimmune-mediated mechanisms. Idiopathic thrombocytopenic purpura (ITP) is the result of platelet-directed autoantibodies and suppression of megakaryopoiesis [5,6]. ITP may occur in isolation or may occur in conjunction with autoimmune hemolytic anemia (Evan's syndrome), or in patients with systemic lupus erythematosus, chronic lymphocytic leukemia, HIV infection, or following stem cell transplantation [5]. Treatment may include steroids, intravenous immunoglobulin, anti-(Rh)D antibodies, and, in severe or refractory cases, splenectomy. ITP is usually a diagnosis of exclusion, as laboratory tests for platelet antibodies are neither sensitive nor specific [6].

Drug-induced thrombocytopenia caused by drug-dependent platelet antibodies has been associated with medications, such as quinine agents and sulfonamides. Removal of the causative agent will often improve platelet count; however, some patients may experience severe thrombocytopenia ($<$10,000/μL) and may require treatment with steroids, IVIg, and/or platelet transfusions. Specialized laboratories may offer testing for the presence of drug-dependent platelet antibodies; however, these assays typically require specialized technical expertise [6].

Heparin-induced thrombocytopenia (HIT) is seen in up to 5% of patients who receive heparin and results from antibodies against heparin–platelet factor 4 (PF4) immune complexes, which engage the Fc receptors on platelets, leading to platelet activation, thrombocytopenia, and risk of potentially fatal arterial and venous thrombosis. Thrombocytopenia is observed following prolonged heparin exposure ($>$4 days), and the CBC will show a drop in the platelet count to approximately half of baseline [5,6]. Patients with HIT should be switched from heparin to an alternative anticoagulant [6]. Immunoassays are available to detect antibodies to heparin–PF4 complexes and to detect the presence of platelet-activating antibodies [5,6]. A heparin-induced platelet aggregation study may also be performed [5]. The serotonin release assay is a more specific testing modality that detects the ability of patient antibodies in a serum sample to activate platelets; however, the assay requires technical expertise and is often not available in clinical laboratories [5,6]. The 4Ts score takes into account the degree of thrombocytopenia, the timing of thrombocytopenia relative to heparin exposure, thrombosis or other sequelae of HIT, and the likelihood that another process is causing the thrombocytopenia. This scoring system is a frequent tool used clinically to determine a patient's likelihood of having HIT [6,30].

Neonatal alloimmune thrombocytopenia (NAIT) is another immune-mediated cause of thrombocytopenia. NAIT results from maternal alloantibodies directed against fetal platelet antigens that are inherited from the father. The majority of cases are due to maternal antibodies against human platelet antigen 1a (HPA-1a). The resulting thrombocytopenia may be severe ($<$20,000/μL), and bleeding complications may ensue. Treatment involves IVIg and/or steroids. If severe thrombocytopenia persists after birth, newborns may require platelet transfusions; however, intrauterine platelet transfusions are less commonly performed. Incompatibility between maternal and paternal platelets may be demonstrated in the laboratory to aid in the diagnosis of NAIT [6,31–35].

Posttransfusion purpura (PTP) is a rare disorder that is also caused by anti-HPA-1a antibodies and can occur in either male or female patients. PTP occurs when an HPA-1a-negative patient receives a platelet transfusion from an HPA-1a-positive donor. Severe thrombocytopenia (platelet count $<$10,000/μL) is seen 5–14 days following the platelet transfusion, which results from destruction of the transfused platelets as well as the patient's own platelets [6,36]. Platelet antibody testing may be performed in order to detect antibodies in the patient's plasma or serum (indirect methods), or to detect antibodies that are attached to the patient's platelets (direct methods), and HPA genotyping may also be performed to help guide clinical management and to confirm antibody specificity. IVIg is most commonly used for therapy in patients with PTP. It is reportedly unusual for patients with PTP to have a subsequent episode with future platelet transfusions [36].

Nonimmune-mediated causes of peripheral platelet destruction include thrombotic thrombocytopenic purpura (TTP), hemolytic uremic syndrome (HUS), and disseminated intravascular coagulation (DIC), all of which frequently result in microangiopathic hemolytic anemia. Acquired TTP is caused by autoantibodies to ADAMTS-13, the protease involved in cleavage of high-molecular-weight von Willebrand factor multimers. A congenital

TABLE 25.3 Most common congenital platelet disorders associated with thrombocytopenia [4–6,18].

Platelet disorder	Inheritance pattern	Genetic abnormality	Clinical findings
Congenital amegakaryocytic thrombocytopenia	Autosomal recessive	*MPL* gene mutation (deletions, missense, or nonsense)	Severe thrombocytopenia, absence of bone marrow megakaryocytes, elevated TPO levels, early pancytopenia (type 1, total loss of TPO), or transient platelet increases with later bone marrow failure
Thrombocytopenia with absent radius syndrome	Autosomal recessive	Unknown/multifactorial (1q21.1 microdeletion, RBM8A exon junction subunit mutations have been reported)	Thrombocytopenia that improves with age, decreased bone marrow megakaryocytes, bilateral absence of the radii, tetralogy of Fallot, atrial septal defects, and lactose intolerance
Bernard–Soulier syndrome	Autosomal recessive	Mutations in the genes (*GP1BA*, *GP1BB*, and *GP9*) encoding platelet membrane proteins (GP1b, GPIX, and GPV)	Mild-to-severe thrombocytopenia with abnormal bleeding times and abnormal ristocetin-induced platelet aggregation studies, large platelets, and normal or slightly increased bone marrow megakaryocytes
Gray platelet syndrome	Autosomal recessive	*NBEAL2* gene mutation	Mild-to-moderate thrombocytopenia, platelets lack α-granules (appear gray on Wright–Giemsa stain), myelofibrosis, and splenomegaly
MYH9 mutation-related disorders (May–Hegglin anomaly, Sebastian syndrome, Fechtner syndrome, and Epstein syndrome)	Autosomal dominant (variable penetrance)	*MYH9* (nonmuscle myosin heavy chain) gene mutations	Mild-to-moderate thrombocytopenia, large platelets, Döhle-like inclusions in WBCs, hearing loss, and nephritis
Mediterranean macrothrombocytopenia	Autosomal dominant	*GP1BA* gene mutation	Mild thrombocytopenia and large platelets
Familial platelet disorder with predisposition to AML	Autosomal dominant (variable penetrance)	*RUNX1* gene mutation	Mild thrombocytopenia, impaired collagen- and epinephrine-induced platelet aggregation studies, dense granule storage pool deficiency, increased risk of developing MDS/AML, or other hematopoietic malignancy at a young age
Paris-Trousseau syndrome	Autosomal dominant	*FLI1* gene mutation	Moderate-to-severe thrombocytopenia that improves with age, abnormal platelet function, psychomotor retardation, congenital heart defects, abnormal facies, and dysmegakaryopoiesis with abnormal or giant α-granules
Wiskott–Aldrich syndrome (X-linked microthrombocytopenia)	X-linked	*WAS* gene mutation	Thrombocytopenia, small platelets with a decreased half-life due to splenic sequestration, immunodeficiency, eczema, normal of increased bone marrow megakaryocytes, and development of autoimmune disorders or lymphoma
X-linked macrothrombocytopenia	X-linked	*GATA1* gene mutation	Moderate-to-severe thrombocytopenia, impaired platelet function, increased and dysplastic bone marrow megakaryocytes, dyserythropoiesis, and anemia

AML, Acute myeloid leukemia; *MDS*, myelodysplastic syndrome; *TPO*, thrombopoietin; *WBCs*, white blood cells.

form of TTP (Upshaw–Schulman syndrome) is an extremely rare disorder due to congenital deficiency of ADAMTS-13. In TTP, the platelet count is often markedly decreased (<50,000/μL), and ADAMTS-13 activity may be <10% of normal levels. ADAMTS-13 autoantibodies may be detected in the acquired form of the disease. TTP is a severe disease with a high mortality rate. In addition to severe thrombocytopenia and microangiopathic hemolytic anemia, patients also may experience renal insufficiency, neurologic sequelae including stroke or headache, and fever. Emergent therapeutic plasma exchange should be strongly considered in patients with TTP, and additional treatments may include steroids, cytotoxic agents, or rituximab [6,37].

Typical HUS is associated with a similar clinical picture to TTP, and patients typically present with bloody diarrhea, renal failure, microangiopathic hemolytic anemia, and thrombocytopenia following an infection with a Shiga toxin-producing bacterial pathogen, such as *Escherichia coli* O157:H7 [6] or *Shigella dysenteriae* [37]. In contrast to TTP, typical cases of HUS are treated with supportive care [6,37]. Atypical HUS is a form of HUS caused by genetic abnormalities in alternative complement regulation. In this disease, there is episodic complement-mediated vascular damage and coagulation. Patients do not usually experience diarrhea, and Shiga toxin is not present. Eculizumab, a monoclonal antibody directed against the complement component C5, is the therapy of choice [6,37].

DIC is a consumptive coagulopathy that leads to widespread thrombus formation, causing thrombocytopenia and microangiopathic hemolytic anemia [6,38]. Causes include systemic infections such as sepsis, trauma or major surgical procedures, malignancy, severe pancreatitis, hemorrhage, hepatic failure, and severe toxic or immunologic reactions [38]. Organ failure develops from microvascular clots, and clotting factors are consumed, leading to bleeding diatheses. The prothrombin and activated partial thromboplastin times are prolonged in the majority of patients. The fibrinogen concentrations may be low in a proportion of cases, and the platelet count drops below 50,000/μL in up to 15% of cases. Treatment involves supportive care, mitigation of bleeding and clotting diatheses, and correction of the underlying cause of DIC [6,38].

Abnormal white blood cell count or differential

Leukocytosis

Leukocytosis, or an elevated WBC count, may be observed infections, inflammatory conditions, or neoplasms. The specific WBC subtype that is elevated can help guide the differential diagnosis in leukocytosis (see "The cellular components of the peripheral blood" section above). The presence of blasts may indicate leukemia or a leukoerythroblastic reaction and may require further investigation, including, but not limited to, flow cytometric and molecular or cytogenetic studies performed on the peripheral blood and/or bone marrow and further clinical evaluation [2,4,5]. It is also important to note that, like patients with thrombocytosis, patients with leukocytosis may have pseudohyperkalemia due to excessive leakage of potassium from the WBCs during or after blood collection [28].

Neutrophilia (PMN count >7000/μL) is the most common cause of leukocytosis. An increase in the absolute or relative concentration of PMNs may occur in infections (i.e., bacterial infections), reactive conditions (i.e., following a surgical procedure), chronic inflammatory diseases (i.e., autoimmune inflammatory conditions and hepatitis), bone marrow stimulation (i.e., recovery from bone marrow suppression, hemolytic anemia, or immune thrombocytopenia), following the use of certain medications (i.e., steroids, beta agonists, lithium, epinephrine, or colony-stimulating factors), or postsplenectomy. Congenital or inherited conditions such as hereditary idiopathic neutrophilia, Down syndrome, and leukocyte adhesion deficiency are rare causes of neutrophilia [5,8].

Lymphocytosis (lymphocyte count >4500/μL or >40% of total WBC count) may occur in patients with infections (i.e., pertussis, syphilis, and viral infections), hypersensitivity reactions, or lymphoproliferative disorders [5,8]. Monocytosis (monocyte count >880/μL) is associated with infections (i.e., EBV, protozoal, rickettsial, or fungal infections), or autoimmune disease [5,8]. Myeloid neoplasms such as acute myeloid leukemia with monocytic differentiation, chronic myelomonocytic leukemia, and juvenile myelomonocytic leukemia are also associated with peripheral monocytosis [5,22]. Eosinophilia (eosinophil count >500/μL) is seen in allergic reactions, parasitic or helminth infections, drug-induced hypersensitivity reactions, many dermatologic conditions [5,8], and rare hematologic malignancies (i.e., myeloid or lymphoid neoplasms associated with eosinophilia) [5,22]. Basophilia (basophil count >100/μL) is rare and may be associated with allergic or inflammatory conditions [8], some viral infections (i.e., varicella infection), endocrine conditions (i.e., hypothyroidism and ovulation), and in chronic myeloid leukemia [22].

Leukocytosis may also be an indicator of a bone marrow disorder, such as leukemia. In acute leukemia, greater than 20% of circulating WBCs will be blasts, or immature blood cells. Blast lineage in peripheral blood samples is best determined by flow cytometric or cytochemical studies, as it is often difficult to accurately determine lineage based on morphology alone [4,5,22,39]. Anemia and/or thrombocytopenia are often seen in patients with acute

leukemia due to replacement of the bone marrow by neoplastic cells [5,39]. Blasts may also be increased in other myeloid neoplasms, such as myelodysplastic syndrome, MPNs, or myelodysplastic/myeloproliferative overlap neoplasms [5,22,39], in patients who have received granulocyte colony-stimulating factor, or in a leucoerythroblastic reaction (i.e., in association with severe infection) [8,39]. Chronic leukemias may be diagnosed in asymptomatic patients and most often show an increase in more mature WBCs (i.e., increased circulating myeloid cells in chronic myeloid leukemia, or increased circulating mature lymphocytes in chronic lymphocytic leukemia) [5,8,22]. Lymphoproliferative disorders including some lymphomas may also present with circulating neoplastic cells (leukemic presentation) [5,22]. Patients with suspected hematolymphoid malignancies should undergo urgent evaluation by a hematologist or oncologist to ensure prompt initiation of therapy if indicated [8,22].

Leukopenia

A low WBC count (leukopenia) may be seen in patients with bone marrow disorders, after use of certain medications (i.e., cytotoxic agents, nonsteroidal antiinflammatory drugs, antipsychotics, antiepileptics, antimicrobial agents, sulfonamides, and gold-containing compounds) [5,40], or in the setting of some infections [4,5]. Neutropenia is most frequently medication-related, but may also result from autoimmune or neoplastic diseases. Lymphopenia is observed in association with infections (i.e., viral or bacterial), autoimmune diseases, or advanced HIV infection. Inherited disorders, such as congenital neutropenia syndromes, Wiskott–Aldrich syndrome, and severe combined immunodeficiency disorder, are rare but may also cause leukopenia [5,40]. Treatment for leukopenia involves addressing the underlying cause. Inherited disorders may be treated with gene therapy or hematopoietic stem cell transplantation [40].

Common errors seen with automated cell counters

Although automated cell counters are generally accurate and reliable, some patient or sample variables may lead to errors in CBC results [1,5]. Many of the errors discussed below will lead to flagged results, which will serve as an alert for further laboratory or clinical investigation. A peripheral blood smear should be reviewed for samples with flagged results or with suspected erroneous results and will assist in identifying the cause of the spurious results. Automated instruments should undergo careful calibration, regular quality assurance testing, and routine maintenance to ensure that the instrument is properly functioning and producing accurate and reproducible results [1,3]. The Clinical and Laboratory Standards Institute and the International Committee for Standardization in Hematology have both established guidelines for instrument calibration and regulatory compliance [1,41].

Errors in red blood cell count

RBC counts may be falsely elevated due to increased RBC or WBC fragments or cryoglobulins. Increased large platelets may also cause a spuriously high RBC count, as the enlarged platelets are counted as RBCs due to increased volume [3,5]. RBC counts may be falsely decreased due to microcytosis; in this case, the small RBCs are counted as platelets by the analyzer. Similarly, increased RBC fragments, or schistocytes, may be incorrectly counted as platelets [1,3,5]. RBC clumps can also cause a spuriously low RBC count [3,5].

Errors in the hemoglobin measurement

Hemoglobin measurements may show false elevation in turbid samples, such as those with a high lipemic index, hypergammaglobulinemia, cryoglobulinemia, hyperbilirubinemia, or marked leukocytosis [1,3,5]. Automated instruments will often have the ability to report lipemic or icteric samples. Chronic smokers will also frequently show an increase in circulating carboxyhemoglobin, which is associated with a left shift in the hemoglobin oxygen dissociation curve, and a higher hematocrit with polycythemia as a physiologic compensatory mechanism [3,5]. Increased sulfhemoglobin, seen in patients following treatment with sulfonamides or nitrogen-containing or aromatic amine drugs and in patients with *Clostridium perfringens* bacteremia, may lead to a spuriously low hemoglobin result [3].

Errors in the mean corpuscular volume measurement

Increased RBC clumps, such as those seen in cold agglutinin disease or paraproteinemia, or hyperosmolar states, may lead to a falsely increased MCV [1,3,5]. Leukocytosis or RBC membrane defects may also cause a spurious increase in MCV, while cryoglobulins, abnormally large platelets, and schistocytes may be associated with an erroneously low MCV [3].

Errors in the platelet count

Causes of a spuriously elevated platelet count include increased RBC or WBC fragments or microcytic RBCs, which are incorrectly quantified as platelets [3,5]. In cryoglobulinemia, protein precipitates may be erroneously quantified as platelets, leading to a false increase in the platelet count.

Pseudothrombocytopenia can be seen in patients with increased large platelets, which are incorrectly identified as RBCs, or in platelet clumping [1,5]. The latter may be induced by EDTA due to platelet-specific antibodies that interact with platelets in the presence of EDTA. This finding is of no clinical significance, and it can be ruled out by review of the peripheral blood smear for platelet satellitism of WBCs [4,5,42] or by repeat testing on a blood sample that is collected in a citrate- or heparin-containing blood tube [5,42].

Errors in the white blood cell count

The WBC count may show spurious elevation in the setting of increased nRBCs, which can be incorrectly quantified as lymphocytes, or in the presence of increased and/or enlarged platelets [1,5]. Cryoglobulinemia or cryofibrinogens may also cause a false elevation in the WBC count when protein aggregates are misidentified as WBCs [1,3,5].

Spurious decreases in the WBC count are most often due to WBC agglutination caused by EDTA, cold agglutinins, or increased circulating immunoglobulins [1,3,5]. Increased WBC fragility resulting in smudge cells, such as the phenomenon seen in chronic lymphocytic leukemia, might lead to a false decrease in the WBC count [3].

Interpretation of the peripheral blood smear

An abnormal CBC or WBC differential will often warrant examination of the corresponding peripheral blood smear to confirm results and/or assess for various disease states. In many labs, any flagged CBC results will trigger peripheral blood smear examination, which may also be useful in excluding spurious results. A peripheral blood smear may also be indicated in instances of suspected malignancy, increased blood counts, and unexplained cytopenias, or to assess for a variety of other disease states [2,5].

Many analyzers are equipped with automated slide makers and stainers that will produce blood smear slides directly from a CBC sample tube [1]. Automated digital image analysis modules that employ convolutional neural networks have the ability to classify blood cells, and are often used to screen blood smears [10,43]. A manual differential is also commonly performed in many laboratory settings.

The peripheral blood smear is evaluated for variations in RBC, WBC, or platelet morphology. Examination of the blood smear can also help identify microorganisms and circulating nonhematopoietic cells. The slide should first be examined at low power to assess for overall cellularity, to check for cellular clumping, to find an appropriate area for morphology assessment, and to evaluate for microfilarial infections [5]. Subsequently, each cellular component should be evaluated at high power for morphologic abnormalities.

Red blood cell morphology

Normal RBCs are approximately the size of a lymphocyte nucleus [2,4,5]. RBCs should be evaluated for abnormal size (i.e., macrocytosis or microcytosis), as well as for morphologic abnormalities including variations in size or shape, and for the presence of intracytoplasmic inclusions.

RBCs may show numerous variations in shape including sickle cells, target cells, ovalocytes, elliptocytes, stomatocytes, echinocytes (burr cells), acanthocytes, schistocytes, spherocytes, bite cells, and blister cells (Table 25.2). RBC inclusions such as Howell–Jolly bodies, Pappenheimer bodies, Heinz bodies, basophilic stippling, or crystals, may be seen (Table 25.4) [2,5]. Infectious organisms such as malaria and Babesia have intracellular forms that infect RBCs, leading to characteristic inclusions; therefore a peripheral blood smear examination should include evaluation for such infections in patients with an appropriate clinical history or symptomology [4].

Platelet morphology

Platelets should be assessed for size and granularity. The peripheral blood smear should also be examined for platelet clumps. Large platelets can be seen during increased platelet production or in inherited disorders. Inherited disorders may also lead to production of small or hypogranular platelets [2,4]. Increased platelet clumping and/or satellitism around neutrophils or monocytes may be seen in samples collected in EDTA-containing tubes (see "Errors in the platelet count" section above) [4,5].

White blood cell morphology

In examination of the peripheral smear, WBCs should be assessed for size, granularity, intracytoplasmic inclusions, and the presence of blasts or circulating nonhematopoietic cells. In cases of leukocytosis, the specific subset of WBCs that is increased may give a clue to the underlying disease process (see "Leukocytosis" section above).

Polymorphonuclear neutrophils (PMNs) have fine cytoplasmic granules and typically have two to five nuclear segments connected by a thin membrane. Hyperlobated PMNs can be seen in megaloblastic anemia and myelodysplastic syndromes. Hypolobated, hypogranular, and/or small neutrophils are seen in myelodysplastic syndrome and genetic disorders. Döhle bodies (blue cytoplasmic inclusions), vacuoles, and prominent azurophilic granules may be seen in reactive or neoplastic neutrophils [4,5].

TABLE 25.4 Common red blood cell inclusions [2–5].

RBC inclusion	Morphologic characteristics	Contents	Associated conditions
Howell–Jolly bodies	Single peripheral body	DNA material	Postsplenectomy, megaloblastic anemia, severe hemolysis, and myelophthisic anemia
Pappenheimer bodies	Multiple small cannon ball-like bodies	Iron material within the mitochondria	Myelodysplastic syndrome, sideroblastic anemia, hemolytic anemia, lead poisoning, and sickle cell disease
Heinz bodies	Single peripheral body visualized with supravital dyes	Denatured hemoglobin	G6PD deficiency and oxidative stress
Basophilic stippling	Multiple punctate granular inclusions	RNA material	Lead poisoning, hemolytic anemia, and pyrimidine 5′-nucleotidase deficiency
Crystals	Dense rectangular crystalline structures, may be intracellular or extracellular	Precipitated hemoglobin C	Hemoglobin C or hemoglobin SC disease

G6PD, Glucose-6-phosphate dehydrogenase; *RBC*, red blood cells.

Reactive lymphocytes are often large in size with abundant cytoplasm that may surround nearby RBCs. Cytoplasmic granules can be seen [4,5]. Circulating neoplastic lymphocytes may also be seen. "Smudge cells" are fragile neoplastic lymphocytes associated with lymphoproliferative disorders that are ruptured during peripheral smear preparation. An albumin preparation may be used to preserve lymphocyte morphology in the setting of numerous smudge cells [39]. Like lymphocytes, reactive monocytes can exhibit increased cytoplasmic granules or vacuoles [4].

Blasts should be exceedingly rare in normal circulation, and their presence should raise suspicion for a neoplasm or leucoerythroblastic reaction. A predominance of circulating promyelocytes, which often have abundant granules and/or Auer rods and may have bilobed or "wasp-waisted" nuclei, should raise suspicion for acute promyelocytic leukemia (APL). Patients with APL are at an increased risk of DIC; however, prompt initiation of therapy with all-trans retinoic acid has proved to decrease the risk of DIC in these patients [4,22,38]. Any patient with a suspected hematolymphoid malignancy should promptly be evaluated by hematology/oncology in order to ensure prompt initiation of therapy if indicated. Additional laboratory studies, including flow cytometry and molecular and/or cytogenetic studies, may be warranted to aid in the diagnosis.

Self-assessment questions

1. Which compound is measured to determine hemoglobin concentration?
   a. methemoglobin
   b. sulfhemoglobin
   c. cyanomethemoglobin
   d. carboxyhemoglobin
2. All of the following are methods used to determine the complete blood count except:
   a. impedance
   b. mass spectrometry
   c. flow cytometry
   d. conductivity
3. The red blood cell or platelet distribution width is a measure of which of the following?
   a. variation in size
   b. variation in shape
   c. variation in cytoplasmic complexity
   d. circumference
4. In flow cytometry, the forward scatter is proportional to which cellular parameter?
   a. cytoplasmic complexity
   b. volume
   c. autofluorescence
   d. CD45 expression
5. True or False: Iron deficiency anemia may cause macrocytic anemia.
6. The platelet count may be falsely increased due to which of the following?
   a. platelet clumping
   b. cryoglobulinemia
   c. large platelets
   d. low white blood cell count
7. EDTA may cause all of the following except:
   a. platelet clumping
   b. white blood cell clumping
   c. platelet satellitism
   d. red blood cell fragmentation
8. A predominance of circulating immature cells should raise suspicion for:
   a. infection
   b. acute leukemia
   c. chronic lymphoma
   d. anemia
9. Megaloblastic anemia may result in which of the following? (Choose all that apply.)
   a. large red blood cells
   b. large white blood cells
   c. anemia
   d. leukocytosis
10. An abnormal complete blood count or white blood cell differential result may lead to which of the following?
    a. review of a peripheral blood smear
    b. a result flag
    c. a manual differential
    d. all of the above

Answers

1. c
2. b
3. a
4. b
5. False
6. b
7. d
8. b

10. d

Chapter 26

Hemostasis

Sean Campbell

Department of Pathology, Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, NY, United States

Learning objectives

After reviewing this chapter, the reader will be able to:

- Describe the progression of hemostasis from initial activation to fibrinolysis.
- Describe the action of platelets in hemostasis.
- Describe the factor proteins and their different roles in hemostasis.
- List ways in which the PT and aPTT relate to the different pathways in secondary hemostasis.
- Discuss the use of secondary testing in coagulation, such as mixing studies and factor assays, to determine common deficiencies and conditions.
- Describe the various common bleeding and thrombotic disorders and their causes.
- List the tests and algorithms used for elucidating bleeding and thrombotic disorders in advanced coagulation laboratories.

The physiology of hemostasis

There are two main ways to conceptualize the hemostasis systems: in vitro and in vivo. Because of the history of coagulation testing, the most common coagulation tests, prothrombin time (PT) and activated partial thromboplastin time (aPTT or PTT), present a somewhat nonphysiologic picture of the hemostasis cascade. As a result, this chapter will review the physiologic mechanisms as well as the laboratory testing associated with the hemostatic system. First, the hemostasis systems will be presented as they exist in the body. In the laboratory testing section, these systems will be described in terms of the aPTT and PT, to best explain how the systems function, as well as how laboratory tests can illuminate disorders within a system. Following this, more esoteric testing and rare disorders will be presented.

In vivo hemostasis can be broken down into three sections: primary, secondary, and tertiary. Primary hemostasis describes the actions of platelets, while secondary hemostasis represents the coagulation cascade (dominated by factor proteins); tertiary hemostasis encompasses the fibrinolytic and anticoagulant systems, which attenuate the coagulation cascade, control runaway coagulation, and dissolve a clot when it is no longer needed.

Primary hemostasis

Primary hemostasis refers to the action of platelets, as well as collagen and von Willebrand factor (vWF), the multimeric proteins responsible for platelet recruitment and activation at the site of vascular injury. When vessel walls are injured, subendothelial collagen and vWF are exposed. Vasoconstriction occurs, allowing platelets more opportunity to attach to the exposed proteins via two main platelet receptor complexes: GP (glycoprotein) Ia/IIa (collagen binding) or GP Ib/IX/V (vWF binding). These two systems act at different locations due to sheer stress, which is the frictional force of blood flow through veins. Shear stress from blood is highest in smaller vessels, where the surface to liquid ratio is highest, and in areas of high flow such as arteries. Collagen binding is weaker and is more critical in areas of low shear stress, such as large veins, while vWF acts in areas of high shear stress such as arteries and capillaries.

Von Willebrand factor

The structure and function of vWF are worth a further look, due to its interesting structural elements as well as its importance in hemophilia testing. vWF is a multimeric protein, with an individual protein size of approximately 250 kDa. The smallest multimer subunit is a dimer; the two proteins are joined via C-terminal disulfide bonds. The dimers are then multimerized through N-terminal disulfide bonds, and vWF multimers range in size from 500 to 20,000 kDa in healthy persons.

vWF is synthesized in both megakaryocytes and endothelial cells. In megakaryocytes, it is packaged into platelet α granules to be released during platelet activation (see below), while in endothelial cells it is

Contemporary Practice in Clinical Chemistry. DOI: https://doi.org/10.1016/B978-0-12-815499-1.00026-0

housed in Weibel–Palade bodies. In Weibel–Palade bodies, some vWF is synthesized as "ultra-large von Willebrand factor multimers" (ULVWFs), greater than 20,000 kDa. ULVWF plays an important role in the very early stages of platelet aggregation, allowing for very rapid recruitment and activation of platelets after a vessel injury, especially in areas of high shear stress where platelet recruitment is more difficult due to the high rate of flow. However, the presence of these multimers can lead to spontaneous or overactivation of platelets, and thus must be cleaved shortly after release, once the initial platelet recruitment and activation have taken place. The protein responsible for this cleavage is ADAMTS13 (a disintegrin and metalloproteinase with a thrombospondin Type 1 motif, member 13), also known as a vWF-cleaving protease, and functions in areas of high shear stress. In both platelets and endothelial cells, vWF is conjugated to the FVIII protein, a coagulation cascade protein, which is discussed below in the secondary hemostasis section.

Upon release, the vWF can take two forms depending on the levels of shear stress. In areas of low shear stress, as well as in storage, vWF adopts a compact, globular shape. This form has low activity toward platelets, as most of the GP Ib/IX/V binding sites are internal. In areas of high shear stress, the multimer unwinds to up to 1300-nm long, exposing many GP Ib/IX/V binding sites and increasing its platelet affinity manyfold. This interaction of GP Ib/IX/V and vWF exposes ADAMTS13 binding sites, allowing for the cleavage of ULVWF. This complex function leads to many possible abnormalities through sequence or posttranslational modification changes. These changes will be explored more fully in the pathophysiology section.

Platelet function

Platelets are highly specialized cell fragments produced by megakaryocytes in the bone marrow. Platelets serve three distinct functions in hemostasis: they provide structure and support to clotting, they release additional coagulation factors to support the coagulation cascade, and they release vWF and fibrin to add to the clot matrix formation. Platelets are roughly disc-shaped in circulation. Electron microscopy analysis of platelets has determined the presence of several defined internal structures of note. First, platelets have two main categories of granules: α granules, of which there are approximately 50–80 per platelet and which contain mainly proteins such as fibrinogen, factor V, factor XIII, vWF, and plasminogen; and dense granules, also known as δ granules, of which there are five to seven per platelet and which contain small molecules such as ADP, ATP, Ca^{2+}, and serotonin. In addition to these granules, platelets also contain fine tubules that connect to the platelet surface, termed the open canalicular system (OCS).

Activation, through binding to collagen and vWF, leads to shape changes that form the platelet into a shape more reminiscent of a dendritic cell, with a spherical center and many long pseudopodia. This shape change allows for easier access of the platelet receptors to their ligands, and constriction of the platelet brings the granules in contact with the OCS, allowing for the rapid release of the contents of said granules into circulation. A final step of platelet activation is the inversion of the plasma membrane phospholipids. In the resting state, platelet outer membranes consist nearly entirely of phosphatidylcholine and sphingomyelin, which are not active in the coagulation pathway. Upon platelet activation, phospholipid "scramblases" such as transmembrane protein 16F (also known as anoctamin 6) are activated and move negatively charged phospholipids such as phosphatidylserine from the inner membrane to the outer plasma membrane. These phospholipids serve as anchor points and activators of other coagulation factors, amplifying the hemostatic process at the site of vascular injury.

Platelet receptors

There are over 50 different receptors present on the platelet surface; of these, only a select number have known clinical significance. Of the clinically significant receptors, the G-protein-coupled receptors (GPCRs) GP Ia/IIa and GP Ib/IX/V have already been mentioned, and allow platelets to bind to collagen and vWF, respectively. In addition to these, GP IV and GP VI also participate in collagen binding, though their role is less well-defined than that of GP Ia/IIa. These receptors help anchor the platelet and begin activation and membrane changes through activation of their associated G-proteins (Fig. 26.1).

These receptor proteins activate phospholipase A2 (PLA_2) and phospholipase C (PLC). Both enzymes act on phosphatidylinositol (PI) in the platelet's inner membrane. PLA_2 releases arachidonic acid (AA) from PI. AA, in turn, is converted into thromboxane A_2 (TXA_2) through the actions of cyclooxygenase (COX) and thromboxane synthase. TXA_2 is released by the activated platelets, and can bind to and activate other platelets through the thromboxane/prostanoid receptor isoform alpha, which inhibits adenylate cyclase (AC), decreasing cyclic adenosine monophosphate (cAMP) and allowing cytoplasmic Ca^{2+} concentrations to rise, as well as directly stimulating calcium release from cell stores through activation of PLC. TXA_2 also spontaneously converts to TXB_2, which is stable and inactive.

Simultaneously, activated PLC forms inositol-1,4,5-triphosphate and diacylglycerol from PI, and these

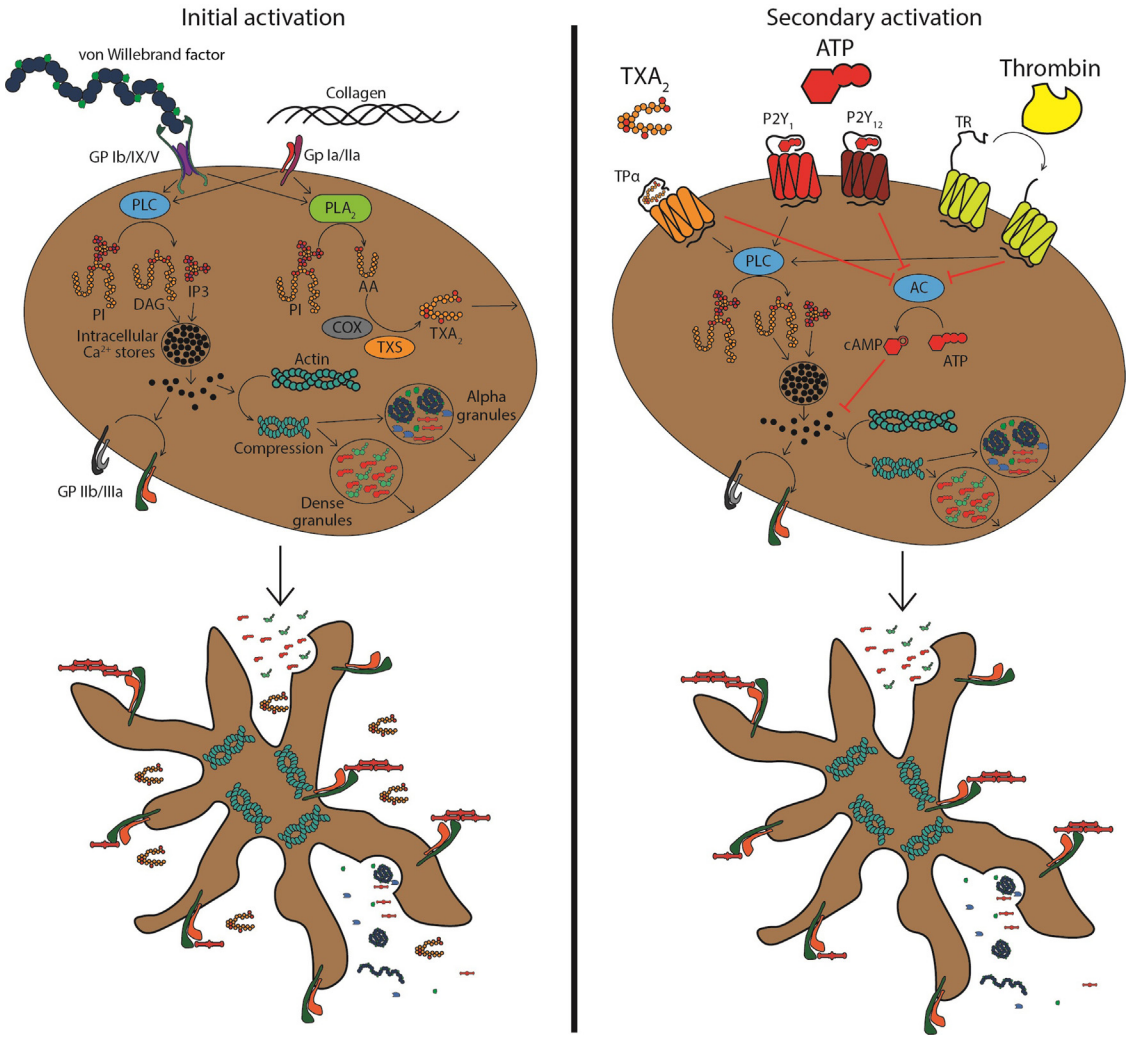

FIGURE 26.1 Pictorial representation of platelet activation. *Left*: During vascular injury, platelets are initially activated through interaction with von Willebrand factor multimers and collagen. These bind to GP Ib/IX/V or Gp Ia/IIa, respectively, which in turn activate phospholipase C and phospholipase A2. Phospholipase C converts phosphatidylinositol into diacylglycerol and inositol-1,4,5-triphosphate. These stimulate release of calcium from intracellular stores. Rising intracellular calcium stimulates actin compression and rearrangement, causing release of granules and membrane changes to change the platelet into a more dendritic shape. It also activates Gp IIa/IIIa, which binds to fibrinogen and anchors the platelet to the growing clot. Phospholipase A2 converts phosphatidylinositol into arachidonic acid, which is then converted to thromboxane A2 through the successive actions of cyclooxygenase and thromboxane synthase (thromboxane A synthase) enzymes. Thromboxane A2 is then released from the platelets. Full activation results in the platelet radically altering shape, releasing granule contents, and binding to fibrinogen. *Right*: After initial activation, release of thromboxane A2 and ADP from activated platelets, as well as active thrombin created from the coagulation cascade, causes a secondary activation of platelets. The three act through associated receptors, thromboxane/prostanoid receptor isoform alpha, $P2Y_1$ and $P2Y_{12}$, and thrombin receptor, to activate phospholipase C and inhibit adenylate cyclase. Adenylate cyclase forms cyclic adenosine monophosphate from ATP, and cyclic adenosine monophosphate suppresses intracellular calcium. Inhibition of adenylate cyclase allows calcium levels to rise, supporting platelet activation.

products directly release intracellular stores of Ca^{2+} and cause actin contraction, leading to pseudopod extension. Ca^{2+} release also results in a conformational change in the GP IIb/IIIa receptor (also known as integrin $\alpha_{IIb}\beta_3$), allowing the platelets to tightly bind to fibrinogen and thereby facilitating platelet-to-platelet interaction within the fibrin clot (Fig. 26.1).

The contraction of actin and pseudopod extension release granules into the OCS, allowing for the activation of additional nearby platelets and circulating coagulation factors. vWF and fibrinogen released from the dense granules help anchor the forming platelet plug, as well as recruit additional platelets to the site of injury. The release of factor V, factor XIII, and Ca^{2+} support the activation of secondary hemostasis. ADP in the α granules activates other platelets through the $P2Y_1$ and $P2Y_{12}$ GPCRs. These, in turn, activate PLC, activating the nearby platelets in a similar way to those activated through GP Ia/IIa, and inhibit adenylate cyclase to support the increase of intracellular calcium.

The thrombin receptor (TR) is the last of these receptors that will be covered in detail. Unlike the GP proteins mentioned previously, the TR is a protease-activated receptor. Cleavage of the receptor N-terminus by thrombin allows for a conformational change to the protein structure, which is then transmitted through the platelet membrane to activate the receptor-associated proteins G_i and G_q, which also stimulate PLC and inhibit AC.

These secondary forms of platelet activation (TXA_2, ADP, and thrombin) lead to further activation and secretion in the platelets, and have the effect of constricting the "core" of the platelet plug into a denser form.

Secondary hemostasis

Secondary hemostasis, also known as the coagulation factor pathway, progresses concurrently to platelet activation, and both contribute to hemostasis in synchrony. Platelets carry many coagulation factors such as factors V and XIII in their granules, and their release helps activate and sustain the signal cascade. In the coagulation factor pathway, activation of prothrombin to thrombin by the coagulation cascade helps to activate platelets further and to form the fibrin matrix that supports the platelet plug.

The factor proteins that control secondary hemostasis are a set of 10 serum proteins typically labeled with Roman numerals: FI (1), FII (2), FV (5), FVII (7), FVIII (8), FIX (9), FX (10), FXI (11), FXII (12), and FXIII (13) (Fig. 26.2). While FI and FII are much more commonly referred to as fibrinogen and prothrombin, respectively, the other factors are exclusively referred to by their factor numbers. An "a" is appended to the proteins to denote their activated form, such as FXa. All factor proteins are protease-activated proteins, though a small fraction (1%–2%) of FVII exists as its active form, FVIIa, in circulation under normal conditions.

There are two essential subgroups of factor proteins: liver-dependent factors and vitamin K-dependent factors. Liver-dependent factors are produced in the liver and thus may be affected by conditions such as cirrhosis and liver insufficiency. These are FV, FVII, FIX, FX, FXI, FXIII, fibrinogen, and prothrombin. Vitamin K-dependent factors

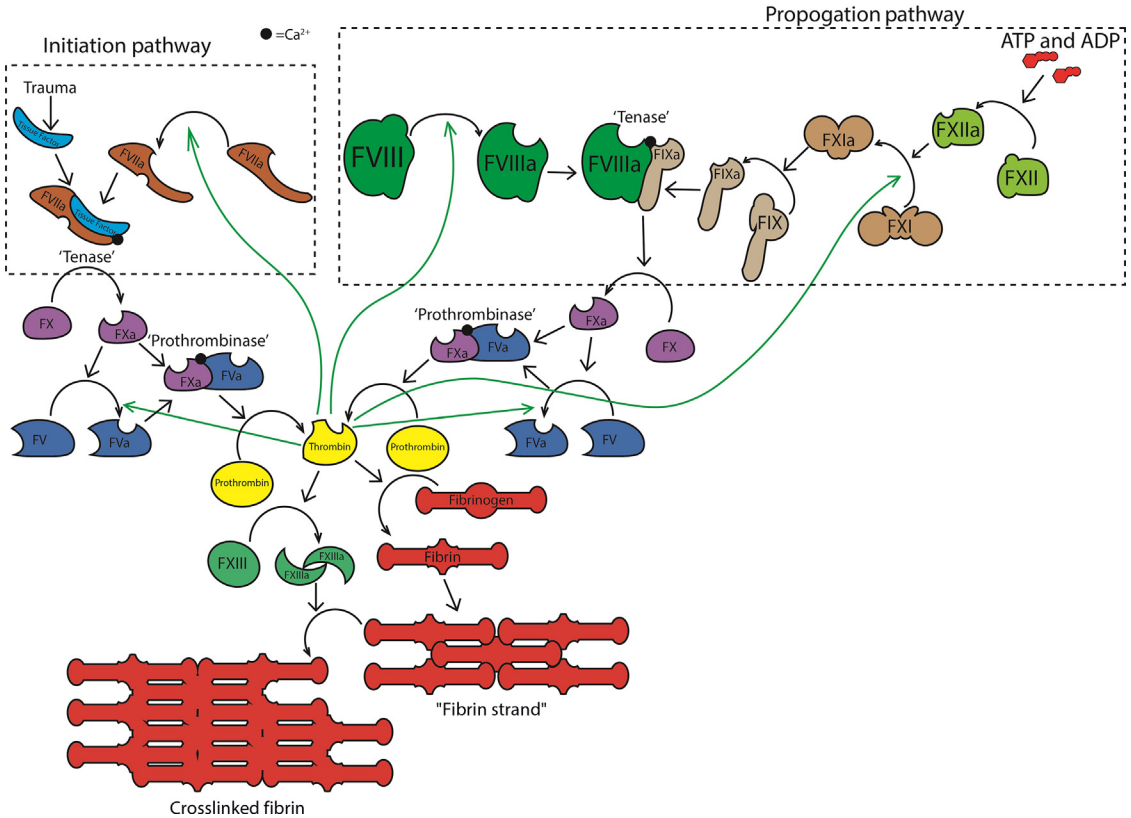

FIGURE 26.2 Pictorial representation of the coagulation factor pathways (secondary hemostasis). The factor pathways are typically initiated by trauma in the initiation pathway (*dashed box, left*). Tissue factor combines with FVIIa to form a tenase complex, which activates FX. The propagation pathway (*dashed box, right*) is initiated on the surface of platelets by the release of polyphosphates such as ADP and ATP. These activate FXII, which activates FXI, which in turn activates FIX. FIXa combines with FVIIIa activated and released from vWF by thrombin to form a different tenase complex to activate FX. FXa generated from either pathway then activates FV and combines with FVa to form prothrombinase, which cleaves prothrombin to thrombin. Thrombin then cleaves fibrinogen to fibrin and FXIII to FXIIIa. Fibrin combines noncovalently with other fibrin molecules to form fibrin strands. These are then covalently bound to form durable cross-linked fibrin by FXIIIa.

all include a *Gla* domain, a conserved protein domain defined by the presence of gamma-carboxyglutamic acid residues. These residues are formed through vitamin K-dependent posttranslational modification of the glutamate residues in a conserved Glu-Xaa-Xaa-Xaa-Glu-Xaa-Cys motif [1]. As the modification is dependent on vitamin K and required for function, these proteins can be affected by malnutrition as well as vitamin K antagonists such as warfarin and superwarfarins like difenacoum (rat poison). Those are FVII, FIX, FX, and prothrombin.

The typical in vivo coagulation cascade starts with vascular injury and the release of a protein termed "tissue factor" (TF). TF is expressed constitutively by many cell types such as fibroblasts, epithelial cells, astroglia, and smooth muscle cells. Importantly, it is not expressed on endothelial cells in the lining of blood vessels; however, it is present in the extracellular matrix around the vessels. The coagulation cascade starts with a vascular injury that releases TF from the extracellular matrix and then proceeds through many steps to the final result, cross-linked fibrin (Fig. 26.2):

1. When blood vessels are damaged, serum from the blood mixes with the extracellular matrix, and TF can come into contact with FVIIa in the serum.
2. FVIIa, TF, and Ca^{2+} form a tenase complex. This complex then cleaves and activates FX to FXa.
3. FXa then cleaves and activates FV to FVa and complexes with it and Ca^{2+} to form prothrombinase. This complex is then cleaves prothrombin to its active form, thrombin.
4. Thrombin then cleaves and activates two other proteins: fibrinogen to its active form fibrin and FXIII to its active form FXIIIa.
5. Fibrin molecules can form noncovalent complexes with other fibrin molecules to form fibrin strands.
6. FXIIIa then cross-links these strands to form a covalently linked polymer and solidify the clot.

Cross-linking fibrin is a very important step in the coagulation cascade, as it allows for the strong base for the mature clot, allowing it to form into a more permanent structure. Changes in fibrinogen structure as a result of mutations or loss of fibrinogen in the blood can lead to highly unstable clots, as platelets adhere to collagen and each other but are unable to solidify into a mature clot.

Fibrinogen is a complex protein consisting of six cross-linked chains, two each of three chains known as Aα, Bβ, and γ. The two Aα chains help form the center of the molecule, also known as the E domain, and the Bβ and γ chains form extensions on either side, termed the D domains (Fig. 26.3). Thrombin cleaves the N-terminal residues of the Aα and Bβ chains, located in the E domain. The cleaved products are known as fibrinopeptides A and B, and leave the α and β chains in the fibrin molecule, now termed a "fibrin monomer." These monomers can noncovalently bind to other fibrin monomers, forming a fibrin strand. This structure is frequently what is measured in coagulation analyzers. Fibrin monomers can then be cross-linked across their D domains by FXIIIa. FXIIIa is a transglutaminase that links γ and α chains to form a covalently linked fibrin clot.

The process described above is the typical initiation of the coagulation cascade in vivo. After initiation, however, in order to strengthen the clot and the clotting response, this clotting cascade will activate a second cascade, known as the propagation cascade, which proceeds through the following steps (Fig. 26.2):

1. Thrombin cleaves FV, FVII, FVIII, and FXI to FVa, FVIIa, FVIIIa, and FXIa. Cleavage of FVIIIa also liberates it from vWF.
2. FVIIa can complex with TF and Ca^{2+} to form more tenase complex to generate additional FXa.
3. FXIa cleaves FIX to FIXa.

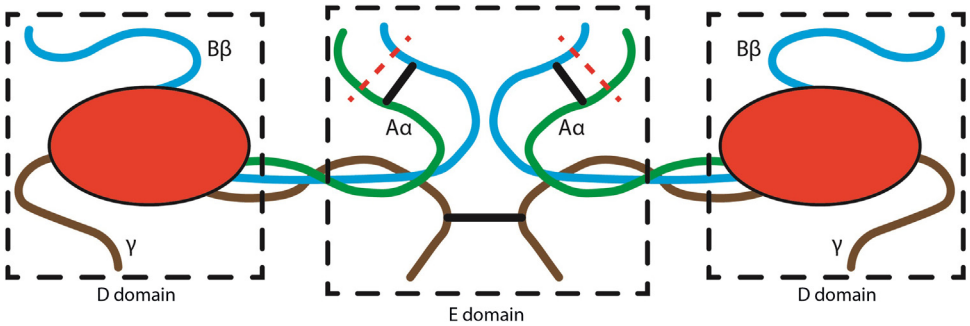

FIGURE 26.3 Schematic of the fibrinogen protein. It is formed through two copies, each of three protein chains: Aα (*green*), Bβ (*blue*), and γ (*brown*). The Bβ and γ chains form the D domain, while the Aα chain coordinates the chains in the center region, termed the "E Domain." The chains are cross-linked across the Aα and Bβ chains, and the two trimers are cross-linked across *y* domains by disulfide bonds to form a single fibrinogen molecule (*black lines*). During coagulation, thrombin cleaves the ends of the Aα and Bβ chains (*red-dashed lines*) to form fibrinopeptides A and B, respectively. This allows the cleaved fibrinogen molecule (now termed a fibrin monomer) to bind to other fibrin molecules noncovalently.

4. FIXa complexes with the FVIIIa activated by thrombin in step 1 and Ca^{2+} to form a tenase complex, which generates additional FXa.
5. The additional FXa generated complexes with FVa cleaved by thrombin to form more prothrombinase.

This additional cascade amplifies the original reaction, allowing for a strong response to the original trauma and expanding the clot to cover the necessary tissue.

Of the factor proteins described earlier, FXII is not mentioned. While initially considered of critical importance to the coagulation cascade, the truth of its necessity was questioned for a period until its physiologic role was discovered. It is now known that, in vivo, FXII is activated by polyphosphates released by platelets, most typically ADP and ATP, as well as phospholipids. FXIIa can then activate FXI, activating coagulation through the propagation stage proteins. As FXIIa cannot activate FVIIIa, the creation of a tenase is very slow without the presence of thrombin, and thus the ability of FXII to start the formation of a clot in isolation is limited. In a forming clot, FXII helps support the propagation cascade. Glass and microsilica particles can activate FXII in a manner similar to polyphosphates, which is important for the aPTT assay discussed later.

Coagulation factors and platelets work in concert, with platelets releasing both factor proteins and additional cofactors, such as Ca^{2+} and the coagulation factors, activating additional platelets. Together, they form the clot that slows bleeding and allows the circulatory system to repair itself (Fig. 26.4). Even small variations in this system can lead to aberrant states of either deficient clotting or unnecessary inactivation.

Tertiary hemostasis

Together, primary and secondary hemostatic processes collaborate to form a thrombus or clot, a mixture of platelets and cross-linked fibrin. However, in the absence of other factors, this process would continue indefinitely. Thus the body also has several mechanisms to both slow and stop the coagulation cascade, so that it does not proceed out of control (anticoagulation), as well as dissolve the clot once it is no longer needed (fibrinolysis). Both of these are part of tertiary hemostasis.

Anticoagulation

The body has several distinct mechanisms of anticoagulation, which function at various points in the coagulation cascade. Many of these also function constitutively, creating a barrier that must be overcome for a thrombus to form, preventing unnecessary coagulation from occurring. Tissue factor pathway inhibitor (TFPI) is a protease inhibitor that, true to its name, inhibits the activity of TF by inhibiting the FVIIa/TF tenase complex and thus inhibits creation of FXa. TFPI is produced constitutively by endothelial cells in the blood vessels and thus acts as a constant control on thrombosis (Fig. 26.5).

Protein C (PC) and protein S (PS) work by inhibiting both prothrombinase and tenase complexes. PC is the functional protein, while PS functions as its cofactor. PS-bound PC is known as activated protein C (APC). APC is a protease that cleaves FVa, and then APC can complex to this cleaved FVa to cleave FVIIIa. This inactivates both the factor proteins and their associated prothrombinases. Both PC and PS are formed by the liver and are dependent on vitamin K for proper function.

Another highly important endogenous anticoagulant is antithrombin (AT), also known as AT III. A serine protease inhibitor, AT works in concert with anionic glycosaminoglycans, the most recognizable of which is heparin. In vivo, AT function is likely potentiated by heparin sulfate, which is a major component of many cell surfaces including endothelial cells. Heparin as a pharmaceutical product is closer to that produced solely by mast cells and is likely not related to coagulation in vivo. The pharmacologic heparin is also known as "unfractionated heparin," in contrast to "low-molecular-weight heparin" (LMWH) which is a more purified form of heparin comprised solely of shorter polypeptides. Unfractionated heparin works by noncovalently joining AT to its targets, thrombin and FXa, which inactivates them. LMWH works by a similar mechanism but is only capable of directly inhibiting FXa. AT is formed in the liver but is not a vitamin K-dependent protein.

Finally, there is protein Z-dependent protease inhibitor (ZPI). ZPI is another serine protease inhibitor, and while it does not require protein Z (PZ) to function, the presence of PZ increases its activity by over 1000-fold. ZPI acts by inhibiting FXa. ZPI and PZ are synthesized in the liver, and PZ is vitamin K-dependent.

Fibrinolysis

Unlike anticoagulation, fibrinolysis is dominated by a single protein: plasmin. Plasmin is a protease-activated serine protease and is the primary driver in the dissolution of a mature clot. Plasmin acts primarily through the degradation of both fibrin and fibrinogen, leading to fibrinogen degradation products (FDPs). D-dimers are a specific type of FDPs that are only found from cleaved, cross-linked fibrin, thus being specific for the action of plasmin on a mature clot. This has implications for testing.

Plasminogen is synthesized in the liver, and its activation to plasmin is started during secondary hemostasis, such that clot degradation is occurring concurrently to the formation. Plasmin is formed through several activation mechanisms, most notably FXIa, FXIIa, and kallikrein.

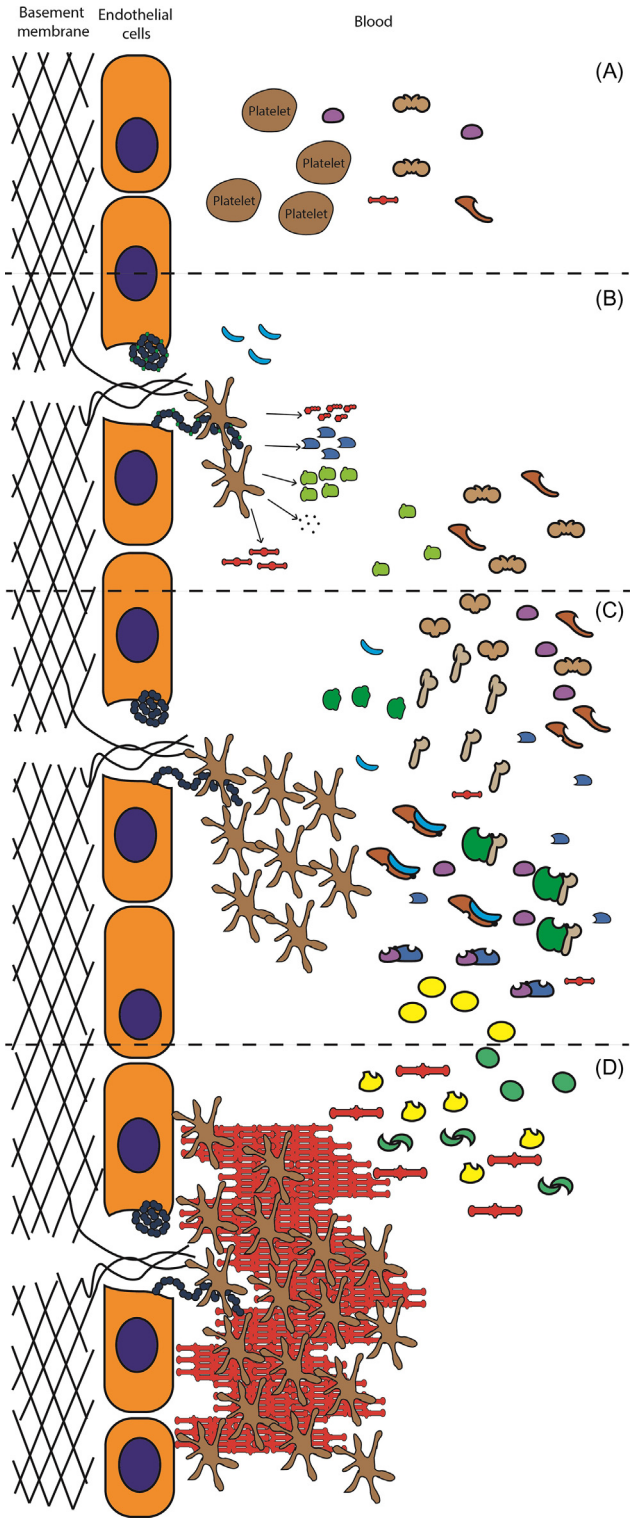

FIGURE 26.4 Pictorial representation of the clotting cascade. (A) No activation has occurred, and factor proteins and platelets both exist in their normal forms. (B) Damage to the endothelial wall has caused the release of collagen and vWF from the basement membrane and endothelial cells, as well as tissue factor. This leads to activation of platelets, which adhere to the site and release factor proteins as well as calcium, ATP, fibrinogen, and other molecules. (C) More platelets have aggregated, and factor proteins are beginning to be activated, leading to the formation of tenase and prothrombinase complexes. (D) Activation of thrombin and subsequently FXIIIa leads to the creation of cross-linked fibrin, which secures the growing clot and leads to a stable protection of the damaged site. Not shown are thrombolytic enzymes, which will break down the clot when it is no longer needed.

(*Continued*)

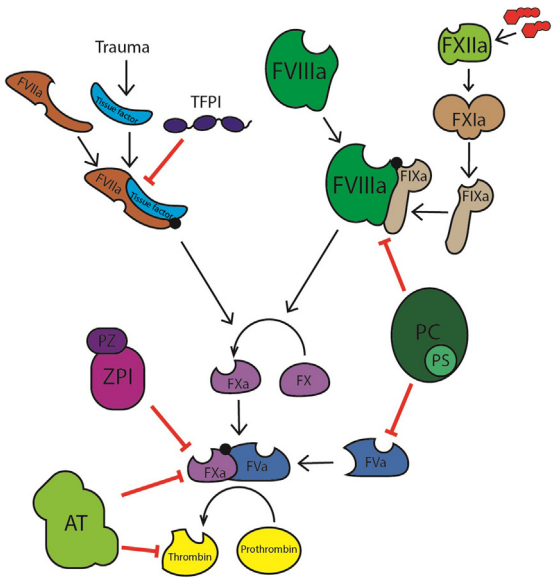

FIGURE 26.5 Simplified diagram of the coagulation system, displaying the action of various anticoagulant molecules (see Fig. 26.1 for full diagram). Tissue factor pathway inhibitor inhibits the tissue factor: FVIIa tenase complex. Protein Z-dependent protease inhibitor inhibits FX (shown in complex with protein Z). Protein C and S inhibit FX as well as FVIII. Antithrombin inhibits factor X as well as its namesake, thrombin.

Kallikrein is a serine protease and is cleaved to its active form by FXIIa. Plasmin can also be formed by the activity of the aptly named tissue plasminogen activator (tPA). tPA is synthesized and released by endothelial cells.

Laboratory testing

The goal of laboratory testing in hemostasis is to diagnose issues in this complex system quickly and accurately. As such, there is a general sequence of testing that occurs for most patients with coagulopathies, as well as most hospitalized patients. This testing typically starts with the most basic coagulation pathway tests, the aPTT (or PTT) and the PT. Both proceed through similar steps, the main difference being the activation process.

For coagulation tests, draw volume is essential. The final concentration of citrate must be accurate, as, unlike other plasma tests, the anticoagulation needs to be reversed. In most cases, coagulation samples are citrated plasma from whole blood collected into tubes with 3.2% (109 mM) liquid sodium citrate. Citrate removes the

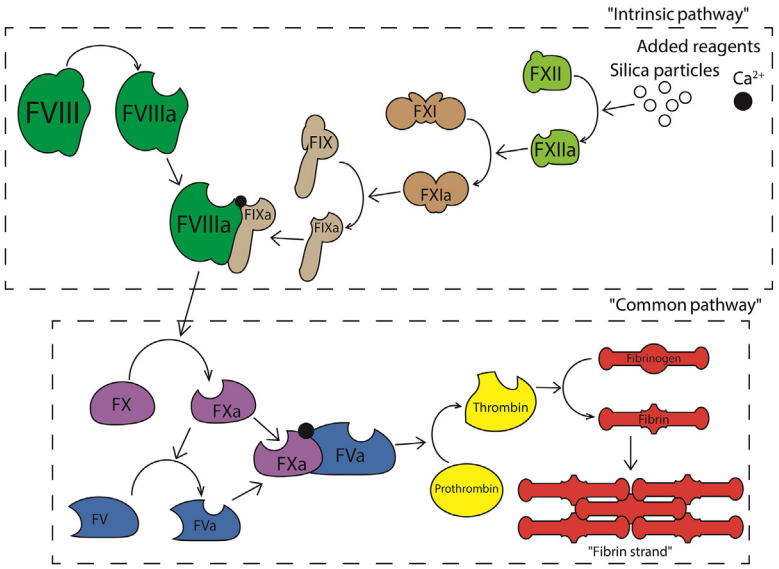

FIGURE 26.6 Pictorial representation of the activated partial thromboplastin time pathway. Silica particles (or another activated partial thromboplastin time activator such as kaolin) and calcium are added to an anticoagulated sample. This activates endogenous FXII, which activates FXI, which in turn activates FIX. FIXa combines with FVIIa and calcium to form a tenase complex. This is known as the intrinsic pathway. This tenase complex then activates FX to FXa, which in turn cleaves and activates FV to FVa. FXa then combines with FVa and calcium to form a prothrombinase complex that cleaves and activates prothrombin to thrombin. Thrombin cleaves fibrinogen to fibrin, which noncovalently binds other fibrin molecules to form fibrin strands. This is known as the common pathway, as it is also activated in the prothrombin time assay. The formation of these fibrin strands is the endpoint of the activated partial thromboplastin time assay.

calcium ions required for coagulation factors to bind to phospholipid membranes, thereby inhibiting coagulation. The final ratio of anticoagulant to blood should be 1:9, which for most blood collection tubes is approximately 90% full. Given a typical hematocrit of 40%, this results in a final citrate concentration of approximately 17 mM. Every lab performing coagulation testing must define specific limits of specimen acceptability for fill volume and hematocrit in order to ensure that this concentration is accurate. In cases of either underfilling or highly aberrant hematocrit, the final sodium citrate concentration will be incorrect and the reversal will not be successful, resulting in falsely long PT and aPTT results, mimicking a coagulopathy.

Another important preanalytical factor in coagulation testing is centrifugation. Serum coagulation testing is meant to measure the ability of the serum proteins to initiate coagulation, not the platelets that carry large stores of additional factor proteins and procoagulation molecules such as calcium. As a result, centrifugation of citrated samples must be sufficient to generate platelet-poor plasma (PPP), which is a plasma with a platelet count of less than 10×10^9 platelets/L, though it is good practice to strive for less than 5×10^9 platelets/L. Platelets will also be activated by the addition of calcium and prothrombotic factors, and their activation and release of additional coagulation factors will result in falsely low PT and aPTT results, mimicking a thrombotic condition.

Activated partial thromboplastin time

The aPTT (or PTT) measures what is sometimes called the "intrinsic pathway" in addition to the "common pathway," which is a result of the method of collection of serum samples. Historically, samples for aPTT testing were collected in glass tubes. The positive charges of the glass surface caused activation of FXII, and thus the aPTT was believed to be the "intrinsic" method of coagulation, since it was observed spontaneously. In current instrumentation, additives such as silica particles are used to activate this pathway (Fig. 26.6).

Most coagulation tests proceed through a series of common steps. First, the sample is warmed to 37 degrees to promote coagulation. Then, a procoagulant is added, which in the case of the aPTT is one of the mentioned additives, such as silica particles or the protein kaolin, in addition to phospholipids. Calcium is then added in order to overcome the citrate anticoagulant. The sample is incubated and measured for signs of coagulation. Depending on the specific instrumentation used, this may be assessed through either measurement turbidity (optical detection) or viscosity (mechanical detection). This approach measures the formation of fibrin strands (fibrinogen that has been cleaved by thrombin and noncovalently bound) but not cross-linked fibrin; thus FXIII deficiencies are not measurable by this method.

As the aPTT is initiated through the cleavage of FXII, it is most sensitive to deficiencies in the intrinsic pathway proteins. It is also dependent on factors synthesized by the liver, and thus is more sensitive to liver dysfunction. The aPTT is often used to monitor heparin levels for inpatients, and a nomogram can be developed by the lab to correlate blood heparin levels and aPTT results, though a direct Xa activity level or anti-Xa assay (discussed later) is generally considered to be a more precise and accurate assay of heparin activity.

Prothrombin time

The PT is performed in a similar manner as the aPTT, the only difference being the initiation of coagulation. For the

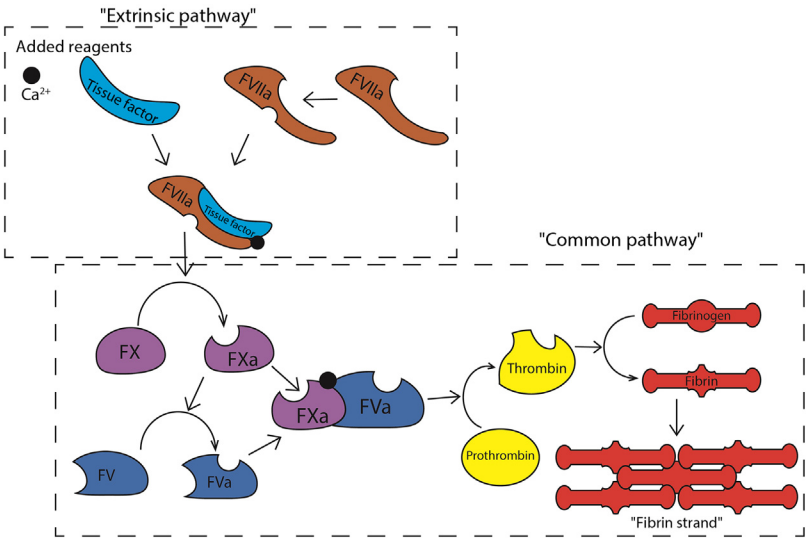

FIGURE 26.7 Pictorial representation of the prothrombin time pathway. Tissue factor and calcium are added to an anticoagulated sample, which combine with endogenous FVIIa to form a tenase complex. This is known as the extrinsic pathway. The prothrombin time then proceeds through the same common pathway as the activated partial thromboplastin time. The formation of fibrin strands is the endpoint of the prothrombin time assay.

PT, coagulation is initiated through the addition of exogenous TF to the plasma, which initiates coagulation through the formation of the TF:FVIIa tenase complex (Fig. 26.7). This TF may be either isolated from animal sources or created recombinantly. Since this approach originally required an additive (unlike the aPTT), this was named the "extrinsic pathway" despite being closer to the in vivo initiation of coagulation. The PT also culminates in the common pathway.

Outside of the initiation phase, this test proceeds in the same manner as the aPTT, though the PT normal ranges are typically much shorter than those of the aPTT as a result of the shorter enzyme cascade required to reach the assay endpoint. In addition, many PT reagents include a heparinase that will neutralize the anticoagulant effect of heparin. As a result, the PT is useful for testing a patient's underlying coagulation state while on heparin but is not useful for heparin monitoring.

International normalized ratio

An important addition to the reporting of the PT is the international normalized ratio (INR). The INR is a calculation that standardizes PT measurement across different reagents. This was created in order to assist in warfarin testing. Warfarin, also known as Coumadin, inhibits vitamin K epoxide reductase, which results in the reduction of previously mentioned vitamin K-dependent factors: FVII, FIX, FX, and prothrombin. Since the extrinsic and common pathways include all of these factors in addition to FV and fibrinogen, the PT is more sensitive to the action of warfarin than is the aPTT. Thus the PT and the associated INR are used as the standard method for warfarin testing.

The INR is a simple calculation, and is typically expressed as $INR = \left(\frac{PT_{specimen}}{PT_{mean}}\right)^{ISI}$. The $PT_{specimen}$ is the result for a given specimen, while the PT_{mean} is the geometric mean PT result for a normal population with the specific assay method, reagent, and lot. The international sensitivity index (ISI) is the numerical value of the assay's sensitivity to warfarin. All manufacturers assign ISI values to their reagents; however, these values must be verified locally in order to ensure their applicability. Verification is conducted through comparison with a reference method and the generation of a log/log plot of the results to determine the slope, which is the ISI. Reagents that are more sensitive to warfarin action will have a lower ISI, typically as low as 0.9, while less sensitive reagents will have higher ISIs, typically as high as 1.5.

Mixing studies

A typical next step in many coagulopathy workups after the discovery of a prolonged PT and/or aPTT is the mixing study. In cases of an isolated factor deficiency, only 50% activity of the factor is required to generate a normal PT or aPTT result. As a result, mixing a patient's sample 1:1 with normal pooled plasma (NPP), defined as pooled plasma with a measured factor activity of 100% in each factor, should normalize a patient's PT and aPTT results even in the absence of a single factor. This is also true for multiple factor deficiencies, such as when a patient is treated with warfarin, though in this case the extent of deficiency is important. Most patients with warfarin in the therapeutic range will correct in a mix. However, this is not the case for inhibitors that will act upon the factors present in NPP and cause the coagulation time of the mixed sample to still be prolonged. Inhibitors may be exogenous, such as heparin or direct oral anticoagulants

(DOACs), or endogenous autoantibodies. In either case, inhibition will cause the mix not to correct back to the normal range for PT or aPTT.

The notable exception to this pattern is in low affinity inhibitors, such as many FVIII inhibitors (seen in acquired hemophilia A; to be discussed later) and some lupus anticoagulants (LAs), which have a unique pattern in mixing studies. Patients with low affinity inhibitors will demonstrate a PT and/or aPTT prolongation (an isolated aPTT prolongation in the case of FVIII and LAs), which corrects upon mixing if the mix is tested right away. However, if the mix is incubated for 2 hours at 37°C, it will again become prolonged. This is because many low affinity inhibitors have slower K_{on} rates, thus requiring incubation in order to see the effects. As a result of this effect, 1- or 2-hour incubations are standard follow-ups for mixing studies that correct in order to confirm the absence of an inhibitor.

Activated clotting time

Activated clotting time [also known as the activated coagulation time (ACT)] is a whole blood clotting assay that is frequently used in point-of-care or near-patient testing. In particular, the ACT is useful in areas where high concentrations of heparin are used, such as cardiac catheterization and extracorporeal membrane oxygenation (ECMO). In these cases, the aPTT is no longer useful, as the concentrations of heparin are such that a clot will not form in PPP. In addition, the possible shorter turnaround time of the ACT as a result of its inclusion in several point-of-care devices makes it useful in operating rooms and cardiac care units. The ACT involves adding a clotting activator, such as celite, kaolin, or glass beads, to a whole blood sample. Clotting is then measured through mechanical (such as measurement of the movement of a metal ball through the serum) or electrochemical (such as measuring electrical resistance of the serum) means. Clotting typically takes between 1 and 3 minutes.

Fibrinogen

Fibrinogen is a key analyte to measure when evaluating coagulation capacity, as it is the functional endpoint of the factor pathways. Fibrinogen may be measured by direct measurement, though the most common method is the Clauss method, a clot-based assay. Most coagulation tests currently performed can be categorized as a "clot-based assay" ("clottable assay") or direct measurement assays (typically called "antigen" assays as many are immunoassays). Fibrinogen is usually performed using a clottable assay, with the endpoint being the formation of fibrin strands.

In the Clauss method, plasma is diluted 10-fold or more, and a large excess of exogenous thrombin is added, as well as calcium, and the time to clot formation is measured. There is an inverse relationship between fibrinogen concentrations and clot time, and a standard curve can be generated through the use of calibrators. Because of the high concentrations of thrombin with respect to plasma, thrombin inhibitors typically do not affect the fibrinogen assay. However, particularly, high concentrations of direct thrombin inhibitors may prolong the assay and thus lower the measured fibrinogen result. In addition, fetal fibrinogen is slightly less reactive to thrombin than adult fibrinogen, and thus measured results may be lower in a clottable assay when used on neonate blood [2]. Dysfibrinogenemia (mutations in fibrinogen) may also lower measured results, as the Clauss method reads only functional fibrinogen.

Factor assays

There are two main forms of factor assays that are performed in coagulation laboratories: clottable, or "one-stage" assays, and chromogenic, or "two-stage" assays. The clottable assays are currently more common, and are called "one-stage" assays as all components are mixed and then immediately tested by either PT or aPTT method, depending on the factor. Chromogenic assays require an activation step, followed by addition of chromogenic substrate for factor Xa. Factor Xa activation is always used as the assay endpoint in chromogenic assays.

In clottable assays, formation of fibrin monomers is the endpoint, the same as in the PT or aPTT assay. However, instead of testing straight patient plasma, the patient's plasma is diluted 1:10 in an isotonic buffer and then mixed 1:1 with plasma that is fully deficient in a single factor. This allows the patient sample to supply the missing factor and complete the coagulation cascade. A PT or aPTT assay is then performed on the mixed sample, depending on the factor being evaluated.

The resulting clotting times can be converted to factor activity using a standard curve, generated with control plasma of known factor concentrations. By convention, a 1:10 dilution (matching the patient sample dilution) of this plasma is set as 100% factor activity, and the plasma is serially diluted to generate the standard curve. The control plasma can also be used in lower dilutions in order to generate a standard curve above 100%. Factor activity is given in percent, and the general conception is that 50% of a factor is sufficient for in vivo clotting; thus normal factor ranges are typically 50%−150%.

In order to exclude the presence of inhibitors, factor assays are typically performed with serial dilutions of patient plasma, such as 1:10, 1:20, and 1:40. If the results of these assays substantially agree after accounting for the

dilution, the results are considered acceptable. However, if the results do not agree, especially if higher dilutions result in higher adjusted factor levels, inhibitors may be suspected.

In addition to one-stage assays, chromogenic assays (two-stage assays) are currently available or in development for many factors, such as FIX, which measure activity through the cleavage of a chromogenic substrate of FXa. In these assays, the patient's plasma is mixed with plasma containing all factors necessary for the activation of FXa except for the factor being tested. The sample is allowed to incubate, and then in the second stage, a solution with chromogenic FXa substrate is added. Activated FXa from the previous step can cleave the substrate, resulting in a chromogenic readout, such as *p*-nitroaniline release, measured by absorbance at 405 nm. The results of these assays should agree with the one-stage assays; however, some cases such as patients on long-acting factor replacements are better monitored through the use of chromogenic assays.

Anti-Xa

A similar assay to the chromogenic factor assays is the anti-Xa assay, commonly used in place of aPTT for heparin monitoring due to the higher specificity and selectivity of the anti-Xa assay. As the name implies, this measures the activity of anti-Xa compounds in the patient's plasma. In this assay, patient plasma is mixed with a solution containing FXa and chromogenic substrate. It may also contain exogenous AT in order to supplement for a patient's potential lack of AT, but formulations differ. Any FXa-inhibiting substances, most typically heparin or LMWH, will inhibit the action of FXa and lower the resulting chromogenic response.

Thrombin time

The term "thrombin time" may be misleading, as the thrombin time is actually independent of endogenous thrombin. It measures the amount of time needed for thrombin to form fibrin strands, and is thus sensitive to the patient's quality and quantity of fibrinogen, as well as to the potential presence of thrombin inhibitors in the sample. The thrombin time is substantially similar to the Clauss method of fibrinogen determination, though the patient sample is not diluted and thrombin concentrations are much lower. Exogenous thrombin, typically bovine or human in origin, and calcium are added directly to a patient's sample, and the time to fibrin strand formation is measured as in the PT or aPTT assays. Low fibrinogen and/or dysfibrinogenemias (mutations in fibrinogen) will prolong the thrombin time. Any inhibitor of thrombin will also prolong the thrombin time, such as heparin or direct thrombin inhibitors (e.g., dabigatran). Notably, LMWH will typically not prolong a thrombin time, as it does not inhibit thrombin; Xa is bypassed in this assay. In addition, elevated fibrin, FDPs, and paraproteins can prolong the thrombin time through interference of thrombin activity or fibrin strand formation. Fetal fibrinogen may also delay clotting times in a similar manner to the fibrinogen assay.

D-dimer

After fibrin monomers are formed, degradation of the solidifying clot by plasmin will result in FDPs, also known as fibrin split products. While assays exist for general measurement of FDPs, this has mostly given a way to the testing of D-dimers, which are a specific subset of FDPs that include cross-linked fibrinogen D domains. Fibrinogen D domains are specifically cross-linked by FXIIIa, and thus D-dimers are only produced in a mature clot. FDPs, however, can be formed by any fibrolytic event, and elevated concentrations are observed in many conditions including liver disease, eclampsia, cirrhosis, and acute thrombotic events. D-dimer is considerably more specific to thrombotic events, and is the preferred analyte to measure if a patient is under suspicion of a thrombotic event.

The D-dimer assay is also useful in the background of pulmonary embolism (PE) and deep vein thrombosis (DVT), where D-dimer has an excellent negative predictive value. The positive predictive value is marred by many possible causes of fibrinolysis such as trauma and recent surgery; however, the D-dimer is a very effective rule-out test for PE and DVT in emergency settings, with negative predictive values of 95%−100% [3,4]. For PE cases with a low pretest probability (which can be calculated with many tools such as the Wells score [5], a method for quantifying PE risk based on clinical features), a negative D-dimer assay can save a patient and care team the time, expense, and radiation exposure of a CT scan.

D-dimer products are typically measured by latex immunoagglutination (LIA) assays. LIA assays are a form of immunoassay, where the antibodies are linked to latex beads. Recognition of the antigen by the antibodies causes agglutination of the beads, and this causes increased turbidity and decrease of absorbance of the sample which can be read by an analyzer. D-dimer units (DDUs) of reporting can cause a great deal of confusion, as they are not standardized across the industry. In general, two units are used: the fibrinogen equivalent units (FEUs) or DDUs. DDU is the simpler unit, as it is only the microgram per milliliter of D-dimer detected in the plasma. FEU, alternately, relates the amount of D-dimer to the amount of fibrinogen that the D-dimer was originally; thus it is 2xDDU. A given manufacturer or reference lab

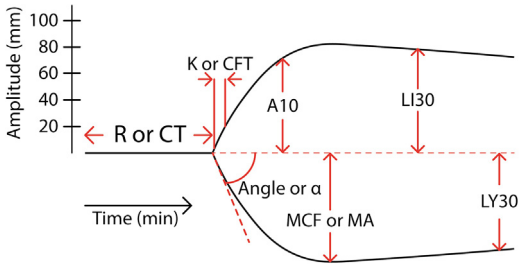

FIGURE 26.8 Typical thromboelastography graph. Parameters for both thromboelastography and rotational thromboelastometry are shown. R or CT is the time for the amplitude to reach 2 mm, and is analogous to the prothrombin time or activated partial thromboplastin time, depending on clot activator used. K or CFT is the time required for the amplitude to increase from 2 to 20 mm. Angle or α is the angle tangent to the curve at the start of clot formation. A10 (rotational thromboelastometry) is the amplitude 10 minutes after CT. The MCF or MA is the maximum "strength" of the clot, and is the maximum amplitude of the graph. LI30 (rotational thromboelastometry) is the reduction in strength of the clot 30 minutes after CT. LY30 (thromboelastography) and the associated LY60 (not shown) are the percent reductions in clot strength 30 and 60 minutes after MA.

may use DDU or FEU, and this should be checked carefully before using the results and should be clear on any results put out by a laboratory.

Thromboelastography

Thromboelastography (TEG) is a whole-blood viscoelastic test, which attempts to capture a large degree of information about a patient's bleeding status. Unlike standard laboratory tests for coagulation, TEG is performed in the presence of platelets as well as other blood factors that may affect clotting typically removed by centrifugation. In addition, as there is no centrifugation required, this technique can be used in a close-to-bedside setting. However, TEG is a nonwaived test and is performed frequently by laboratory personnel. There are two main devices that are used for this purpose in laboratory settings: the TEG (Haemonetics, Braintree, MA, USA) and rotational thromboelastometry (ROTEM; Instrumentation Laboratory, Bedford, MA, USA). These devices work under the same principle: a sample of anticoagulated whole blood is placed in a heated circular cup with a pin in the center. The sample is warmed, calcium and clot activator are added, and then either the pin (ROTEM) or cup (TEG) is rotated back and forth to generate a low shear stress. The force applied on the pin by the forming clot is translated into an amplitude, which is then plotted, and several different factors calculated from this graph (Fig. 26.8).

The CT (ROTEM) or R (TEM) is analogous to the PT or aPTT, depending on the clot activator used. Beyond this, various factors calculate the overall clot strength, which is dependent on fibrin strength and platelet activation, and fibrinolysis. The results of TEG can be used to help guide blood component replacement, and several studies have shown its utility in decreasing blood component cost through more specific direction in settings such as cardiac surgery [6,7].

There are many calculated variables and modifications to TEG, which purport to give additional information on hemostasis and alter the testing time necessary. The breadth of these variables and modifications is outside the scope of this work. For more information, please see various reviews such as "TEG and ROTEM: technology and clinical applications" by Whiting and DiNardo in the *American Journal of Hematology*.

Pathophysiology and advanced coagulation testing

Hemostasic disorders can be broadly categorized as either increased bleeding or increased clotting (thrombophilia). Bleeding disorders are predominantly caused by von Willebrand disease (vWD) with specific deficiencies observed less frequently, while thrombophilias are a more diverse group that may be caused by autoimmune inhibitors, exogenous inhibitors, and deficiencies. Most testing for these disorders is typically termed "advanced coagulation testing" or "special coagulation testing," and may not be performed in a core laboratory.

Bleeding disorders

Von Willebrand disease

As previously mentioned, bleeding disorders are dominated by vWD, which is itself a cluster of different disorders based around the functioning of vWF. Through testing of the vWF activity, antigen amount, FVIII activity, multimer pattern, and platelet response to ristocetin, these disorders can be distinguished from one another (Table 26.1). A typical workflow for suspected vWD includes testing vWF antigen (a mass assay, typically by immunoassay) and activity along with FVIII activity. Those with suspected Type 2 vWD should have multimers tested, followed by ristocetin-induced platelet aggregation (RIPA) testing in those with suspected Type 2B [8,9]. RIPA testing is described in more detail in the platelet aggregation section, below.

Ristocetin is commonly used in assays for vWF activity. Originally utilized clinically as an antibiotic, it was removed from the market due to causing thrombocytopenia. Ristocetin facilitates the GP Ib/vWF interaction, which causes platelets to be activated and then removed from circulation. In the ristocetin cofactor assay, patient's plasma is mixed with exogenous GP Ib (typically in the form of normal platelets or GP Ib-coated beads) and

TABLE 26.1 Typical results for vWD tests for all major subtypes.

vWD type	vWF antigen	vWF activity	FVIII activity	Multimer pattern	RIPA response
Type 1	Low	Low	Low	All present at lower concentrations	Normal response
Type 1C[a]	Low	Low	Low	Often has ultra high-molecular-weight bands present	Normal response
Type 2A	Normal	Low	Normal	Loss of high-molecular-weight bands	Reduced response at 1 mg/mL ristocetin
Type 2B	Normal	Low	Normal	Loss of high-molecular-weight bands	Increased response at 0.5 mg/mL ristocetin
Type 2M	Normal	Low	Normal	Normal pattern or increase in high-molecular-weight bands	Reduced response at 1 mg/mL ristocetin
Type 2N	Normal	Normal	Low	Normal pattern	Normal response
Type 3	Very low	Very low	Very low	No bands	Reduced response at 1 mg/mL ristocetin

RIPA, Reistocetin-induced platelet aggregation; *vWD*, von Willebrand disease; *vWF*, von Willebrand factor.
[a]*Type 1C will show an elevated vWF propeptide-to-antigen ratio where this testing is available.*

ristocetin. If the vWF in the patient's plasma is normal, ristocetin will facilitate the vWF binding to GP Ib and cause agglutination, which can be measured optically. If the patient's vWF is unable to bind GP Ib, agglutination will be highly reduced or absent, causing a lower reading.

VWD can be the result of either a quantitative loss of vWF or a qualitative dysfunction. It results in inadequate primary hemostasis, which may manifest as epistaxis, heavy menstrual bleeding, and easy bruising. The condition can be associated with the decreased antigen and functional activity (Types 1 and 3) or with a relatively normal antigen concentration and reduced functional activity (Type 2). vWD, as defined by laboratory testing, has an overall prevalence of 8000 per million population, while clinically significant disease with bleeding affects about 100 individuals per million population. The most common quantitative disorder, Type 1, can occur for many reasons and constitutes 90% of all vWD. Known causative mutations are found in ~65% of cases, and are an autosomal dominant condition. It is diagnosed as vWF activity and antigen below 50% of normal serum, and is also associated with low FVIII activity. This can come about through missense, nonsense, and promoter mutations in the vWF gene, as well as through consumption. As vWF is activated and exposed to ADAMSTS13 in areas of high shear stress, introducing more stress can reduce levels of active vWF such as in ECMO. This is also termed "acquired Type 1 vWD." Other sources of acquired Type 1 vWD include monoclonal gammopathies, non-Hodgkin's lymphoma, myeloproliferative disorders, some solid tumors, hypothyroidism, sodium valproate, and ciprofloxacin treatment, among others. Type 1 vWD is both the most common (up to 2% of the population is affected) and one of the most diverse bleeding disorders from a causative standpoint.

In comparison with the classic Type 1 vWD, there is an alteration in the clearance known as "Type 1C vWD." Type 1C is characterized by a significant rise in vWF clearance, resulting in low vWF levels and increased responsiveness to desmopressin (DDAVP); however, there is also a significantly shortened half-life for DDAVP treatment. Patients with Type 1C are identified by an abnormal vWF-propeptide to vWF antigen ratio (elevated in patients with Type 1C vWD). Type 1C can also be found through a time course study, which is typically performed on new DDAVP patients. Type 1C patients will show normal or high response to DDAVP (seen as increase in vWF antigen and activity 1 hour after administration), followed by a significantly higher reduction at 4 hours after administration. This has therapeutic implications, as DDAVP is typically used to prepare Type 1 patients for minor surgery and may not be suitable for Type 1C patients. It should be stated that individuals with blood group "O" are known to have lower vWF levels in general, most likely through an increased clearance. The significance of this decrease in levels to the diagnosis of vWD is debated, and symptomatic correlation is suggested in these patients [10].

Type 2 vWD is defined as a qualitative loss of vWF activity. This can come about through various causes, which breaks down the different subtypes. In almost all cases, the defining feature is a discrepancy between the activity and antigen results. In most cases, the vWF activity to antigen ratio should be greater than 0.6. In Type 2

vWD, the antigen will be normal or slightly decreased, while the activity will be much lower. This is true for types A, B, and M. Another informative test in vWD Type 2 is to examine the state of multimerization of vWF. Multimer patterns are typically assessed by electrophoresis on agarose gels followed by Western blot analysis with a specific antibody to vWF. Normal plasma produces an extended ladder of multimers, including high-molecular-weight forms.

In Type 2A vWD, there is a mutation in the ADAMTS13 cleavage site which causes increased cleavage. These mutations are of various types and at various locations on the vWF sequence, leading to either a dominant or recessive phenotype. In all cases, vWD Type 2A results in a loss of high-molecular-weight vWF. This also leads to a lack of response of platelets to ristocetin, which can be seen in platelet aggregation studies.

Type 2B is from a gain of function mutation in the GP Ib/IX/V binding site. This causes vWF to be inappropriately bound to platelets and removed from circulation. This results in the loss of very high MW vWF multimers as well as mild thrombocytopenia, as bound platelets are also removed from circulation. Platelets from these patients are also more sensitive to low-dose ristocetin.

The opposite of Type 2B, Type 2M, is the result of a loss of function mutation in the GP Ib/IX/V binding site on vWF. As the multimers do not bind platelets well, this leads to either a normal distribution of multimers or even an increase in high-molecular-weight multimers. The response to ristocetin by these platelets is muted, similar to Type 2A.

The last Type 2, Type 2N, is the result of mutations involved in the binding of FVIII to vWF. As a result, FVIII cannot bind to vWF, and free FVIII is cleared quickly from the circulation resulting in deficient FVIII activity levels though vWF activity, antigen, and multimers are all typically in the normal range. There is also no effect on a patient's platelet's response to ristocetin.

The last type of vWD, vWD Type 3, is a more severe form of Type 1 and results from mutations that lead to a complete loss of vWF. vWF activity, antigen, and FVIII activity are all significantly decreased to immeasurable, and bleeding is typically severe and can easily occur in both mucosa and soft tissues. Without treatment, vWD Type 3 is fatal.

Hemophilia A and B

Hemophilia A and B are the results of single-factor deficiencies, either FVIII (hemophilia A) or FIX (hemophilia B). They are often inherited as X-linked disorders and affect up to 1 in 5000 patients; as many as 30% of all cases are the result of de novo mutations. Hemophilia A is the most common and accounts for approximately 85% of cases, and hemophilia B accounts for approximately 14% of cases. The remaining 1% of cases are the result of other deficiencies, such as FXI, and are exceedingly rare. The exception to this is FXI deficiency in Ashkenazi Jewish populations, where the incidence can rise as high as 4%. However, FXI levels are only weakly correlated with bleeding.

Hemophilia A and B have the same classification and symptoms. Both conditions can be classified into three distinct categories based on their factor activities: (1) factor activity between 6% and 20% is "mild"; (2) factor activity between 1% and 5% is "moderate"; and (3) $<1\%$ is "severe." Bleeding is directly correlated with factor levels, and factor replacement is often used to treat hemorrhage or to prepare for invasive surgery. Severe forms may require chronic infusions. Treatment of these conditions can also be complicated by the development of autoimmune factor inhibitors. Because of the constant use of exogenous factors, up to 30% of severe hemophilia A patients and 2%–3% of hemophilia B patients develop these alloantibodies after several doses, which can be determined through a lower than expected response to factor infusion as well as through an inhibitor assay.

In rare cases, a patient may develop a spontaneous autoimmune FVIII inhibitor. This is termed "acquired hemophilia" and affects one in a million patients. Clinical symptoms are severe and mimic severe hemophilia A, though it typically occurs in elderly patients and frequently with comorbid autoimmune conditions such as lupus or rheumatoid arthritis. Similar to the alloantibodies mentioned previously, an autoimmune inhibitor can be detected through an inhibitor assay. A mixing study will also reveal the presence of an inhibitor, though a specific inhibitor study is needed to determine severity.

Factor deficiencies

Congenital factor deficiencies beyond VIII and IX are extremely rare. Specific acquired deficiencies are also quite rare but do occur more often, and the inhibitors that are at fault in these cases can be determined through an inhibitor assay in the same manner as acquired hemophilia, using the affected factor assay as a basis. The original deficiency can be found with factor assays, with inhibitor assays utilized after the specific deficiency is pinpointed.

As mentioned previously, both liver and vitamin K status can profoundly influence the coagulation cascade. Both will extend the PT, and severe forms of both will prolong the aPTT. However, liver disease will have a more pronounced effect on the aPTT than that of the PT. A typical response to an isolated prolonged PT, especially without overt bleeding symptoms, will be a two-factor

test—usually FV and FVII or FV and FX. As FV is vitamin K-independent, both tests will only be low in the case of liver disease. If only FVII or FX is low, vitamin K deficiency is more likely.

Platelet disorders

Platelets are composed of many highly specialized receptors and organelles, and congenital or acquired disruption of these can cause many bleeding disorders, though most present similarly as mucocutaneous bleeding of various severities and may or may not present with thrombocytopenia. Many of these disorders or deficiencies can be determined through the use of platelet aggregometry, which measures both the ability of platelets to aggregate as well as the ability of the platelets to secrete. Platelet aggregometry can be performed on either platelet-rich plasma or whole blood. Aggregometry performed on plasma uses light transmission for detection, which increases upon platelet aggregation, while whole blood uses electrical impedance, which also increases upon platelet aggregation. Both whole blood and plasma aggregometry typically include the use of the luciferase enzyme that causes a measurable output of light when platelets release ATP from their dense granules. A normal control is always used for comparison to the patient sample, and then both pools of blood or plasma are challenged with various agonists to induce aggregation or granule release. Typical agonists include thrombin, AA, ADP, collagen, and ristocetin. Epinephrine may be used, though this is only utilized in PPP.

Most agonists produce platelet aggregation through a GP IIb/IIIa-dependent mechanism with the notable exception of ristocetin. RIPA depends on the presence of both vWF and the GP Ib/IX/V complex, and is independent of the GP IIb/IIIa receptor. RIPA is reduced or absent in most forms of vWD, whereas ADP, epinephrine, AA, and collagen produce normal aggregation responses in this condition. The exception is vWD Type 2B, which shows an increased response to low-dose ristocetin. Various platelet disorders can be determined through the particular pattern of aggregation and release that each disorder shows. Also, microscopy can help to confirm the diagnosis, especially in the cases of storage pool disorders.

Acquired platelet disorders

Many conditions may cause platelet function defects, either congenital or acquired. Acquired disorders are more common and have a staggeringly large number of sources. For this section, we will focus only on the most common.

By far, the most common cause of acquired platelet dysfunction is aspirin use. Aspirin irreversibly inhibits COX proteins, leading to a profoundly impaired or even absent aggregation and release in response to AA, the substrate of COX-1, as well as reduced response to ADP and collagen. In whole blood, ADP may still show a normal aggregation response. However, thrombin, which activates platelets independently of COX-1, will show a normal response. A failure to aggregate or secrete with all of these agonists with preserved thrombin response may be attributable to aspirin use and may suggest a retest if a platelet function disorder is still suspected.

Most nonsteroidal antiinflammatory drugs (NSAIDs), which likewise function as COX inhibitors, also impair platelet function. However, as these are not irreversible inhibitors, the time frame of inhibition is much shorter. Typical doses of other NSAIDs, such as naproxen sodium or ibuprofen, may show selective inhibition of platelet activity for up to 3 days. While not typically classed as an NSAID, acetaminophen can also affect platelet function with a similar pattern. It has an even more reduced effect, however, beginning to correct within 90 minutes of administration. As such, inhibition by acetaminophen should only be considered if use is suspected very close to the time of draw.

Clopidogrel is another antiplatelet drug that is commonly used alongside aspirin and inhibits the $P2Y_{12}$ receptor, which is targeted by ADP. As such, response to ADP is reduced. Unlike aspirin, the $P2Y_{12}$ effect is limited to ADP and collagen, which will both show a reduced response in terms of aggregation and secretion.

Congenital platelet disorders

Most platelet aggregation is done to diagnose congenital disorders, which can take many forms. Lack of α granules, dense granules, deficiency of secretion enzymes, and membrane receptor defects are all described and have different patterns of aggregation, release, and microscopy (Table 26.2).

Deficiency of α granules is also known as "gray platelet syndrome," as alpha granules give platelets their distinctive speckled appearance on light microscopy and the platelets are too large. Since α granules contain various coagulation factors as well as vWF, lack of α granules results in a muted response to all agonists.

Deficiency of dense granules has a similar effect, though this will not be visible using light microscopy. Electron microscopy is capable of imaging dense granules and can illustrate their absence. Platelet aggregation will show a similarly muted response to all agonists, especially in terms of granule release, which is measured based on dense granule ATP release. If this defect is suspected, electron microscopy can be performed, which can determine if dense granules are decreased relative to normal patient controls. When dense granules are

TABLE 26.2 Aggregation results for various platelet disorders when tested by platelet aggregometry.

Disorder	ADP	Epinephrine	AA	Collagen	Thrombin	Ristocetin

Membrane defect	Reduced	Reduced	Normal	Reduced	Normal	Normal

AA, Arachidonic acid.
[a]*Glanzmann's thrombasthenia will typically show normal ATP release by platelets with all agonists.*
[b]*Dense and α granule storage pool disorders can be distinguished by microscopy. Loss of α granules results in large, "gray" platelets (no visible granules) on light microscopy. Loss of dense granules can be seen in electron microscopy.*

decreased in patients with oculocutaneous albinism, Hermasky–Pudlak or Chediak–Higashi syndrome should be suspected. In those males with decreased dense granules and without oculocutaneous albinism, Wiskott–Aldrich syndrome is most likely.

Defects in COX enzymes can also occur, which will result in lab results that are highly similar to those of aspirin treatment, and may be called an "aspirin-like defect." In this case, very careful patient histories and repeat testing may be required to distinguish the disorder from a drug effect.

Platelet type or pseudo-von Willebrand disease (pseudo-vWD) is a platelet receptor defect disorder that causes a similar clinical and laboratory picture as vWD Type 2B. This does not involve any mutation on vWF but is instead a mutation of the GP Ib/IX/V receptor. A gain of function mutation in GP Ib increases affinity for vWF in a similar manner to vWD Type 2B, resulting in a similar clinical picture. Testing will also show similar results, with a loss of high and intermediate size vWF multimers and increased platelet response to ristocetin. One method to distinguish the two is through the addition of vWF to patient platelets, typically through the use of cryoprecipitate. If a patient has vWD Type 2B, the addition of cryoprecipitate will at least partially correct the response to ristocetin. In pseudo-vWD, the error is on the platelets, and thus the addition of vWF will not correct the results [11].

Much as pseudo-vWD may masquerade as vWD Type 2B, Bernard–Soulier syndrome (BSS) may masquerade as vWD Type 2M. This disease is the result of a decrease or loss of the GP Ib/IX/V complex on the surface of platelets. Multiple different mutations may cause this disorder, spread across the three component proteins. All of these mutations result in the same features of thrombocytopenia as well as characteristic large platelets, as the GP Ib/IX/V complex is also required for proper production of platelets by megakaryocytes. In platelet aggregation studies, BSS patients will react similarly to vWD Type 2M and show a normal response to almost all agonists except for ristocetin, which will display a markedly reduced or absent response. BSS and vWD Type 2M can also be distinguished through the use of exogenous vWF. As the platelets are affected in BSS, addition of vWF will not correct the response to ristocetin, while in vWD Type 2M, the addition will correct the response.

Glanzmann thrombasthenia (GT) is the result of a defect in the GP IIb/IIIa platelet surface receptor. GT is characterized by prolonged or spontaneous bleeding from birth, presenting as easy bruising, gum bleeding, and epistaxis, as well as petechiae and hematomas. As in BSS, the causative mutations vary and can occur on either the IIb or IIIa protein. The GP IIb/IIIa receptor is required for platelets to bind fibrinogen; thus the formation of clots is highly attenuated in this condition. As a result, platelet aggregometry will show little to no aggregation for all agonists except ristocetin, which may show aggregation as platelets bind to vWF. However, fibrinogen binding is required to form a mature clot, and so disaggregation is sometimes seen with ristocetin aggregation. Also, all reagents will typically show degranulation and ATP release, as GP IIb/IIIa is not required for degranulation.

Testing for bleeding disorders

Most patients with bleeding are tested with PT and aPTT and a complete blood count when presenting to a hospital, and these results can help guide further testing. Isolated increases should be followed by mixing studies. Correction in the mix indicates a factor deficiency. Isolated PT prolongation or prolongation in both with correction should be followed by clinical correlation and factor assays to assess liver function and vitamin K status. Isolated aPTT prolongation with correction should be followed by testing for FVIII inhibitors and hemophilia. Correction on mix but prolongation on incubation is

highly indicative of an FVIII inhibitor (acquired hemophilia A).

Bleeding in the absence of PT or aPTT prolongation, especially with normal platelet counts, should be followed by vWD testing, which should be both activity and antigen testing to determine vWD Type 1 (concordant low results), 2 (discordant results), or 3 (concordant severely low results). Suspicion of Type 2 should prompt multimer and RIPA testing, if available, to determine subtype. Mucocutaneous bleeds, especially in the setting of normal PT, aPTT, and vWD testing, should prompt platelet aggregation testing to isolate a platelet function disorder if drug effect can be ruled out. Abnormal platelet aggregation should also be followed by light and electron microscopy if the results are consistent with a storage pool disorder.

Thrombophilias

Thrombophilias are a diverse group and are defined primarily by an increased risk for the formation of a venous thromboembolism (VTE). VTEs include both deep-vein thrombosis as well as PE. This increased risk can come about through either hyperactivation of the coagulation pathway or a lack of proper controls. VTEs are also distinct from arterial thrombosis, which are typically caused by cardiovascular or cerebrovascular issues. The acquired causes are by far the most common, and while there is a tendency to focus on those thrombotic conditions for which well-established tests exist, it is worthwhile noting that the majority of acquired thrombotic disorders are not amenable to laboratory testing. These include:

- inflammation, trauma, and postsurgical states;
- venous stasis and limb immobilization;
- estrogen-containing oral contraceptives and pregnancy; and
- malignancy.
